Short biography of the editors

Severin Amelinckx was born in Willebroek, Belgium, in 1922. He studied at the University of Ghent, receiving his first degree (licence) in mathematics in 1944, his doctorate in physics in 1952, and his aggregation in physics in 1955. Currently he is Emeritus Professor of General Physics and Crystallography associated with the EMAT laboratory of the University of Antwerp (RUCA). Until 1987 he was Director General of the Belgian Nuclear Research Establishment at Mol. He is a member of the European Academy and of the Koninklijke Academie voor Wetenschappen, Letteren en Schone Kunsten van België and former chairman of the division of sciences of this academy.

His research interests include electron diffraction contrast imaging, defects in solids, phase transformations and their resulting domain structures, crystal growth, dislocations, fullerenes and nanotubes, the structure of high-T_c superconductors, modulated structures, and order–disorder in alloys.

Joseph Van Landuyt, who was born in St. Amandsberg, Belgium, in 1938, obtained both his licence (1960) and doctorate in physics (1965) from the University of Ghent. At present he is Professor of General Physics and Crystallography at the University of Antwerp (RUCA and UIA) and of Electron Microscopy at UIA and the Flemish University of Brussels (VUB). He is a member of the Koninklijke Academic voor Wetenschappen, Letteren en Schone Kunsten van België.

His research interests are centered on the study of nanostructural features in alloys, ceramics, and minerals (in particular gems), with special interest in defects in semiconductors and their relation to device performance. More general subjects of interest are structural variants, defects, and phase transitions in various solids.

Gustaaf Van Tendeloo, born in Lier, Belgium, in 1950, received his licence in physics from the University of Brussels (VUB) in 1972, his doctorate from the University of Antwerp (UIA) in 1974, and his aggregation from the University of Brussels (VUB) in 1981. He has been associated with the University of Antwerp (RUCA) since 1972, but has spent extended periods of time as a researcher in Berkeley (USA), Caen (France), and elsewhere. He is currently Professor of Solid-State Physics at the University of Brussels (VUB) and of the Physics of Materials at the University of Antwerp (RUCA and UIA).

His research interests include the electron microscopy of inorganic solids (in particular high-T_c superconductors), solid-state phase transitions, modulated structures, fullerenes, defects in crystals order–disorder in alloys, and nanostructural features in general.

Dirk Van Dyck was born in Wilrijk, Belgium, in 1948. He studied physics, receiving his licence from the University of Brussels (VUB) in 1971 before moving to the University of Antwerp (UIA) for his doctorate (1977) and aggregation (1987). He has been associated with the University of Antwerp since 1971, and is at present Professor of Theoretical Mechanics, Digital Techniques and Image Processing at the University of Antwerp.

Among his research interests are theoretical aspects of dynamic electron diffraction and imaging, holographic reconstruction and structural retrieval, image processing and pattern recognition, and artificial intelligence. In particular, he is involved in the development of a 1 Å resolution microscope in the framework of the Brite/Euram program of the European Union.

The four editors belong to the Electron Microscopy for Materials Science (EMAT) laboratory, University of Antwerp (RUCA), which was founded in 1965. All four have contributed significantly to the development of electron microscopy and its application by numerous publications in journals and books and are members of editorial boards of several international journals in the field of materials science. They have also delivered numerous invited lectures at international conferences in their respective areas of research.

General Introduction

The importance of microscopic imaging has in recent years been recognized repeatedly by the awarding of Nobel prizes to the inventors of a number of such methods.

As a consequence of the decreasing scale of many devices, high resolution characterization methods have become of vital importance for further development in these areas. Recent advances in data processing have made it possible to develop imaging modes for a number of methods of chemical analysis, based on particle beams; they have been considered as forms of microscopy, particularly as they are often accessories to microscopic equipment.

The systematic development of new materials strongly relies on their characterization at various and increasing levels of resolution. Structure, microstructure, and defect geometry, as well as chemical composition and spatial distribution are important parameters determining the behavior of materials in practical applications.

At present the materials scientist has a large number of methods at his or her disposal to determine these parameters. In applying these methods, use is made of some kind of probe and the response of the sample to this probe is detected and recorded. In many cases the probe consists of a beam of particles such as neutrons, ions, or electrons, or of electromagnetic radiation such as light, X-rays, microwaves, infrared radiation, or sound waves. However the probe may also be a very fine point or fiber in close proximity to the sample surface leading to some form of interaction (mechanical, optical, electrical, magnetic). The probe may be operated in either a stationary or a scanning mode.

As a guiding principle in selecting the characterization methods to be addressed in the Handbook of Microscopy, we used the requirement that the method should give spatially localized information of the microstructure and/or the composition. Moreover, in order to qualify as 'microscopy', the method should have the potential to provide a magnified real-space image of the sample.

An introductory discussion of the physicochemical principles underlying tthe different methods and the type of information which they can provide is the subject of the first two Volumes of the Handbook, *Methods I* and *Methods II*. The chapters have been written by experienced scientists working in the various fields, the main objective being to provide the reader with sufficient insight and information to allow an optimal choice of the method(s) to be used in order to obtain the desired information.

No materials scientist can master more than a few of these techniques, and presumably would not have access to the

instrumentation necessary to apply a number of them. However, on the basis of these descriptions, it should be possible to judge what results can be expected from the various methods and what their limitations are.

Also problems of image recording and data processing are treated in *Methods II*, in relation to the quantitiative evaluation of microscope images in general. The prospective evolution of recently developed methods and the possibilities of new methods still under development are also briefly discussed.

Different classes of materials and different applications of the same material may require different characterization methods; a single method is usually not applicable to all materials. It is therefore meaningful to illustrate the use of the different methods by a number of case studies classified according to the type of material or to its use. This is the objective of the third volume, *Applications*.

The three volumes are complementary. The *Methods I* and *II* volumes mainly address the operator of the instruments and the scientist who wants to understand and interpret the images, while the *Application* volume will be particularly helpful for materials scientists who has to decide which methods looks most promising for their purposes. Together the three volumes form a state of the art account on the subject, essential for the optimal use and application of microscopy techniques.

As the number of available methods grows, increasingly detailed information can be obtained. However, it also becomes increasingly difficult for a materials scientist to make an adequate choice. This Handbook aims to provide a tool to aid in making such a choice possible and to ease access to the vast literature.

The Editors wish to thank the authors for their efforts to provide, in a limited number of pages, clear overviews that are understandable by the nonspecialist.

We are also indebted to the editorial and production staff of VCH for their efficient help in acquiring the manuscripts of so many authors and for turning them finally into finished, well-presented books.

Special thanks are due to Dr P. Gregory, Dr U. Anton and Dr J. Ritterbusch from the Editorial Office for ensuring excellent communications with VCH.

We are grateful for the confidence of the management of VCH in us and for their continuous support.

1 Metals and Alloys

1.1 Imaging Metals and Alloys: Introduction

Mechanical properties of metallic systems are particularly structure-sensitive. The microstructural features in turn are determined by chemical composition and processing. Consequently, most advanced microstructural investigations require a microscope with a resolving power of the order of a nanometer or even better. When the need for such a high-resolution microscope became apparent, it was clear that another type of radiation than ordinary light had to be used to make an image of the specimen. The following considerations concerning the radiation were made: Since the resolving power of an imaging microscope is limited to a value approximately equal to the wavelength of the radiation used, the wavelength should be of the order of 1 nm or smaller. Further, it is essential that the radiation can be manipulated in order to form an image. It does not matter whether this is done by lenses or by mirrors. It is in fact this condition that excludes the use of X rays. Finally, it is a prerequisite that the radiation does not destroy the samples. Furthermore, the transmission coefficient of the sample for the radiation used should be significantly greater than zero. These conditions exclude, for instance, ions and low-energy electrons, respectively. It turned out that electrons, with an energy of the order of 100 keV or more, constitute the most suitable form of radiation. This led to the development of the electron microscope. The main disadvantage of electrons is that they are quite strongly absorbed by matter—including air. This implies that the sample thickness is limited to values considerably smaller than 1 μm and that electron beam interaction with the specimen should take place in vacuo.

With all these possibilities available nowadays, it is usually argued that it is necessary to characterize the microstructure at the *highest* levels of resolution possible in order to understand the behavior of materials and to facilitate the design of either new or improved metallic systems [1–3]. The question is whether this is really true. In other words: does transmission electron microscopy really solve materials problems and what level of resolution is it appropriate to look for? Is the highest resolution the best route to understand properties which are structure-sensitive or not?

This section deals with metallic systems. From the start of transmission electron microscopy (TEM) with the observations of Heydenreich of aluminum foils in 1949 [4] a vast amount of work has been

devoted primarily to metallic systems. As a matter of course it would be simply impossible to cover five decades in one single chapter or even in one book. For that reason we took a different approach. The principal motivation for doing TEM on materials is to image microstructural defects and to derive from these observations their influences on the physical properties. However, one should critically evaluate which defects might be relevant, what kind of information is needed, and, most importantly, on what scale? Following these guidelines we left out all the beautiful electron microscopic work that is focused exclusively on the structural aspect of metals and which does not make a linkage to the physical property relationship as such.

Here we will deal mainly with those defects which contribute to the microstructural features in metals and alloys, that is, those which are not in thermodynamic equilibrium, such as two-dimensional and one-dimensional defects, for example, grain boundaries and dislocations, but also three-dimensional defects such as precipitates and noble gas bubbles. The latter are chosen as an illustration of an area of research in metallic systems to which TEM has contributed a lot. It will be shown that in some cases it is crucial to have information on an atomic level available, but this is not always necessary, and it is sometimes more appropriate to image defects on a micrometer scale instead to correlate the structural information to physical properties.

Mechanical strength is strongly affected by internal interfaces such as grain boundaries. For instance, segregation of alloying elements frequently makes the boundaries particularly suitable paths for brittle cracking at low temperatures. Similarly, segregation of alloying elements has a pronounced influence on fractures occurring during creep by cavitation at boundaries. Both the effect of segregated impurities on cohesion and their fast diffusion along grain boundaries play major roles in the recently discovered brittle fracture at high temperatures. Grain boundary cracking is also the main problem encountered in intermetallic compounds, which would otherwise be attractive structural materials for high-temperature applications.

All the boundary phenomena controlling the above-mentioned material properties occur in the region of the core of boundaries, a few atomic spacings wide. Hence, it is the atomic structure of boundaries in alloys which needs to be understood in order to establish the physical mechanisms of boundary phenomena. Direct observations in boundary structures have become possible recently with the advent of high-resolution electron microscopy and scanning tunneling microscopy. General features of the atomic configurations of grain boundaries have been established on the basis of computer modeling of grain boundary structures which were instrumental in advancing the knowledge of boundary structures [5, 6]. The same arguments are valid for the bonding behavior between dissimilar materials such as metals and ceramic, where it is thought that microscopic information at an atomic level on the interface structure is crucial in understanding and predicting the mechanical properties. In this Section we will present some examples of studies on the structure of grain boundaries, on grain boundary segregation, and on the

structure of interfaces between dissimilar materials where sometimes atomic resolution is necessary to solve a particular materials problem but sometimes information on a micrometer scale is more appropriate.

Besides the planar defects we will also concentrate on line defects, that is, dislocations. With respect to the mechanical properties this is quite obvious. The hardening curve of stress versus strain and the corresponding microscopic structures are the striking features of the mechanical properties of ductile materials. Despite the enormous effort that has been put into experimental and theoretical investigations, a completely satisfactory theory has not yet been attained. The principal reason for this is that a proper theoretical analysis of the highly nonlinear and nonequilibrium effects does not exist.

From a basic physical point of view a plastically deformed material is a highly nonlinear system that is driven far from thermodynamic equilibrium. Instability transitions and corresponding structural transitions are typical for these systems. To analyze plastic behavior, that is, nonlinear effects, two different approaches to microplasticity are currently under investigation: the theory of dislocations and continuum mechanics, respectively. The theory of dislocations has provided a thorough understanding of the behavior of individual defects and the interactions between them. However, it is doubtful whether this is a proper theory for describing a complex behavior of a dislocation structure under dynamic conditions, such as the formation of cells, veins, braids, or dipolar walls. The continuum approach, on the other hand, is complementary to the classical theory of dislocations and it is to some extent rather its counterpart. The advantage of a continuum mechanics approach is quite obvious: it may be very suitable for describing the global cooperative behavior of moving dislocations. This approach was initiatied by Holt [7], and extended by others [8, 9]. We will come to these points again in Section 1.5 of this Chapter.

In the following we take the classical theory of dislocations as a starting point since most TEM studies concentrate on differences in the hardness of various materials rather than explaining the complete hardening curve.

Theoretical descriptions of the strengthening of crystalline solids, as based on the classical theory of dislocations, involve the movement of dislocations against the resistance provided by various types of obstacles. The basic idea of strengthing is thus to introduce obstacles into the glide plane of dislocations. We may have one or more of the following obstacle types: forest dislocations, substitutional impurity atoms, and various kinds of precipitates. The strength of these obstacles depends on the exact nature and size of the obstacles. The resultant flow stress of the material can be calculated using the random obstacle theory for localized obstacles. In the case of coherent precipitates with a substantial misfit parameter, or when pressurized bubbles are considered, diffuse instead of localized forces may be used. Obviously, not only the nature and size of the obstacles but also their dispersion and concentration play important roles in such a calculation.

Undoubtedly, TEM has contributed a lot to the understanding of the physical nature and operative mechanisms of all these effects on the mechanical strength

of metals and alloys. However, the scientific questions that should be addressed by TEM remain open: in other words, does it really solve materials problems. Instead of giving a complete survey of the existing literature we intend to show some limited case studies within the realms and wealth of TEM in the field of metals and alloys. As stated before, when the scientific work is aimed at scrutinizing the structure–property relationship it would be of crucial interest to have suitable processing tools available to modify the structure as well, since structural features are also determined by the processing. It is well known that different heat treatments of metallic systems may produce various microstructures depending on the quenching rates applied. In our case a high-power carbon dioxide laser system turned out to be an excellent instrument for imposing heat treatments by which various structural features can be generated, depending on the interaction time with the specimen. Besides heat treatments, 'mechanical' impact by shot peening techniques and, on a more atomic level, by ion implantation are effective ways of altering the microstructural features. Both techniques have provided an impetus to the field of microscopy on metals and alloys.

Besides these more static investigations, that is, of the postmortem type, in situ deformations studies in TEM also made an impact to the understanding of the mechanical behavior. For that reason we include some observations on the interaction between dislocations and grain boundaries in ordered compounds by which we stress the materials investigations aspect of electron microscopy. The same point of view is taken regarding the structural aspects of boundaries investigated by means of high-resolution electron microscopy.

Finally, this Section is ended with an outlook and some conclusions.

1.2 Apparatus and Techniques for Imaging Metallic Systems

All electron microscopic observations presented in the following are carried out with either a JEOL 200CX microscope or a JEOL 4000EX/II ultra-high resolution microscope, unless otherwise stated. The general construction of a transmission electron microscope is discussed at length in part I of this series. An electrically heated tungsten or LaB_6 filament emits electrons, which are accelerated up to 200 keV. Focusing of the electrons is accomplished by using several electromagnetic lenses and electrical deflectors. For more information on the basic design of electron microscopes, reference should be made to Hirsch et al. [1]. The use of magnetic lenses makes it difficult to examine ferromagnetic materials, which interfere with the imaging magnetic fields. Generally the images obtained from such specimens are strongly astigmatic.

The most straightforward way to obtain information is to form an image of the transmitted beam. This is called bright-field imaging. Some of the electrons, however, are elastically scattered, leading to diffracted beams. In the normal bright-field mode diffracted beams are not allowed to pass through the objective aperture. The formation of an image of the sample is not the only way to obtain information. Another possibility is to use

the diffracted beams more explicitly. Some applications of electron diffraction are given by Hirsch et al. [1] and Thomas and Goringe [3]. This technique, that resembles other diffraction techniques, can provide information about the atomic structure of the sample. A diffraction pattern is obtained in the following way. For the directions for which the Bragg law, $n\lambda = 2d \sin\theta$, is satisfied, constructive interference of scattered electrons may lead to a diffracted beam. Here λ is the de Broglie wavelength, d_{hkl} the reflecting h, k, l plane distance, and θ is the half-angle between incident and scattered beam. The intensity of these beams is proportional to the geometrical structure factor [10]:

$$S_g = \sum f_j \exp(-2\pi i \boldsymbol{g} \cdot \boldsymbol{r}_j) \qquad (1)$$

where f_j is the atomic form factor and j runs over all the atoms of the basis, positioned at $\boldsymbol{r}_j$. Further, $\boldsymbol{g}_{hkl}$ denotes the reciprocal lattice vector, equal to $\boldsymbol{k}_0 - \boldsymbol{k}_i$, that is, the difference between the diffracted and the incident beams. The result of such a calculation is that for most crystals not all reflections are present. In an f.c.c. lattice, for instance, only those reflections for which h, k, l are all even or are all odd are present. In a b.c.c. lattice, only the reflections for which $h + k + l =$ even are present.

All beams for which the geometrical structure factor is not equal to zero (and the transmitted beam) are focused in the back focal plane of the objective lens. By suitable settings of the intermediate lenses, an image of this diffraction pattern can be obtained on the viewing screen or on a photographic plate. By placing an aperture in the image plane of the objective lens only that part of the specimen that is located inside of this aperture will contribute to the diffraction pattern. This technique, called selected area diffraction (SAD), is used to obtain certain information of a single grain or a large precipitate in a specimen, for example the crystal structure or the orientation. If a material is polycrystalline with a grain size much smaller than the selected area, many differently oriented grains contribute to the diffraction pattern. In this way a ring pattern, instead of a spot pattern, is obtained. It must be remembered that when correlating the SAD pattern to the image, all rotations caused by the magnetic lenses must be accounted for.

Making use of a diffracted beam instead of the transmitted beam is called dark-field imaging. Since the diffracted beams normally do not coincide with the optical axis of the microscope, the obtained image will not be of maximum quality, as far as spherical aberration is concerned. To overcome this problem the beam is tilted in such a way that the desired diffracted beam passes along the optical axis. Application of this technique leads to high-contrast images of various types of defects. Whenever an image of a lattice defect is formed by diffraction contrast, the specimen is tilted into a so-called two-beam condition. In this way only one set of diffracting planes contributes to the image formation, which makes interpretation of the micrograph more straightforward.

When dislocations are to be imaged, it is often better to tilt the crystal slightly further by such an amount that the exact Bragg condition is only fulfilled within a small region near the dislocation. The deviation from the exact Bragg condition for a perfect crystal is then given by $\boldsymbol{s} = \boldsymbol{k}_0 - (\boldsymbol{k}_i + \boldsymbol{g})$. In this

way a high-resolution image is obtained in which the dislocation shows up as a white line. This is called weak-beam imaging [11].

The amount of extra tilting can be determined accurately by the relative position of the so-called Kikuchi pattern with respect to the diffraction pattern. The origin of this Kikuchi pattern lies in the elastic rescattering of inelastic scattered electrons. It is almost independent of the incident beam direction but seems to be connected to the lattice. The position of the diffraction spots, however, is determined by the incident beam direction. As a consequence, the exact deviation from the Bragg condition is specified, and a numerical value of s can be obtained.

The magnitude of s is related quantitatively to the resolution of a dislocation image in the following way. The width of a dislocation image is approximately $0.3\xi_g$. Here ξ_g is the extinction distance for a certain reflection, defined for $s = 0$ (non-relativistic):

$$\xi_g = \frac{\pi V \cos\theta}{\lambda s_g} \tag{2}$$

and ξ_g is of the order of 15–200 nm for most metals. V is the volume of the unit cell and θ is the scattering angle for the specific reflection. The width of a dislocation imaged in bright field or dark field (i.e., $s_g = 0$) can be detrimental to observations of, for example, the separation between two dislocations that are very closely spaced. In the case of a tilt away from the Bragg condition, the periodicity of the oscillation is calculated from two-beam dynamical theory, in which it is assumed that the incident wave amplitude ϕ_0 and the diffracted amplitudes ϕ_g both vary with depth, z:

$$\xi_g^{\text{eff}} = \frac{\xi}{\sqrt{1 + w_g^2}} \tag{3}$$

where $w_g = s_g \xi_g$. From this equation it can be concluded that the effective extinction distance decreases for increasing deviation away from the Bragg condition. If a large deviation from the Bragg position ($s_g > 0.2\,\text{nm}^{-1}$) is established, the effective extinction distance decreases according to Eq. (3), and a much sharper dislocation image is obtained. This technique is called weak-beam diffraction. The width of a dislocation image can be reduced to values of the order of 1–5 nm.

Planar faults, such as stacking faults, will have a displacement $\boldsymbol{R} = 0$ above the fault and $\boldsymbol{R} = \boldsymbol{R}_f$, the fault vector, below the fault. If the fault is inclined to the foil surface, an oscillation in the intensity of the fault image is produced, unless $\alpha = 2\pi \boldsymbol{g} \cdot \boldsymbol{R}_f$ equals $n2\pi$. In this case no phase change is introduced, and the fault will be invisible. Application of the kinematical theory for electron diffraction, which assumes that the crystal is so thin or s so large that the intensity of the diffracted beam is small compared to the intensity of the transmitted beam, results in the following expression for the amplitude of the diffracted beam:

$$\phi_g = \frac{\pi \mathrm{i}}{\xi_g} \phi_0 \int_0^t \exp(-2\pi \mathrm{i} s_g z)\, \mathrm{d}z \tag{4}$$

where t is the thickness of the foil. The kinematical theory is qualitatively quite successful but is not quantitatively reliable since it assumes that ϕ_0 is constant with depth z. It becomes clear that sometimes unphysical results may be obtained, such as for small s and large $t|\phi_g(t)|^2$ exceeds

$|\phi_0|^2$. This can be concluded from the evaluation of the integral, which yields the following expression for the diffracted intensity as a function of foil thickness (assuming $\phi_0 = 1$):

$$I_g = \frac{\pi^2 \sin^2(\pi t s)}{\xi_g^2 (\pi s)^2} \tag{5}$$

provided that s is large, that is, the kinematical theory is applicable. It is easy to see that the diffracted intensity thus oscillates as a function of depth, giving rise to the so called thickness fringes. These fringes, occurring with a periodicity ξ_g^{eff}, can be used to estimate the foil thickness. Such an estimate must be done carefully, because a small deviation from the Bragg condition already results in a significant effect on the extinction distance. Therefore, the value obtained must be regarded as an upper limit rather than an exact value.

Contrast of lattice imperfections is described by a modified version of Eq. (4) [12]:

$$\phi_g = \frac{\pi i}{\xi_g} \phi_0 \int_0^t \exp[-2\pi i(s_g z + \boldsymbol{g} \cdot \boldsymbol{R})] \, dz \tag{6}$$

where $\boldsymbol{R}$ describes the displacement of a particular atom from the perfect lattice, in the vicinity of an imperfection, and can be calculated using (an-)isotropic linear elasticity theory [13, 14]. Although a precise calculation of the image contrast of, for instance, a dislocation is quite complicated, this equation allows one to predict the visibility of a dislocation. For the most simple case, the pure screw dislocation, we know that $\boldsymbol{R}$ has the same direction as the dislocation Burgers vector, $\boldsymbol{b}$. Therefore, all contrast of a screw dislocation vanishes when $\boldsymbol{g} \cdot \boldsymbol{b} = 0$, and the dislocation is invisible. General dislocations usually have a dislocation displacement field with more components, and now the conditions for invisibility become $\boldsymbol{g} \cdot \boldsymbol{b} = 0$ and $\frac{1}{8} \boldsymbol{g} \cdot \boldsymbol{b} \times \boldsymbol{u} \leqslant 0.08$, where $\boldsymbol{u}$ is the dislocation line vector.

Equation (6) can also be used to calculate the contrast of coherent precipitates, since the lattice is often distorted by such a particle. Semi- and incoherent precipitates, showing little or no strain contrast, can best be imaged by making a dark field image using a precipitate reflection. This leads to high-contrast images of bright precipitates in a dark matrix. Apart from these two sources of contrast, precipitates may also become visible through absorption differences or by the presence of Moiré and thickness fringes [1].

In the case of voids and bubbles, image contrast is formed in several ways [15]. Absorption contrast will dominate when the bubble diameter forms a significant fraction of the foil thickness. In this case a bubble will appear as a bright object. When diffraction contrast plays a role, a bubble can also appear as a dark object, strongly depending on s [16]. Highly pressurized bubbles deform the host lattice, and the strain field can be imaged. Bubbles also give rise to phase contrast, which can be used to enhance the contrast. This is carried out by defocusing the image [17]. In an under-focus condition the bubble appears as a bright area with a dark periphery, whereas in an over-focus condition the contrast is reversed. The diameter of the bright area in an under-focus condition is generally regarded as the real diameter.

Sometimes image and diffraction information is not sufficient to identify the nature of a certain precipitate. This may

be the case since lattice parameter measurements using TEM are not very accurate, and additional information can be obtained by energy dispersive spectrometry (EDS) [18]. In this technique, the electron beam is focused onto the precipitate to be analyzed. Energy, absorbed by sample atoms, is partly released by emitting X rays. From the X-ray spectrum the chemical composition can be derived.

1.3 Metallic Specimen Preparation for Transmission Electron Microscopy

Because of the high electron absorption of the samples, the maximum sample thickness should be of the order of a few hundred nanometers. Thinner samples, however, result in an improved image quality. To obtain such a thin foil, which is also sufficiently rigid to be handled, requires the following procedure. First a thin sheet (100–200 μm thickness) of the material to be examined is cut. When a laser-treated material is to be examined, this usually means that the sheet is cut plan parallel to the treated surface. This is done by using a low-speed diamond saw with low mechanical distortion. Then from this sheet, disks (3 mm diameter) are produced using a spark cutter or a mechanical puncher. Subsequently, these samples are thinned from one or both sides in such a way that in the center of the disk the removal rate is slightly higher than away from the center. As soon as an optical system detects a hole in the center of the disk, the process is stopped. In this way, a wedge-shaped electron transparent region comes into being at the edges of the hole. The actual thinning can be accomplished in two ways, as described below.

1.3.1 Electromechanical Thinning

With this technique, the specimen is thinned by the removal of material in an electrochemical process. This technique should be preferred over other techniques because mechanical and thermal distortion are almost negligible. The polishing process is performed while keeping the sample under a positive electrical voltage with respect to a polishing solution. An extensive list of electropolishing solutions has been published by Kelly et al. [19]. For most iron alloys a solution of 10% perchloric acid, 85% acetic acid, and 5% water suffices. For aluminum alloys other specific solutions are necessary. The electrical current is adjusted in such a way that a viscous layer is obtained at the sample surface. Only then polishing instead of etching takes place.

The formation of a viscous layer is also favored at low temperatures. Development of gas bubbles at the surface should be avoided since this leads to irregular surfaces. These can be avoided by lowering the temperature or the electrical voltage. Apart from the sample and the electrolyte, a light source and a sensor are used. When the sensor detects light, the sample is sufficiently thinned and the polishing process is stopped; the sample is then removed and rinsed in alcohol and methanol.

This process works best in the case of a bulk sample consisting of a homogeneous single-phase material. In multiphase

materials there is nearly always the problem of preferred polishing. Preferred polishing is also often observed just near the edges of laser tracks, and is caused by structural and compositional changes at these points.

When an ion-implanted material is to be examined, thinning must be done from one side only, the bulk side. The implanted surface is covered with wax so that only the bulk side is in contact with the polishing solution. Often, when the sample is perforated, the polishing solution creeps between the wax and the edge of the perforated foil, thereby etching away the implanted layer. To overcome this and the aforementioned problem with the laser-treated materials, another thinning technique is also applied, namely ion milling.

1.3.2 Ion Milling

An ion milling machine for TEM specimen preparation was first constructed by Castaing [20]. Nowadays, milling machines, such as the Gatan Dual Ion Mill Model 600 used in our research, are constructed. The sample is mounted on a rotating sample holder in a vacuum chamber. Two ion guns are pointed at the sample center under a low incidence angle (5–15°), from both the top and the bottom. With this technique, thinning takes place by sputtering caused by the incident focused ion beam. As a rule, argon ions are used, because of their inertness and their low solubility in metals. Additionally, they have a good damage to sputtering ratio. The sputter rate can be further optimized by working in a good vacuum, in order to prevent continuous formation of surface layers such as oxides and hydrocarbons. The milling process is stopped when a laser optical system detects a hole in the specimen.

Prior to ion milling the samples are treated with a mechanical dimpler (Gatan Model 656 dimple grinder in our research), in order to reduce the milling time or to select the depth of the electron transparent region. This is accomplished by making shallow dimples on one or both sides of the specimen. The sample is mounted on a rotating table, while a rotating grinding wheel covered with a diamond slurry removes small amounts of material. This process is carried out under a small load and with a low speed until a thickness of approximately 40 μm is reached.

Implantation damage is the main disadvantage of the milling technique, and can become visible as small argon bubbles or as clustered point defects. Furthermore, thermal damage can be a problem because the heat conduction in thin foils is evidently not rapid. This complication plays a role especially in the case of low melting point metals such as aluminum. To circumvent this problem, the sample holder can be cooled down to liquid nitrogen temperature. An optimum must be found between the sputter rate and specimen damage. In practice, this means that the gun voltage and current are set to 3–4 kV and 1 mA, respectively, while the angle of incidence is 10–15°.

The main advantage of this specimen preparation technique is that almost every material can be prepared. Only metal–ceramic composites may give rise to problems because of a large difference in sputtering yield. The most important advantage is that the electron transparent region can be positioned quite accurately.

This is particularly important for laser-treated samples, where the microstructure may change when going from the center to the edge of the track.

1.4. Typical Examples

1.4.1 Observations of Static Dislocations by Transmission Electron Microscopy

As said before, the leading theme of this Section is to show how electron microscopy may be used to relate structural information to the physical properties of metallic materials. Let us concentrate first on the microstructural analyses of metallic systems heat treated by a less conventional technique such as laser processing, and see how transmission electron microscopy reveals the relevant physical mechanisms in enhanced mechanical properties. Generally, a fine solidification structure and an enhanced solid solubility form the basic concepts behind improvements by laser melting. Further, freezing-in of metastable phases, creation of metallic glasses, or even formation of quasicrystalline phases are also feasible.

Apart from these advantages, there also exist disadvantages: during cooling, the metal surface will shrink locally, usually leading to substantial stresses. Sometimes these stresses will cause severe cracking. In other cases the tensile stress will only lead to a decreased behavior of wear or fatigue. To overcome the stress-related problems, the combination with ion implantation has been explored [21, 22]. In addition, another novel approach was invented: laser melting combined with a shot peening treatment afterwards [23, 24].

While it is in use it is often the surface of a workpiece that is subjected to wear and corrosion. Recent research has been devoted to the modification of only the surface of a relatively cheap material, instead of making the entire workpiece from a higher grade of metal. In view of the practical implications, the development of wear-resistant surfaces has been taken as a starting point in this work.

As a general rule, wear is determined by the interplay of two opposing properties: ductility and hardness. Wear can be reduced by modifying the surface layer in such a way that it acquires higher ductility, so that greater plastic deformation can occur without particles breaking off. Soft surface layers can be very effective in reducing wear due to delamination. Resistance to wear by abrasion, on the other hand, is then low.

However, wear can also be reduced by making the surface layer harder. Then again, increasing hardness also means an increase in the elasticity limit and a reduction in ductility, leading to a lowering of fatigue resistance and hence to brittle fracture. The characteristics of the system (i.e., whether the wear is caused by delamination or abrasion) determine which of these two methods should be chosen.

Over the past few decades, ion implantation has been promoted for the modification of surface layers of materials. Machines for ion implantation have so far been developed primarily for the semiconductor industry. Although the improvement of the mechanical properties of ion-implanted surfaces is also known to be considerable, it should not be assumed

that the technique has been fully perfected for tribological applications. Commonly used ions in the field of ion implantation metallurgy are those of nitrogen, carbon, boron, titanium, molybdenum, and chromium, where the first species are mainly used to form second phase particles and the last ones form a surface alloy. The mechanisms leading to improved surface properties are: initiation of a more favorable wear mechanism, increasing the hardness through the formation of second-phase particles or through solid solution hardening, and surface alloying that may improve the corrosion resistance.

As the penetration depth is inversely related to the ion mass, at constant accelerating voltage, light elements are favorable. In this context one should also mention the recent development to increase the implantation energy, up to the megaelectronvolt regime [25], and the mechanism of so-called tribo-enhanced diffusion [26]. The latter mechanism applies to nitrogen implantations, where it has been reported that the layer with increased wear resistance sometimes extends up to several micrometers, which is an order of magnitude deeper than the original implantation depth. Analysis showed that nitrogen was still present in the near-surface layer after a long period of surface layer removal by wear.

The basic idea behind our approach of applying ion implantation to laser-treated metals is to build up a compressive stress that might be able to reduce or even reverse some unfavorable properties such as tensile stresses and retained austenite of laser-treated materials. For a better understanding, these two topics will be investigated from the TEM viewpoint to see whether this basic idea is right or wrong.

1.4.1.1 Atomic Peening

RCC steel (2.05 wt.% carbon, 11.05 wt.% chromium, 0.62 wt.% tungsten, and the balance iron) is very suitable for laser treatment when a constant hardness profile is required [27]. Because a martensitic transformation is absent, the tensile stresses are remarkably high after laser treatment [28]. The dislocation density is also high, but not extremely so, 10^{12}–$10^{14}\,m^{-2}$. After laser melting, a dendritical solidification structure develops, consisting of austenitic cells surrounded by M_3C carbides. Before implantation the samples were smoothened by grinding with SiC paper followed by polishing with a 3 μm diamond paste.

Implantations were carried out with doses of 3×10^{16}, 1×10^{17}, and $3 \times 10^{17}\,Ne^{+}\,cm^{-2}$ at 50 keV. Figure 1 shows a TEM image of an implanted foil, exhibiting the depth distribution of the bubbles throughout an austenitic cell. A distribution of the bubble radii is shown in Fig. 2. The mean bubble radius is 20 nm and the mean volume is $4.5 \times 10^{4}\,nm^{3}$.

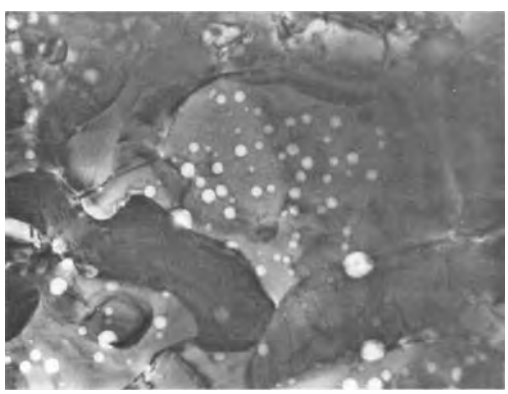

Figure 1. TEM image of neon bubbles in laser-treated RCC steel (stereo angle 20°, dose $3 \times 10^{17}\,Ne\,cm^{-2}$).

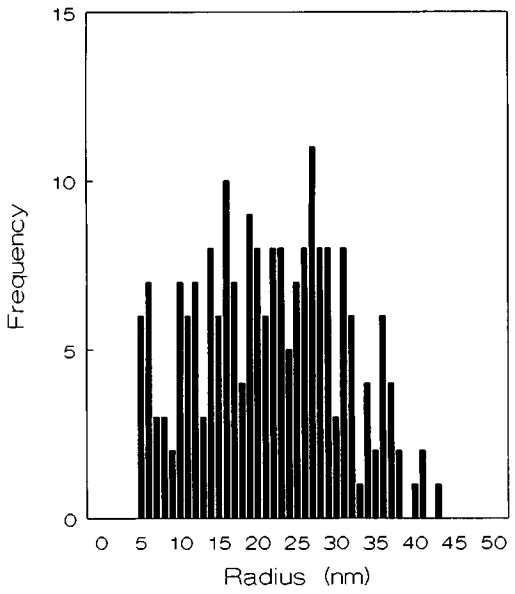

Figure 2. Bubble size distribution after implantation of 3×10^{17} Ne cm^{-2} into laser-melted RCC steel.

The bubble density amounts to 5.7×10^{20} bubbles m^{-3} [21].

One of the remarkable findings by TEM is that the stereo measurement of the depth distribution reveals that the mean implanted range is approximately twice the distance expected. This might be explained by channeling of neon during the first stage of implantation. The mobility of neon, which gives rise to the observed bubble formation, may also contribute to an extension of the implantation profile. Furthermore, it is known that large stresses, which are present in these samples, may enhance the diffusion [29, 30]. Finally, a high dislocation density may also promote diffusion by a pipe diffusion mechanism.

The mechanical properties of laser-melted RCC steel are significantly improved by neon implantation [22, 31], and the question is whether TEM can shed some light on the relevant mechanism. It turned out that (Fig. 3), in contrast to the original idea of pressure-induced hardening, this improvement is likely to be due to the dislocation–bubble interaction. Dislocations may bypass the bubbles either by pure glide (Orowan process) and cross slip, or by shearing the bubbles. The stress field around a bubble determines whether a dislocation will reach the bubble and penetrate or will bypass by bowing around the bubble. Usually, in aged-hardened alloys the contribution of modulus hardening to the shearing force, required to cut a particle by glide dislocations, is small. Since the elastic energy of a dislocation is proportional to the shear modulus, a change of energy and hence a force will be associated with a dislocation interacting with a particle whose shear modulus differs from that of the matrix. The extreme case is the interaction with a void or a bubble, in which the elastic energy is reduced to zero and the system can be described by image forces. So, the modulus hardening in the case of neon bubbles may be a crucial contribution to the hardening, since in the neighborhood of the bubbles the dislocations always experience an attractive force component towards the bubbles, which is confirmed by TEM observations.

In Fig. 3a the critical shear stress [32] is depicted as a function of bubble size, given a volume fraction of 0.025. In this graph, the Orowan stress is calculated using the traditional Orowan expression, rewritten for spherical obstacles of radius R and a fixed volume fraction [33]. Pressure hardening is calculated, combining an expression for shearable objects [34], and an expression for the average force between an edge dislocation and a

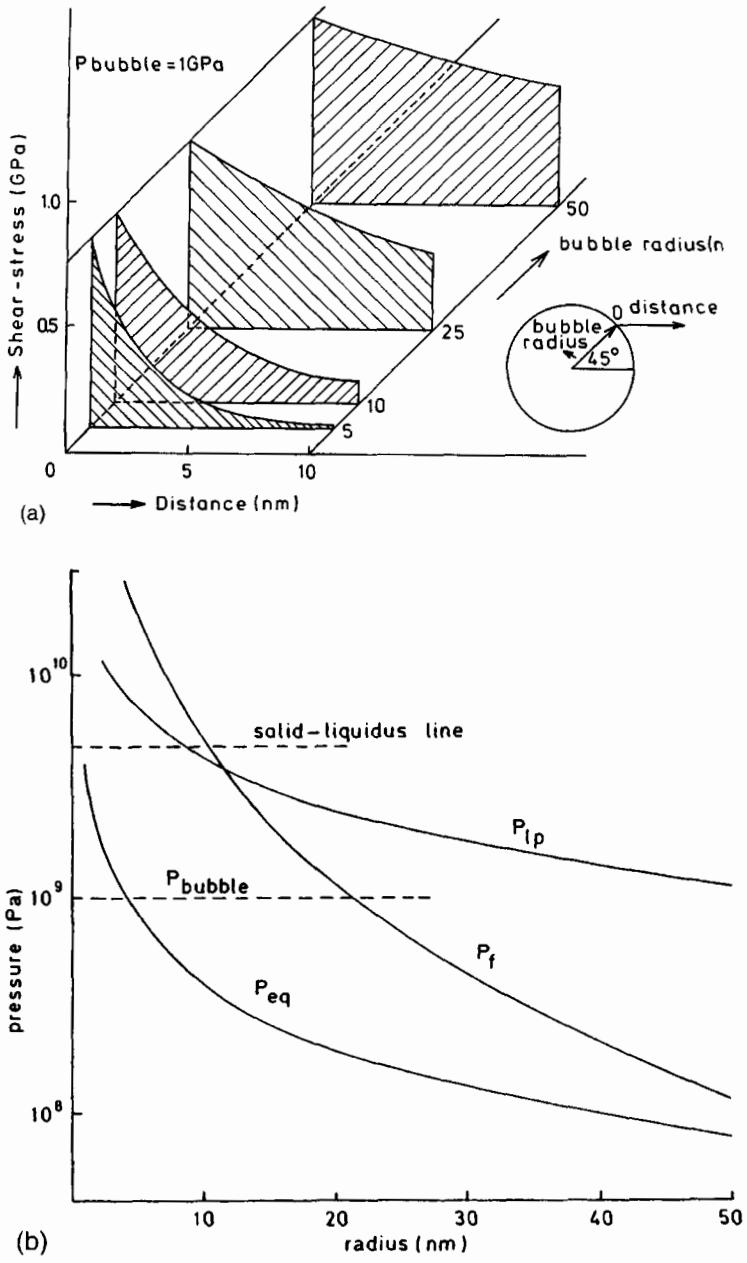

Figure 3. (a) Shear field of a bubble as a function of distance and size of the bubble. (b) Bubble pressure versus bubble radius. P_{eq} represents the equilibrium pressure, P_f is the pressure for interbubble fracture, and P_{lp} represents the minimum pressure for loop punching.

pressurized bubble [35, 36]. Finally, modulus hardening is calculated using an expression quoted by Hanson and Morris [37]. It is easy to see that modulus hardening contributes considerably compared to Orowan and pressure hardening. Apart from the hardening caused by the interaction of neon bubbles and dislocations, the reduction of the tensile stresses will also contribute to the

improved wear behavior. Still another possible cause of the improved wear behavior may be formed, namely by the local stress field around the individual bubbles, which might influence the work hardening rate.

1.4.1.2 Stress Fields in the Implanted Layer

During implantation, Frenkel pairs are produced; about 450/neon atom at 50 keV. Most of them annihilate, but neon will be trapped by the remaining vacancies. As a consequence the interstitials, forming loops or trapped at dislocations, will contribute to a compressive stress. This stress field can be of the order of 1 GPa [38, 39]. When a neon–vacancy complex absorbs an interstitial neon atom or coagulates with another bubble, the pressure in the new bubble may exceed the equilibrium pressure ($P_{eq} = 2\Gamma/r$, where Γ is the surface free energy; $\Gamma = 2.5\,\mathrm{J\,m^{-2}}$ is often used for f.c.c. iron [39]). This excess pressure can be reduced by emitting interstitials or dislocation loops, thereby contributing to a compressive stress. The bubbles have a stress field consisting of hydrostatic and shear components [40]:

$$\sigma_H = \frac{\bar{p} f_v}{1 - f_v} + \frac{(p - \bar{p})\alpha f_v}{1 - \alpha f_v}$$

$$\tilde{\sigma}_{ij} = \frac{R^3}{2r^3}\left(\delta_{ij} - 3\frac{x_i x_j}{r^2}\right) \times \left(\frac{\bar{p}}{1 - f_v} + \frac{p - \bar{p}}{1 - \alpha f_v}\right) \tag{7}$$

where f_v is the volume fraction of the bubbles. r and x_i represent the length and components of the radius vector with the origin in the center of the bubble of radius R. δ_{ij} is the unit tensor and α is defined by

$$\alpha = \frac{1 - \bar{G}/G}{1 + 4\bar{G}/3K} \tag{8}$$

where $\bar{p}$ and $\bar{G}$ represent the average pressure and average shear modulus, respectively. The idea is that around each bubble a cell is constructed and that this cell is embedded in an effective medium with elastic constants $\bar{G}$ and $\bar{K}$, containing all other bubbles with an average pressure of $\bar{p}$. However, in general the individual pressure p of a bubble will differ from this average pressure. It is easy to see that σ_H plays a minor role because it scales with f_v. Now the question is whether for the TEM data we can derive an estimate of the pressure in these bubbles, P_{eq}. We know already the equilibrium pressure as a function of the radius. Suppose the thermal vacancy concentration is rather low, then the bubbles may grow by punching out dislocations. For large dislocation loops of radius R_l, the minimum pressure for loop punching is simply

$$p_{lp} = \frac{2\Gamma}{r} + \frac{Gb}{2\pi(1 - \nu)R_l}\ln\frac{R_l}{r_{eh}} \tag{9}$$

where r_{eh} is the equivalent hole radius (including core energy effects). With increasing bubble concentration, inter-bubble fracture may take place. For a cubic array of bubbles, the pressure needed for fracture is [41]

$$p_f = \frac{2\Gamma}{r} + \sigma_f\left(\frac{1}{\pi r^2 C_b^{2/3}} - 1\right) \tag{10}$$

where σ_f is the fracture stress and C_b is the bubble concentration. An estimate of the fracture stress might be the theoretical fracture stress of cleavage fracture. The

interbubble distance is considered to be large [42]. A more appropriate value is the strength needed to overcome the lattice resistance to dislocation motion, which is approximately 0.001 G for f.c.c. metals. In the present case, p_f might be somewhat larger because of the rather flat distribution of bubble radius, and small as well as large bubbles coexist. In Fig. 3b the pressure is presented according to these predictions. To a first approximation the bubble pressure is at least equal to the equilibrium pressure for small bubbles. Therefore, TEM predicts for the bubble pressure 1 GPa (dashed line in Fig. 3b).

The shear stress can be calculated as a function of bubble size at various distances from the edge of the bubble. This is illustrated in Fig. 3a, assuming a realistic bubble pressure of 1 GPa. When there are two bubbles close to each other the fields will accumulate and may lead to interbubble fracture when the interbubble distance becomes small. When on the other hand the interbubble distance becomes too large, there is no repulsive force on emitted dislocation loops, and the pressure can more easily be lowered to equilibrium pressure.

Figure 4 shows TEM micrographs of an SS304 sample implanted with $3 \times 10^{17}\,Ne^{+}\,cm^{-2}$, and prepared following the bulkside-thinning method. Here, bubble radii up to 40 nm are observed within a broad distribution. From the diffraction patterns and the dark field micrographs it became evident that the dark areas represent a b.c.c. phase. In contrast to other reports in the literature [43, 44] the b.c.c. phase has hardly any orientation relationship with the matrix. It is also noteworthy that the size of the particles is smaller than that observed previously [43]: 50 nm instead of 120 nm.

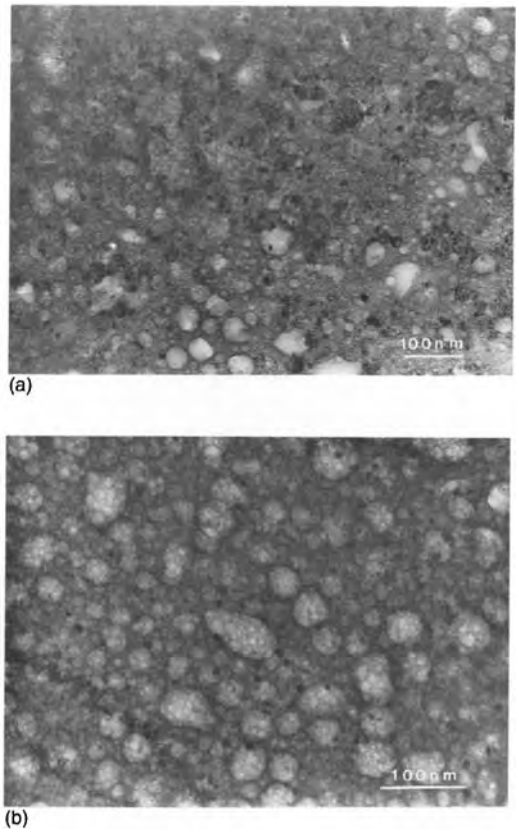

Figure 4. (a) Bright field transmission electron micrographs of an implanted bulkside thinned sample (dose $3 \times 10^{17}\,Ne^{+}\,cm^{-2}$) and (b) an implanted thin foil, showing bubbles and b.c.c. particles.

In a thin foil, implanted with $1 \times 10^{17}\,Ne^{+}\,cm^{-2}$, the bubble radii vary from 1 to 5 nm, and no b.c.c. phase can be detected. When a thin foil is implanted with $3 \times 10^{17}\,Ne^{+}\,cm^{-2}$, the bubble size distribution is the same as in the bulkside-thinned sample, but the b.c.c. particles look more spherical and are even smaller: about 8 nm in diameter (Fig. 4b). In this case there is no orientation relationship at all. The critical dose

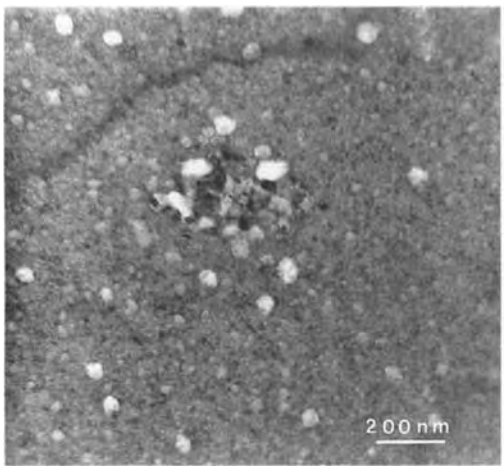

Figure 5. Bright field transmission electron micrograph showing b.c.c. particles in the vicinity of bubbles, grown after an anneal (dose 1×10^{17} Ne^+ cm^{-2}).

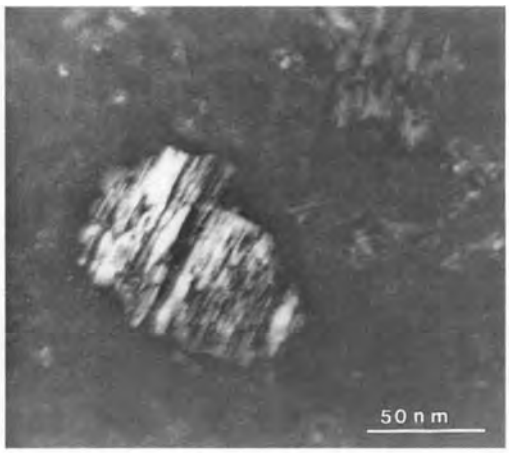

Figure 6. Dark field micrograph of a large twinned b.c.c. particle.

for transformation in thin foil samples amounts to about 1.5×10^{17} Ne^+ cm^{-2}.

To investigate the effect of the bubble size, an implanted thin foil, dose 1×10^{17} Ne^+ cm^{-2}, has been annealed at 400°C for 144 h. After this anneal the maximum bubble size has increased from 5 to 25 nm. Figure 5 shows that in the vicinity of a cluster of bubbles, a few b.c.c. particles have grown.

In the annealed thin foils, twinning is frequently observed, e.g. Fig. 6 shows a b.c.c. particle which is larger than average and internally twinned in a sample annealed for 67 h. The twins are 1–4 nm in size and are observed in the bulkside thinned samples as well.

Analysis of the experimental results suggests that a shear stress produced at the neon bubble is a plausible nucleation site for the martensitic transformation. Although the magnitude of the stress field is large, its range strongly depends on the bubble size. The critical dose of about 2.3×10^{17} Ne^+ cm^{-2} (in the bulk samples), is exactly in the range where there is a strong increase in bubble size.

Beside the stress fields of the bubbles there is also a radiation damage-induced stress field. Assuming that a biaxial compressive stress of 1 GPa exists in the top layer, this means that apart from a hydrostatic component of 670 MPa, a shear stress of 500 MPa acts on two planes. It is unlikely that this stress is the main reason for the transformation, because especially in the thin foil experiments an efficient phase transformation was observed, whereas it seems impossible that such large stresses can exist in a thin foil. On the other hand one must realize that in a thin foil a martensitic transformation easily occurs because of the large free surface. By inspecting stereomicrographs it was not possible to obtain a three-dimensional impression of the b.c.c. particles because of the random orientation and thus random Bragg conditions. Therefore, it is not possible to conclude whether the phase transformation occurs preferentially at the bubble surface or in between two bubbles due to the

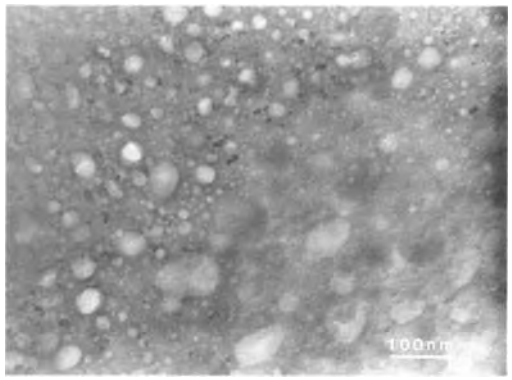

Figure 7. Bright field micrograph of a bulkside thinned sample showing no b.c.c. phase at the edge.

accumulation of the stress fields. The empty region of the edge of the bulk-side thinned samples, which represents the top of the implanted layer, supports the conclusion that the transformation does not start at the surface, but deeper down where there is a higher bubble density (Fig. 7). Preferred nucleation was observed several times at grain boundaries in thin foil samples implanted below the crucial dose (Fig. 8). Observation in an off-Bragg condition reveals a coarsening of the bubbles along the grain boundary. It is likely that this coarsening is caused by an enhanced diffusion process along the boundary. The large bubbles at the boundary may cause the transformation, but it is also likely that the nucleation energy at the grain boundary is lower anyway [45]. It cannot be concluded which factor is predominant.

From the annealed specimens we prove that the bubble size is a crucial factor in the martensite nucleation. It is important that the bubbles in the annealing experiments maintain their pressure. This means that it is not allowed to raise the temperature to a value where thermal vacancies become available, because in that case the bubbles might grow by absorption. According to Evans [46], one should keep the temperature below $0.45T_m$, which is satisifed in our experiment. So it is reasonable to assume that the large bubbles in the annealed samples still are at least pressurized to the equilibrium pressure of the small bubbles from which they are grown. If coarsening takes place, then there are two possible explanations. First, the gas in the bubbles may go back into solution, re-emerging preferentially into larger bubbles where the pressure might be lower. Secondly, the small bubbles themselves may migrate as entities, collisions between bubbles may follow, leading to coalescence and hence coarsening. There is no evidence

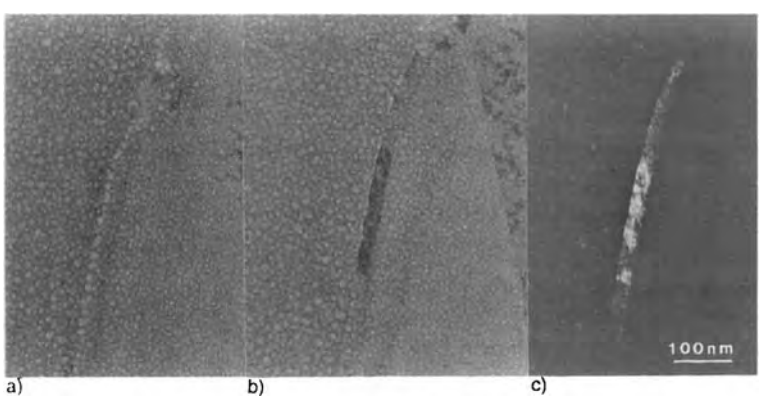

Figure 8. (a) Bright off-Bragg condition, (b) Bright in-Bragg condition, and (c) dark field micrographs of α-phase at a grain boundary in a thin foil sample (dose 1×10^{17} Ne^+ cm^{-2}).

in favor of the first alternative. The difficulty of it lies in the high energy of solution (about 5 eV for neon in iron) rather than the migration energy. Taking the second alternative, neon bubble migration can be expected in a temperature gradient, and due to interaction with dislocations during annealing. Since bubble migration requires the transfer of solid material from one side of the bubble to the other, it seems likely that surface diffusion around the bubble periphery occurs upon annealing at 400°C. Further, when dislocations move by climb during annealing one may expect them to sweep up the bubbles in their path, and hence cause a coarsening. In addition, Goodhew [47] pointed out that around the annealing temperature of $0.45T_m$, surface diffusion is the predominant mechanism of coarsening. The growth rate appears to increase with increasing bubble concentration. In the present study the bubble concentratton is very high, that is, 10^{24} bubbles m^{-3}.

The main difference between our result and the ones obtained previously [43, 44] is the lack of a distinct orientation relation. However, it has to be emphasized that Johnson et al. [43] refer to antimony implantations, implying that the stress fields are not localized around bubbles, and to krypton as an implant [44]. Since neon possesses a much higher compressibility compared to krypton, it is quite obvious that the critical dose of neon implantations should be higher. Consequentially, the nucleation behavior is altered in such a way that the volume fraction and bubble sizes are much larger in our case. This, together with the high pressure in the bubbles, causes a deformation around the bubbles, and a reduction of the maximum size of the nuclei. The small size together with the deformation causes the random orientation. This is in agreement with the increase in the orientation relationship when we compare the unannealed thin foil samples (3×10^{17} Ne^+ cm^{-2}), that is, substantially deformed with the bulk-side thinned (3×10^{17} Ne^+ cm^{-2}) or annealed thin foil samples (1×10^{17} Ne^+ cm^{-2}), as can be concluded from Fig. 9. In the case of the bulk-side thinned samples there is a restriction to the deformation because there is only one free surface. In the case of the annealed samples the volume fraction of the bubbles is much lower, causing less deformation. The variation in sizes of the b.c.c. particles supports this idea.

The interesting outcome from the TEM observations is that, primarily, noble gas bubbles have been shown to be detrimental for wear resistance, unless they play an active role in, for example, pinning of dislocations or favoring an f.c.c. to b.c.c. transformation, as observed in implanted 304 steel. The austenite stability is not low enough in the case of laser-treated RCC steel, since no transformation has been observed in the implanted samples. Nevertheless, one expects an increased work hardening rate in such a layer. Concerning the f.c.c. to b.c.c. transformation, we can state that the shear field of an inert gas bubble may induce a local martensitic transformation, provided the bubble size and pressure are large enough. Further, the austenite stability must be low.

1.4.1.3 Micro-Peening

Shot peening is a process of cold working applied to the surface of metals by the

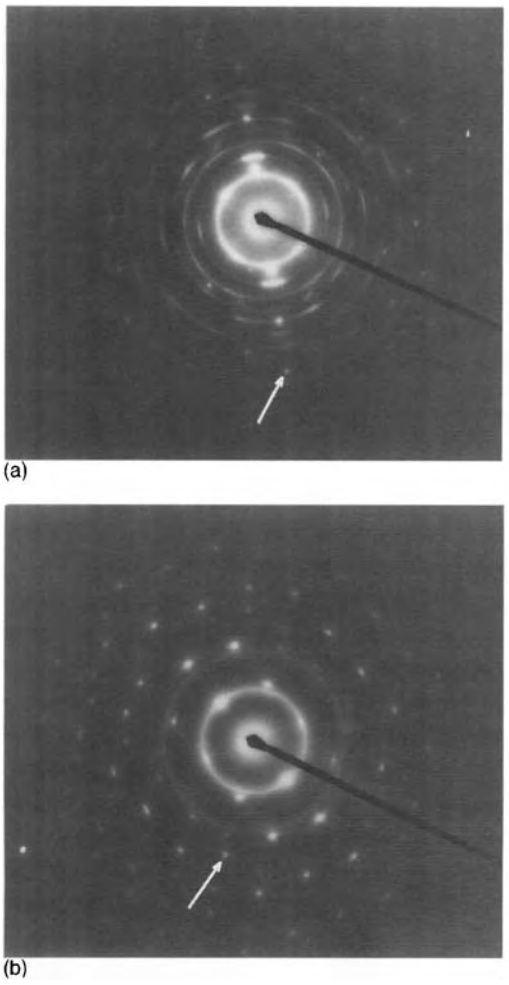

Figure 9. Diffraction patterns of implanted samples, showing (a) angular intensity dependence of the b.c.c. rings in the case of the bulkside thinned sample and (b) a constant intensity in the case of the thin foil sample. In both patterns a ⟨400⟩-type f.c.c. reflection is indicated that can be used for indexing the b.c.c. rings.

impingement of a stream of particles under controlled conditions. Although this is a recent definition, similar processes such as hammering have long been used [48]. Modern techniques, for example robotics, make a controlled and reproducible process feasible. It is even more important that modern analyses of peened surfaces provide a feedback control, so that the process parameters can be optimized. In the past decades this has provided a new impetus to shot peening.

The principal aim of shot peening is to improve the fatigue lifetime, stress corrosion resistance, and other tensile stress-related metal failures. These improvements are achieved mainly by the compressive surface stress state that arises by this treatment. In such a layer it is more difficult for existing cracks to propagate and to nucleate. This compressive stress also acts as an off-set when a workpiece is loaded in such a way that the resultant surface stress state would be a tensile one. Because shot peening is capable of inverting a tensile stress state to a compressive one it is an appropriate treatment of a surface after grinding, machining or any other treatment that caused the surface to be in a tensile stress state. It must be noted that, while a workpiece is in service, stress relaxation will take place. Therefore, repeening may be useful to restore resistance to fatigue failure [49].

Apart from changing the stress state, shot peening may also be applied to clean, form and strengthen metal surfaces [50]. The reduction of wear rate after shot peening of steel is reported by Jiawen [51] and Ritchie [52]. Strengthening of a metal surface will also have an effect on the fatigue behavior. Usually the higher dislocation density, as introduced by peening, has no beneficial effects. In softer alloys the improvement of the fatigue behavior is mainly due to strain hardening [53].

It has already been stressed by other researchers that not only the peening conditions but also the microstructural state of the material is crucial with respect

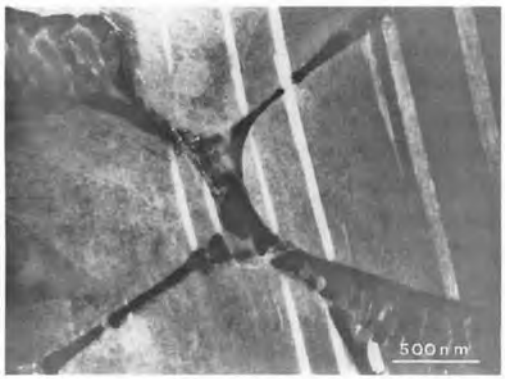

Figure 10. Dark field transmission electron micrograph showing strain-induced martensite in austenitic cells.

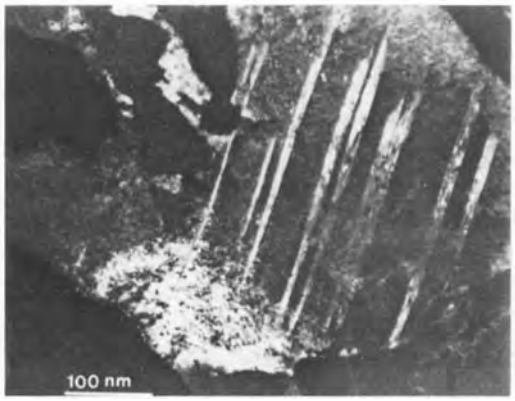

Figure 11. Wear induced α-martensite near the surface.

to the final results [54]. They studied the mechanical properties of two aluminum alloys, peened at different stages of the heat-treating process. Their results showed strikingly different resultant properties with changing tempering conditions. It also became clear that no general conclusion can be drawn, since the optimal treatment depends on the composition of the alloy as well as on the requested specific property. An interesting TEM observation is displayed in Fig. 10, showing an RCC sample after shot peening. TEM specimens are prepared using a dimpler followed by ion milling in such a way that various depths below the surface can be inspected (Fig. 10). At depths of at least 15 μm, stress-induced martensite is found with the same morphology as observed in a worn laser-treated RCC sample (Fig. 11). At a depth of 30 μm only an increase in dislocation density was found: $10^{13}\,m^{-2}$ before and more than $10^{14}\,m^{-2}$ after peening.

Theoretical descriptions of the shot peening process are not readily available. The stress fields that arise from the multiple impact are quite complicated, which makes application of work hardening theories complex. Therefore, research in the field of shot peening is still characterized by its empirical nature. It is likely that this situation will not change very quickly unless more TEM research is carried out. So far, because of the analogy with Hertzian stress analysis, the best results are obtained in predicting residual stress profiles.

Next, two different examples are presented of aluminum alloys, shot peened and investigated by TEM afterwards. In the past decades many aluminum alloys have been designed to serve various purposes. Binary Al–Si alloys, for instance, show superior cast properties, but have a low strength. Alloys containing copper, magnesium and small fractions of other alloying elements, on the other hand, possess poor castability, but develop high strength after appropriate heat treatments. Improvement of these alloys by conventional processes has its limits, and therefore alternative techniques such as splat cooling and laser melting are increasingly being explored. The surfaces are given a shot-peening treatment to improve the

residual stress state, and the resultant microstructure is investigated with TEM. Here we will concentrate on a eutectic Al–12 wt.% Si (Al–12 Si) alloy representing the class of cast alloys, whereas Al 2024 was chosen to represent the commercial Al–Cu–Mg class of alloys.

One of the reasons for choosing an Al–Si alloy is its simple phase diagram, that is, no intermetallic compounds. Further, eutectic Al–Si alloys are commonly used for automotive parts such as cylinder heads and pistons. These types of alloys combine, apart from good castability, low density, good corrosion resistance and low thermal expansion. The mechanical properties can be further improved by small additions of sodium or strontium [55]. These impurities cause a change in the morphology of the silicon particles, and a decreased spacing between them. The amount of modifier, however, is quite critical since over-modification results in reduced mechanical properties. Furthermore, losses from the melt and the formation of undesired intermetallic compounds cause additional problems.

Rapid solidification by means of laser surface melting offers another way of achieving a fine distribution of the silicon phase [56]. The cellular solidification results in cell sizes of the order of 1 μm, depending on the scan velocity. The depth of the laser tracks is 50–500 μm, which is enough to allow further machining, and depends on the process parameters. In addition, laser surface treatment is a process that offers greater precision and less distortion than most other surface techniques.

Comparison of the optical micrograph of Al–Si in the as-cast condition (Fig. 12) with the transmission electron micrograph

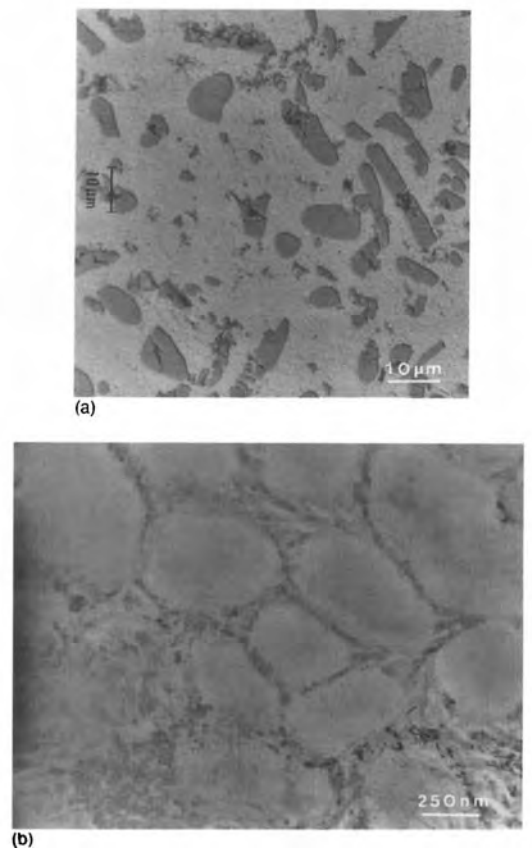

Figure 12. (a) Optical micrograph of aluminum–silicon in the as-cast condition and (b) transmission electron micrograph of the cell structure after laser melting at 8 cm s^{-1}.

of the cell structure after laser melting (Fig. 13) clearly reveals the refined structure caused by the rapid solidification after laser treatment. Transmission electron micrographs are used to estimate the dislocation density of the samples before and after shot peening. Because the observed densities are without exception very high [56] (see Fig. 13), only rough estimates can be given here: 10^{13} m^{-2} for a low laser scan velocity without shot peening and more than 10^{14} m^{-2} for a high laser scan velocity after 360 s of shot peening. Dislocation cell

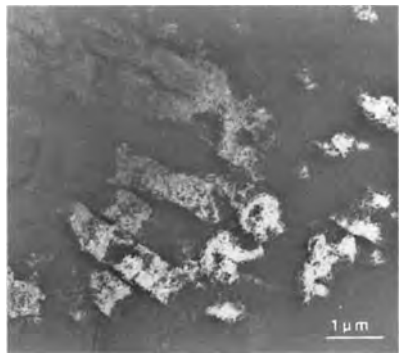

Figure 13. Dark field transmission electron micrograph showing the dislocation structure in peened Al–12 Si (laser scan velocity 8 cm s^{-1}).

structures are not observed to be formed during the shot peening. Apparently, the sizes of the cells to start with are too small to allow further division. Minimum energy configurations by the formation of a checkerboard-like structure of the original cells are sometimes observed (Fig. 13).

An important TEM observation is the difference in mobility of the dislocations in the low and the high laser scan velocity samples. In the $\frac{1}{8}$ cm s^{-1} samples the heat input from the electron beam was sufficient to cause thermal activated dislocation movement. In the 8 cm s^{-1} sample this was not observed.

The low laser scan velocity samples reveal a breaking up of the solidification structure after shot peening. This change of structure is not accompanied by an increased dislocation density, which implies dynamic recovery during deformation. The result is a fine granular structure with a typical grain size of 0.5–1 µm (Fig. 14). Silicon particles originally forming the eutectic cell walls are then more randomly distributed.

Another observed phenomenon in high laser scan velocity samples after shot peening is the formation of silicon precipitates.

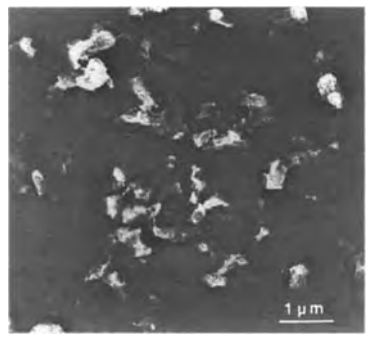

Figure 14. Dark field transmission electron micrograph of the fine granular structure in a sample with a laser scan velocity of $\frac{1}{8}$ cm s^{-1}, after shot peening.

The sizes of these precipitates vary from approximately 5 to 50 nm (Fig. 15).

Most important is the breaking of the original silicon particles in the peened bulk samples (Fig. 16). This indicates that this alloy in the as-cast condition is not suitable for a shot-peening treatment.

In this section an estimate is presented of the contribution to the flow stress originating from the obstacles present in our samples. The following relevant obstacles are present: substitutional silicon atoms, forest dislocations and silicon precipitates. The strength of these various types of obstacles can be calculated,

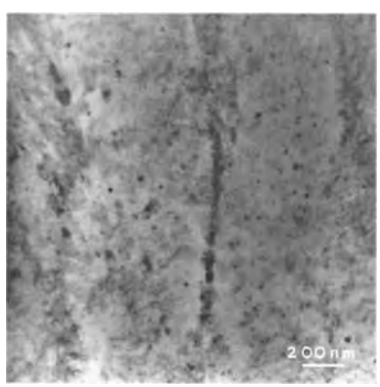

Figure 15. Precipitates in shot-peened Al–12 Si (laser scan velocity 8 cm s^{-1}).

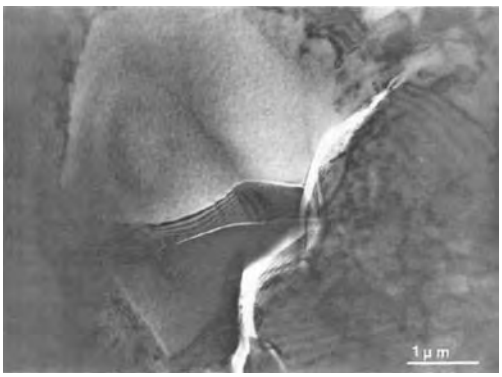

Figure 16. Shot peening induced breaking of primary silicon particles in the as-cast Al–12 Si alloy.

approximating the flow stress by

$$\tau = \tau_{\text{subst}} + \tau_{\text{disl}} + \tau_{\text{prec}} \tag{11}$$

where the first two contributions can be described using Friedel's relation [23]:

$$\tau_{\text{subst,disl}} = \frac{Gb}{L} \cos^{3/2}\left(\frac{\phi_c}{2}\right) \tag{12}$$

where G, b, L, and ϕ_c are the shear modulus, magnitude of the Burgers vector, obstacle spacing and critical break away angle, respectively. In the material the relatively high amount (up to 2%) of silicon in solid solution is likely to play an important role. The maximum solubility of silicon in aluminum is only 1.5% at the eutectic temperature, and it decreases to 0.05% at 300°C [57]. This low solubility is caused by the large misfit between aluminum and silicon, while silicon still occupies substitutional sites. This large misfit (18%), however, gives the silicon atoms a large interaction strength, and thus an already large contribution to the flow stress at relatively low concentrations. To calculate the numerical value of this contribution an estimate of the interaction strength ξ is made by comparing ξ with misfits in other systems [58]. ξ depends on the critical break away angle being $\xi = \cos(\phi_c/2) = 0.04$. This value, together with L rewritten as $b/\sqrt{c}$, results in a contribution to the flow stress of $10^{-3}G$, at a solid solution concentration of 1.5%. This value of the flow stress has to be considered as an upper limit since a justification of Friedel's relation can be given only for not too weak obstacles and for a low concentration of impurities, that is, when the mean distance between obstacles is larger than the minimum curvature radius of the dislocation at the obstacle. In fact the critical condition of Friedel's approximation [59], $cW^2/\xi b^2 < 1$, indicates that the present situation is a borderline case (W represents the width of the dislocation). A different approach as presented in Mott–Nabarro's model [60], taking into account the internal stress around each solute [61, 62], predicts a contribution of the flow stress of $4 \times 10^{-4}G$.

Regarding the misfit between aluminum and silicon, one should note that silicon is a nonmetal and that the tabulated atomic radius might change significantly when embedded in a metal. The rate of lattice contraction, when it is added as a solute, indicates that the misfit is smaller than that based on the atomic radii.

In addition, Fleischer [62] pointed out that the modulus mismatch is just as important as size mismatch when considering solid solution hardening. To take modulus hardening into account one should have a knowledge of the relative change of the shear modulus G^{-1} $(\delta G/\delta c)$ as solute is added. Since silicon is virtually insoluble in aluminum this change is very difficult to measure, and to our knowledge no values have been reported in the

literature. Nevertheless, the modulus mismatch will have its effect on the interaction strength. Therefore, we have made an approximation of this mismatch by applying the following relations [63]:

$$\frac{(G_{Al}+G_l)f_v}{G_{Al}+G_l+(G_{Si}-G_{Al})(1-f_v)} \leqslant \frac{G-G_{Al}}{G_{Si}-G_{Al}} \leqslant \frac{(G_{Al}+G_g)f_v}{G_{Al}+G_g+(G_{Si}-G_{Al})(1-f_v)} \tag{13}$$

where, if $(G_{Si}-G_{Al})(K_{Si}-K_{Al}) \geqslant 0$,

$$G_l = \frac{3}{2}\left(\frac{1}{G_{Al}}+\frac{10}{9K_{Al}+8G_{Al}}\right)^{-1}$$

$$G_g = \frac{3}{2}\left(\frac{1}{G_{Si}}+\frac{10}{9K_{Si}+8G_{Si}}\right)^{-1}$$

In these equations $G_{Al,Si}$ and $K_{Al,Si}$ represent the shear and bulk moduli of the aluminum and silicon phases, respectively, and f_v denotes the volume fraction of silicon. It must be emphasized that this method neglects all electronic effects, and should only be used as a first-order approximation.

The resulting value of the relative modulus change and the value of the change in the lattice parameter can be combined using the method developed by Fleischer [62] in order to obtain a numerical value for the interaction strength. This method results in $\xi = 0.042$, which is very similar to the estimate based upon the nonembedded atomic radius.

The second contribution to the flow stress, arising from the dislocation–dislocation interaction, also needs to be considered. The numerical value of the dislocation density can be obtained by TEM. The estimates based on the transmission electron micrographs are of the order of $10^{13}\,m^{-2}$ after laser melting, and are raised by one or two orders of magnitude after subsequent shot peening. To calculate the numerical value of the contribution to the flow stress, Friedel's equation is rewritten as

$$\tau_{disl} = \alpha G b\sqrt{\rho} \tag{14}$$

where α is $\frac{1}{3}$, and ρ represents the dislocation density. This equation is valid if internal stresses are absent. In heavily deformed materials the internal stress takes up about 80% of the applied stress [64]. Therefore, the effective contribution to the flow stress amounts one-fifth of the value calculated with the equation above, resulting in a value of τ_{disl} of $2 \times 10^{-4}G$ for a dislocation density of $10^{14}\,m^{-2}$.

During shot peening, the measured concentration of silicon in solid solution significantly decreases, and silicon precipitates appear. This low-temperature precipitation must then be assisted by pipe diffusion. Because the capture radius of the dislocations is undoubtedly small compared to the initial dislocation spacing, a lot of deformation is needed. This is confirmed by TEM observations. The presence of these silicon precipitates form the third contribution to the flow stress. Since these precipitates are incoherent they will not be sheared. Then the critical shear stress is given by the Orowan stress [65]:

$$\tau = \frac{0.84Gb}{2\pi(1-\nu)^{1/2}}\frac{\ln(2R_s/r_0)}{(L-2R_s)} \tag{15}$$

where R_s represents the particle radius and r_0 is the dislocation core radius.

To calculate the contribution of the precipitates to the flow stress, their average

spacing is needed. This is a difficult task because the small precipitates in particular are easily overlooked, due to the random orientation of the precipitates and the heavily deformed condition of the material. Therefore, only an estimate of 0.1 μm is used here. This value results in an Orowan stress of $4 \times 10^{-3}G$.

Comparison of the calculated contributions to the flow stress indicates, based on TEM analyses, that the high hardness values after laser melting and shot peening are caused mainly by precipitation hardening and, to a lesser extent, by solid solution hardening. The dislocation–dislocation interaction seems not to be the predominant factor either.

The considerations mentioned above do not include any possible changes in cross-slip behavior. We have not yet discussed the large difference in dislocation density in samples treated at low and high laser scan velocities, as observed by TEM. Examination of the experimental results indicates that a changed cross-slip behavior might be responsible for this phenomenon.

An increase in hardness can be achieved if one could eliminate or postpone the onset of cross-slip (stage III). From that point on, the work-hardening rate is decreasing with increasing strain. In our samples we see that after an initial period of approximately linear hardening, the work-hardening rate indeed decreases, but the peening time at which the saturation starts increases with increasing laser velocity. This indicates that the onset of cross-slip might be postponed by an increased laser velocity. This observation is in line with the observed higher dislocation density in samples treated at high laser scan velocity. In the present case the cross-slip behavior can be affected in various ways.

First, the introduction of impurity atoms affects the stacking fault energy and therefore the stress necessary to constrict the partial dislocations to cross-slip. In the case of aluminum the stacking fault energy is of the order of $200\,\mathrm{mJ\,m^{-2}}$. This high value results, applying linear elasticity, in an equilibrium separation less than one Burgers vector for a screw dislocation. Since in our samples the maximum amount of silicon impurities is 2%, it is not very likely that the stacking fault energy is lowered by such an amount that the cross-slip behavior changes significantly.

A second mechanism by which, in our case, the cross-slip behavior can be altered has to do with the prerequisite of the cross-slip process to occur, namely that the dislocation is in the pure screw orientation over some distance. When impurities with sufficient stress fields are present, the dislocations will show deviations from straightness, and the activation energy for cross-slip will apparently be raised.

A study of the coarse slip bands after deformation may reveal whether this second mechanism plays a dominant role or not. Small additions of copper or magnesium in aluminum, elements that cause a significant misfit, have been shown to increase the stress for the onset of cross-slip [66] whereas addition of silver has no such effect. Since there is almost no size difference between aluminum and silver, this is in accord with the second mechanism described above. As already mentioned, there is a large misfit in the case of silicon in aluminum, so that, in our case, it is likely that cross-slip is hindered by this mechanism (see Fig. 17).

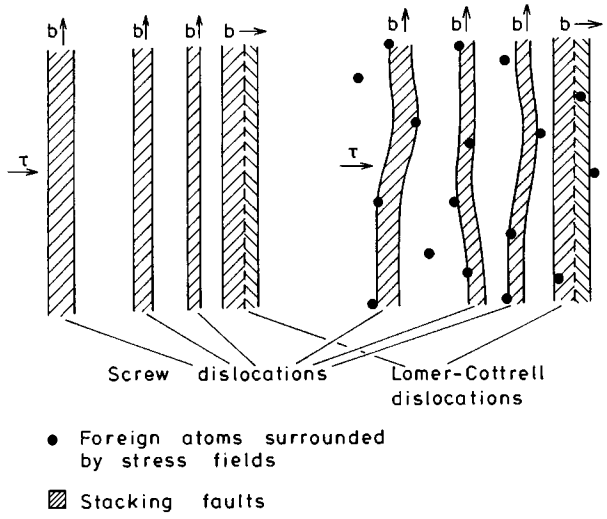

Figure 17. The inhibition of cross-slip by foreign atoms interacting with dislocations.

It has been found that laser treatment of an as-cast eutectic Al–Si alloy leads to a very fine dispersion of the silicon phase in an aluminum matrix. Further, it turned out that this laser treatment is able to amplify considerably the effectiveness of a subsequent shot-peening treatment. In particular, the maximum attainable hardness and compressive stress increase upon increasing the quench rate, that is, upon increasing the laser scan velocity. From TEM observations the creation of shot-peening induced silicon precipitates forms the most striking result of this study. It is likely that this precipitation is caused by the capturing of silicon atoms by moving dislocations. The resultant distribution of small silicon precipitates make up the predominant contribution to the flow stress.

Another example concentrates on aluminum alloys containing copper, magnesium and small weight percentages of other alloying elements which develop high strength after appropriate heat treatments. Conventional hardening treatments of these aluminum-base alloys usually exploit the beneficial effects of a high concentration of precipitates. In binary Al–Cu alloys that form the basis for all alloys in the 2XXX series, usually containing 4 wt.% of copper, the precipitation of intermetallic compounds is known to proceed through a series of different precipitates. Normally, ageing starts with fully coherent Guinier–Preston (GP) zones, which can initially be regarded as copper disks, one atomic layer in thickness. As the GP zones grow, they lose coherency in the direction normal to the disk. This gives rise to GP-II zones or θ'' precipitates. These platelets, approximately 0.5 nm thick and 10 nm across, lie parallel to the {100} planes in the aluminum matrix. On raising the temperature these platelets transform into other semi-coherent platelets, designated as θ'. These precipitates have the same orientation relationship with the matrix, but are an order of magnitude larger than the θ'' platelets. The series terminates with the incoherent equilibrium phase θ. The elimination of the internal stresses associated with the semicoherent

precipitates and the accompanying coarsening are responsible for the softening observed when the precipitation sequence reaches this stage.

If the alloy also contains magnesium, the Al–Cu precipitates are partly or completely replaced by Al–Cu–Mg precipitates. These precipitates are also platelets, and are called S′ and S in the literature. The composition, crystal structure and orientation relationship of these precipitates depend on the copper/magnesium ratio. With magnesium in excess of 4 wt.%, freezing of an Al–4.4 wt.% Cu alloy may follow the Al–S branch leading to the so-called T phase (approximately $CuMgAl_6$). If no copper is present, Mg_2Al_3 will be formed.

Here, laser hardening of an Al 2024 alloy was carried out to investigate the possible hardening mechanisms in laser-treated Al–Cu–Mg alloys. Normally, hardening by laser treatment is achieved primarily by the small grain sizes that are formed as a result of the rapid solidification process. The flow stress varies as $d^{-\alpha}$ where α depends on the cell size and cell wall type. Since the cell size is inversely related to the solidification rate, generally an increasing hardness is observed with increasing laser scan velocity. The nucleation and growth of precipitates that would contribute predominantly to the hardness of laser-melted materials is usually suppressed by the high cooling rates involved, typically of the order of 10^4–10^5 K s^{-1}. In an Fe–W–C tool steel, however, the presence of precipitates in a surface that was 'autotempered' by applying overlapping laser tracks was reported [27]. Nevertheless, in overlapping laser tracks, precipitation processes are not likely to occur.

In aluminum–copper alloys, however, the precipitation may start with (semi-) coherent platelets which significantly lowers the nucleation energy. Therefore, in such alloys precipitation may be a feasible process. The scan velocity was varied over two orders of magnitude to obtain various stages in the precipitation sequence. Subsequent hardness measurements were carried out, before and after the shot-peening treatment, to study the work-hardening behavior of the laser-treated material. In addition, attention was paid to the microstructure and the residual stress state in the samples.

Samples of commercial Al 2024-T3 (4.4% copper, 1.5% magnesium, 0.6% manganese and the balance aluminum; solution treated, cold rolled and naturally aged) were given the same laser treatment as the Al–Si samples. For this material,

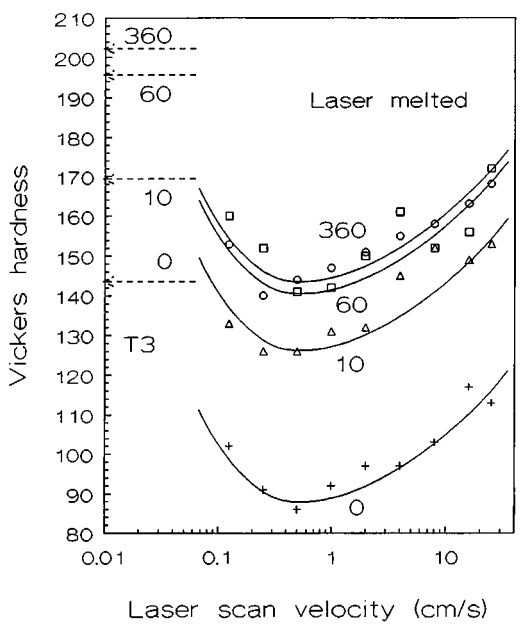

Figure 18. Hardness profile as a function of laser scan velocity and shot-peening time (seconds).

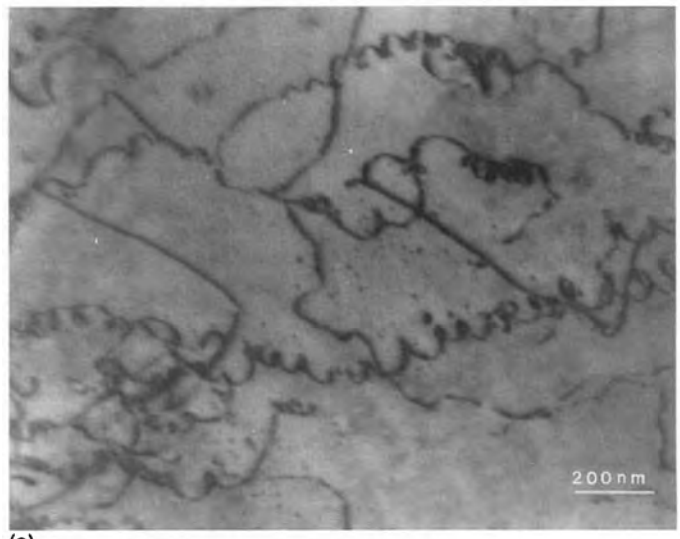
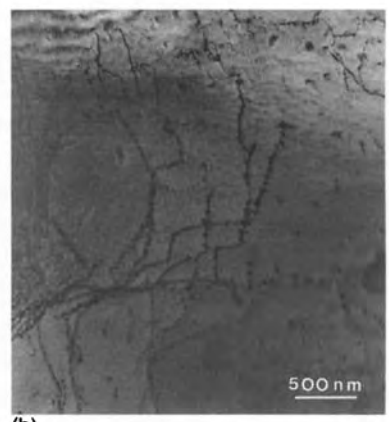


(a)



(b)

Figure 19. Helical dislocations in a sample treated at a laser scan velocity of $\frac{1}{8}$ cm s^{-1}: (a) grown by vacancy absorption and (b) by interaction of a screw dislocation with prismatic vacancy loops. Schematic representations of the operating mechanisms are depicted in (c) and (d), respectively.

however, there are no homogenization problems. Therefore, the scan velocity range was extended up to 25 cm s^{-1} (single pass). It should be emphasized that of all the elements in Al 2024, magnesium has by far the lowest boiling point (1390 K), and it is therefore to be expected that a substantial fraction of magnesium will actually evaporate during the laser treatment. Some extra samples of pure aluminum, Al–2.32 wt.% Cu and Al–4.5 wt.% Cu, were also given a laser treatment. Subsequent shot peening was carried out only for the Al 2024 samples. TEM investigations are used to explain the remarkable behavior of the mechanical properties of this alloy as displayed in Fig. 18.

TEM specimens taken from Al 2024 samples and exposed to different laser scan velocities, before shot peening, show marked differences in microstructural features. The samples treated at lower scan velocities, $\frac{1}{8}$ to $\frac{1}{2}$ cm s^{-1}, are mainly precipitate-free, although in some areas

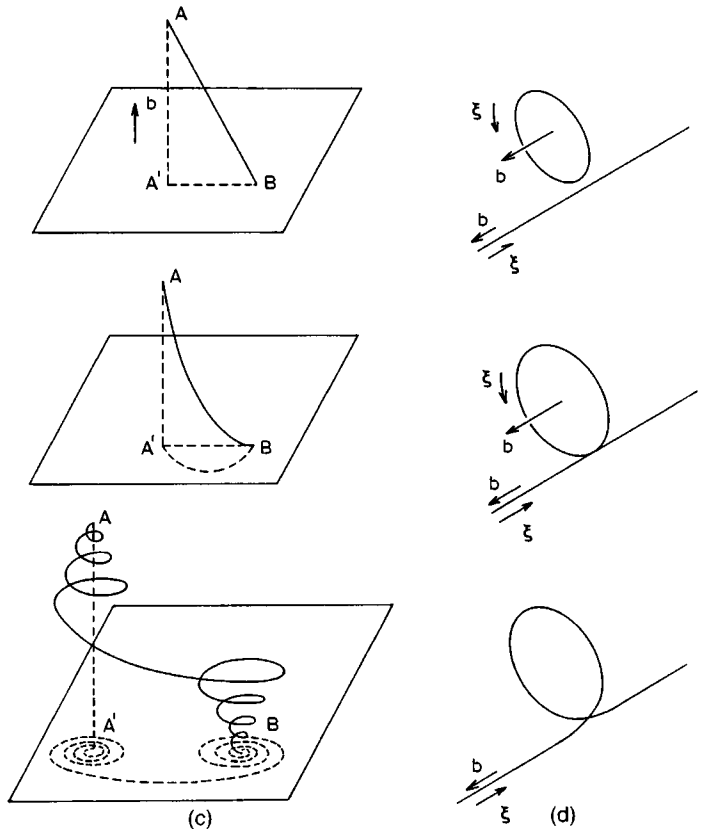


Figure 19. *Continued*

coarser precipitates could be observed. However, it is uncertain whether these are partly dissolved cell boundaries or real precipitates.

The most striking feature is the formation of helical dislocations (Fig. 19a and b), as observed in all samples treated at low laser scan velocity. Most of these dislocations exhibit a uniform equilibrium shape with respect to pitch and radius. At the lowest scan velocity, however, non-uniform shapes are occasionally observed (Fig. 20).

In samples treated at laser scan velocities of between 1 and 4 $cm\,s^{-1}$ the precipitation of the tetragonal platelets, with an average size of 150 nm, is observed, as can be seen in a bright field micrograph (Fig. 21). Since these platelets are oriented parallel to the {100} faces of the aluminum matrix, we may conclude that these precipitates are not the so-called S′ precipitates (Al_2CuMg). The S′ precipitates grow locally on {120} planes, giving {110}, {100} or {130} as an overall growth plane [67, 68]. In addition to the platelets a more globular precipitate is also observed in these samples, mainly nucleating on the edges of the θ' plates and on dislocations. This could be the θ phase as well as the S or S′ phase. Since in alloys with a copper/magnesium ratio of less than 8/1, Al_2CuMg precipitates can start to play a role [69], the existence of the S and S′

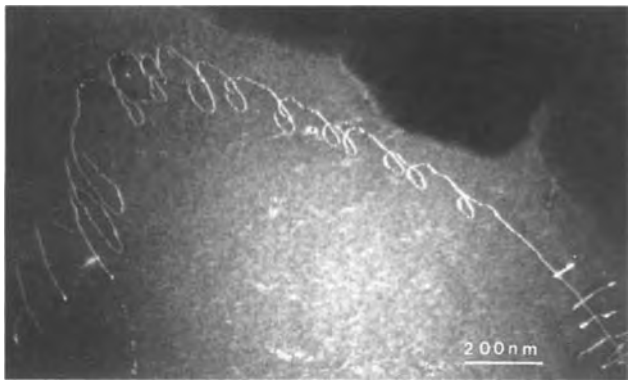

Figure 20. Dark field transmission electron micrograph of a nonequilibrium helical dislocation.

phases cannot be excluded. Electron diffraction patterns have not yet revealed the nature of these precipitates.

Samples treated at laser scan velocities of 8–25 cm s^{-1} show only a cellular structure, in which it is seen that the cell boundaries act as obstacles for dislocation motion. GP zones, which could precede the formation of the θ' plates, are not observed.

After shot peening, in all samples a higher dislocation density was observed by TEM. Apart from the increased dislocation density, however, precipitates could now be detected in samples that did not develop observable precipitates before shot peening. A typical example of this precipitation process induced by shot peening in a sample treated at a low laser scan velocity of $\frac{1}{8}$ cm s^{-1} is shown in Fig. 22.

The concentration of precipitates seems also to be higher than before peening in samples treated in the scan velocity range of 1–4 cm s^{-1}. This might indicate an increased solid solution in these samples, but the smaller average size, 100 nm, will also result in a higher concentration. Again, most of these precipitates are θ' platelets, aligned with the cubic axes. A second type of precipitate, smaller in size but also of the shape of a platelet, is identified as the S′ phase, initially growing on [120] planes. These precipitates have a

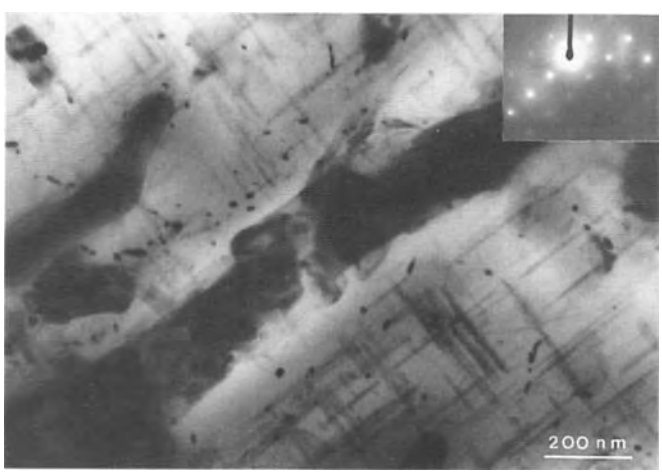

Figure 21. Bright field transmission electron micrograph showing θ' platelets and some incoherent θ or S precipitates, in a sample treated at 2 cm s^{-1}.

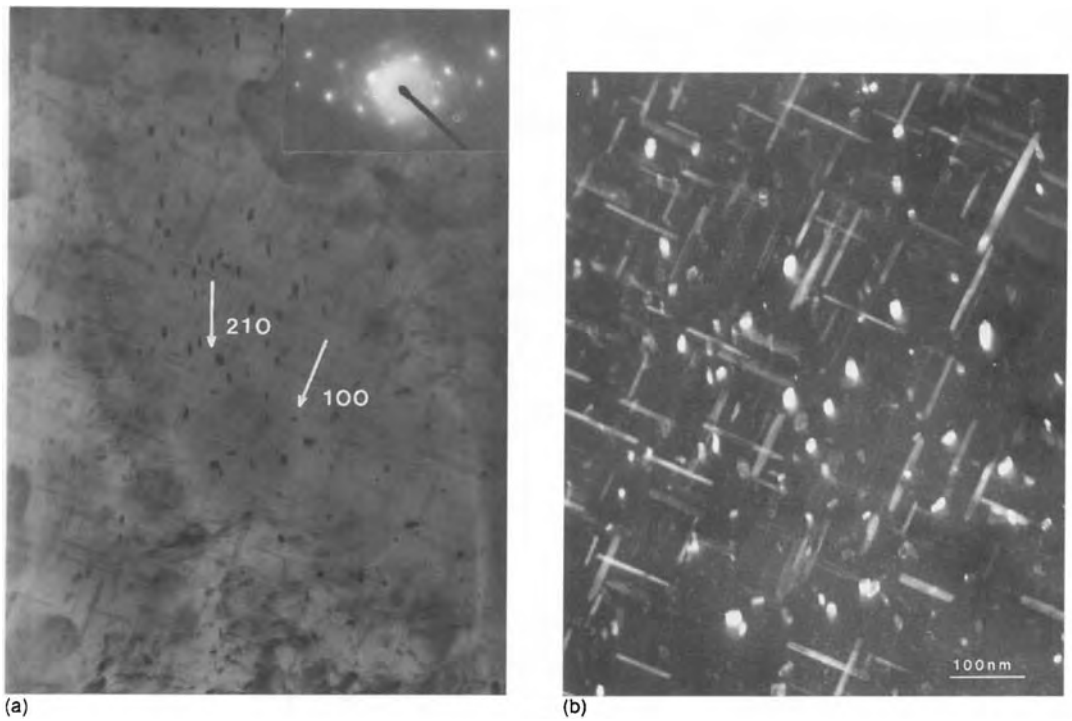

Figure 22. (a) Bright and (b) dark field transmission electron micrographs of shot-peening induced θ' and S' precipitates in a sample treated at a laser scan velocity of $\frac{1}{8}$ cm s^{-1}, peened during 360 s. The crystallographic planes on which the precipitates are observed to grow are indexed.

much smaller width-to-thickness ratio and will therefore contribute less to an increase of the flow stress than the θ' plates (at the same volume fraction). The very broad size distribution, down to only 2 nm, makes this contribution more uncertain.

To discuss the TEM results and to see how they can contribute to the explanation of the hardness profile, the laser scan velocity range is divided into two regimes: the low scan velocity regime ($\frac{1}{8}$ to $\frac{1}{2}$ cm s^{-1}) and the high scan velocity regime ($\frac{1}{2}$ to 25 cm s^{-1}).

Low scan velocity regime

Since the cooling rates are lower in the low laser scan velocity samples, compared to 2 cm s^{-1} samples, in which precipitation of the θ' plates is observed, one would expect to see an increasing nucleation and growth of precipitates in these samples. In contrast, below 1 cm s^{-1} no significant precipitation is observed. The explanation for this observation lies in the decreasing vacancy concentration with decreasing laser scan velocity. Apparently at the lower laser scan velocity the vacancies are annealed out before the temperature reaches values that would favor the nucleation and growth of observable precipitates, a.o. by absorption at dislocations causing the formation of helical dislocations. The rise in hardness values in the low-velocity regime cannot be caused by precipitation hardening

but must be due to two other contributions.

First, the dissolution of the cell walls and subsequent homogenization will play an important role. Since there exists only a small temperature interval during which homogenization takes place, as can be determined from [70], the cooling rate must be low enough to allow sufficient time for diffusion. The copper (and magnesium) brought into solid solution will contribute to an enhanced hardness, but for reasons described above, copper will not form any precipitate. The dissolution may continue as long as not all cell walls have been fully dissolved, provided that the cooling rate is low enough. Obviously this situation has not been reached in practice, and it explains why the hardness is still increasing with decreasing laser scan velocity.

In the additional experiments performed on the alloy with 2.32 wt.% of copper, it was observed that the cell walls were completely dissolved, only near the edges of the low scan velocity ($\frac{1}{8}$ cm s^{-1}) laser tracks. This observation is illustrated in Fig. 23. From this experiment we conclude that to a first approximation only half of the copper is in solid solution in Al 2024 treated with a scan velocity of $\frac{1}{8}$ cm s^{-1}. A calculation of the diffusion distance in a $\frac{1}{8}$ cm s^{-1} track, during cooling in the interval between 660 and 450°C, applying the analytical model for the temperature profile [71], yields a distance of approximately 0.1 μm. A calculation for magnesium yields a similar value. These values, which should only be regarded as being a first approximation, are too small for significant homogenization. Nevertheless, it shows that homogenization may play a role only at the lowest scan velocities.

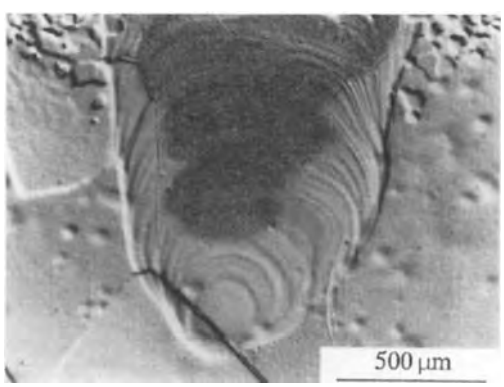

Figure 23. Dissolved cell walls in a $\frac{1}{8}$ cm s^{-1} track on an Al–2.32 wt.% Cu sample.

To quantify the contribution of solid solution to the hardness the same methods as in the previous section dealing with Al–Si are applied, taking size as well as modulus mismatch into account. This calculation yields for copper and magnesium the same critical break away angle, for which $\cos(\theta_c/2) = 0.036$. In the case of copper this high value is mainly due to modulus mismatch, whereas in the case of magnesium, size mismatch contributes most. The corresponding contribution to the flow stress amounts to 19 MPa at 2.32 wt.%.

Besides homogenization, a second contribution to the increased hardness in the low scan velocity regime is related to the formation of helical dislocations. Since the glide of a helical dislocation is restricted to its cylindrical surface on which it is wound, these dislocations are essentially immobile. The formation of helical dislocations is observed in all samples treated at low laser scan velocity.

From the geometry of these dislocations it is concluded that they arise from both climb of the part of a mixed

dislocation of edge character (see Fig. 19a and c) and from the interaction with prismatic vacancy loops (see Fig. 19b and d). Both mechanisms require a supersaturation of vacancies [13, 72]. A large quantity of vacancies is present because of the substantial cooling rates. The reason that the formation is possible only in samples treated at the low laser scan velocity is that only here is the cooling rate at intermediate temperatures low enough to allow for adequate vacancy diffusion. Once the temperature is too low for significant vacancy diffusion, the dislocations become immobile over the distance that has been affected by climb or by the interaction with the vacancy loop. The equilibrium shape of a helical dislocation is one of constant pitch and loop radius [13]. Since a nonequilibrium shape is sometimes observed, we conclude that in the sample treated at the lowest scan velocity the annealing time is still not long enough for all the dislocations to reach this equilibrium situation. This in turn can be caused by the continuous formation of new helical segments, which means that not all vacancies are used, or by an increased locked segment through relaxation to the equilibrium shape. These explanations are also in line with the fact that the hardness curve is still rising at the $\frac{1}{8}\,\mathrm{cm\,s^{-1}}$ point (see Fig. 18). Nevertheless, we do not expect that this mechanism will dominate over the role of homogenization as described previously.

High Scan Velocity Regime

The increased hardness in the high-velocity regime, reflects the generally observed trend, and is caused by two reasons. First, the cell size decreases upon increasing the laser scan velocity, and causes a hardening that depends on K and a in the following equation: $\tau = K/d^{\alpha}$. Unfortunately, the values of α and K are not easily derived. α may vary from $\frac{1}{2}$, in the Hall–Petch relation, up to 2, as has been described by Hegge and De Hosson [56]. Furthermore, precipitates will contribute to the hardness, and this contribution may be even larger than the contribution arising from the small cell size. The presence of these precipitates is observed in samples with scan velocities of 1 to $4\,\mathrm{cm\,s^{-1}}$.

To calculate the contribution of the precipitates to the hardness one needs to know the average size and volume fraction as deduced from TEM observations. Since the θ' precipitate is commonly regarded as giving the most important contribution, attention will be paid only to this precipitate.

Because the shape of the θ' precipitate deviates strongly from spherical, some corrections to the observed dimensions are required to obtain the dimensions in the glide plane. In the glide plane, the mean length of the obstacles D' is $\pi D/4$, and the mean thickness d' is $d\sqrt{3/2}$. Given a volume fraction f_v, the mean center-to-center spacing is: $\lambda' = \sqrt{D'd'/f_v}$.

A distribution of linear parallel obstacles of length $L = D' - d'$ will contribute to an increase in flow stress that is $1 + (L/\lambda')$ times greater than for the associated distribution of point defects. The latter applies to aligned obstacles only. If we take into account the finite thickness of plate-shaped particles, the effective separation between the precipitates is [73]

$$\Lambda_p = \frac{\lambda'}{1 + L/\lambda'} - d' \tag{16}$$

The flow stress is then given by

$$\tau = \tau_0 + \frac{k_1 k_2}{2\pi \Lambda_p} Gb \ln\left(\frac{\Lambda_p}{b}\right) \qquad (17)$$

where k_1 is a statistical factor equal to 0.85, and k_2 is a factor depending on the character of the dislocation varying between 1 and 1.5 [74]. The contribution to the flow stress arising from other effects is represented by τ_0. From TEM observations, $D = 150\,\text{nm}$, $d = 6\,\text{nm}$ and $f_v = 0.02$. Substituting these values into Eqs. (16) and (17) results in an Orowan stress of 49 MPa.

The absence of GP zones in samples that have not yet developed precipitates, in the range between 8 and $25\,\text{cm s}^{-1}$, might be explained by the fact that the amount of copper in solid solution is less compared to conventionally heat-treated Al 2024. In aluminum with 2 wt.% of copper, GP-I zones do not appear, and the precipitation sequence starts with GP-II [69]. Furthermore, it has been reported that in rapidly quenched samples the early stages in the precipitation sequence are accelerated and that GP-II zone formation is suppressed in favor of the θ' phase. If both effects are present in our samples, the θ' phase is indeed the first precipitate to be observed.

An additional point that might explain the absence of the GP zones is that these precipitates are related to the stress condition of the matrix. Since GP zone formation is accompanied by a decrease in average atomic volume, the resultant hydrostatic tensile stresses will contribute to the formation energy. When a hydrostatic tensile stress is already present, the formation of GP zones will be hindered. In our samples, tensile stresses arise because of shrinkage during solidification. These stresses are of the order of 100 MPa, which is of the same order of magnitude as in Al–Cu containing silicon or Al_2O_3 particles. As a consequence, GP zone formation may also be hindered by the presence of the hydrostatic stresses in our case.

When explaining the hardness curve versus laser scan velocity (see Fig. 18) based on the above-mentioned TEM observations, it will become clear that the contributions of cell boundary strengthening and solid solution strengthening do not completely explain the decrease in hardness with increasing laser scan velocity in the lower scan velocity regime. In fact the contribution of the cell boundary strengthening increases over the whole regime. Taking the proportionality constant K of the Hall–Petch relation for cell boundaries (upper limit) to be one-half of that for grain boundaries (about $0.07\,\text{MN m}^{-3/2}$ [75]) the cell boundary strengthening may increase from 20 to 35 MPa in the low-velocity regime, whereas the contribution by solid solution strengthening decreases from a maximum of 19 MPa, based on 2.32 wt.% of copper in solid solution in the samples treated at the lowest laser scan velocity of $\frac{1}{8}\,\text{cm s}^{-1}$. In total it results in a much too small increase in hardness at the lowest scan velocity of $\frac{1}{8}\,\text{cm s}^{-1}$. So, in this regime the immobilizations of dislocations by the helical segments and by preferential nucleation of solutes have also to be considered to explain the increase in the flow stress in a more quantitiative way.

After shot peening, an increase in hardness independent of the laser scan velocity is observed. This is not what one would expect since the microstructure is quite different at different scan velocities.

However, the precipitation induced by shot peening that was observed earlier in a laser-melted Al–Si alloy explains why the observed values are the same for the low and high scan velocities: after shot peening, precipitates are present independent of the scan velocity regimes, whereas the amount of alloying elements in solid solution is expected to be much less than before shot peening.

A calculation applying the same methods as in the samples with platelets before shot peening results in a contribution to the flow stress of 76 MPa. The TEM values taken for the size and volume fraction are $D = 100\,\text{nm}$, $d = 5\,\text{nm}$ and $f_v = 0.03$. The 3% volume fraction is also in agreement with a comparison with the 2.32 wt.% copper alloy in which the cell walls are just fully dissolved in $\frac{1}{8}\,\text{cm s}^{-1}$ tracks, thereby taking into account that copper is also participating in the S′ precipitates in Al 2024.

Obviously after shot peening the contribution of helical dislocations to the change in hardness is not relevant, whereas the contribution from the increased dislocation density is approximately the same in all cases. Following the same methods as before, the contribution to the flow stress amounts to 25 and 79 MPa for dislocation densities of 2.5×10^{15} and $2.5 \times 10^{16}\,\text{m}^{-2}$, respectively.

The minimum value of the hardness of samples treated at a scan velocity of $\frac{1}{2}\,\text{cm s}^{-1}$ is still present after shot peening, and is also visible in the curves of the residual stresses as well as of the dislocation density versus laser scan velocity. Apparently the amount of alloying elements brought into solid solution during laser melting has a minimum for this scan velocity. At higher scan velocities, more copper and magnesium is retained during the rapid solidification process, and for the lower ones the homogenization time during cooling is longer.

The remarkable feature that the hardness curve observed has a minimum, at a laser scan velocity of $\frac{1}{2}\,\text{cm s}^{-1}$, is quite different from the monotonically increasing curves, usually detected in many other laser-treated materials. The reason for this observation can be explained by TEM investigations, and is linked to the minimum in the solid solution concentration. By varying the quench rate it is possible to achieve different stages in the precipitation sequence: it turned out that depending on the laser scan velocity, nucleation and growth of precipitates could either be enhanced or suppressed. The formation is suppressed by quenching too rapidly using a high laser scan velocity, whereas at too low a scan velocity the formation is suppressed due to a lack of sufficient vacancies. In the latter case, the vacancies are trapped by dislocations, leading to the formation of helical dislocations, that is, before the temperature is low enough to develop a driving force for precipitation.

The mechanisms by which the hardening occurs are the same as the ones in conventionally hardened specimens, except for the contributions originating from the small cell sizes and from the formation of helical dislocations. The latter, however, do not seem to contribute significantly. Only at lower laser scan velocities does dissolution of cell walls lead to an increased amount of copper and magnesium in solid solution and, therefore, to an increase of the hardness caused by solid solution hardening.

From comparison of the absolute hardness values between the laser-treated samples and the T3 samples, one might conclude that laser surface melting is not a suitable technique for obtaining hard surfaces. This conclusion is wrong, since the amount of copper that is brought into solid solution is far less than what ultimately is possible. In fact, one should not use a hypoeutectic alloy when a high solid solution concentration is required. In the past it has been shown, by applying splat cooling of a eutectic Al–Cu alloy, that all of the copper (33%) can be retained in solid solution [76]. Furthermore, it was shown that the precipitation sequence was still the same as in the more dilute alloys. A higher concentration of copper obtained by laser melting of such an alloy will likely lead to a high density of θ' platelets, resulting in substantially higher hardness values.

Cracking of the samples limits the practical applicability of laser treatments of this alloy. In order to prevent cracking, it might be beneficial to use an alloy with a high copper content, with possibly some supplementary silicon, since these elements reduce the thermal expansion coefficient. A higher copper content thus results in a higher strength and a reduced thermal expansion.

So far we have restricted ourselves to the derivation of the physical properties of metals from static dislocation configurations. Of course the collective dynamic behavior of groups of dislocations determine these properties. Therefore, dynamic TEM observations are extremely relevant but sometimes rather complicated to analyze thoroughly. This will be the topic of the next section.

1.4.2 Dynamic Transmission Electron Microscopy Observations: In Situ Deformation

As far as metallic systems are concerned, a vast number of TEM investigations have been devoted to intermetallic systems. Intermetallics represent a class of materials with interesting mechanical properties for applications. Why? Most metals having an f.c.c. structure are ductile and their strength decreases with increasing temperature. In contrast, intermetallic ordered compounds having the $L1_2$ structure (space group $Pm3m$) show many remarkable and unusual mechanical properties. For example, many exhibit a temperature anomaly: a rise of their strength with increasing temperature, up to many hundreds of degrees. Besides the strength at high temperatures, the moderate strength at lower temperatures has the additional advantage that shaping at room temperature is relatively easy. These properties, together with the chemical resistivity that most ordered compounds show, make this class of materials very versatile for applications in hostile environments. In general these materials are very attractive for high-temperature applications. However, although many of the ordered compounds with strong ordering tendency are ductile as single crystals, they show brittle fracture in their polycrystalline form. As a matter of course this hampers considerably their application.

Ni_3Al, with an $L1_2$ structure, is one of the ordered compounds that is a very promising candidate for various applications, such as turbine blades used by the aircraft industry. Aoki and Izumi [77] showed that the ductility at room

temperature of nickel-rich polycrystalline Ni_3Al can be improved notably by addition of small amounts of boron. However, the increase in ductility drops again at high temperatures. If useful structural materials based on these intermetallic ordered compounds are to be further developed it is crucial to scrutinize the reasons for their brittle behavior. A possible reason could be low cohesion of the grain boundaries. If the energy of a grain boundary is not much lower than the sum of the energies of the two surfaces that are created by fracturing along the grain boundaries, intergranular fracture can occur by simple de-cohesion of the grain boundary.

The work presented here, however, deals with a different approach by considering explicitly the plasticity near grain boundaries, as deduced from TEM observations. Consequently, the ultimate objective is to establish a link between intergranular brittleness and the interaction between dislocations and grain boundaries. In this way, the macroscopic mechanical properties of a number of ordered compounds are explained in terms of the atomic structure that is present in these materials.

There exists experimental evidence that in Ni_3Al the dislocation mobility in the vicinity of grain boundaries may be strongly enhanced when ductilization takes place [78] and that plastic flow precedes intergranular fracture [79]. Considering these experiments, it might be reasoned that the passage of gliding dislocations arriving from the lattice might be hindered by grain boundaries. A third point of view is that in ordered compounds, the grain boundary itself might have less ability to act as a source of dislocations. Here, in situ TEM deformation studies of Ni_3Al are presented. In this type of experiment, the development of the interaction between dislocations and grain boundaries can be followed and characterization of these defects can be carried out.

Various approaches exist to the experimental study of the interaction between lattice dislocations and grain boundaries. Slip line analysis [80] reveals the steps in the surface of a deformed sample that dislocations leave behind as they glide. There are only steps in the surface if the Burgers vectors of the dislocations are not parallel to the surface. The surface of the sample should be polished before deformation, to be able to observe these surface steps, called slip lines, with an optical microscope. Etch pitting [81] displays the site where the dislocation emerges at the surface. If a surface is etched, atoms are preferentially removed at the position of the dislocation line, and in this way an etch pit is created. Both techniques can show the changes in the propagation of dislocations when a slip band containing many dislocations impinges on a grain boundary. However, these techniques are not capable of giving information about the nature of the dislocation and the grain boundary, such as the line direction and the Burgers vector of a dislocation, the orientation of the grain boundary plane and the misorientation between the two grains. In contrast, TEM is a technique that allows observation of defect configurations in thin foils and also provides information on the nature of the defects.

In many TEM experiments (e.g., see Dingley and Pond [82] and Elkajbaji and Thibault-Desseaux [83]), bulk samples of different materials have been deformed, and these samples have been prepared for

study in the transmission electron microscope. Although a full analysis of the dislocation–grain boundary configuration is possible, the development of the interaction has to be deduced from the configuration that is left behind after the interaction has taken place.

In situ deformation in a transmission electron microscope is one of the very few techniques by which the development of the interaction between lattice dislocations and grain boundaries can be studied and which at the same time allows analysis of the configuration. By this technique, samples which have not yet been deformed are strained inside the microscope in a special straining holder. In practice there are a number of complexities. The dislocations may have high velocities and therefore they may be difficult to observe when moving. As the strains are usually very small in in situ experiments, the deformation is not homogeneous and therefore it may take place in a different part of the sample: in the region that is not transparent for electrons or in a part of the electron transparent region that is not in contrast at that moment. In addition, the fact that the interaction is being studied in a very thin foil could have a substantial influence (remember that we are interested in bulk properties): the electron transparent region may have a complicated geometry because of the thinning and therefore the stresses in the thin region may be different from the bulk stress state. Further, an oxide layer on the surface may hinder the motion of dislocations. Therefore, care must be taken to study the interactions in the thicker regions of the foil. Nevertheless, in many cases the in situ TEM technique is a promising tool for investigations of dislocation–grain boundary interactions. As the state prior to deformation is known, the changes that have been introduced because of the deformation can be deduced even if the interaction has not been observed directly. Analogous to the slip lines at the surface of a bulk sample, each dislocation that moves may leave behind an atomic step in the surface of the thin foil. Under the right imaging conditions, these atomic steps give rise to diffraction contrast and, therefore, even if a dislocation has not actually been seen to move, it may be possible to deduce the motion of a dislocation by the slip traces that it has left.

To transfer slip from one grain to another in a polycrystalline material, various mechanisms may occur which depend on the misorientation between the grains and the grain boundary plane itself. For those readers not familiar with some of the concepts in the description of grain boundary structures a very concise summary is presented on the coincidence site lattice (CSL) and the displacement shift complete (DSC) lattice which are used in the TEM analysis of the interaction between lattice dislocations and grain boundaries in ordered alloys.

1.4.2.1 Grain Boundary Structures

A grain boundary interface has eight degrees of freedom: the misorientation axis and angle, the boundary plane normal and the relative translation of the two grains with respect to each other. For ordered alloys the position of the boundary plane in the direction of its normal, corresponding to different chemical compositions of the boundary plane, is an

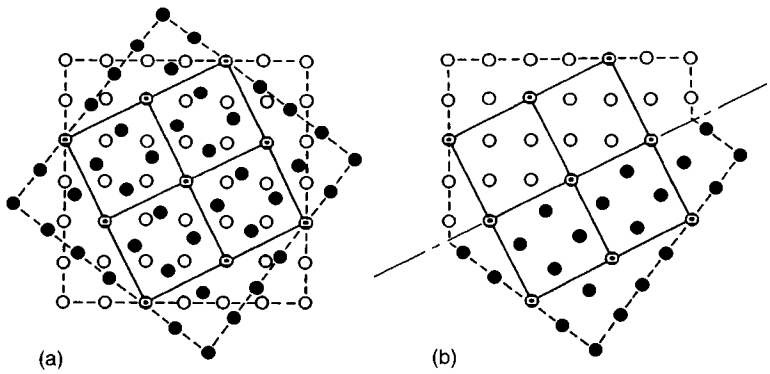

Figure 24. (a) The dichromatic pattern of a $\Sigma = 5$ boundary in a simple cubic structure. Projection along the [100] direction. Coincidence of black and white sites is indicated by black sites containing a white circle. The solid lines connecting the coincident sites indicate the CSL. The CSL periodicity in the [100] direction out of the plane of the paper is equal to the lattice periodicity. (b) Grain boundary constructed on the basis of the dichromatic pattern of (a). The broken line indicates the grain boundary plane.

extra degree of freedom. A model that is not restricted to low misorientation angles is the CSL model [84, 85].

This model uses the dichromatic pattern which is created by hypothetically allowing the lattices of the two grains to interpenetrate. The lattice sites belonging to grain 1 are considered white whereas the lattice sites of grain 2 are black. For certain misorientations a new (super-) lattice of coincident lattice sites of the white and the black lattice, a CSL, exists (Fig. 24). The parameter Σ is defined as the ratio between the volume of the CSL unit cell and that of the primitive unit cell. The density of coincident lattice sites in space equals $1/\Sigma$. A grain boundary is constructed by inserting a plane in the dichromatic pattern and letting the atoms occupy the white sites on one side of the plane and the black sites on the other side of the plane. The location of the plane can be chosen such that it intersects coincidence points (Fig. 24). In the early stages of the development of this model, it was reasoned that a high density of coincidence sites in the boundary plane would mean a low grain boundary energy. Nowadays, it is considered that this relation is not so simple, but for some low boundaries (and thus for a high density of coincidence sites) lower energies are indeed found. Also, it has been established that there may exist a relative translation away from exact coincidence for the equilibrium structure of a low Σ boundary, and the individual atoms at the grain boundary plane may have been displaced. It has to be noted that the CSL is a mathematical model: an infinitesimal rotation or translation of one grain with respect to the other destroys the whole CSL. Nevertheless, a grain boundary with the same misorientation but translated away from coincidence is still regarded as being a boundary of the same special coincidence and as having the same Σ value. The translational symmetry of such a boundary is the same as that of the boundary in exact coincidence. Grain boundaries in the ordered structure may have different ordering configurations, that is, there exist configurations that are topologically identical, but the positions of the A and B atoms are different [86]. The

ordering configuration with the lowest energy can be regarded as the equilibrium structure of the grain boundary. The DSC lattice [85, 87] of a bicrystal in CSL orientation is the lattice of the displacement vectors of one grain with respect to the other that keep the dichromatic pattern (black and white sites) unchanged except for a translation. In other words, if the black lattice is displaced over a vector belonging to the DSC lattice, the black atoms that were in coincidence with the white atoms may have lost their coincidence, but somewhere else black and white atoms will now be in coincidence and the dichromatic pattern (and the CSL) will have the same shape as before (Fig. 25). The DSC lattice is the coarsest lattice that contains both crystal lattices of the two grains as sublattices. It has smaller unit vectors than the unit vectors of a perfect lattice. Note that each CSL has a specific DSC lattice associated with it.

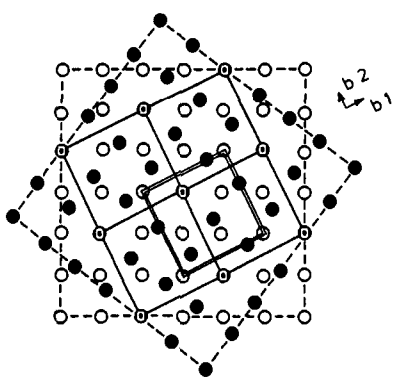

Figure 25. Same boundary as Fig. 24. The basis vectors $\boldsymbol{b}_1$ and $\boldsymbol{b}_2$ of the DSC lattice belonging to this boundary are indicated. $\boldsymbol{b}_3$ points out of the plane of the paper. The double lines indicate the new location of a CSL unit cell if the black lattice is translated with respect to the white lattice over $\boldsymbol{b}_1$. The vector connecting the original and the new position of the CSL unit cell is called the step vector associated with the $\boldsymbol{b}_1$ DSC vector.

The fact that the dichromatic pattern is unchanged for a displacement over a DSC vector of one grain with respect to the other has consequences for the types of Burgers vectors that are allowed for dislocations in the grain boundary plane. A perfect dislocation must have a Burgers vector that is a translation vector of the material in which it exists. Now, if we have a grain boundary, we have just seen above that a displacement over a vector that belongs to the DSC lattice leaves the dichromatic pattern unchanged except for a translation. Thus, in a grain boundary, grain boundary dislocations (also called DSC dislocations) with Burgers vectors belonging to the DSC lattice can exist. The displacement over a DSC vector may cause a shift in the dichromatic pattern, over a vector, called the step vector (Fig. 25).

The dislocation is then associated with a step in the grain boundary plane, located at the core of the dislocation [88]. The height of the step in the grain boundary plane can conveniently be expressed in terms of interplanar spacings, that is, the distance between crystallographic planes parallel to the boundary plane. Dislocations in a grain boundary having a Burgers vector that belongs to the DSC lattice and that is not a lattice translation vector of either grain can only exist in the grain boundary, and the movement of these dislocations is reconstricted to the grain boundary plane. As the DSC lattice is specific to a CSL orientation, each grain boundary has specific allowed Burgers vectors for grain boundary dislocations.

A number of interaction processes between lattice dislocations (the designation 'lattice' is used to discriminate these from grain boundary dislocations) and

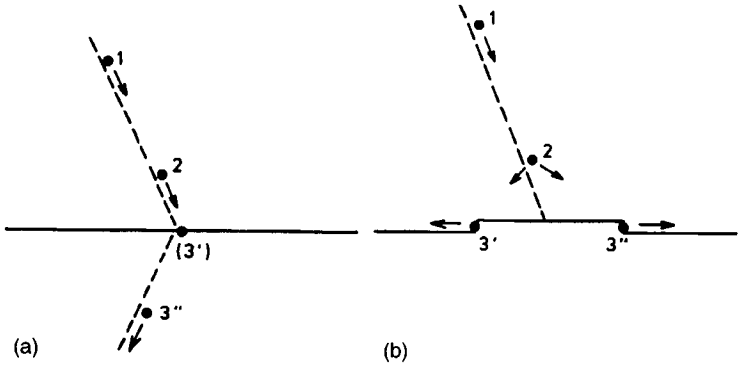

Figure 26. Interaction mechanisms between lattice dislocations and grain boundaries. (a) Transmission: another lattice dislocation emerges at the other side of the grain boundary and a residual dislocation may be left at the grain boundary. (b) Absorption: the lattice dislocation dissociates in the grain boundary plane into DSC (or grain boundary) dislocations, and a step in the grain boundary plane is created between the DSC dislocations.

grain boundaries may be discriminated (Fig. 26). A dislocation may move into the grain boundary, while another lattice dislocation emerges from the grain boundary into the other grain. As the other grain has a different orientation, the outgoing dislocation may have a Burgers vector that differs from the incoming dislocation. A residual dislocation remains in the boundary plane with a Burgers vector that is equal to the difference in the Burgers vectors of the incoming and outgoing dislocations. The residual dislocation is always a DSC dislocation. This mechanism is referred to as transmission. Another possibility is that the lattice dislocation can dissociate into grain boundary dislocations or DSC dislocations. In this way the elastic energy of the dislocation can be reduced. This mechanism is referred to as absorption. Between the grain boundary dislocations, a step in the grain boundary plane may be created. The atoms in the region which belonged to the lower grain before the lattice dislocation was absorbed and after absorption belong to the upper grain have to adapt their positions to the lattice of the upper grain. If the step in the grain boundary plane is larger than one interplanar spacing, the adaptation cannot be achieved by means of a simple rigid-body translation, but a less ordered relocation, called shuffling, of the atoms will take place. Analogous to lattice dislocations, grain boundary dislocations may dissociate in the grain boundary plane into partial grain boundary dislocations, creating a fault in the grain boundary plane between them. In addition there are more complex mechanisms, such as absorption and reemission of a lattice dislocation at another site in the boundary.

The grain boundary dislocations that stem from an absorbed lattice dislocation or that are the residual dislocations after transmission of a lattice dislocation are called extrinsic grain boundary dislocations, as opposed to intrinsic grain boundary dislocations, which form the secondary dislocation network in a grain boundary. Besides these mechanisms describing the

interaction between lattice dislocations and grain boundaries, dislocations may be nucleated at the grain boundary. A grain boundary can act as a source of dislocations that can be generated under the influence of a stress field. The dislocations can be generated in either grain and in the boundary plane.

In a CSL model of the grain boundary structure, moving dislocations which are of course lattice dislocations and therefore also vectors of the DSC lattice may interact with the boundary structure in various ways, for example the dislocation forming a line of intersection at the boundary may lower its energy by the generation of secondary dislocations with smaller DSC vectors [89–91]. It depends on the orientation of these new secondary dislocations how they react with the already existing secondary dislocations of the boundary structure. To the best of our knowledge, Schober and Balluffi were the first to observe such interactions in (001) twist boundaries [92], followed by others extending these observations to a whole range of twist as well as tilt boundaries [93–99]. For example it was observed that the unitary $\frac{1}{2}\langle 110\rangle$ lattice dislocations in polycrystalline steel dissociated into five secondary grain boundary dislocations upon interaction with a $\Sigma 29$ grain boundary [92, 94]. Indeed, although the Burgers vector were not analyzed in detail, this observation is consistent with the dissociation reaction into two sets of partials, $2(\frac{1}{58})[10\,4\,0]$ and $3(\frac{1}{58})[370]$, which are DSC vectors of $\Sigma 29$.

However, despite these observations on the interaction between lattice dislocations and secondary grain boundary dislocations, there has been quite a debate in the literature on the necessary and sufficient conditions under which dislocations transmit through the grain boundary. This has to do with the question what slip system might be activated in the other grain. Several of the criteria are summarized by Shen et al. [100, 101]:

(i) The following summation should be a maximum for the active slip system in the other grain:

$$(\boldsymbol{\eta}_1 \cdot \boldsymbol{b}_2) \times (\boldsymbol{\eta}_2 \cdot \boldsymbol{b}_1) + (\boldsymbol{\eta}_1 \cdot \boldsymbol{\eta}_2) \times (\boldsymbol{b}_1 \cdot \boldsymbol{b}_2),$$

where $\boldsymbol{\eta}$ are the slip plane normals and $\boldsymbol{b}_i$ are the slip directions in both crystals.

(ii) The force on the transmitted dislocation is a maximum for the active slip system in crystal 2.

(iii) Another conceptual idea is that the dislocation line has to rotate from the line of intersection between the boundary plane and the slip plane in crystal 1, $\boldsymbol{\xi}_1$, to the corresponding line of intersection in crystal 2, $\boldsymbol{\xi}_2$, before transmission may occur. Consequently the criterion is to maximize $(\boldsymbol{\xi}_1 \cdot \boldsymbol{\xi}_2)(\boldsymbol{b}_1 \cdot \boldsymbol{b}_2)$.

(iv) Finally, one should derive the slip direction from (ii) and the slip plane from (iii).

Although Shen et al. [100, 101] were able to predict the correct slip direction and active slip plane using these criteria, it was shown by Lee et al. [102] that the magnitude of the residual grain boundary dislocation should also be considered explicitly. They state:

(i) The outgoing slip plane is determined by minimizing the angle between the intersections of incoming and outgoing slip planes, where $\boldsymbol{\eta}_1 \cdot \boldsymbol{\eta}_2$ should be maximized.

(ii) The magnitude of the Burgers vector of the residual dislocation left in the grain boundary should be a minimum.
(iii) The outgoing slip system should have the maximum resolved shear stress from the piled-up dislocations.

Criteria (ii) and (iii) may be contradictory with respect to the prediction of the Burgers vector of the outgoing dislocations. Lee et al. [102] find in their observations that criterion (ii) seems to dominate.

1.4.2.2 TEM Holder for Straining at Temperature

Ni_3Al was prepared by arc melting 99.99% pure nickel and 99.999% pure aluminum. The material was homogenized at 1100°C (1373 K) for 5 days, resulting in grain sizes of 1 mm. Miniature tensile specimens (6×3 mm, with a thickness of 350 μm) were cut out of the bulk material by spark erosion. There were two holes in the sample through which it was held by the pins of the two grips of the deformation holder (see also Fig. 39).

The sample was necked in the middle, so as to maximize the likelihood that the deformation would start near the future electron transparent region. Care was taken to have a grain boundary, preferably a coherent twin boundary, present in the middle of the sample.

Next, the sample had to be thinned, to obtain an electron transparent region. First, the sample was ground to a thickness of 150 μm using a Gatan disc grinder, and then the sample was dimpled on both sides at the location of the grain boundary, reducing the thickness locally from 150 μm to around 60 μm. This was done to increase the probability of having the grain boundary in the thin area. The last step of the preparation process was the final thinning of the specimen in a Struers Tenupol electropolishing unit, using a mixture of 70% methanol and 30% nitric acid at 0°C, at an applied voltage of 8 V. In the Tenupol apparatus, the sample is thinned by two jets of electropolishing fluid, which are directed at both sides of the specimen. Platinum diaphragms having a hole with a radius of 2 mm were used to ensure that only the center of the sample could be reached by the electropolishing fluid. If the right voltage is applied between the fluid and the sample, material will be removed from both sides of the specimen by the electropolishing process. The polishing process was stopped when enough material had been removed from both sides such that the sample was perforated in the center. The perforation is detected by light shining through the sample, and immediately after perforation the process stops automatically. The area around the hole now is transparent for electrons. The specimen was mounted in a special single-tilt in situ deformation holder, built on principles taken from Kubin and Veyssière [103]. The interesting point here is that in situ deformation experiments can be carried out also at high temperature. Commercially available holders usually separate elongation from high-temperature applications. We made the tip of the holder, 95 mm long, of the nickel-base superalloy Nimonic 115, which exhibits excellent creep properties. A temperature of 1000°C can be achieved by dissipation of about 13 W in a tungsten filament that heats the specimen by radiation rather

than by conduction. Temperature measurements were done via a thermocouple, and minimization of heat losses (mainly by radiation) was achieved by enclosing the specimen in a double box of gold sheet. The boxes (except the bottom) as well as the filament can be taken out for mounting the specimen within the limited space available. The filament can be taken out of the holder easily, because the electrical contacts of the filament with the wires to the power supply consist of flexible platinum-sheet lips. The specimen itself is held by two Nimonic pins, a fixed one on the tip side of the holder and a mobile one which is connected by a pulling rod with metal bellows on the outside end of the holder, providing a vacuum seal, and a second metal bellows, connected to the primary vacuum pump of the microscope. A maximum load of about 30 N can be applied. An electrical control system offers the possibility of cyclic straining, and the strain rate can also be varied. The pressure in the bellows is measured by a transducer (1 mbar to 1 bar $\pm$ 1%) with a recorder. The control system consists of four valves. Two solenoid-operated isolation valves determine whether the bellows shrink by pumping or expand by air inlet. Two needle valves determine the rate of expansion or shrinkage. The strain rate as well as the minimum and maximum pressure can be chosen at the control panel. In situ creep experiments can be done with the same equipment by reducing the amplitude of the pressure cycle to zero.

The advantage of the pneumatic straining is the absence of vibration, which offers the possibility of TEM observations of crack growth or dislocation motion in front of a crack tip during cyclic straining. For example, it has been observed that a triangular variation in pressure (amplitude 25 mbar) around 720 mbar causes cyclic straining with an amplitude of about 100 nm. A typical value for the cycle time is 30 s, and therefore strain rates $\dot{\epsilon}$ are in the domain of conventional values (10^{-4}–$10^{-5}\,s^{-1}$). Although tilting is limited to a single tilt ($\pm 30°$), one or two suitable diffraction conditions (two beams, $s_g \neq 0$) can be obtained generally. The processes during deformation could be monitored by a TV system and recorded on video. The deformation was stopped before total disruption of the specimen.

The deformation holder has only one tilt axis. Therefore, the specimen usually cannot be tilted to the right with respect to the electron beam so as to excite the different reflections that are used in the analysis of the defects present in the sample. As a consequence, after the in situ deformation, specimens that promised to be interesting were shaped into 3 mm diameter disks by very cautious grinding, taking care that the thin area was protected. In this way they fitted into a TEM holder with two tilt axes, and the defects could be analyzed in detail.

The determination of the orientation relationship between the two grains was done as follows. The crystallographic direction of the incident electron beam can be determined using the diffraction pattern of a crystal. When the Kikuchi lines are visible, the incident beam direction can be determined very accurately. Kikuchi lines are formed by inelastically scattered electrons that are subsequently rediffracted. These lines indicate the orientation of the crystallographic planes by which the electrons are rediffracted. The direction of the incident beam is determined by measuring the distance of

several Kikuchi lines to the undiffracted beam in the diffraction pattern. The incident beam direction is determined in each grain, taking care to keep the orientation of the bicrystal fixed while moving from one grain to another. In this way, two parallel crystallographic directions in the two grains are found. By determining the incident beam direction in the two grains several times, with different orientations of the bicrystal, a rotation matrix transforming the coordinate system of one grain into that of the other grain is determined. As the crystals have cubic symmetry, this rotation matrix is not unique. Using a computer program the equivalent rotation matrices describing the same orientation relation are also calculated. From the set of equivalent matrices, the characteristic misorientation can be determined by finding the matrix describing a 180° rotation. All low boundaries have a rotation axis that belongs to a 180° rotation. The Miller indices of this axis give the characteristic misorientation [104]. For example, the twin boundary, $\Sigma = 3$, has its 180° rotation axis along [111].

1.4.2.3 In-Situ Deformation Results

Dislocation-Grain Boundary Interactions in Ordered Structures

In many samples, cracks (some of which were already present before the deformation started) were observed that had initiated at the edge of the thin foil, propagating along planes. Dislocations were often seen to be emitted from the crack tip, in the plane of the crack and sometimes also on inclined planes. In addition, observations were made of dislocations arriving from the bulk, although these observations were not so numerous. The dislocations from the bulk never arrived all on the same slip plane, but seemed to appear in slip bands. Quite frequently, the propagation of the crack occurred with a jerky type of motion, and it was then impossible to observe any dislocation motion.

In many of the specimens there was a grain boundary, often a coherent twin boundary ($\Sigma = 3$, 109.47° around [110] with a boundary plane), visible in the electron transparent region. A number of observations were made of individual dislocations that had been emitted from cracks. Sometimes dislocations arriving from the bulk impinged on twin boundaries and were arrested at the boundary plane. Cracks were seen that had grown through a twin boundary and had changed their direction of propagation upon crossing of the boundary plane.

One sample showed a crack which had grown during the in situ deformation to the close vicinity of a coherent twin boundary, but which had not crossed the boundary (Fig. 27).

On the other side of the boundary, starting exactly from the line of intersection of the crack plane and the boundary plane, slip traces could be observed leading into the other grain, to a large number of dislocations that all had the same slip plane (Fig. 28).

This sample was chosen for further analysis in the double-tilt holder. The rotation of the boundary under study could be described within the margins of error as a 109.5° rotation around [110], characteristic for a twin boundary. By tilting to an edge-on position, the

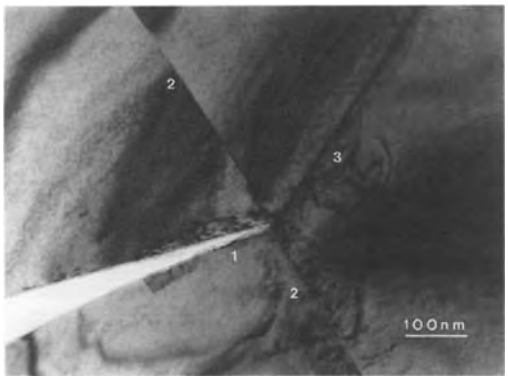

Figure 27. A crack that has grown very close to a $\Sigma = 3$ coherent twin boundary and slip lines on the other side of the boundary. 1, crack; 2, boundary plane; 3, slip lines.

boundary plane was determined to be $(\bar{1}11)$, which is equal to $(\bar{1}1\bar{1})_{II}$. The index 'II' indicates the coordinate system of the grain containing the dislocations. The grain containing the crack is denoted if no index is used. In a similar way, the plane of the crack was determined to be close to $(1\bar{1}1)$ and the slip plane of the dislocations was determined to be $(1\bar{1}\bar{1})_{II}$. By the $\boldsymbol{g} \cdot \boldsymbol{b} = 0$ invisibility criterion, the Burgers vector of the dislocations was determined to be parallel to $[110]_{II}$; this is the [110] direction that is common to both grains. The line direction was determined to be $[230]_{II} \pm 13°$, which is close to the $[110]_{II}$ screw direction.

Let us concentrate on the interaction between lattice dislocations with low-angle grain boundaries. In one sample, in the thin electron transparent region many low-angle grain boundaries were present, but no high-angle grain boundaries were visible. In this sample there were only a few holes of approximately 5 μm in diameter, and there were no cracks in the sample at all, in contrast to most samples that contained a hole of about 50 μm in diameter

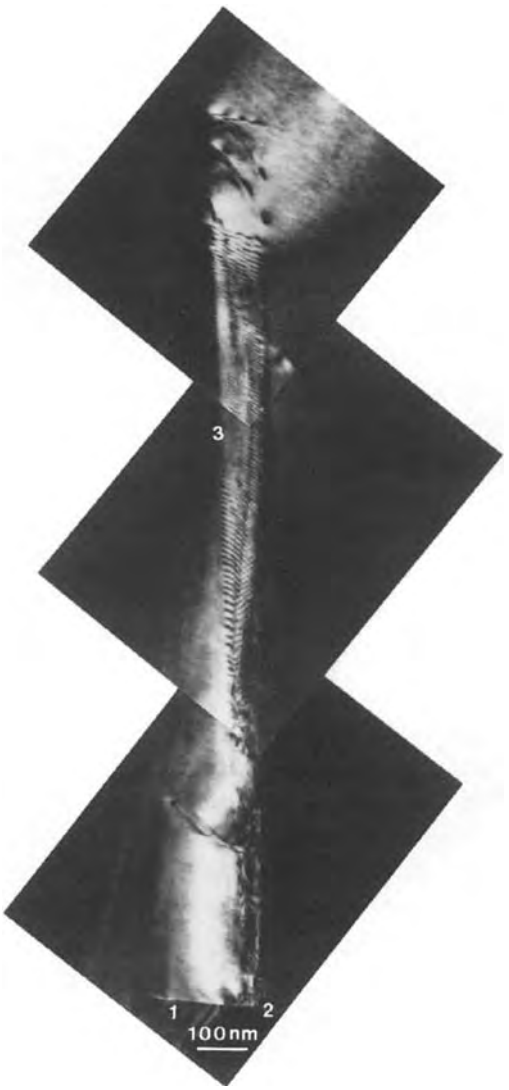

Figure 28. The dislocation configuration that was found attached to the slip lines. 1, crack; 2, boundary plane; 3, dislocation array.

and a few small initial cracks. The external force that had to be applied to cause deformation in the thin region was twice as high as usual for samples of the same thickness. This might be explained by the absence of stress concentrations because of cracks or large holes. During the

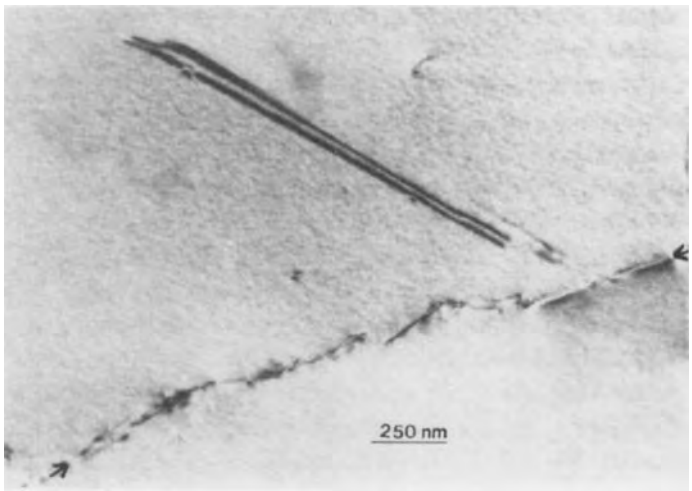

Figure 29. Stacking fault near a low-angle grain boundary (arrows), showing characteristic fringe contrast.

experiment, many dislocations were seen gliding, almost exclusively in one slip band, in parallel planes. It was observed that at several places elongated stacking faults, hundreds of nanometers long, had been created at the intersections of the slip band with low-angle grain boundaries (Fig. 29). The faults always lay at the same side of the boundaries: the direction of motion of the gliding dislocations always pointed from the boundary to the faults. Thus, it can be assumed that the faults have been created by interaction of the gliding dislocations with the dislocations in the boundary. Also, at several other locations along the slip band, away from the intersections with low-angle grain boundaries, gliding dislocations had formed faults. The deformation experiment was stopped after a crack had developed, originating from one of the holes. The sample was shaped into a 3 mm disk for further investigation in a double-tilt holder. One of the intersections of the slip band with a low-angle grain boundary where faults had formed was chosen for detailed analysis. Three faults can be seen that are close to three dislocations in the low-angle grain boundary, at distances varying from less than 50 to 200 nm (Fig. 30).

The foil normal was $[10\,3\,11] \pm 3°$, which is 11° from [101], and the foil thickness at the point of interest was 110 ± 15 nm. If we assume that the macroscopic tensile axis was perpendicular to the foil normal and parallel to the line

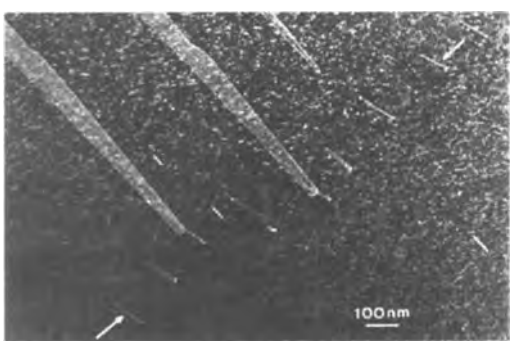

Figure 30. Weak-beam micrograph of superlattice intrinsic stacking faults (SISFs) near a low-angle grain boundary. The arrows indicate the location of the low-angle grain boundary or cell wall, consisting of an array of parallel dislocations spaced about 200 nm apart. Only one of the three SISFs can be seen fully; the other two are only partially in view.

connecting the two grips by which the sample was held, this axis could be determined to be $[4\bar{7}\bar{2}] \pm 10°$. It has to be noted that similar fault configurations close to a low-angle grain boundary were observed in thicker parts of the specimen, farther down the same slip band. The average line direction of the dislocations constituting the low-angle grain boundary was $[02\bar{5}] \pm 5°$. The dislocations in the boundary had two different Burgers vectors: $[1\bar{1}0]$ or $[110]$. The dislocations that were close to the faults all had a Burgers vector of $[1\bar{1}0]$. The dislocations in the boundary that had $\boldsymbol{b} = [110]$ were dissociated so widely into two $\frac{1}{2}[110]$ superpartial dislocations in the (100) plane, that the individual partials could be resolved by weak beam microscopy (Fig. 30).

The plane of the faults was determined to be $(1\bar{1}1)$ by tilting the faults to an edge-on position. The fault vector $\boldsymbol{R}_f$ was determined to be $\pm\frac{1}{3}[1\bar{1}1]$ by applying the invisibility criterion $\alpha = 2\pi \boldsymbol{g} \cdot \boldsymbol{R}_f = n2\pi$. However, for a fault of this type the positive and the negative fault vectors are not equivalent. In one case, a $(1\bar{1}1)$ plane is removed (superlattice intrinsic stacking fault, SISF; this is a shear fault) and in the other case an extra $(1\bar{1}1)$ plane is added (superlattice extrinsic stacking fault, SESF; this is no shear fault). The exact nature of the fault can be determined in the following way. The contrast of the edge fringe (the fringe at the intersection with the foil surface) in bright field images with $s = 0$ depends on the sign of $\sin\alpha$ [1]. If $\sin\alpha > 0$ the fringe is bright and if $\sin\alpha < 0$ the fringe is dark. The values of $\sin\alpha$ are listed in Table 1 for reflections which have been used to image the faults in bright field.

Table 1. Values of $\sin\alpha$ for different reflections and fault vectors

R_f	$\boldsymbol{g} = [002]$	$\boldsymbol{g} = [00\bar{2}]$
$\frac{1}{3}[1\bar{1}1]$	$-\frac{1}{2}(3^{1/2})$	$-\frac{1}{2}(3^{1/2})$
$-\frac{1}{3}[1\bar{1}1]$	$\frac{1}{2}(3^{1/2})$	$-\frac{1}{2}(3^{1/2})$

The experimental observations were that the edge fringe was dark for $\boldsymbol{g} = [002]$ and bright for $\boldsymbol{g} = [00\bar{2}]$, and therefore the fault vector $\boldsymbol{R}_f$ is $+\frac{1}{3}[1\bar{1}1]$. As the foil normal (pointing upwards) is close to [101], $\boldsymbol{R}_f$ points to the upper surface of the foil. The $\boldsymbol{R}_f$ is defined as the displacement of the material below the fault with respect to the material above the fault, and thus the fault corresponds to a removal of one $(1\bar{1}1)$ plane, and the fault is of intrinsic nature, that is, an SISF.

From the direction of the slip traces left behind by the gliding dislocations it was deduced that the $(1\bar{1}1)$ plane of the faults is the same plane as the slip plane of the gliding dislocations. The faults are partially bounded by the intersection of their $(1\bar{1}1)$ plane and the upper surface of the foil and partially by dislocations with Burgers vector $\pm\frac{1}{3}[\bar{1}12]$ (Fig. 31).

The Burgers vector of the dislocations bounding the SISFs has been determined using the $\boldsymbol{g} \cdot \boldsymbol{b}$ invisibility criterion. The invisibility criterion for partial dislocations, such as a dislocation bounding a fault, is slightly different from that for perfect dislocations. For a Burgers vector of the type $\frac{1}{3}\langle 112\rangle$, the criterion for invisibility is $\boldsymbol{g} \cdot \boldsymbol{b} = 0, \pm\frac{1}{3}[1]$ and furthermore (for $s > 0$) $\boldsymbol{g} \cdot \boldsymbol{b} = -\frac{2}{3}$. Care was taken to use only reflections for which the fault is invisible, to prevent any uncertainty regarding visibility of the dislocation. The dislocations were invisible for $\boldsymbol{g} = [220]$ and for $\boldsymbol{g} = [13\bar{1}]$; they were

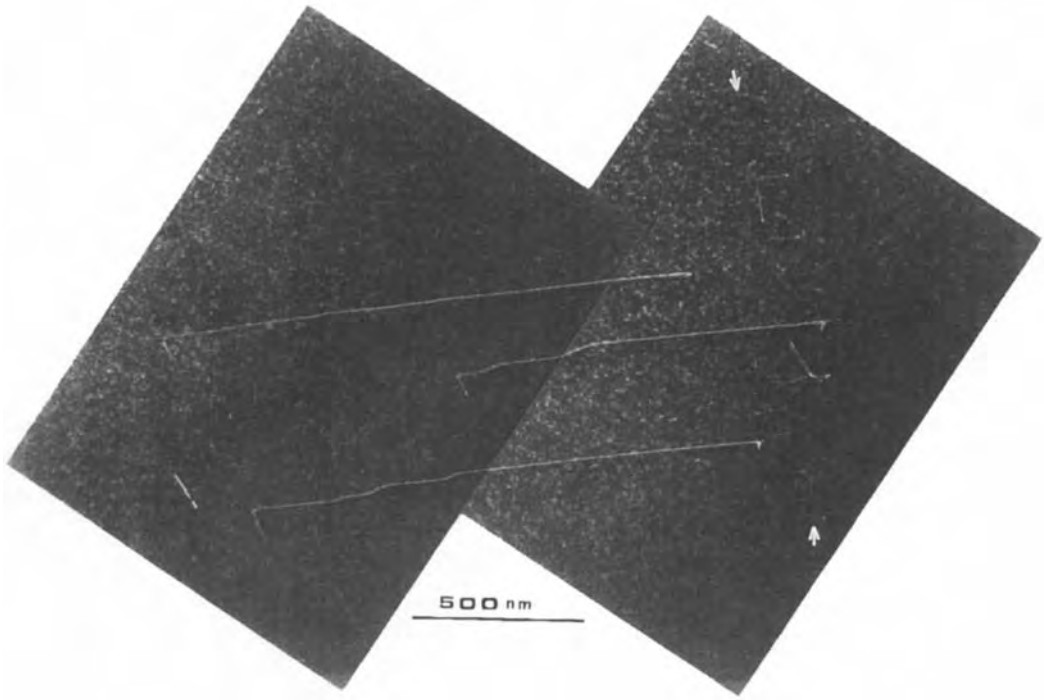

Figure 31. Weak-beam micrograph of the dislocations partially bounding the faults of Fig. 30. Where not bounded by a dislocation, the faults are bounded by the surface of the thin foil. The fringe contrast of the faults is invisible for this imaging condition. The arrows indicate the location of the low-angle grain boundary (cell wall).

visible for $\boldsymbol{g} = [022]$, $\boldsymbol{g} = [1\bar{3}\bar{1}]$, $\boldsymbol{g} = [\bar{1}\bar{1}3]$. The $\boldsymbol{g} \cdot \boldsymbol{b}$ product for dislocations that can bound an SISF is given in Table 2. From Table 2, it can be concluded that the Burgers vector of partial dislocations bounding the SISFs is $\pm\frac{1}{3}[\bar{1}12]$.

The results of the TEM work on the interaction between lattice dislocations with a $\Sigma = 3$ coherent twin boundary show that cracks may emit dislocations parallel to their own plane during propagation. In the case of the sample containing a twin boundary that was analysed in detail, the plane of the crack crossed a coherent twin boundary ahead of the crack, and it might be envisaged that a number of dislocations were emitted from the crack tip in the $(1\bar{1}1)$ plane and

Table 2. $\boldsymbol{g} \cdot \boldsymbol{b}$ product for partial dislocations bounding an SISF on $(1\,\bar{1}\,1)$

$\boldsymbol{b}$	$\boldsymbol{g} = [220]$	$\boldsymbol{g} = [13\bar{1}]$	$\boldsymbol{g} = [022]$	$\boldsymbol{g} = [1\bar{3}\bar{1}]$	$\boldsymbol{g} = [\bar{1}\bar{3}3]$
$\pm\frac{1}{3}[121]$	2	2	2	−2	0
$\pm\frac{1}{3}[21\bar{1}]$	2	2	0	0	−2
$\pm\frac{1}{3}[\bar{1}12]$	0	0	2	−2	2
$\pm\frac{1}{3}[1\bar{1}1]$	0	−1	0	1	1

impinged on the boundary. The slip traces emanating on the other side of the boundary indicate that a number of dislocations have emerged from the boundary in the $(1\bar{1}\bar{1})_{II}$ plane exactly at the point where the plane of the crack intersects with the boundary plane. Thus, it is probable that these dislocations have been emitted from the crack tip and transmitted through the grain boundary. As the [110] direction is common to both grains, the Burgers vector could remain the same in both grains, and no residue is left in the boundary. The line vector is parallel to the intersection of crack plane and the outgoing slip plane, and, thus, transmission could occur without rotation of the dislocation line in the boundary plane. The large number of dislocations may indicate that there was a large force on the leading dislocation of a pile-up in front of the boundary, necessary to cause transmission of the dislocations to the other grain. Grain boundary sources of course cannot be ruled out completely as the origin of the observed dislocations. However, very often, if operation of grain boundary sources is observed, there is generation of dislocations on many different slip planes [105] (our own observations in two other samples indicate the same), while here all the dislocations are on one slip plane.

As low-angle grain boundaries, also called cell walls, consist of a dislocation network, the interaction between gliding lattice dislocations and low-angle grain boundaries is essentially a dislocation–dislocation interaction. In order to find an explanation for the formation of the SISFs, it is useful to know the type of the dislocations that were gliding in the slip band. Therefore, a number of dislocations showing such a configuration, so that it could be expected that they had been gliding in the slip band, were analyzed. Most of the dislocations found in the slip were screw dislocations with a Burgers vector of [011]. We may assume that the gliding dislocations in the slip band had a Burgers vector of [011]. This assumption can be supported as follows. If we suppose that the $\frac{1}{3}[\bar{1}12]$ dislocations bounding the SISFs were created by the gliding dislocations, the Burgers vector of the gliding dislocations could either be [011] or $[\bar{1}01]$, as only these dislocations are glissile in the $(1\bar{1}1)$ plane and at the same time can have $\frac{1}{3}[\bar{1}12]$ as one of their dissociation products. If we consider the tensile axis in the thin region to be the same as the macroscopic tensile axis, the Schmid factor for the [011] dislocations in the $(1\bar{1}1)$ plane is 0.38, while the Schmid factor for the $[\bar{1}01]$ dislocations is 0.15. Therefore, we can conclude that the gliding dislocations had a Burgers vector of [011]. As the dislocations in the slip band that were analyzed had mostly screw character, we may assume that the gliding dislocations also had screw character. Also, it can be expected that the gliding dislocations were dissociated into two $\frac{1}{2}[011]$ superpartials, which is the dissociation that is usually found in Ni_3Al. A schematic overview of the configuration is given in Fig. 32.

Now, we consider the formation mechanism of the SISFs in more detail. A gliding dislocation intersects a dislocation in the cell wall. Although the dissociation of the perfect dislocation in the cell wall into superpartial dislocations is not clearly visible, we may assume that it is dissociated in the cell wall into two $\frac{1}{2}[1\bar{1}0]$ partials. Because of the intersection, two jogs (steps in the dislocation line; the steps do not lie in the slip plane) of $\frac{1}{2}[1\bar{1}0]$ have

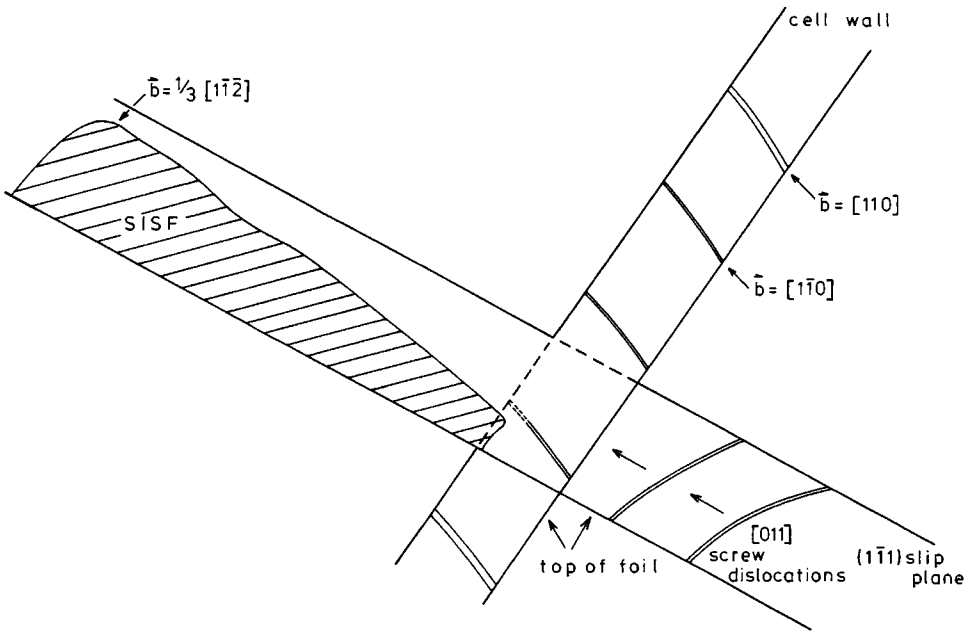

Figure 32. Schematic view of the gliding dislocations, the low-angle grain boundary (cell wall) and the SISF that is formed. The intersections of the slip plane of the gliding dislocations with the upper and lower surfaces of the thin foil are indicated. Also, the intersection of the grain boundary plane and the foil surfaces has been indicated.

been created in the line of the gliding dislocation. As the separation between the two $\frac{1}{2}[1\bar{1}0]$ partials in the cell wall is very small, the jogs are very close to each other. The jogs cannot glide in the $[2\bar{1}1]$ direction of motion of the [011] screw dislocation in the $(1\bar{1}1)$ plane, and therefore the motion of the jogs can only occur by climb, and as this is a slow process the motion of the dislocation is hindered at the jogs, that is, the dislocation is pinned by the jogs. The dislocation will bow out at both sides of the pinning point under the influence of the stress. The leading $\frac{1}{2}[011]$ superpartial dislocation can be allowed to move under the applied stress in the following way: if a $\frac{1}{6}[21\bar{1}]$ Shockley partial dislocation moves from the trailing to the leading superpartial, the antiphase boundary (APB) separating the $\frac{1}{2}[011]$ partials is transformed into an SISF, which has much lower energy. By the exchange, the trailing $\frac{1}{2}[011]$ superpartial transforms to a $\frac{1}{3}[\bar{1}12]$ dislocation partially bounding the SISF (Fig. 32).

In this way, the force keeping the two $\frac{1}{2}[011]$ dislocations together because of the high APB energy is greatly reduced as the SISF energy is much lower than the APB energy and, thus, the leading $\frac{1}{2}[011]$, together with the $\frac{1}{6}[21\bar{1}]$ can proceed, and then a large region if SISF can be formed. It might be envisaged that the termination of the SISF region develops in a similar way as the loop-pinching mechanism described by Pak et al. [106]. In our case, we are dealing with a partial loop that is bounded by the foil surface and no next

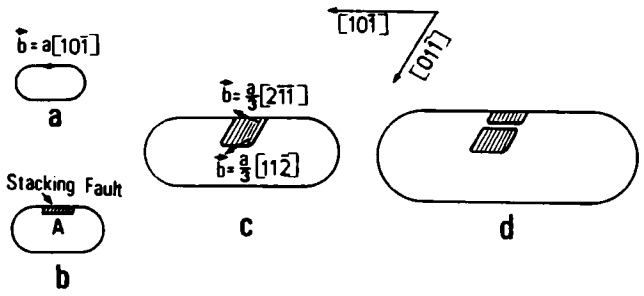

Figure 33. The SISF formation mechanism proposed by Pak et al. [106]. Part of an expanding perfect dislocation loop is dissociated into two $\frac{1}{3}\langle 112\rangle$-type partials with an SISF in between. As the perfect loop expands further, the separation between the two partials increases, until the SISF is pinched off.

loop of SISF is created, but instead a new [011] perfect dislocation might be formed, which proceeds in the $(1\bar{1}1)$ plane. Another way, differing in detail, of describing the generated SISF is by a dissociation of the leading superpartial into $\frac{1}{6}[21\bar{1}]$ and $\frac{1}{3}[\bar{1}12]$. The superpartial $\frac{1}{3}[\bar{1}12]$ is repelled from the Shockley partial, which in turn may react with the trailing $\frac{1}{2}[011]$ dislocation to form $\frac{1}{3}[121]$ [107, 108].

There have been a number of other observations of SISFs in ordered alloys such as Ni_3Al. In Ni_3Al, Baker and Schulson [109] observed pairs of $\frac{1}{3}\langle 112\rangle$ dislocations with an SISF inbetween, separated by around 100 nm. The $\frac{1}{3}\langle 112\rangle$ pairs had parallel Burgers vectors and antiparallel line vectors. These pairs were thought to be elongated dislocation loops that were truncated because of the thinning process during preparation of the foil. Some observations were made of rows of loops of SISF that were several hundreds of nanometers long. Pak et al. [106] made observations in Ni_3Ga, which is a very similar material to Ni_3Al, of widely extended SISFs with lengths of several hundreds of nanometers to a few micrometers, elongated along $\langle 110\rangle$ directions and bounded by $\frac{1}{3}\langle 112\rangle$-type partial dislocations. Veyssiere et al. [108] made observations of two $\frac{1}{2}\langle 110\rangle$ superpartials that were dissociated in a $\{100\}$ plane, connected by a ribbon of APB. Parts of one of the $\frac{1}{2}\langle 110\rangle$ dislocations had dissociated in an inclined $\{111\}$ plane into a $\frac{1}{6}\langle 112\rangle$-type edge Shockley partial and a $\frac{1}{3}\langle 112\rangle$ type partial dislocation. These two dislocations were connected by a ribbon of SISF on the $\{111\}$ plane.

Several explanations have been put forward for the SISF formation. Pak et al. [106] explained the formation of loops bounding SISFs by means of an expanding perfect dislocation loop (Fig. 33), which partially dissociates into two $\frac{1}{3}\langle 112\rangle$ partial dislocations. Upon further expansion of the perfect loop, the SISF is elongated and, finally, part of the SISF is pinched off, and a faulted loop containing the SISF is created. Kear et al. [110] discussed mechanisms by which gliding dislocations on intersecting slip planes could react, and they showed that an SISF is formed in certain reactions. The mechanism described by Kear et al. is essentially a dislocation interaction mechanism involving two different slip planes, while the mechanism described by Pak et al. is essentially a single slip mechanism. Pak et al. do not go further into the reason for the initial dissociation of part of the perfect dislocation loop into $\frac{1}{3}\langle 112\rangle$ partial dislocations. The SISF formation in our observations resembles the mechanism of Pak et al., as

only one slip plane is involved. The creation of jogs in the line of the gliding dislocations because of the intersection with the dislocations in the cell wall could be the reason for the dissociation into $\frac{1}{3}\langle 112\rangle$ partials under the influence of the applied stress.

Observations of the same dislocation–grain boundary system were made in type 304 stainless steel by Clark and Wagoner [111] and in 310 stainless steel by Lee et al. [112]. In the 304-type stainless steel, a configuration in lightly deformed material was observed which showed a pile-up of dislocations on one side of the boundary and dislocations which appeared to have emerged on the other side. It was concluded that transmission through the twin boundary had taken place. Lee et al. observed the same mechanism of transmission for the same type of dislocations through the same boundary in their in situ deformation experiments in 310-type stainless steel.

There are some special boundaries, such as a coherent $\Sigma 3$ boundary as investigated here, which at first sight would not act as strong barriers. This certainly is so in the case of $\Sigma 3$ for polycrystalline f.c.c. metals where the slip planes in both grains are symmetrically disposed and have a common line of intersection with the grain boundary plane. Lattice dislocations of the type $\frac{1}{2}\langle 110\rangle$ may transmit directly from one grain to the other or by the generation of a residual $\frac{1}{6}\langle 112\rangle$ dislocation in the grain boundary plane itself. It is quite clear from the analysis mentioned above that the situation is far more complex in $L1_2$ ordered alloys, for example. This has to do with both the fact that we have to deal with superlattice dislocations, that is, two unitary $\frac{1}{2}\langle 110\rangle$ lattice dislocations bounding an APB as well as the $\Sigma 3$ boundary structure in ordered compounds after the interaction with the complete Burgers vector being quite different from the situation in pure f.c.c. metals. Tichelaar [113] made a TEM analysis of the various grain boundary structures that arise after the interaction of superlattice dislocations with a coherent twin boundary in $L1_2$. When an APB terminates in a coherent twin boundary it causes a translation of $\frac{1}{2}\langle 110\rangle$ of the two crystals with respect to each other, that is, the boundary may change from a symmetrical configuration (S) into an asymmetrical one (A). These changes between S and A may also occur by a glissile superlattice dislocation or by a grain boundary dislocation of the type $\frac{1}{6}\langle 112\rangle$. It should be realized that there are three crystallographic variants of type A, meaning that either Shockley partial dislocations in the boundary or a terminating APB may also cause a transformation among the A structures themselves. Of course, the energies of the various A structures should be identical based on symmetry arguments. In Tables 3 and 4 some energies of these faults are listed, calculated using N-body potentials [114].

Table 3. Calculated planar fault energies ($mJ\,m^{-2}$) for different shear faults [114]

Planar fault	APB on (001)	ABP on $(1\bar{1}1)$	CSF on $(1\bar{1}1)$	SISF on $(1\bar{1}1)$
Translation vector	$\frac{1}{2}[110]$	$\frac{1}{2}[110]$	$\frac{1}{6}[121]$	$\frac{1}{3}[21\bar{1}]$
Cu_3Au	55	56	40	16
Ni_3Al	53	227	191	12

Table 4. Calculated grain boundary energies ($mJ\,m^{-2}$) for different ordering states after relaxation. The cubic sublattices containing the B atoms are indicated by their relative translation vector (in the coordinate system of the upper grain). The relaxed configuration with full symmetry (i.e., B atoms are mirror related to B atoms) is indicated by S [114]

Ordering state	Materials	S	A1	A2	A3
Translation vector		[000]	$\frac{1}{2}$[110]	$\frac{1}{2}$[101]	$\frac{1}{2}$[011]
$\Sigma 3$	Cu_3Au	7	47	47	47
	Ni_3Al	6	208	208	208
$\Sigma 11$	Cu_3Au	363	344	358	359
	Ni_3Al	506	490	605	606
$\Sigma 27$	Cu_3Au	697	701	737	737
	Ni_3Al	996	994	1105	1105

It turns out that eight different configurations are possible when a superlattice dislocation with total Burgers vector ⟨110⟩ is absorbed in a {111} coherent twin boundary (Fig. 34). In fact, the self energy of the grain boundary dislocations can be lowered by the dissociation into Shockley partials which can be easily anticipated by looking at the various energies involved as compiled in Table 4. It should be realized that here we have assumed that the superlattice dislocation enters the boundary structure at the S configuration. However, if it arrives at the grain boundary in an A configuration, different configurations may arise depending which of the A structures is actually involved; for example, A1 is changed into A3 but the energy is unaltered, meaning that the absorption of lattice dislocation is favorable since the APB in the bulk is removed. However, A2 may also be transformed upon interaction into a symmetrical S structure, that is, lowering its energy (Table 4), but is transformed back again upon absorption of the trailing unitary $\frac{1}{2}$⟨110⟩ dislocation.

It is interesting to compare the in situ observations of Ni_3Al with those of Cu_3Au [112]. The micrographs displayed

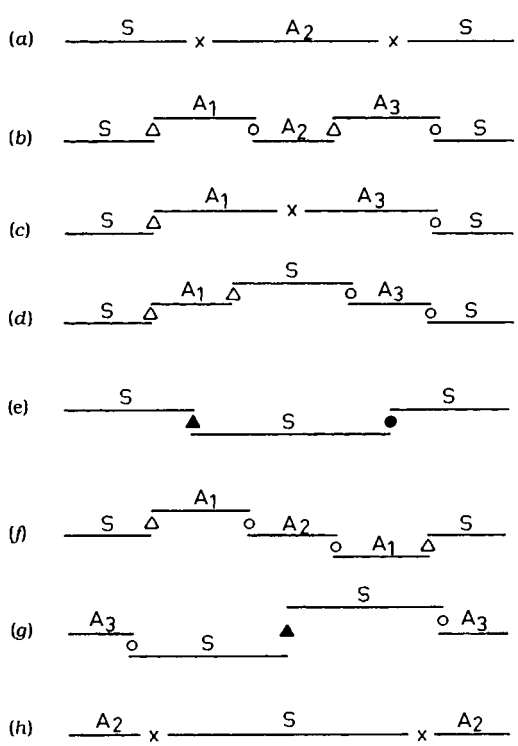

Figure 34. Different dissociation schemes of a [101] superlattice dislocation in $L1_2$ structure absorbed in a $(11\bar{1})$ coherent twin boundary. Superpartials $\frac{1}{2}$[101] (×) may dissociate into Shockley partial dislocations with Burgers vectors $\frac{1}{6}[2\bar{1}1]$ (△) and $\frac{1}{6}$[112]. ○ and ▲ refer to DSC dislocations with $\frac{1}{3}$[112] and $\frac{1}{3}[2\bar{1}1]$, respectively.

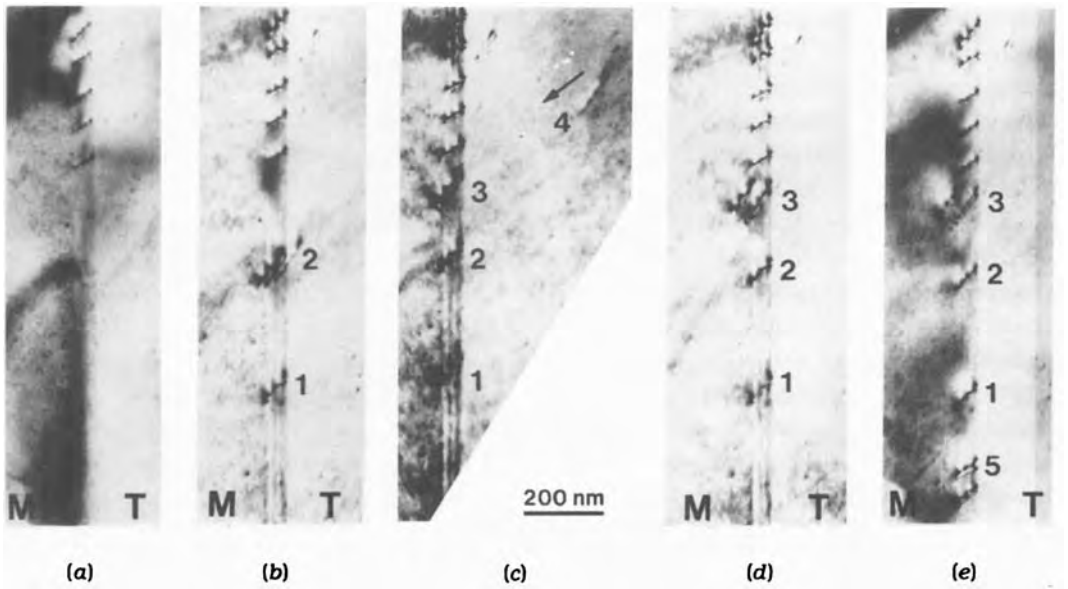

Figure 35. Dark field TEM images. Upon increasing strain, additional superlattice dislocations arrive at the twin boundary.

in Fig. 35 show the dislocation activity after incremental deformation. Following a large strain (Fig. 35e, position 5), a dislocation pair was observed to move. This dislocation pair was present in the A structure whereas the other dislocation pairs were present in the S structure. It can be concluded that most of the superlattice dislocations moving in T were absorbed into the boundary plane. Also, transmission was observed into M, leaving slip traces in a direction parallel to the slip plane. On increasing deformation, dislocations were seen to move slowly into T. In this case the dislocation traveled as the usual type, which can be confirmed from the APB contrast (Fig. 36). In Fig. 37 another view of the boundary structure is presented. Here, the boundary is imaged using weak-beam common fundamental reflection, showing dislocation pairs, as well as using a common superlattice reflection showing APB-type contrast between the dislocation pairs. It can be concluded that before the superlattice dislocation arrived, the boundary structure was S but has altered locally to A.

In these experiments, it was deduced from examinations of the activated slip systems that the symmetric slip plane in the other grain had the highest Schmid factor. Although there were a number of observations of transmission, absorption in the boundary plane was also observed. A possible explanation of the tendency for absorption could be found in a lower value of the energy of the ordering fault in the grain boundary plane between the two $\frac{1}{2}[110]$ superpartial dislocations compared with the value of the APB between the superpartials in the bulk. Computer simulations show that for Ni_3Al this energy difference is $25\,mJ\,m^{-2}$ (for Cu_3Au it is $16\,mJ\,m^{-2}$) [114]. Thus, regarding this energy difference, absorption in the boundary might be expected.

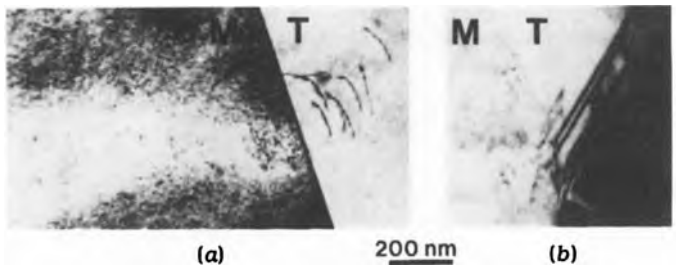

Figure 36. Bright field TEM images of the same area as depicted in Fig. 35 using (a) a fundamental reflection and (b) a superlattice reflection.

It turned out that the mechanism of the interaction between lattice dislocations and grain boundaries is similar for boundaries in ordered and disordered (or f.c.c.) materials [114]. In the case of absorption into grain boundary dislocations in ordered material, during movement of the grain boundary dislocation an ordering fault is left behind in the boundary plane, and anti-site defects may be created. Because of these phenomena, movement of grain boundary dislocations in ordered material is hindered, and, in the case of extended slip, stress concentrations will develop at the boundary upon arrival of more lattice dislocations at the same location in the boundary plane. In the case of transmission, computer simulations [114] show that transmission through an ordered boundary occurs at high stress

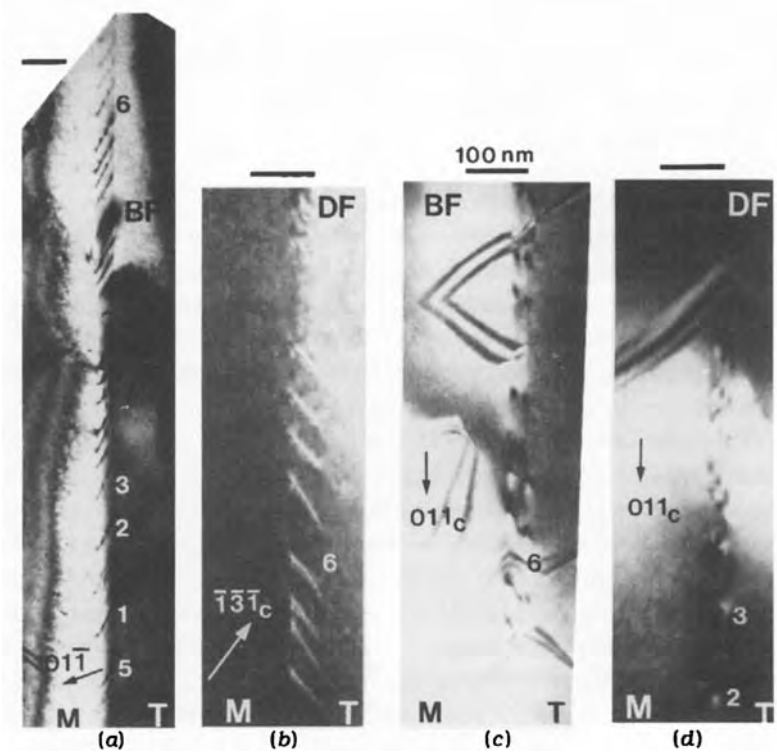

Figure 37. Bright field and dark field TEM images of the coherent twin boundary. (b) Dislocation pairs are imaged using a weak-beam fundamental reflection. (c, d) A-type structure is imaged as APB contrast. (d) The area shown here is directly below the areas shown in (b) and (c).

levels and the two superpartial dislocations constituting the arriving dislocation will decrease their separation in response to the applied stress, when the leading superpartial dislocation is halted at the boundary. In this way, stress concentrations near the boundary will be generated. The effects mentioned above are greater for higher ordering tendency. The results obtained indicate that the interaction between lattice dislocations and grain boundaries, as observed by TEM and computer modeling, is essential for the explanation of the intergranular fracture occurring in a number of ordered compounds, in particular those with a high ordering energy.

In this view, the mechanism by which the ductility of hyperstoichiometric (i.e., nickel-rich) Ni_3Al is increased by the addition of small amounts of boron could be explained as follows. It has been established that boron segregates to the grain boundaries in Ni_3Al [115, 116]. Nickel atoms are thought to cosegregate with the boron atoms [117–119], thus causing a nickel-rich grain boundary. In this way, the long-range order could be disturbed in a region very close to the grain boundary. Although there is still some debate, there is experimental evidence that there indeed exists a disordered region at grain boundaries in nickel-rich Ni_3Al [120, 121]. As shown in the simulations [114] in f.c.c. material, which is essentially 'disordered $L1_2$', the grain boundaries in disordered material are much more transparent for dislocations. As a consequence of the 'disordered region' in Ni_3Al by boron additions, the net result may be that slip can be transmitted via the nucleation of superlattice partial dislocations under a severely reduced stress. The reduction will be of the order of γ_{APB}/b (size of the Burgers vector), that is, about 900 MPa (ignoring the lattice hardening due to boron strengthening effects [122]).

Finally, one should be careful in generalizing these results obtained for all $L1_2$ ordered systems. Indeed, as the mechanical properties of more $L1_2$ materials have been investigated experimentally, it has been found that several of them are intrinsically brittle because of intergranular failure, similarly to Ni_3Al. However, it has to be emphasized that in intermetallics, as in Al_3Ti, cleavage fracture is also found to be the failure mode, rather than intergranular failure. In cleavage fracture it is feasible that a mechanism for crack tip plasticity exists that does not require macroscopic dislocation motion at all [123]. Local shears produced at the crack tip which reverse once the crack has passed by is one of the possible mechanisms.

Particle-Hardened Materials

Direct observations of crack propagation and crack tip deformation are also possible via in situ TEM experiments. To be somewhat consistent with the previous experiments we describe as an example some in situ experimental results on the deformation characteristics of superalloys, that is, nickel-base matrix containing Ni_3Al–$L1_2$ ordered precipitates (MA 6000 and PM Astroloy). The common feature of nearly all nickel-base superalloys is a dispersion of an f.c.c. intermetallic phase, called γ' in an f.c.c. solid solution γ. Although γ' is based on Ni_3Al, it may contain substantial amounts of other alloying elements such as titanium, cobalt, tantalum and molybdenum [124]. The coherently ordered γ' is the most important hardening phase in

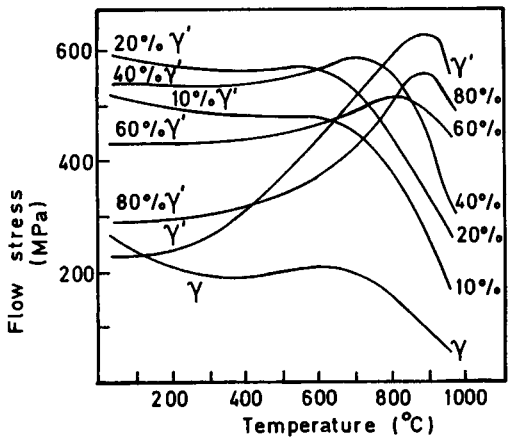

Figure 38. The temperature dependence of the 0.2% flow stress for Ni–Cr–Al containing different volume fractions of γ'.

superalloys. In the cubic morphology, γ' precipitates are aligned along preferred directions such that the faces of the cubes are parallel to $\{001\}\gamma$. Figure 38 shows the exceptional temperature dependence of the flow stress of γ', which increases strongly from room temperature to 900°C, after which the stress rapidly falls off [125]. A successful theory to account for this effect is that of Takeuchi and Kuramoto [126], in which dislocations on {111} planes are assumed to become locally pinned by thermally activated cross-slip onto {001} planes, a process driven by the anisotropy of the APB energy and aided by the resolved shear stress for cubic slip. The qualitative explanation is that an increase in temperature promotes cross-slip, and therefore a higher flow stress. The decrease in flow stress at higher temperature is contributed to macroscopic slip on {001} planes. Alloys with large fractions of γ' reflect the pure γ' behavior, and about 50% γ' gives the best overall properties. For some information on the mechanical properties of these two phase systems, see

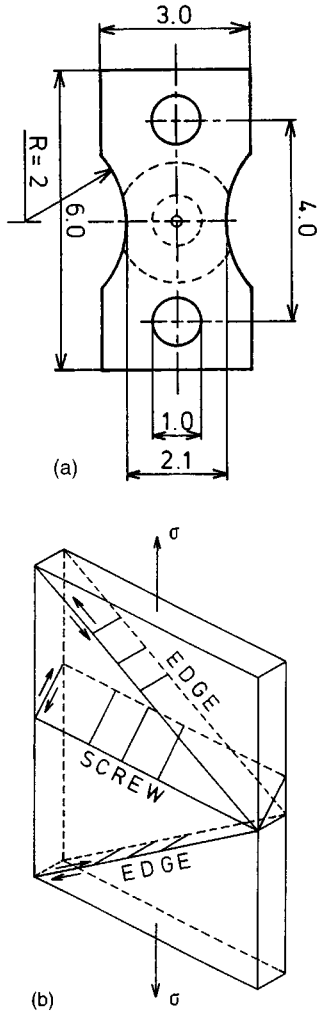

Figure 39. (a) Specimen for in situ observations and (b) the slip geometry expected.

Heredia [127]. Let us return to the possibilities of in situ crack propagation and crack tip deformation in TEM.

A typical specimen for the in situ observations is shown in Fig. 39. The specimen was cut by spark erosion and ground to a thickness of 130 μm. The final configuration was reached by electropolishing in two steps: first thinning of the

gauge section with a diaphragm of 2.5 mm and subsequently polishing with a diaphragm of 1 mm until perforation. Ohr [128] has analyzed the configuration in Fig. 39, and has calculated the planes of maximum shear stress, which are depicted in Fig. 39b. To minimize their line length, dislocations lie across the thickness of the sheet. The dislocations on planes 1 and 3 are predominantly of the edge type, while those on plane 2 are predominantly of screw type. When edge dislocations are emitted simultaneously on the two inclined slip planes, the resulting Burgers vectors of these dislocations are in the direction parallel to the tensile axis, and the induced crack opening displacement is parallel to the tensile stress (mode I). Mode II crack tip deformation occurs if edge dislocations are emitted on one of the inclined planes. Screw dislocations on slip plane 2 give rise to mode III crack tip deformation. The three modes of fracture and crack tip deformation are depicted in Fig. 40. The choice of the slip system is dictated by the shear stress close to the crack tip, whereas the bulk Schmid factor influences dislocation behavior in the region outside the crack tip area. In fact, Ohr has found no case of a pure single mode of loading, and among the three modes of deformation,

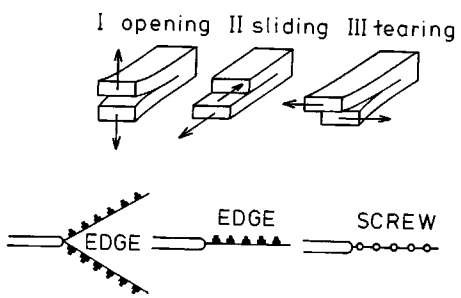

Figure 40. The three modes of fracture.

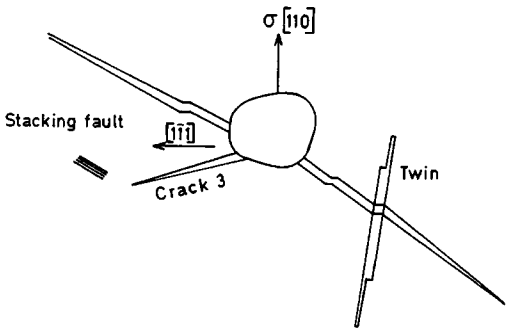

Figure 41. Schematic representation of the crack configuration.

mode III was favored over mode II and in turn mode II was preferred over mode I.

At room temperature, mechanical stress was applied to a sample of MA 6000 with longitudinal grains in the direction of the applied stress. Two cracks were initiated at the edge of the hole and propagated as indicated in Fig. 41, at about 55° to the tensile axis, which is the longitudinal [110] grain direction. By cyclic deformation at about 600°C a third crack was initiated. The two directions of crack propagation coincide with the orientation of twins; a third twin orientation has been observed as well.

In thin areas near the hole a crack propagates in a straight line. The propagation of a crack across a twin in a thin area has been scrutinized. Before a crack propagates across a twin a plastic zone is built up on the opposite side of the twin. Finally, the crack cuts through the twin in a different direction and propagates on the other side parallel to the original direction, resulting in a step in the crack surface. In Fig. 42 the part of the twin below the crack is out of contrast. In thicker areas, crack propagation occurs by forming spherical cavities in front of the crack tip. The cavity increases in size, and at a further stage the

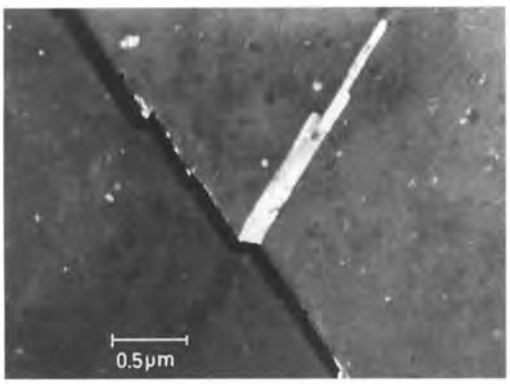

Figure 42. A crack through a twin.

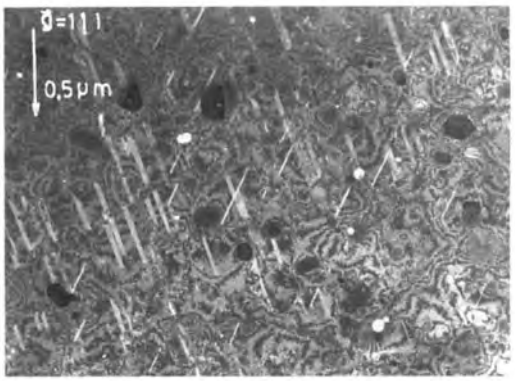

Figure 44. Stacking faults inside γ' precipitates.

crack grows until it reaches the cavity. In front of the third crack tip, stacking faults are located at a distance of about 3 μm (see Fig. 43). The orientation difference between the crack and faults is 46°. These stacking faults lie in the direction of the primary cracks. Due to the slip of partial dislocations the fault contrast disappears, but returns as expected in the case of the growth of a microtwin. The growth of a stacking fault inside a precipitate has been observed as well. Besides partial dislocations, as depicted in Fig. 43, slip traces were also observed in the direction of the crack at a distance of 5 μm. It seems that the third crack propagates by a combination of the opening mode with either the sliding mode or the tearing mode. As far as the primary cracks are concerned no evidence was found for the opening mode.

The in situ straining experiments show that at low and intermediate temperatures, that is, below about 800°C, MA 6000 deforms by the glide of dislocations in planar arrays. As observed in situ, partial dislocations cause stacking faults (Fig. 44) in the precipitates, and successive dislocations produce microtwins (Fig. 45). These twins have also been found after fracture

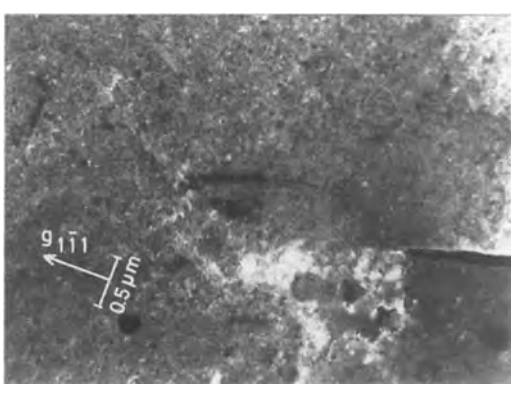

Figure 43. Stacking faults in front of a crack tip.

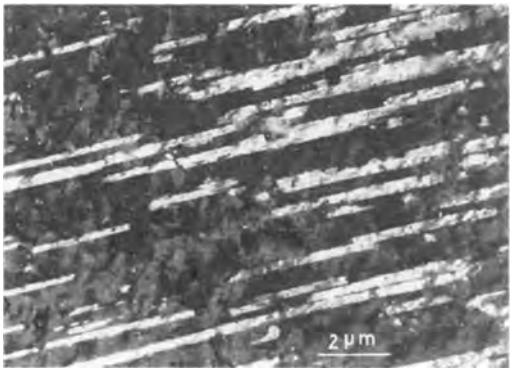

Figure 45. Twins after deformation until fracture at 760°C.

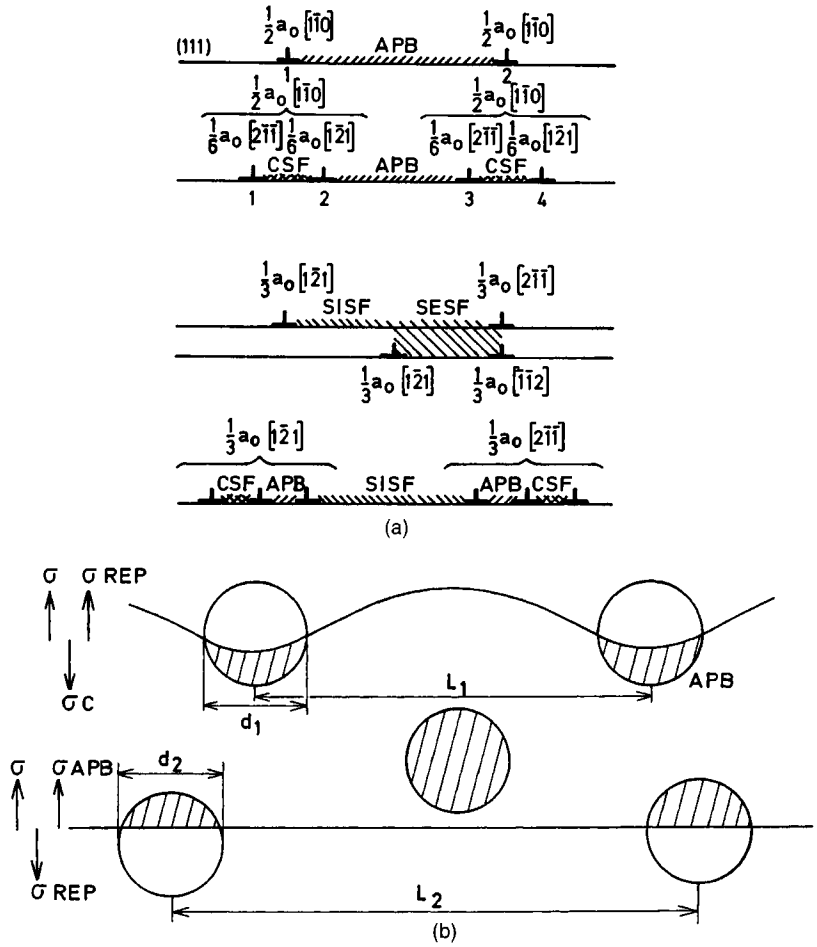

Figure 46. (a) Dissociation of superlattice dislocations in $L1_2$. (b) Dislocation pair in its glide plane.

at room temperature but in a lower density than after fracture at around 800°C. In a typical twin [011] diffraction pattern a $[1\bar{1}1]$ twin axis has been found, proving that the twin plane is an octahedral plane.

The main dissociation mechanisms of unitary dislocations in $L1_2$ ordered materials were described at the beginning of this section (see also Table 3 and Fig. 46A). Here the mechanisms will be applied to $L1_2$ ordered precipitates. In the case of a low APB energy, dislocation motion is not seriously hindered by precipitates. To shear the precipitates no rearrangement of the dislocation is necessary. If the matrix stacking fault energy is high, unit dislocations are not dissociated in the matrix, and shearing of the precipitates and matrix will occur by single-unit dislocations or by paired dislocations according to the physical picture depicted in Fig. 46B, where the shear stress is given by [129]

$$\sigma = \frac{\gamma_{APB}}{2b}\left(\frac{d_1}{L_1} - \frac{d_2}{L_2}\right) \tag{18}$$

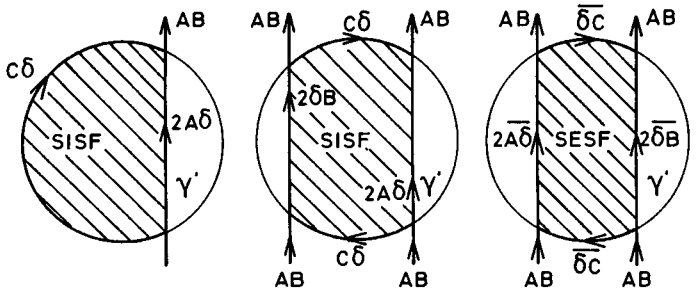

Figure 47. Top view of SISFs and an SESF in γ' precipitates.

If the matrix stacking fault is low, precipitates and matrix will be deformed by partial dislocations which create stacking faults in the matrix and complex stacking faults (CSFs) in the precipitates. In the present case of the nickel-base superalloys, both the stacking fault energy and APB are considered to be high. So, the matrix will be deformed easily by unit dislocations that are halted at the interfaces between the matrix and precipitates. An ordering fault can be avoided if the precipitates are sheared by $2A\delta$ (Thompson notation [130, 131]), depicted in Fig. 47. A second dislocation confines the stacking fault (Fig. 47b). The same mechanism is applicable for extrinsic faults (Fig. 47c) [132, 133]. The dissociation of AB is also possible into Shockley partial dislocations according to $2AB \rightarrow \bar{A}\bar{\delta} + A\delta + \delta B + \delta\bar{E}$ (Fig. 48). In this case $2\delta\bar{B}$ is coupled to $2\bar{A}\bar{\delta}$ by a CSF–APB fault that produces a highly constricted configuration. However, a relaxed mode of dissociation is reached if $\delta\bar{B}$ is separated from δB, which is also located between $\bar{A}\bar{\delta}$ and $A\delta$ [134]. Then the double fault in Fig. 48a is transformed into an SISF (Fig. 48b). The dipole displacement is indicated by the symbol $\diamondsuit$, and the dissociation has the following form:

$$2AB \rightarrow \bar{A}\bar{\delta} + \diamondsuit + A\delta + \delta B + \diamondsuit + \delta\bar{E}.$$

Deformation of precipitates by partial dislocations according to Fig. 48b is energetically favorable in comparison with Fig. 48a because of the lower energy of an SISF relative to the CSF–APB fault. The reduced interaction energy must offset the higher core and elastic energies of the

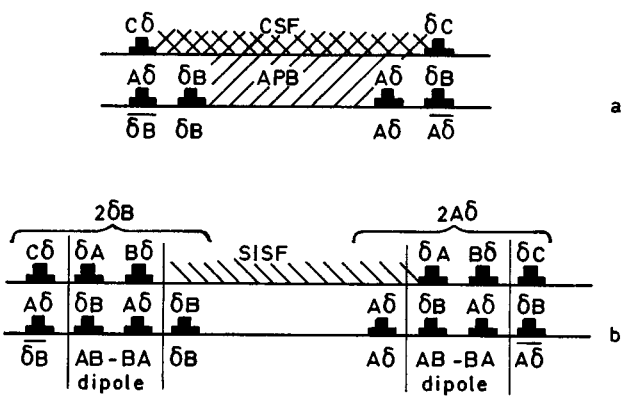

Figure 48. Dissociation of 2AB without and with dipole rearrangements.

dislocations. The difficult step is clearly associated with the formation of a dipole at the interface between matrix and precipitate. This dissociation scheme seems to be appropriate only for high-temperature deformation where thermal vacancies may interact with dislocation cores to provide the required dipole displacements. This slip mode is termed viscous slip because the necessary vacancy migration is thermally activated. The hard sphere model of Strutt et al. [135] clearly shows the effect of such a dipole displacement.

If the matrix stacking fault energy is low enough to make dissociation of unit dislocations feasible, deformation will no longer occur by unit dislocations because the two total superlattice dislocations with Burgers vectors at 60° can react to form intrinsic–extrinsic fault pairs. These fault pairs with a net Burgers vector of $6A\delta$ have been observed in precipitation-hardened alloys as well [136], but will not be considered here since dissociated matrix dislocations were not observed by CTEM in the present case.

An experimental TEM method to verify whether the faults inside γ' precipitates are CSFs or SISFs is to determine the Burgers vector of the leading dislocation of a fault. The analysis is along the same lines as listed in Table 2. Here the determination of the Burgers vector is performed with the invisibility criterion $\boldsymbol{g}\cdot\boldsymbol{b} = 0, \pm\frac{1}{3}, -\frac{2}{3}, \frac{4}{3}$. In all cases the deviation from the Bragg reflection is taken as positive ($s > 0$). The results are summarized in Table 5. The invisibility for $\boldsymbol{g}\cdot\boldsymbol{b} = +\frac{4}{3}$ is ambiguous. Nevertheless, comparison of Fig. 49a ($\boldsymbol{g}\cdot\boldsymbol{b} = +\frac{4}{3}$) with Fig. 49b ($\boldsymbol{g}\cdot\boldsymbol{b} = -\frac{4}{3}$) reveals a clear difference in contrast. Care was taken on reversing $\boldsymbol{g}$ to maintain the

Table 5. $\boldsymbol{g}\cdot\boldsymbol{b}$ and $\boldsymbol{g}\cdot\boldsymbol{R}$ analyses of the fault configurations shown in Figs. 49 and 50 (i, invisible; v, visible). The extinction criteria for a stacking fault are $\alpha = n\pi$.

same value for the deviation of the Bragg condition. The occurrence of an $a/6[11\bar{2}]$ partial dislocation is excluded because of the visibility of the leading dislocation of the fault for $\boldsymbol{g} = [\bar{2}\bar{2}0]$. From Table 5 it may be concluded that an $(a/3)[11\bar{2}]$ partial dislocation creates the fault inside the γ' precipitate. By observing the outermost fringes, the intrinsic character of the faults has been proven. The dislocation fault configuration shown in Fig. 49 is just one example of a large number with the same extinction behavior. Along the fringes of some superlattice intrinsic stacking fault a dislocation segment can be resolved. In Fig. 50 such a segment is visible, where it can be seen that this fault extends over the whole γ' precipitate. Here again with the invisibility criterion the character of the dislocation can be determined. The Burgers vector is $\frac{1}{6}[1\bar{2}\bar{1}]$ (see Table 5). Although the plane of the fault has been determined by tilting, the exact value of the displacement is unknown. The three possible values of $\boldsymbol{R}$ are: $\frac{1}{3}[\bar{2}1\bar{1}]$, $(a/3)[112]$ and $(a/3)[1\bar{2}\bar{1}]$. The third would imply that $(a/2)[1\bar{2}\bar{1}]$ is operative, which is rather unlikely

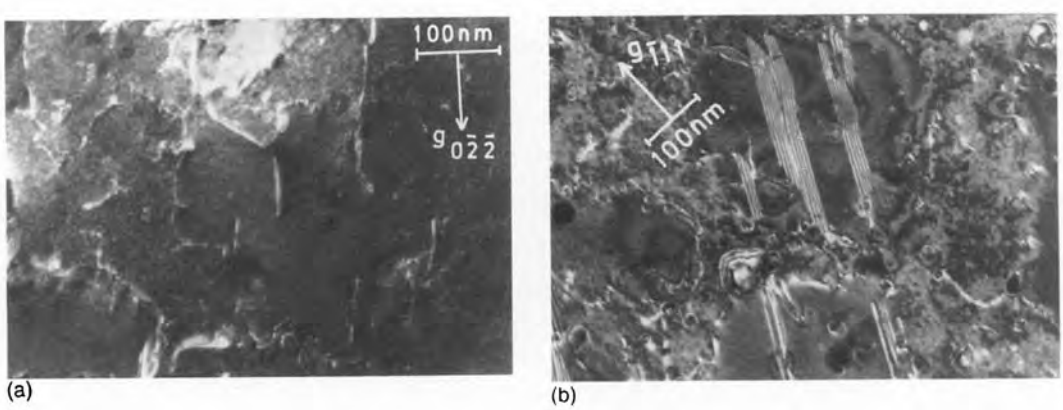

Figure 50. $(a/6)[1\bar{2}\bar{1}]$ dislocation along the fringes of an SISF. (a) $\boldsymbol{g}\cdot\boldsymbol{b} = +1$ and (b) $\boldsymbol{g}\cdot\boldsymbol{b} = -\frac{2}{3}$ (see Table 5).

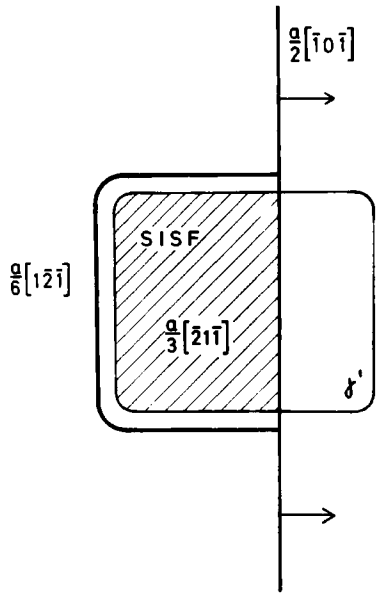

Figure 51. Schematic view of the creation of stacking faults inside a γ' precipitate.

because $(a/2)\langle 112\rangle$ partial dislocations have not been observed. The presence of an $(a/6)[1\bar{2}\bar{1}]$ loop together with $\boldsymbol{R} = (a/3)[\bar{2}1\bar{1}]$ or $(a/3)[112]$ leads to the following dislocation dissociation mechanism of a unit dislocation:

$$(a/2)[\bar{1}0\bar{1}] \rightarrow (a/3)[\bar{2}1\bar{1}] + (a/6)[1\bar{2}\bar{1}]$$

This particular dislocation reaction is confirmed by the presence of unit dislocations which were apparently obstructed at the γ–γ' interfaces. The situation is shown schematically in Fig. 51.

As a result of the $\langle 110\rangle$ grain orientation, two slip systems are easily activated. The occurrence of two slip systems also causes typical faults. Some of the stacking faults inside the γ' precipitates indeed reveal a line of intersection of two $\{111\}$ slip planes. By edge-on tilting it was found that part A of a fault such as that in Fig. 52 is located on (111) along $[\bar{2}11]$, and part B

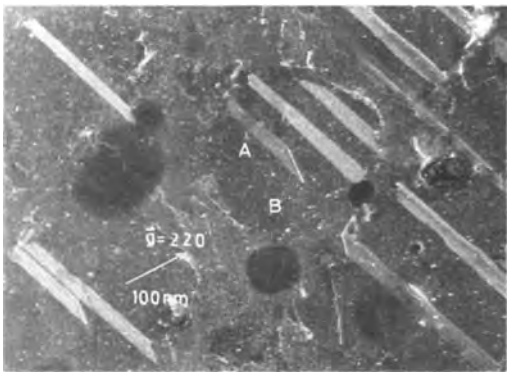

Figure 52. A stair rod dislocation is visible along the line of intersection of the two-fault plane.

on $(11\bar{1})$ along $[1\bar{2}\bar{1}]$. It is likely that the $(a/3)\langle 112\rangle$ partial dislocations, which have created the faults, have formed a stair rod dislocation at the line of intersection of the two slip planes. In fact, several stair rods can be formed if two $(a/3)\langle 112\rangle$ dislocations on these slip planes meet. Regarding the self energy, $(a/3)\langle 110\rangle$ is the most likely. Assuming the leading $(a/3)\langle 112\rangle$ partial dislocations which have created the fault to be of pure edge character, the exact Burgers vector may be deduced from the direction of the faults. This implies a dislocation reaction according to

$$(a/3)[\bar{2}11] + (a/3)[1\bar{2}\bar{1}] \rightarrow (a/3)[\bar{1}\bar{1}0].$$

In silicon, grown-in faults have been observed with a similar stair rod dislocation [137]. The stair rod in Fig. 52 is one side of a triangle which reveals a contrast typical for two faults, one above the other, which have a symmetrical inclination to the foil. The fringes are modulated parallel and perpendicular to the stair rod dislocation.

From these results it is concluded that upon deformation at temperatures near 800°C, $(a/3)\langle 112\rangle$ partial dislocations are

mobile in spite of a high Peierls stress. At room temperature, deformation until fracture produces a rather low density of twins. Calculations show that $(a/3)\langle 112\rangle$ partial dislocations may have glissile and sessile core structures. Therefore, the explanation might be that at room temperature $(a/3)\langle 112\rangle$ partial dislocations are less mobile [138]. From the separations between two $\frac{1}{2}\langle 110\rangle$ dislocations the APB energy is estimated to be $144 \pm 15\,\mathrm{mJ\,m^{-2}}$, which is less than the fault energy calculated (see Table 3) for pure Ni_3Al. Veyssière [139] has calculated that an $(a/3)\langle 112\rangle$ partial dislocation has a stable position at a certain distance from a Shockley partial dislocation provided $\gamma_{SISF}/\gamma_{APB} < 0.1$. In the present case this would imply $\gamma_{SISF} < 14\,\mathrm{mJ\,m^{-2}}$. However, a spontaneous dissociation of a $\langle 110\rangle$ dislocation into two $(a/3)\langle 112\rangle$ partial dislocations has not been observed. Therefore, $\gamma_{SISF}/\gamma_{APB} > 0.03$, that is, $\gamma_{SISF} > 4\,\mathrm{mJ\,m^{-2}}$.

At higher temperatures dislocation climb cannot be ignored. A typical example of a superlattice dislocation pair with a Burgers vector of $(a/2)[\bar{1}0\bar{1}]$ is depicted in Fig. 53. Two micrographs forming a stereo set were used to construct a three-dimensional image. A well-defined image of the dislocation has been obtained by a deviation from the Bragg position $w = 8.7$. To determine the value for $w = s_g \cdot \xi$ one needs to know the extinction distance ξ. Assuming a statistical distribution of the elements over the relevant sublattices in $L1_2$, ξ is found to be 42 nm. At first sight the superlattice dislocation can be divided into three parts [140]. However, a more detailed identification of the crystallographic planes revealed four sections, which are specified in

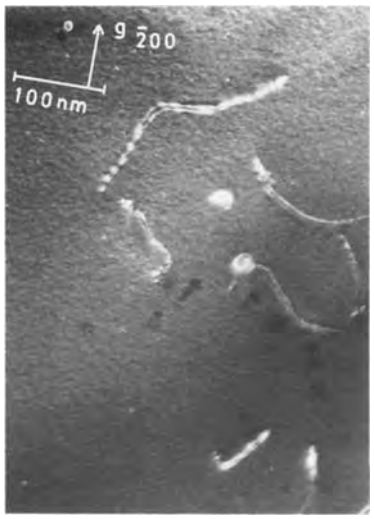

Figure 53. TEM image of a climbed superlattice dislocation.

Table 6 and schematically represented in Fig. 54. It may be surprising that only one segment of the superlattice dislocation is dissociated on a cubic plane whereas dissociation on an octahedral plane does not occur at all. The second, third and fourth segments have not reached their actual position by pure glide. It was also found by Veyssière et al. [141] in polycrystalline Ni_3Al that screw dislocation segments were dissociated on {001} planes whereas nonscrew segments were dissociated by a combined glide–climb process. The results listed in Table 6 confirm these findings. The fact that dissociation occurs by a thermally activated process may offer

Table 6. Specifications of Figs. 53 and 54 (length measured in the (001) projection).

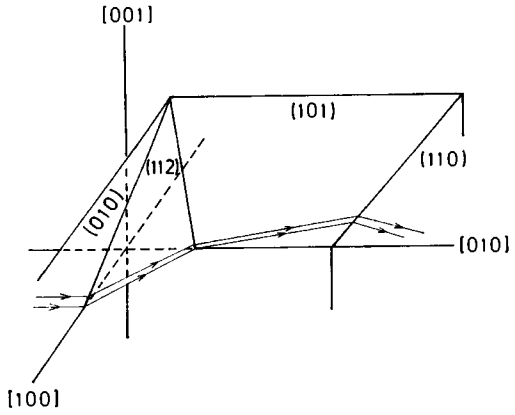

Figure 54. Schematic representation of the dissociation depicted in Fig. 53.

an explanation of the anomalous temperature dependence of the strength of $L1_2$ ordered alloys. At a certain temperature the dislocation segments on nonglissile planes may become mobile since the Peierls stress is lowered at increasing temperature. However, it should be emphasized that any detailed explanation of the yield stress anomaly in terms of dislocations must invoke intrinsic properties of dislocations, like core structure, mobilities and dissociations. At least six different models are proposed in the past to explain also related properties of the rate sensitivity and thermal reversibility [142–151].

At the end of this section it should be mentioned again that the tilting in the deformation holder was limited to a single tilt ($\pm 30°$), and thus the specimen sometimes could not be double tilted to the right with respect to the electron beam so as to excite the different reflections that are necessary in a complete characterization and analysis of the defects present in the sample. As a consequence, after the in situ deformation, specimens that promised to be interesting were shaped into 3 mm diameter discs and mounted in a TEM holder with two tilt axes. After the development of these in situ single-tilt TEM holders in the early 1970s [152–156], new double-tilt heating-straining stages became available (illustrations can be found in the literature [157, 158]).

Thus far we have been concerned with relating physical properties of metallic systems to structural information, either static or dynamic, but still on a micrometer scale. The question addressed in the following section is whether it is necessary and relevant to go beyond this scale, that is, to look for structural information on an atomic scale.

1.4.3 High-Resolution Transmission Electron Microscopy

Generally speaking, two ways of imaging in the transmission electron microscope can be distinguished. In conventional TEM, diffraction contrast is employed where the contrast in the image is determined by the intensity of the imaging beams, that is, the beams enclosed by the objective aperture. As is shown in the previous sections, rather low resolution information about the structure of the sample viewed along the direction of the incident beam can be obtained. In modern analytical transmission electron microscopes with reduced spherical aberration, a larger objective aperture can be used by which a large number of diffracted beams may interfere in the image improving the image resolution. With the advent of (ultra-)high resolution TEM (HREM) it is nowadays even possible to derive from the images structural information at an atomic scale. The technique of HREM

has its origins in the technique of phase contrast microscopy, which was introduced by Frits Zernike [159] of the University of Groningen for optical microscopy. In 1953 he received the Nobel prize in physics for this invention, which has found particular applications in the biological sciences.

HREM imaging is based on the same principles of phase contrast. Phase contrast imaging derives contrast from the phase differences among the different beams scattered by the specimen, causing addition and subtraction of amplitude from the forward-scattered beam. Components of the phase difference come from both the scattering process itself and the electron optics of the microscope. In a weak phase object the amplitude of the Bragg scattered beam is small compared to that of the forward-scattered beam. Most high-resolution images are made under conditions where visual contrast is best, that is, usually corresponding to a small defocus value.

The formula for the combined phase shift due to the optics of the microscope can be formulated at [160–162]

$$\chi(u) = \frac{2\pi}{\lambda}\left[C_s\left(\frac{\lambda^4 u^4}{4}\right) + \Delta f\left(\frac{\lambda^2 u^2}{2}\right)\right] \quad (19)$$

where C_s represents the spherical aberration coefficient of the instrument. The microscopist may control the amount of defocus Δf, and thus the phase shift of the off-axis beam. Underfocusing the lens ($\Delta f < 0$) compensates in part for the detrimental effects of spherical aberration. Overfocusing exaggerates the effect. Contrast originates from the difference in amplitude between the incident wave and the sum wave after scattering. The phase contrast transfer function $T(u)$ is related to $\chi(u)$ and the aperture function $A(u)$ by

$$T(u) = A(u)\sin\chi(u) \quad (20)$$

which describes how the microscope affects the phases of the imaging beams located at positions u (reciprocal coordinate). The problem, however, is that the contrast in fact oscillates, sometimes light against dark, and sometimes dark against light. Some amount of underfocus ($\Delta f < 0$) is needed to counteract the effects of spherical aberration. The optimum defocus condition was presented by Otto Scherzer [163], and is the value for which $|\sin\chi(u)|$ is close to unity for the largest possible range of u. The optimum defocus value is then found by setting the derivative of $\sin\chi(u)$ with respect to u equal to zero for $\chi = 2\pi/3$, leading to

$$\Delta f_s = -\sqrt{\tfrac{4}{3}C_s\lambda} \quad (21)$$

The $\sin\chi(u)$ crosses the axis for $\chi = 0$, that is (see Eq. (19)),

$$u_m = 2(3C_s\lambda^3)^{-1/4} \quad (22)$$

The resolution, defined as the least resolvable distance in the image, is then taken to be equal to u_m^{-1}. In that sense the resolution of HREM has traditionally been defined in terms of its Scherzer resolution limit at optimum defocus. Even beyond the Scherzer limit, spatial frequencies can be transferred from the specimen to the image, out to the so-called information limit of the microscope. The image detail thus obtained, however, is no longer directly interpretable due to the oscillatory contrast behavior. Coene et al. [164] have proposed a phase retrieval procedure to make the high-resolution information interpretable, which provides the aberration-corrected electron wave from a

focal series of HREM images. The ultimate goal of course is to achieve 0.1 nm structural resolution by using the information limit rather than the point-to-point resolution of the microscope. The information limit is extended to about the 0.1 nm range by the much better spatial and temporal coherence of the field emission gun as compared with the commonly used LaB_6 sources. Besides variation of focus as a method of phase retrieval, electron holography [165] seems to be a promising technique with which to achieve 0.1 nm structural resolution.

Roughly speaking, HREM of metallic systems can be divided into two different categories: one dealing with the atomic structure of defects and the other with chemical ordering in ordered compounds. The latter in particular comprises a panoply of structures. A rich literature exist on superstructures, domain structures and stacking disorder to which the Antwerp group under the leadership of Amelinckx and Japanese groups have contributed most substantially [165–175]. In itself it is understandable that ordered compounds are relatively popular here since these alloys are usually well ordered along the projection axis and, as shown by Amelinckx et al., it is feasible to obtain chemical and topological information by reference to either bright field or dark field images that may reveal the positions of the minority atomic columns [171]. More recently a detailed study of the atomic structure of antiphase boundaries in $L1_2$ ordered compounds has been published as well [176, 177].

In the category of defects the work on metals using HREM is less extensive. Work has been done on point defects in metals, related to radiation damage [178, 179], small metallic clusters [180, 181] and bulk dislocations [182–184], mostly in semiconductors [185–187]. However, following the CTEM work on interfaces, most HREM investigations have been devoted to interfaces for obvious reasons since many interesting physical properties are in fact determined by their atomic structures. However, in contrast to the work on ordered compounds, this does not mean this is an obvious choice from an HREM point of view. Quite frequently the boundaries in metallic systems are stepped or curved so that the requirements needed to determine the atomic arrangements are not met. In principle, the boundary should have an edge-on configuration to the incident beam direction with no interfacial steps normal to the beam direction. However, when the number of steps is still at a rather low density, high-resolution imaging might still be useful. Further, edge-on boundaries are most useful indeed, but HREM could still have some meaning in the study of inclined boundaries [188].

One of the earliest studies on grain boundary structures in aluminum and molybdenum were carried out by Bourret, Penisson and Gronsky [189, 190], at relatively low accelerating voltage (100 kV), whereas at high voltage (500 kV) tilt boundaries in gold were investigated by Ishida's group [191]. More examples are given by Smith and Barry [192].

At first sight one would think that all the aforementioned constraints would limit the usefulness and potentiality of HREM substantially to the field of materials science. So, the question to be asked again is whether HREM can help to solve materials problems, and not just reveal the structure of interfaces at some

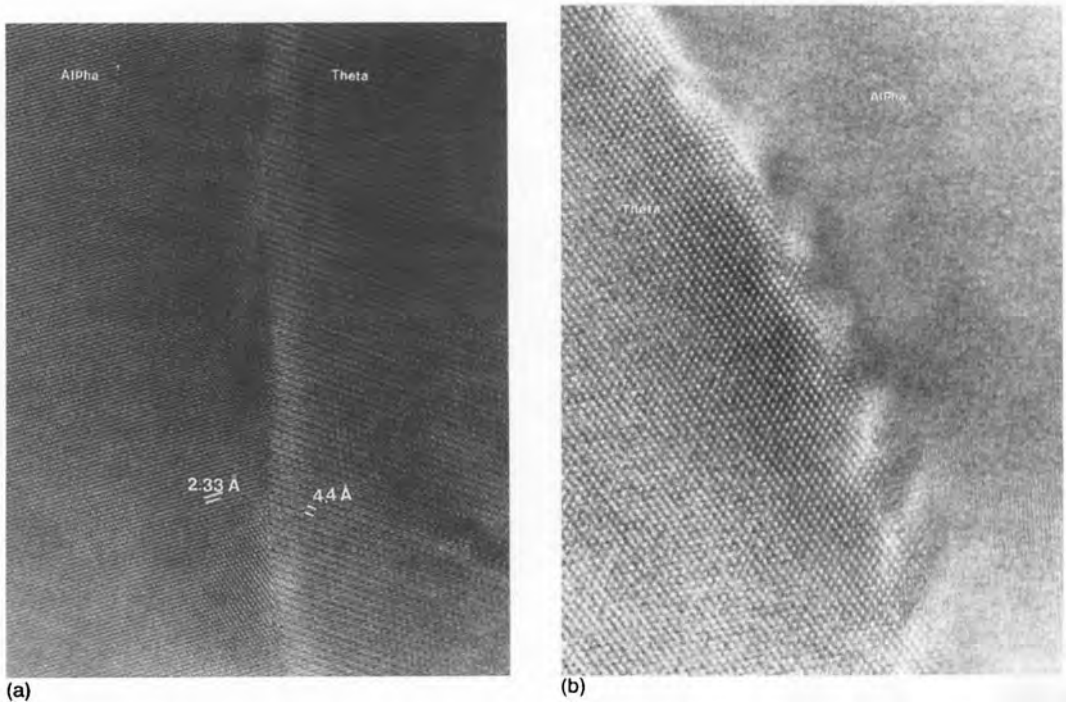

Figure 55. (a) α/θ interface in $[110]_\alpha$ zone axis orientation. Note the overlap between the phases. (b) α/θ interface. Note the ledge-type interface structure.

level of resolution. Fortunately, special boundaries dictated by symmetry arguments are more favored and relevant for some of the material properties than general boundaries (for a review, see Sutton and Balluffi [193]). In addition, as a matter of course, short periodic boundaries derived from symmetry arguments are much more popular with computational materials scientists, as a result of which HREM observations are often combined with atomistic calculations [194, 195]. This more recent alliance between experimental microscopists and theoreticians has turned out to be extremely useful and to some extent even essential.

To illustrate the possibilities and difficulties with HREM analysis, a typical example is shown in Fig. 55, where precipitation reactions are used to impose symmetry constraints for HREM research. To be somewhat in line with the previous sections, a θ interface is depicted inside an α matrix close to a [110] zone axis orientation in a laser-treated Al–5 wt.% Cu alloy (laser beam velocity $0.00125\,\mathrm{m\,s^{-1}}$). The magnification was calibrated on the 111 fringes in the α phase, which are $d_{111} = 0.233\,\mathrm{nm}$ apart. The fringe spacing inside the θ phase is 0.44 nm, which corresponds to the interplanar spacing of 110 planes. The lighter area at the interface clearly indicates that the two phases overlap there, and although there is contrast in both phases, the interface between them is not edge on. Figure 55b shows clear contrast in the θ phase, and little or no

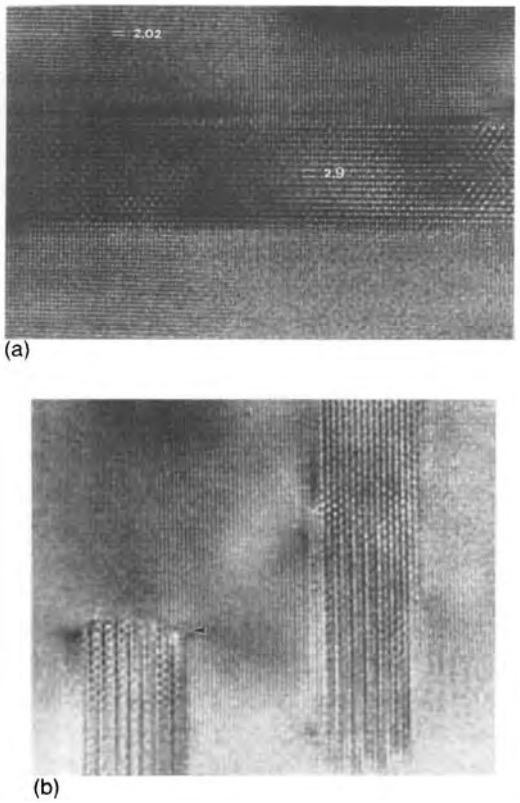

Figure 56. (a) θ' plate in [100] zone axis. (b) $[100]_{\theta'}$. The arrow indicates a misfit dislocation.

contrast in the α region. The wide parallel areas at the interface indicate the presence of some sort of ledge-type structure at the interface. Again this tells us that the interface is not edge on. So, this α/θ interface is not a good candidate for HREM. A much better choice is to focus on θ' precipitates which are semicoherent with the matrix. In Fig. 56 the matrix is tilted to a [100] orientation, showing $d_1 = 0.202\,\text{nm}$ fringes and illustrates how the (001) planes of the matrix are coherent with the (001) planes of the θ' precipitate. The fringes in the plate that are parallel to the interface were measured to be $d_2 = 0.29\,\text{nm}$ apart, which corresponds to the (002) fringes in θ'. Along the plate the contrast inside the plate changes from rectangular to diagonal fringes. Apparently the foil has a variation in thickness which causes the change in contrast. The thickness of the plate is estimated to be 17 atomic planes. At the end of the platelets, Moiré fringes can be seen in Fig. 56b. Their spacing is 0.66 nm, which corresponds to a Moiré fringe spacing expected from the overlap of the c axes of α and θ: $d_1 d_2/(d_1^2 + d_2^2 - 2d_1 d_2)^{0.5}$. At the top of the left-most plate an extra half plane can be seen in the matrix (arrow), which can be identified as a misfit dislocation accommodating the mismatch in lattice parameter. It has been shown [193] that θ' may nucleate on existing $\frac{1}{2}\langle 011\rangle$ dislocations that are dissociated by the reaction on a $\{001\}$ plane according to $\frac{1}{2}\langle 001\rangle + \frac{1}{2}\langle 010\rangle$. Therefore the interface can be regarded structurally as a stacking of partial $\frac{1}{2}\langle 001\rangle$ dislocations in the matrix that accommodate the mismatch with the precipitate. Similar symmetry-confined precipitates are found in the Al–Ag system [196, 197].

So far we have summarized the potential applications of HREM to structural aspects in metals and illustrated some of the complexities in resolving the structure at an atomic level. Actually, we have not referred to any material property that was elucidated by HREM itself. To be consistent within the scope of this contribution let us direct ourselves to a material property such as intergranular fracture and ask ourselves whether HREM has contributed towards solving the basic question in materials science why some additional elements in metallic systems promote embrittlement and others do not. In fact, there are not many clear examples presented in the literature, which is after

all mainly devoted to structural aspects as such and not directly to metallic properties. In contrast, a very nice example is presented by Luzzi et al. [198] studying the segregation of bismuth on grain boundaries in copper. In their synergistic approach of theory and experiment not only the structure of a copper grain boundary is characterized, as done before [194, 195], but also the chemical nature of the atoms is revealed. A long-standing materials problem here is to provide some clue why bismuth in particular leads to embrittlement of copper, while antimony, for example, does not. As both are in the same column of the periodic table, this would imply that the chemistry of these two elements should be about equal and the most important difference would be due to size effects. Ference and Balluffi have shown that segregation of bismuth to the grain boundary induces a faceting transformation at the boundary [199]. Although this is a quite common observation in this system, it turns out that $\Sigma 3$ boundaries in particular exhibit this behavior very strongly, that is, about 30% of the total grain boundary area is made of faceted $\Sigma 3$ boundaries. Luzzi et al. [198] were able to solve the atomic structure of the $\Sigma 3(111)//(11\,1)$ boundary by HREM. An example of their result is depicted in Fig. 57. The experimental image (left column) is compared with a calculated image at various defocus values. The images were obtained from grain boundary structures, calculated using *N*-body empirical potential as derived from the ab initio full-potential linear muffin tin orbital method, within the multislice formalism. The interesting point is that, due to the size effect of bismuth, the pure twin in copper with a stacking of A–B–C–B–A is

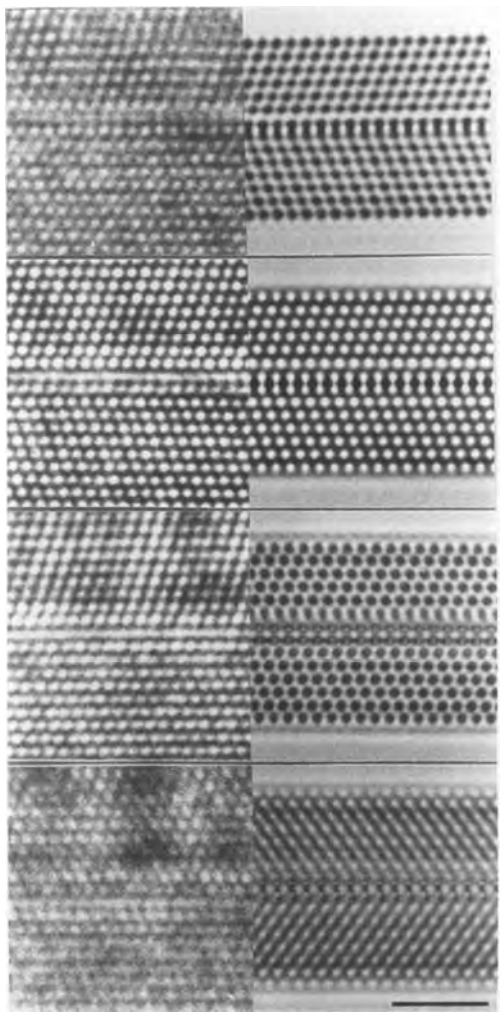

Figure 57. (a) Experimental (left column) and calculated (right column) images series with the objective lens underfocus increasing down the figure (−31.6, −63.6, −82.8 and −101.0 nm from defocus, respectively). The marker represents 1.5 nm. (Courtesy D. Luzzi)

altered to A–B–C′–C(Bi)–B–A. In fact, the bismuth atoms are centered outside the original C plane (Fig. 58). Although it is hard to say that we have a thorough understanding how embrittlement works in the Cu–Bi system (plasticity has been neglected) a comparison with antimony is

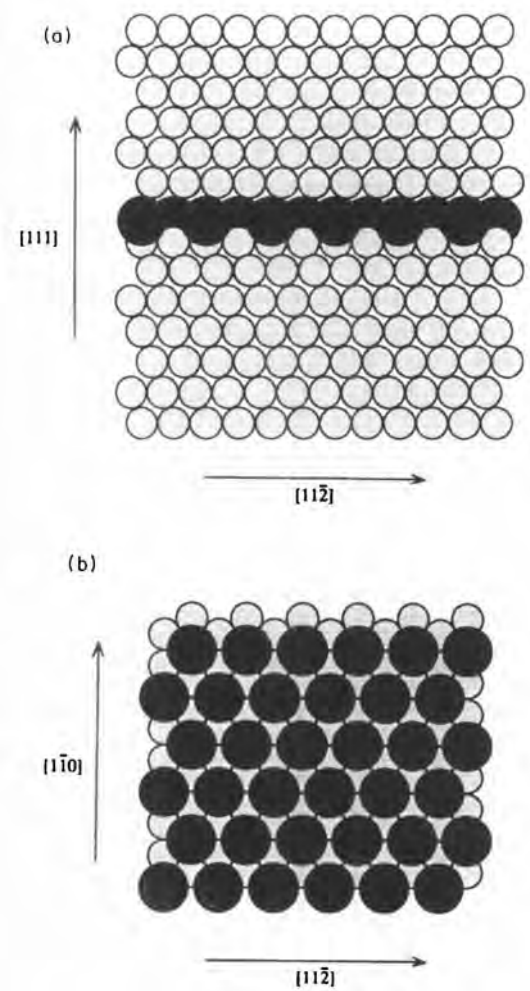

Figure 58. The relaxed final structure shown in two projections: (a) edge-on to the interface in the same direction as shown in Fig. 57b and in the plane of the interface. Bismuth atoms (dark) form an ordered hexagonal array with the interface between the adjacent copper atoms (light).

obvious now. Since the size effect of antimony is less, one would expect less faceted boundaries in the case of Cu–Sb in comparison with Cu–Bi and considerably less grain boundary expansion and a more ductile behavior instead. Indeed this is what is found experimentally [200]. Whereas faceted $\Sigma 3$ boundaries in Cu–Bi are as much as 30%, in Cu–Sb it is just 4%. Although the driving force for the (111)//(111) facets observed at the $\Sigma 3$ boundaries are also due to the pressure of the antimony, the large grain boundary expansion like in Cu–Bi system is not observed.

1.5 Imaging Metals and Alloys: Conclusions

The main emphasis of this contribution is on the structure–property relationship, so as to bridge the length-scale gap involved in the study of the stability of metallic systems. This section focuses on several aspects within this framework by looking at the detailed atomic structure on nanometer and micrometer scales, using TEM as the main tool. With all the possibilities that modern microscopes now allow [201], it is usually argued that it is necessary to characterize the microstructure at the highest levels of resolution possible in order to understand material behavior and to facilitate the design of either new or improved metallic systems. The question is whether this is really true. In other words: do we really solve materials problems, and what level of resolution is appropriate? Is the highest resolution the best route to understand properties which are structure-sensitive?

The basic philosophy should be that depending on the material property one wishes to investigate, it is necessary to consider the appropriate length-scale where the relevant processes take place. The challenging part of this rather mesoscopic approach is of course to define the

physical basis at the various length-scales and the corresponding transitions involved. For that reason, various case studies are presented here.

This section deals with metallic systems. We have not attempted to include every microscopic aspect of metallic systems. The important field of transformation in metals was only slightly touched upon. Reviews and applications of TEM in this field can be easily traced in the literature [202–205]. It is simply impossible to cover five decades of microscopic research on metals and alloys in one single review or even in one book. For that reason we took the different approach of explaining several case studies. Although the principal motivation for TEM of metals and alloys is to image microstructural defects and to derive from these observations their influences on the physical properties, the underlying scientific message is that one should be critical in the microscopic evaluation, for example, which defects are relevant, what kind of information is needed and, most importantly, on what scale?

The structure–property relationship of materials is in itself a truism. However, the actual linkage between structural aspects of defects in a material studied by TEM on one hand and its physical property is elusive. The reason for this is that many physical properties are actually determined by the collective behavior of defects rather than by the behavior of one singular defect itself. For instance, there exists a vast number of TEM analyses in the literature on ex situ deformed metals which try to link observed dislocation patterns to the mechanical behavior characterized by stress–strain curves. However, in spite of the enormous effort that has been put into both theoretical and experimental work, a clear physical picture that could predict the stress–strain curve on the basis of these TEM observations is still lacking.

There are at least two facts that hamper a straightforward correlation between microscopic structural information and materials properties: one fundamental and one practical.

Of course, it has been realized for a long time that in the field of dislocations and interfaces we are facing highly nonlinear and nonequilibrium effects. The defects determining many physical properties are in fact not in thermodynamic equilibrium and their behavior is very much nonlinear. This is a fundamental problem since an adequate physical and mathematical basis for a sound analysis of these highly nonlinear and nonequilibrium effects does not exist. Nevertheless, the situation is not hopeless since there are two approaches to circumvent these problems, and TEM may still contribute quite a lot. One had to do with numerical simulations that incorporate the behavior of individual defects as known from both classical theory and from TEM observations of individual dislocations/interfaces [206–208]. For example, to have a thorough understanding of the generation of cellular dislocation structures, vein structures, tangles, subgrain boundaries and persistent slip bands, important input for these numerical simulations on the behavior of individual dislocations such as cross-slip behavior, climb and bipolar structures, and so forth, may be provided by TEM research. The other approach is the counterpart of numeric simulations, namely a continuum mechanics approach, initiated by Holt [7]. This provides a description of

the global cooperative behavior of defects [209–216] and focuses on the instability transitions and accompanying structural transformations. Here also, experimental knowledge provided by TEM, in combination with complementary techniques [217], is inevitable.

To correlate the microstructural information obtained by TEM of an interface to the macroscopic behavior of polycrystalline solids is even more complex than in the case of dislocations. The reasons for this are numerous, for example the limited knowledge of the interface structure, that is, both topological and chemical, at an atomic level of only a small number of special cases, the complexity due to the eight degrees of freedom of an interface and the lack of mathematical–physical models to transfer information learned from bicrystals to the actual polycrystalline form. It has been shown that in some cases it is crucial to have information on an atomic level available but surely it is not always necessary and sometimes rather more appropriate to image defects on a micrometer scale instead to correlate the structural information to physical properties. An interesting approach to this end, that is, to couple boundary to boundary variations and to couple processes in the boundaries to the grain interiors, is presented by Nichols et al. [218–220] based on the concepts of percolation theory. Actually, these workers introduce new measures at a different length-scale and microscopic features such as the radii of gyration and clusters that are joined by like boundaries. Therefore, it is argued that for a more quantitative evaluation of the structure–property relationship of materials it requires a de-emphasis of analysis on an atomic scale [221].

Another more practical reason why a quantitative TEM evaluation of the structure–property relationship is hampered has to do with statistics. This is not specific of course for metallic systems. The metrological considerations of quantitative TEM from crystalline materials have been summarized by Goodhew [222, 223], one of which is the statistical significance of the TEM observations. In particular, in situations where there is only a small volume fraction of defects present (see Sec. 1.4.1 of this Chapter) or a very inhomogeneous distribution, statistical sampling may be a problem. An interesting plot is produced by Chone [224], depicted in Fig. 59. It indicates the necessary volume to be examined as a function of volume fraction of particles of various sizes with a precision of about 20%. So, in our case of gas bubbles of the order of 10 nm and a volume fraction of the order

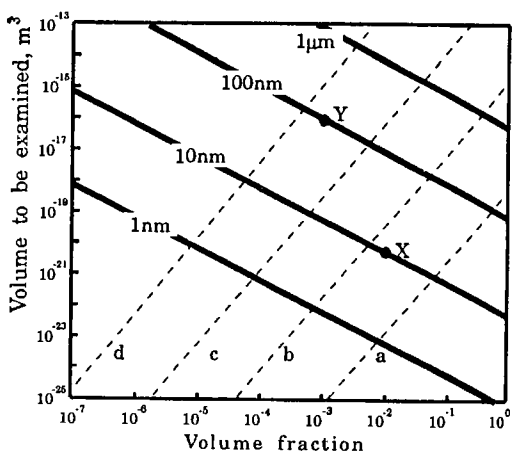

Figure 59. The volume to be examined as a function of the volume fraction at various diameters of inclusions (solid line). The dashed line refers to the number of fields of view (or screens) needed. ($a = 1$, $b = 10$, $c = 100$ and $d = 1000$.)

of 1% it is necessary to view about 10^{-20} m^3 (point X). At smaller sizes and volume fraction of course a smaller volume has to be examined (point Y). Goodhew has added to Fig. 59 lines of the particular number of fields of view (or screens) necessary, assuming that each field is explored at the most suitable magnification of a foil of uniform thickness of 100 nm. Here it would imply that for X about 10 screens are necessary, whereas for the situation at Y about 1000 micrographs are needed for an appropriate statistical sampling. In our case where bubbles are overlapping (see Fig. 4), quantitative measurements are almost impossible without applying stereo TEM (see Fig. 1). In the case of dislocations and interfaces one should also be aware of these aspects of quantitative metrology with TEM. For example, to support or reject various models of the structure–property relationship, such as the relationship between impurity segregation and interface structure, it is necessary to measure the boundary misorientation at very high precision [225], and they should all be aligned parallel to the electron beam for an effective quantitative analysis with TEM. This is virtually impossible, and only qualitative conclusions can be drawn.

Based on these fundamental and practical complexities of correlating quantitative microstructural TEM information to material properties, we conclude that TEM characterization, accompanied by complementary techniques, may serve as a crucial input for a deeper understanding of the structure–property relationship, but that one should focus more on the generic features of defects using a mesoscopic approach including various length-scale transitions.

It has also been supported by the Netherlands Foundation for Technical Sciences (STW) and IOP-Metals (The Hague). Special thanks are due to Dr. Paul Bronsveld for scientific discussions and contributions. Thanks are also due to an exciting Ph.D. student–thesis supervisor relationship—equally important as the structure–property relationship!—in this field of electron microscopy on metals that I experienced over the years with Bert Huis in 't Veld, Hans de Beurs, Herman Hegge, Eric Gerritsen, Joeke Noordhuis, Bart Pestman, Willem-Pier Vellinga, Lodewijk de Mol van Otterloo and Paul Pos. Some of our joint work has been included in this contribution.

1.6 Imaging Phase Transformations in Metals and Alloys

1.6.1 General Introduction

Since the early days of the study of phase transformations in metals and alloys, microscopy techniques have played a crucial role in characterizing and understanding the features of the various phases and microstructures involved. Although this Handbook contains a separate chapter on phase transformations (see Chap. 2.2 of this Volume), the combination of both issues in one section allows us to present some previously undiscussed but typical microscopy contributions. For the basics of the different techniques mentioned, the reader is referred to the relevant chapters in the Volumes I and II of this Handbook. Some basic and recent works

on phase transformations, including metals and alloys, are listed [226–229].

From the viewpoint of experiments involving microscopy techniques, phase transformations in metals or alloys can readily be subdivided into different classes depending on the atomic rearrangements occurring during the transition (see also Chap. 2.2 of this Volume). The first class contains those transformations in which the basic lattice virtually remains unchanged but the actual occupation of a given lattice site will change: these transformations are called *diffusive* because of the relatively large distances (i.e., several interatomic distances) that atoms can travel during the transformation. In principle, all disorder–order transformations fall into this category. Due to the ordering, slight changes in the lattice parameters or symmetry of the basic lattice can occur, sometimes leading to specific microstructures [230, 231]. A typical example of this are the diamond-like plate configurations in CuAu thin films when transformating from the high-temperature disordered f.c.c. state to a low-temperature ordered orthorhombic structure [230]. The second class contains *displacive* transformations in which the main characteristic of the transition is the change in basis lattice between the parent and product phases. Here, there is no diffusion involved and thus the existing ordering is inherited through the transformation. The classic example of this type of transformation are the martensitic transformations [232] but the ω transition consisting of pure shuffles not changing the lattice parameters of the unit cell also belongs in this class [233]. Of course there exist a number of intermediate cases in which the transition has characteristics of both of the above extremes. Bainitic [234] and near ω-type transformations such as Ni_2Al (see below) qualify for inclusion in this intermediate class.

In the present section a few typical case studies each belonging to one of the above-mentioned classes will be discussed on the basis of the microscopic investigations performed on them. Examples of in situ experiments will be shown as well as cases in which information on the phase transformation was obtained through pre-treated samples. The former usually yields direct information on the transformation path while the latter allows for a higher resolution. For the diffusional transformations, some TEM studies of long- as well as short-range effects of disorder–order transformations in some binary alloys will be discussed. Contributions on different aspects of martensitic transformations including precursors, nucleation and growth obtained using different microscopy techniques such as optical microscopy (OM), scanning electron microscopy (SEM) and TEM are then reviewed. Finally, some examples in the field of mixed cases are also discussed.

1.6.2 Diffusive Phase Transformations in Alloys

Diffusive phase transformations generally introduce a change in symmetry, which results in domain formation due to the presence of different variants. These variants can be orientation variants, creating twin boundaries or inversion boundaries, or they can be translation variants creating APBs. A prediction of the number of orientation and translation

variants can be done based on simple group theoretical considerations [235–237]. In the present contribution we will concentrate on the microstructure resulting from ordering as well as on the microstructural changes when approaching a diffusion-controlled phase transformation. We will investigate the short-range order (SRO) when approaching the transition from above and the wetting of ordering defects such as APBs when approaching the transition from below.

We know that in general HREM images vary substantially with focus and sample thickness; however, for alloys, based on a simple lattice such as the f.c.c. (or b.c.c.) lattice, the interpretation simplifies considerably. The reason being that when such structures are viewed along a simple zone axis, for example [001], we obtain a column structure with the different columns separated by 1.8–2.0 Å. Such atom columns, parallel to the electron beam, constitute a potential well with cylindrical symmetry, and the electrons 'channel' through this potential well, continuously focusing and defocusing with a periodicity varying between 40 and 100 Å, depending on the nature of the constituent atoms (Fig. 60). One can show that as long as the columns do not come too close, electrons channeling in different columns will not mutually influence each other [238, 239]. Therefore for ordered alloys the image contrast of a particular column will only be determined by the chemical composition of that column and will not be influenced by the composition of neighboring columns [238]. This aspect of HREM imaging in column-type structures allows one to interpret ordering phenomena in ordered compounds.

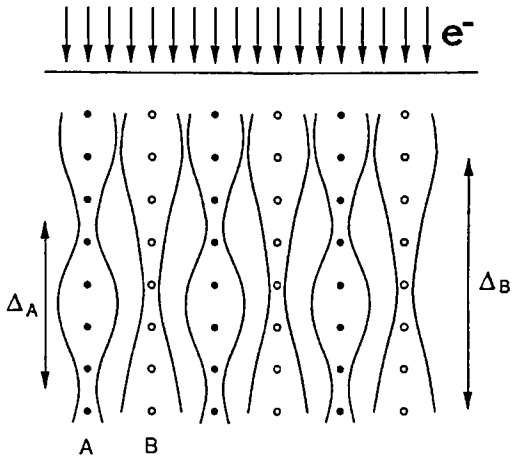

Figure 60. Electrons traveling through a column-type structure.

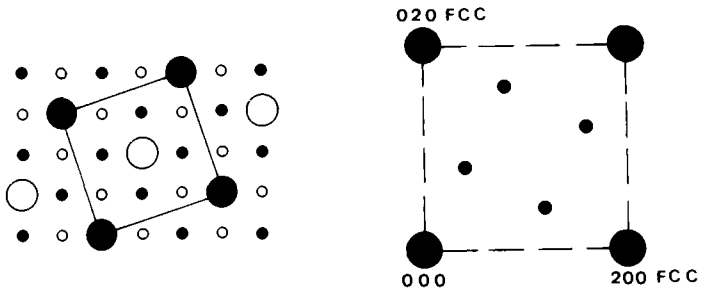
In practice, the choice of objective aperture used to select the diffracted beams contributing to the HREM image will determine the type of information which is observed in the image [240]. In Fig. 61 the different choices are shown for a [001] zone of the ordered Au_4Mn compound [241]. The unbroken circle is a dark field superlattice mode in which only ordering reflections are included after centering the aperture around the optical axis (i.e., under tilted illumination). In this mode the minority atom columns will always show up bright, and the image will be practically independent of thickness and defocus. An example of such an image is shown in Fig. 62 for a long-period superstructure in $Au_{11}Mn_3$ [242] where only the minority atom columns are visible. The higher intensity of the row of dots at the APB is also visible in simulated images and is due to the fact that the imaging mode is asymmetric with respect to the twofold axis of this boundary [240]. When the bright field basic reflections mode is used (dotted circle in Fig. 61),



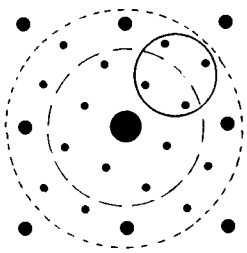


Figure 61. Different modes for HREM imaging by using different diffracted beams to form the image (Au_4Mn [001] pattern): unbroken circle, dark field superlattice mode, using only super-reflections; dashed circle, bright field superlattice mode; dotted circle, bright field basic reflection mode using basic as well as superstructure reflections.

the basic lattice will also become visible, and the actual image contrast will depend strongly on the imaging conditions to the point that it can show more bright dots than there are minority atom columns. An example of this is shown in Fig. 63 for Pt_8Ti, where the experimental image corresponds to the case of white dots on the positions of minority atoms. A slight change in thickness or defocus, however, would produce a white dot square with lattice parameters twice as small, as seen from the simulations [243]. The

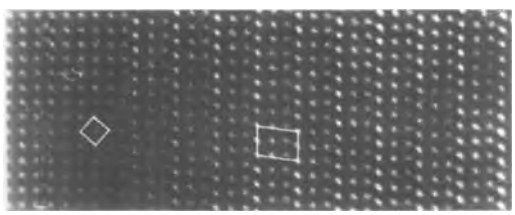

Figure 62. HREM example of long-period structure in $Au_{11}Mn_3$ using the dark field superlattice mode.

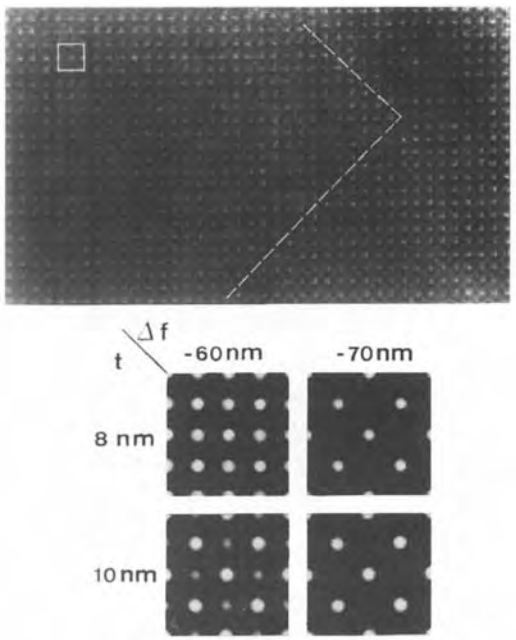

Figure 63. HREM example of Pt_8Ti obtained in the bright field basic reflection mode including simulations showing different white dot patterns for different conditions.

straightforward nature of the interpretation of these superlattice images in which only minority atom columns are made visible under known imaging conditions allows one to easily recognize and interpret new types of ordered structures or long-period variants of a given basic unity. Typical examples of this procedure are found in, for example, the Pt–Ti [244] and Au–Mn [241, 242, 245] systems.

1.6.2.1 Long-Range Ordered Alloys

It is clear that ordering in alloys can be detected by electron microscopy. Because of the lowering in orientation symmetry, twin variants or inversion domains will appear; if the translation symmetry is lowered, out of phase domains will appear. These different variants can be discerned even by conventional microscopy, and have been reported in the early literature on electron microscopy in materials science. A compilation of the different contrast effects produced by the various interfaces is shown in Fig. 64. More details on the identification of the different planar defects can be found in the literature [246]. With the recent developments of HREM it is possible to image the atomic configuration of such defects directly; we will treat two examples: Au_4Mn and $Cu_{3\pm x}Pd$. We will use these examples further when studying of the evolution of microstructure or the behavior of the alloy in the vicinity of the ordering temperature.

Au_4Mn as well as Ni_4Mo, Au_4V, Au_4Cr and Au_4Ti all have the D1a structure as the ordered structure, the structural representation of which is shown in Fig. 65c. As we will see later, all of them also have a SRO state of the type '$1\frac{1}{2}0$'. The disordered f.c.c. lattice has cubic symmetry, while the ordered structure has tetragonal $4/m$ symmetry. This results in six orientation variants; the tetragonal c axis can be along any of the cube axes and for every choice of the c axis, two orientations are possible of the a and b axes (see Fig. 65c). These six orientation variants, however, only produce two essentially different twin interfaces [241, 247]. The volume of the primitive unit cell of the ordered structure is five times larger than the primitive cell of the disordered structure, and therefore five translation variants, separated by four different APBs, result [235]. Ordering introduces a fragmentation into these different variants, resulting in patterns such as Fig. 66, where a twin interface between two orientation variants with a parallel c axis and two APBs are visible (compare with Fig. 65c). In Fig. 66 the Au_4Mn superstructure has been imaged using the dark field superlattice mode and only the manganese configuration is visualized as bright dots. The defects in the long-range order (LRO) state are now adequately studied and well understood [241].

The structure of Cu_3Pd is based on the $L1_2$ (Cu_3Au-type) structure. However, with deviating compositions from the 3:1 composition or with changing temperature, different long-period superstructures (LPSs) are found. Such LPSs consist of a regular occurrence of APBs, along the cube planes; depending on the displacement vector or the APBs, such APBs can be conservative or nonconservative. The average distance between the boundaries is termed M. At low temperatures and for well-annealed materials, the value of M is mostly commensurate and locked in at simple values (between 3 and 10 for $Cu_{3\pm x}Pd$ alloys) [248, 249]. An

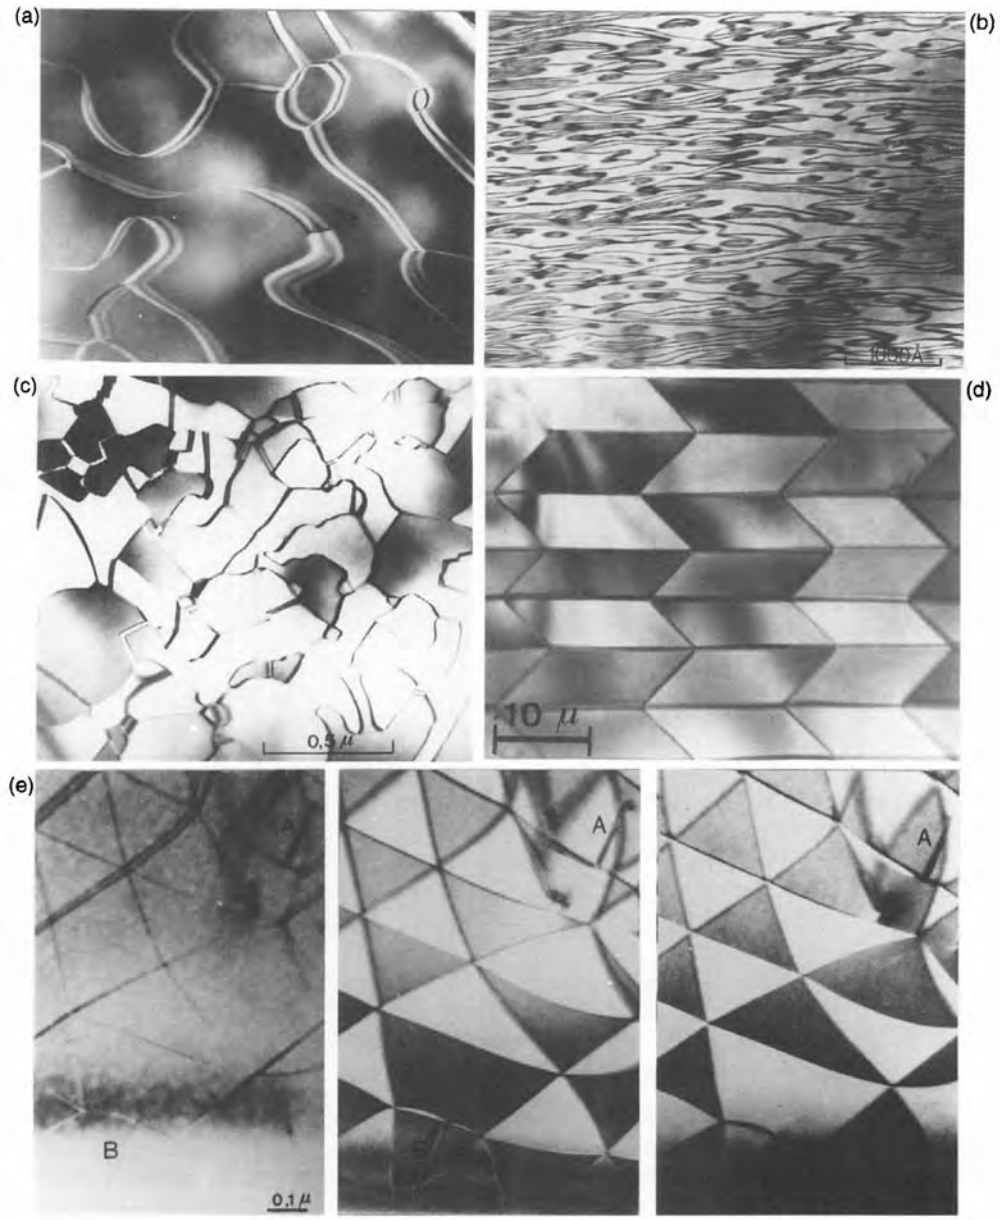

Figure 64. Diffraction contrast of different planar defects in long-range ordered materials. (a) APBs in Ni_4Mo; no background contrast difference is observed on both sides of the interface. (b) High-density and pseudoperiodic arrangement of APBs in Ni_3Mo. (c) Twin domains with a common c axis in Ni_4Mo; the corresponding diffraction is Fig. 65b, and the schematic configuration is reproduced in Fig. 65c. Note the differences in background contrast between different twin domains. (d) Regular twin configuration in γ-brass (courtesy of M. Van Sande). (e) A bright field image and two dark field images of inversion boundaries in the χ phase (courtesy of M. Snykers). Inversion boundaries appear in APBs in bright field, but are characterized by contrast differences in multiple beam dark field images.

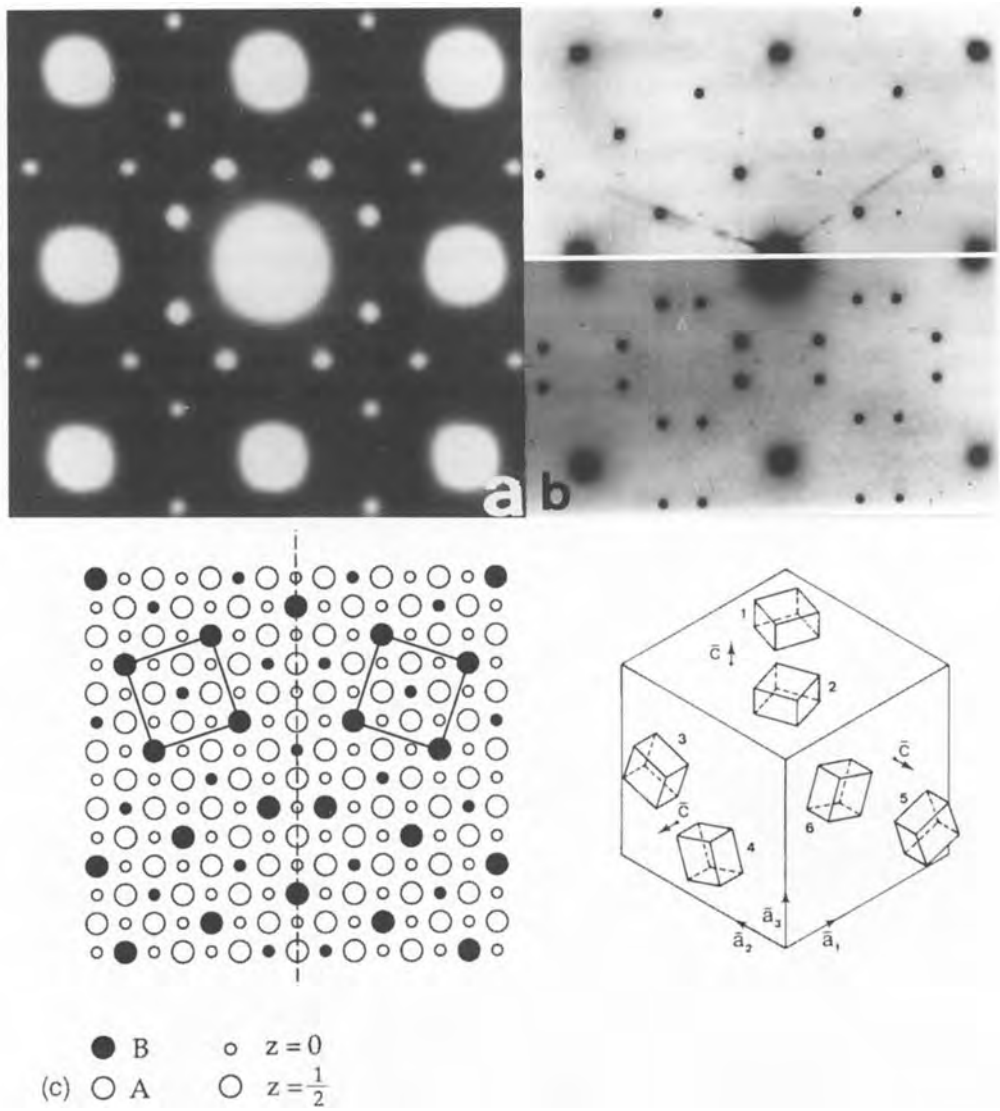

Figure 65. (a) [001] diffraction pattern of the '$1\frac{1}{2}0$' SRO state in Ni_4Mo. (b) [001] diffraction pattern of the LRO state in Ni_4Mo; the upper part is for one variant; the lower part for two variants with a common c axis. (c) [001] projection of the LRO state of D1a, showing two different orientation variants with parallel c axes and projection of the six different orientation variants on a cube.

image at high resolution is shown in Fig. 67. The interfaces are straight, sharp and well defined. Under the imaging conditions used, the bright dots can be identified as the palladium atoms; the shift at the individual interfaces is clearly visible.

1.6.2.2 Short-Range Order and Initial Stages of Ordering in D1a-Type Alloys

Studying SRO in alloys by electron microscopy is barely possible in situ since oxidation inside the electron microscope

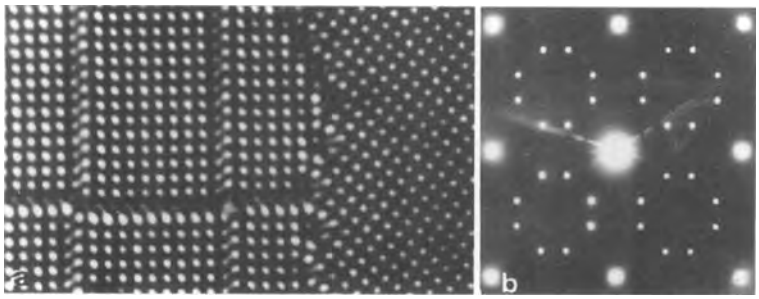

Figure 66. (a) High-resolution image of Au_4Mn with limited resolution. (b) The diffraction pattern, indicating the selected beams.

tends to limit the studies, even for alloys with a low transformation temperature. The only way to obtain information on the SRO state is by quenching the alloy from high temperature to room temperature and hoping that the state of order is retained. For a number of alloys, such as CuAu or CuPt, this procedure is not effective, ordering proceeds too fast and only the initial stages of LRO can be studied. For other alloys, however, the ordering is sluggish enough to maintain the SRO or the very initial state of LRO after quenching. Such kinds of alloy are chosen here to study the order–disorder transition. We have particular interest in so-called '$1\frac{1}{2}0$' alloys since the LRO reflections (mostly of the D1a-type structure) do not coincide with the SRO reflections (see Fig. 65). Examples of such alloys are Ni_4Mo, Au_4V, Au_4Cr, Au_4Fe, Au_4Mn and Au_4Ti. The SRO and LRO (e.g., in Ni_4Mo) has been studied since 1965 [247, 250], but discussion is still going on about the actual SRO state in a real space description: do we have ordered clusters, microdomains or a statistical distribution described by a concentration wave model? The actual difference between a cluster and a microdomain model is a matter of correlation length. The concentration wave model, first described by Khachaturyan [251], is basically a description in reciprocal space. The microdomain model and the concentration wave model, however, have to be considered as two descriptions of the same physical reality [252]; indeed, the materialization of a concentration wave in a discrete medium results in a geometrical pattern that can be considered as a cluster. In the past, a number of alloys showing a particular SRO or transition state between SRO and LRO have been studied in reciprocal space. The locus of diffuse intensity enables us to reduce a relation between some of the occupation sites of the fundamental lattice [253, 254]. Neutron and X-ray diffraction provide more accurate numerical data, but the fundamental limitation to pair correlations and the practical limitation to large selected areas still holds.

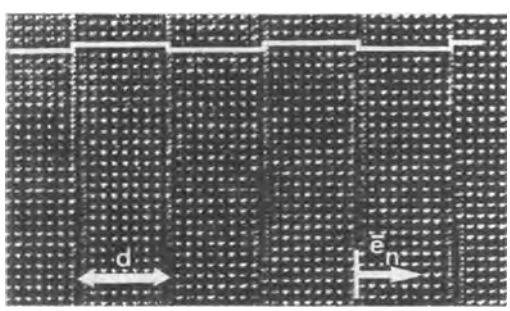

Figure 67. HREM of a commensurate LPS structure of $Cu_{3+x}Pd$ where APBs occur with periodicity $M = 8.0$.

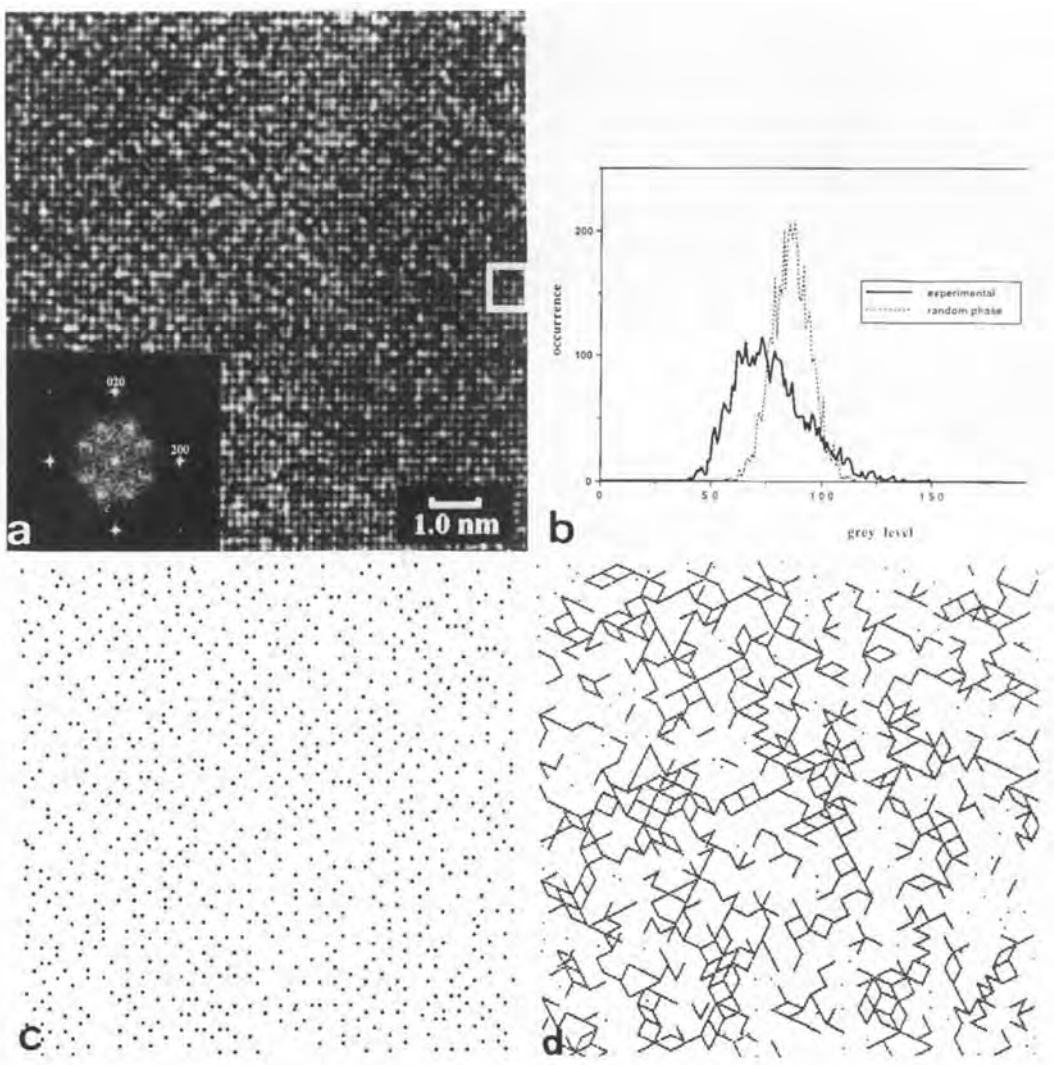

Figure 68. (a) HREM image of the SRO state in Au_4Cr; the power spectrum of (a), indicating the presence of SRO in the alloy, is shown as an inset. (b) A histogram of gray levels obtained from the SRO state, compared with a histogram from a 'random phase' distribution. (c) Result of image processing the original image (a). (d) The same as (c), but typical clusters of the type $\{2, 1\}$ have been indicated.

It is possible, however, to perform HREM observations on the SRO state in Ni_4Mo, Au_4Cr and Au_4Mn (Fig. 68). In spite of the fact that we have a column-type structure, based on a simple f.c.c. lattice, we realize that the interpretation of such images is far from straightforward. However, we have been able, with the necessary care and adapted image processing, to extract very useful information about the ordering. The Fourier transform of the HREM image of Fig. 68 indeed shows diffuse intensity similar to the electron diffraction pattern of Fig. 65a,

and therefore the ordering information is concealed within the HREM image. The main problem in HREM of such imperfect structures is the projection of a three-dimensional structure into a two-dimensional image. One can show, however, that for atom columns consisting of a random or almost random composition, the projection approximation still holds. Although this does not lead us to a direct correspondence between the column composition and its gray value—because of differences of thickness and focus—the differences in composition are still reflected in the image. If we classify for a disordered A_4B_1 alloy all [001]-type columns according to their chemical content, a binomial distribution is expected, which will be asymmetric [255]. For larger thicknesses, all columns will become equivalent, and the distribution will tend towards symmetry. We have digitized the experimental image of Fig. 68a and obtained a histogram of all gray levels (Fig. 68c); the asymmetry is clearly present. We can further show that whenever an asymmetrical histogram is obtained, the brightest dots in the HREM image correspond to columns deviating strongly from the average composition [255]. For images (such as Fig. 65a) which fulfill the binomial criterion, most information is found in those columns which appear less frequently, that is, which deviate most from the average composition. We can develop an image-processing routine to enhance the 'in-plane' correlations between these columns which give rise to the SRO intensity. From the experimental image of Fig. 68a we obtain a processed image (Fig. 68d). The Warren–Cowley SRO parameters $a_{i,j}$ can be directly calculated from the power spectrum, but also from counting the pairs in the binary image. It then turns out that pairs of the type $\{2, 1\}$ occur most frequently, indicating a preference of the structure to form identical columns separated by a vector $\{2, 1\}$. When these pairs are connected in Fig. 68d, we obtain the final image of Fig. 68e, where not only isolated lines can be discerned but also clusters of the D1a-type structure as well as of the DO_{22} structure. This is hardly surprising because the $\{2, 1\}$ pairs are the constituent vectors of both of these structures. We can now apply the same technique to the different stages of ordering between the SRO and the LRO states and follow the ordering kinetics. The Au_4Cr alloy is particularly suitable for such experiments because the ordering kinetics are very slow and therefore every state of order can easily be quenched in. Of importance—and beyond the scope of classic diffraction experiments—is the direct observations of clusters, larger than pairs, in these '$1\frac{1}{2}0$'-type alloys. We are aware that we have to include a certain 'error bar' for a quantitative interpretation of our results, because of ambiguities in judging the image intensities, but we are convinced that we are very near to the true projected structure. A strong argument being the fact that the obtained distributions are consistent with the experimental electron diffraction patterns. We therefore strongly believe that the present method opens new perspectives for studying SRO and ordering phenomena, including kinetics, in real space.

1.6.2.3 Interface Wetting in Ordered Alloys

When approaching the order–disorder transition from below, disordering will

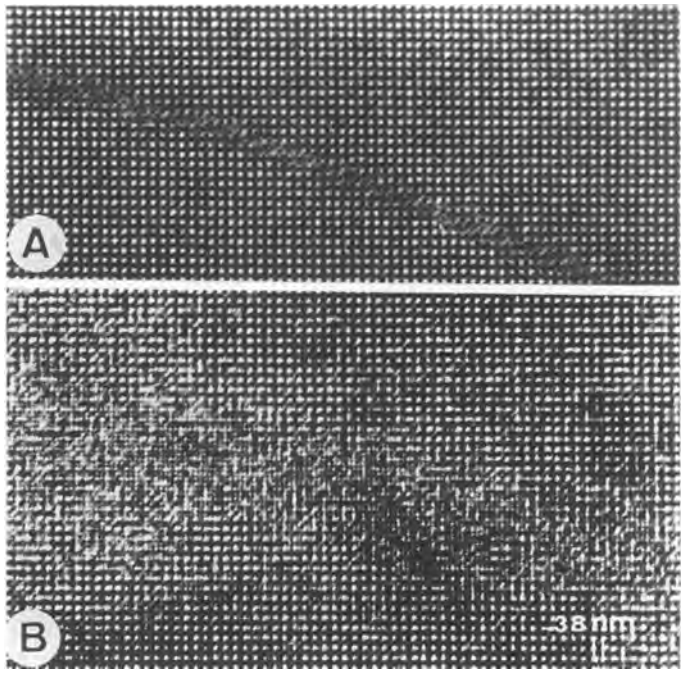

Figure 69. High resolution image along [001] of APBs in the $Pt_{70}Cu_{30}$ alloy (A) when annealed well below T_c and (B) when annealed just below T_c.

start from imperfections such as APBs [256] or twin interfaces [257]. Planar interfaces will be 'wetted' by the disordered phase at temperatures close to the transition temperature. We will first study the Pt–Co compound with the composition $Pt_{70}Co_{30}$, where the ordered structure is the $L1_2$. Further, we will consider the Cu–Pd compound which shows one- and two-dimensional long-period superstructures.

In the ordered compound $Pt_{70}Co_{30}$, APBs with a displacement vector of the type $\boldsymbol{R} = \frac{1}{2}\langle 110\rangle$ appear as a consequence of the decrease in translation symmetry. When the material is heat treated at temperatures well below T_c, these APBs show a normal behavior, that is, under two-beam conditions (0, $\boldsymbol{g}$), the boundary is out of contrast for $\boldsymbol{g} \cdot \boldsymbol{R} = n$. Under high-resolution conditions as in Fig. 69a the displacement vector can immediately be identified. The HREM imaging conditions are such that the bright dots in Fig. 69 represent the cobalt configuration. It should be noted that the structure is perfect up to the boundary plane and that the width of the interface is restricted to a single atomic plane. When annealing the material at temperatures close to T_c, the width of the interface gradually increases [258]; this is obvious from Fig. 69b. The APB is 2–4 nm wide, and at the interface the basic square f.c.c. lattice of 0.19×0.19 nm can be recognized, indicating the presence of disordered material between the two ordered regions.

In the Cu–17% Pd compound, Ricolleau et al. performed highly controlled heat treatments in the range between T_c −10°C and T_c with temperature steps of 0.2°C in order to characterize the nature of the divergence of the width of

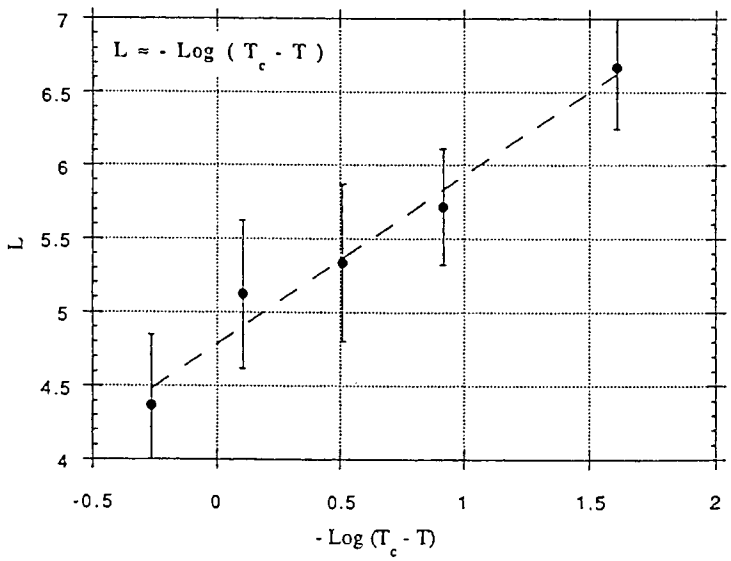

Figure 70. Variation of the width of the APBs in the vicinity of T_c, as a function of temperature. (Courtesy of C. Ricolleau [259].)

the domain walls [259]. Although the concentration of the alloy was chosen to avoid two-phase effects, the Cu–17% Pd system still presents a two-phase field about 1° wide. The presence of this two-phase field hampers the boundary-width measurements as well as the analysis of interface instabilities in the immediate vicinity of T_c; on the other hand, the measurements clearly allow us to distinguish between the wetting regime and the two-phase regime. In order to measure the exact width of the APB a number of precautions have to be taken. However, some problems persist: (a) the width of the interface is always measured at room temperature after quenching, (b) high-resolution images invariably show a sharper interface than conventional dark field images, and (c) close to T_c the APBs show a tendency to fluctuate dramatically and they may indicate the initial stages of formation of a long-period superstructure. The results of the change in boundary width as function of temperature are shown in Fig. 70. They show a good agreement with statistical mechanics calculations which predict that the width of the interface logarithmically diverges as $\log(T_c - T)$ [260].

When the palladium content of the alloy is increased in the Cu–Pd system, the $L1_2$ structure becomes unstable towards APB formation, and a one-dimensional long-period superstructure is formed. The average spacing between subsequent interfaces increases and is a function of composition and temperature [248, 261]. Close to the disordering temperature the interfaces exhibit similar wetting phenomena as the individual boundaries; this is clear from the image of Fig. 71, which is from a Cu–19 at.% Pd alloy annealed only 5°C below the disordering temperature. The disordered region is 1–2 $L1_2$ unit cells wide and, moreover, the interfaces, which at lower temperature are strictly bound to (001) planes, now become more or less wavy. The inset to Fig. 71, which is a processed

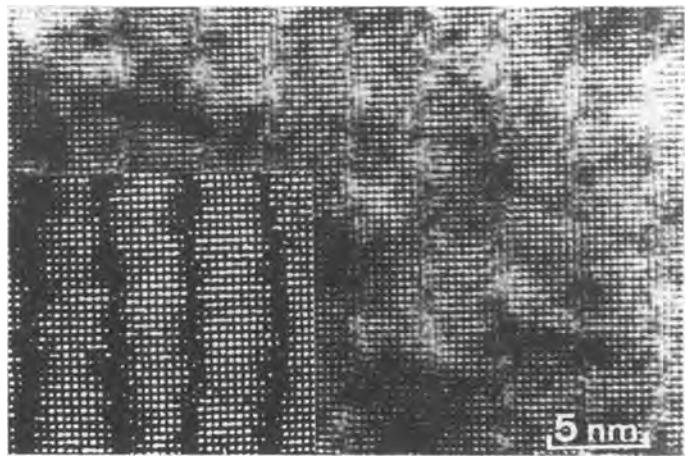

Figure 71. High-resolution image along [010] of the incommensurate long-period structures in $Cu_{81}Pd_{19}$; the processed image is shown as an inset.

image of the original HREM, accentuates the local changes at the interface. These effects are a general feature of long-period superstructures which are formed from a solid solution.

1.6.3 Displacive Transformations in Metals and Alloys

Microscopic investigations have played and are still playing a crucial role in the understanding of the different aspects of martensitic and other displacive transformations. These aspects cover a whole range of length-scales going from meso-scale surface configurations to atomic scale lattice structures. As a result, these studies have included the use of a large variety of microscopy techniques such as OM, SEM, TEM and HREM, each with its own aim and resolution. Also, recent advances mainly in the field of SP microscopy techniques have been applied with success, although the interpretation of images obtained by the latter is still subject to a lot of discussion.

The main points of interest in the study of martensitic transformations can be related to the crystallographic relation between parent and product phases, the microstructure of the product phase, the existence and atomic structure of internal defects and interfaces, the atomic and domain configurations leading to tweed or other precursing patterns and the understanding of the dynamics of the transformation. In the following, some typical results of microscopic investigations on these topics will be presented.

1.6.3.1 Microstructures

As a result of the strain-driven character and a lowering in symmetry during martensitic transformations, typical microstructures and well-defined habit planes and interfaces minimizing the strain energy are formed. The study of these configurations involves the observation of groups of martensite plates and the determination of their relative orientation relationships as well as that with the parent phase. The choice of microscopy technique

will depend on the length-scales of these microstructures. In the case of OM the orientation of the different structures or variants has to be determined separately by, for example, back-reflection X-ray Laue diffraction. In most cases the latter experiments involve the use of single-crystal parent phase material. Some recent examples of such an experiment are shown in Fig. 72 where an optical microscope is placed above a flat single crystal of Cu–14.0 wt.% Al–3.9 wt.% Ni with its parent phase surface normal along a (a) [111] and (b) a [100] axis [262]. The transformation in Fig. 72a is induced by in situ cooling

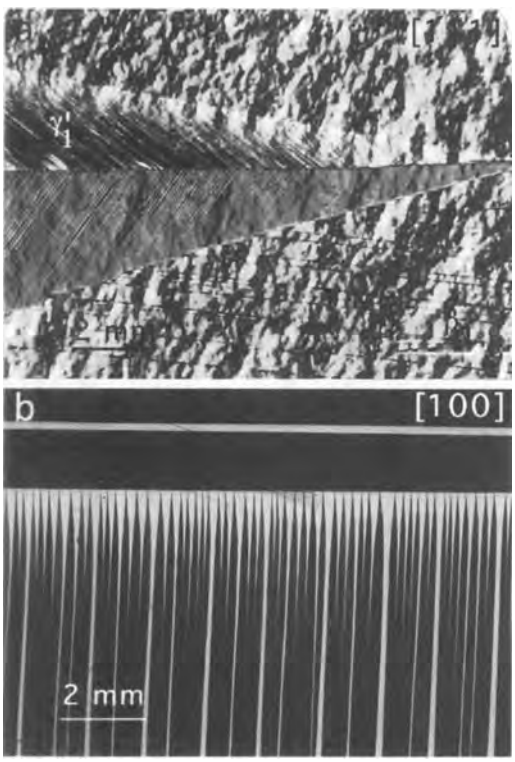

Figure 72. OM images of the β_1 to γ_1' martensitic transformation in Cu–14.0 wt.% Al–3.9 wt.% Ni. (a) Wedge-like microstructure with type II twins and (b) compound twins of different variants. (Courtesy of R. James [262].)

without stress, while in that in Fig. 72b a biaxial stress along [01$\bar{1}$] and [011], that is, normal to the edges of the specimen, was added. In Fig. 72a a wedge-like martensite microstructure with internal type II twinning and embedded in the austenite is observed, a configuration which can only be expected for special values of the lattice parameters [263]. By carefully monitoring the tension strengths, the sharp habit plane can be seen to proceed through the crystal. Figure 72b shows compound twins of which the volume ratio can be changed by cycling the specimen and changing the respective loads on the different stress axes. Also, twin layering and branching can be observed in the martensite. Due to accurate knowledge of the experimental conditions, the observations and measurements in this type of experiment can easily be compared with theoretical predictions, in this case of the newly developed non-linear elastic theory [264]. In order to obtain good contrast the surface has to be properly polished while the material is in the parent phase.

When the length-scale of the microstructures becomes smaller, for example, below 100 μm, a probe with shorter wavelength has to be used, and one is usually referred to the different modes of electron microscopy. The possibility of combining conventional imaging, transmission as well as scanning, with diffraction in a given experimental set-up is very powerful. Although many materials have been investigated in this way, new cases are still being discovered and analyzed. In Ni–Al, for example, Maxwell and Grala for the first time used the term 'martensite-like' in a technical report in 1954 [265] showing OM images indeed revealing the typical microstructures that were

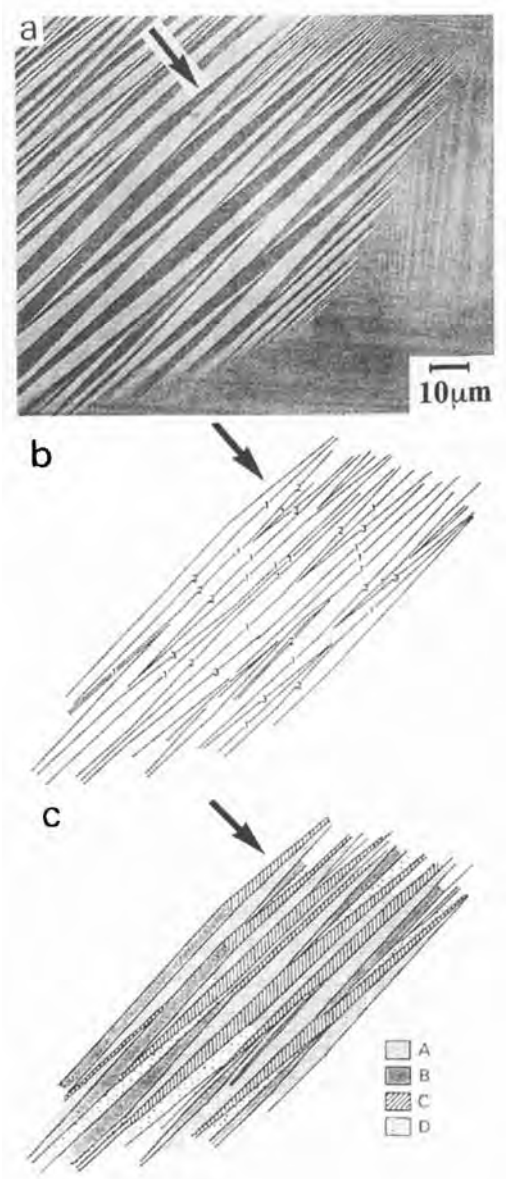

Figure 73. (a) SEM image of a self-accommodating group of 14M Ni–Al martensite. X-ray diffractometry yields the different orientations of the plates which reveal (b) three orientations of twin boundaries and (c) four habit plane variants of plates. (Courtesy of Y. Murakami et al. [267].)

characterized before as belonging to brass martensites. The first extensive report on the crystallography of the 2M or 3R martensite structure in Ni–Al was presented by Chakravorty and Wayman [266], using a combination of optical, interference and TEM techniques. Careful investigations of the traces of habit planes and plate interfaces yielded experimental values that could be compared with theoretical predictions based on strain energy minimization in linear elastic theory [227], confirming the influences of elastic strains on the microstructure of the martensite. Recently, Murakami et al. revisited this system and discussed the self-accommodation of martensite plates of the 14M structure, which is a long-period microtwinned version of the 2M structure (see also below) [267]. In Fig. 73 a SEM image and corresponding interpretation based on X-ray diffractometry of such a group is shown. Later, the same group also showed a perfect match between the theoretical predictions and experimental measurements on habit planes and the orientation relationship for the same martensite structure but stress induced [268].

1.6.3.2 Internal and Atomic Structure

When the interest lies in the internal or atomic structure of the martensite plates, one has to turn to higher magnifications including HREM studies. Again for binary Ni–Al, Mohanty and Rath presented the first transmission electron micrographs of the martensite phase in this system [269] at the 30th Annual EMSA meeting in 1972, their pictures clearly showing heavy faulting inside the

martensite plates which were identified as $\{111\}_{f.c.t.}$ twins. These twins are on close packed planes of the martensite $L1_0$-type structure, resulting from the tetragonal distortion of the B2 CsCl-type austenite. When the resolution of the instruments was improved, the regularity of these twins could be investigated in more detail. Schryvers combined data on the distribution of microtwins as gathered by image processing of TEM and HREM images from different martensite plates with different length-scales in order to obtain the surface energy of the microtwin planes after fitting with theoretical predictions [270]. A similar study in Ni–Mn by Baele et al. showed a correlation between the composition, namely the e/a ratio, and the microtwin periodicity [271]. Using selected area electron diffraction (SAED) in combination with one-dimensional line resolution, Chandrasekaran et al. observed several microtwin stacking sequences in local regions of Ni–Al martensite [272, 273]. The most frequently observed regular sequence in this system, however, has a 14-layered sequence indicated as 14M (or 7R in earlier publications), which was first detected by Reynaud in an in situ SAED cooling experiment [274]. Later, the actual stacking sequence of $(5\bar{2})_2$, first suggested by Martynov et al. on the basis of X-ray diffraction [275], was directly confirmed by Schryvers et al. using HREM [276], and is seen in Fig. 74. Recently, new stacking variants such as 14M, 12M and 10M have been reported in ternary alloys of Ni–Al–Mn by Inoue et al. [277].

A complementary technique to HREM imaging is the analytical site determination technique ALCHEMI in which the site occupation for a given atom type can

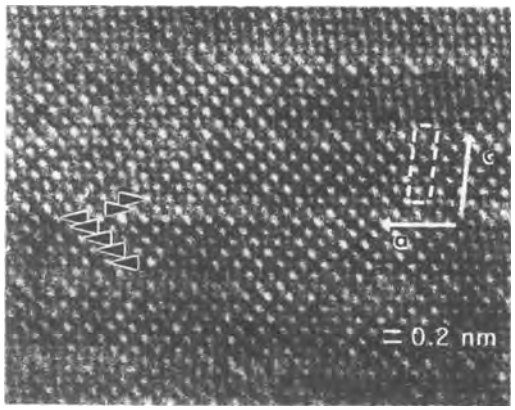

Figure 74. HREM image showing the $(5\bar{2})$ stacking of the 14M structure in $Ni_{62.5}Al_{37.5}$ [276].

be determined by taking energy dispersive X-ray spectroscopy (EDX) patterns under different excitation conditions. An example is shown in Fig. 75 where positive and negative excitation errors with respect to the 200 reflection give a different EDX

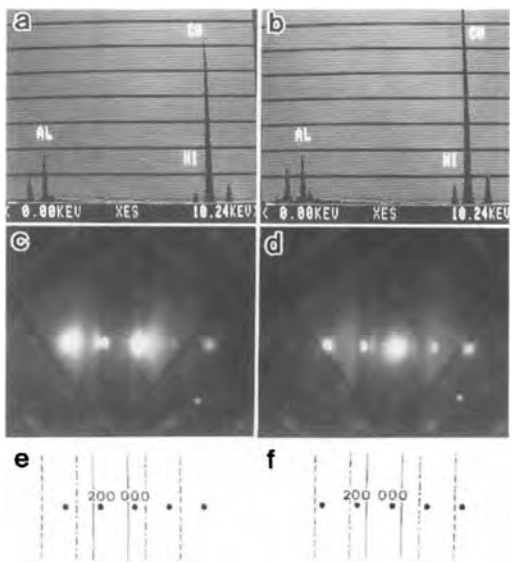

Figure 75. EDX spectra taken under different excitation conditions ((a) $s > 0$ and (b) $s < 0$) in Cu–Al–Ni from which a nickel occupation of the pure copper sublattice was concluded. (Courtesy of Y. Nakata et al. [278].)

signal for the nickel atoms in a Cu–Al–Ni parent DO_3-type phase. From this and related spectra from differently treated samples it was concluded that the nickel atoms occupy the pure copper plane in this structure and that the rise of M_s with aging of the parent state is attributed to the progress of the second nearest-neighbor ordering between aluminum and copper atoms [278].

1.6.3.3 Interfaces, Defects and Precipitates

Using HREM, irregularities in the stacking as well as local defects such as ledges on a twin interface or stacking fault can be investigated. Such phenomena often occur close to large-scale defects such as grain boundaries, precipitates or even the thinned edge of a TEM sample. In the latter case, the specific orientation of the surface might induce thin foil effects which should be taken into account when interpreting the micrographs. An example of this is shown in Fig. 76, where the microtwin width increases when approaching the edge of the foil [276]. In the above examples the atomic structure was always considered to be ideal irrespective of whether one looks far away from or close to a twin or habit plane. An extensive HREM study on nickel–manganese indeed could not prove any distortion near these boundaries.

Crystallographic information of single defects can also be obtained by large angle convergent beam electron diffraction (LACBED). An example is the determination of the Burgers vector $\boldsymbol{b}$ of dislocations in the austenite of a Ni–Ti–Co alloy as shown in Fig. 77 [279–281]. Here the Fourier and direct space information is

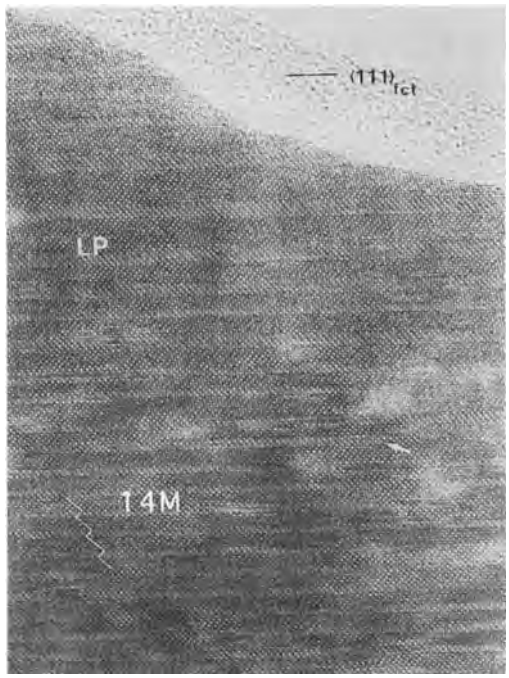

Figure 76. Effect of foil thickness on the microtwin width in Ni–Al martensite [276].

combined in a single micrograph (obtained at the objective back focal plane) where the cross-overs of dark Bragg lines with an oriented dislocation line produces fringes at the intersections. The number of fringes n follows the formula $n = \boldsymbol{g} \cdot \boldsymbol{b}$, with $\boldsymbol{g}$ the

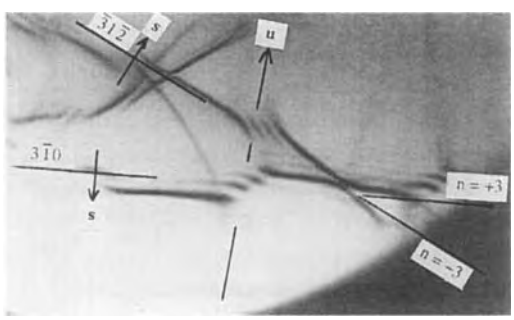

Figure 77. Burgers vector determination by LACBED in Ni–Ti–Co ($\boldsymbol{u}$, direction dislocation line; $\boldsymbol{s}$, indicates sign of excitation error outside Bragg line; $\boldsymbol{b}$, [100]). (Courtesy of J. Pons et al. [279].)

Bragg line indices, from which the Burgers vector can be determined when using at least two independent Bragg lines.

In some cases the displacive transformation only occurs in precipitates distributed in a matrix. In alloys, an extensively studied example is that of copper precipitates in thermally aged or electron irradiated Fe–Cu material in which these precipitates undergo a transformation, thought to be martensitic, from b.c.c. to a 9R twin stacking as shown in Fig. 78 [282, 283]. It was found that the transformation occurs for a particle size below 4–5 nm, after which they grow by adding twin planes. A very important advantage of these type of electron microscopic observations is that one immediately recognizes the orientation relationship between the parent and product phases as well as that with the surrounding matrix. Moreover, the well-defined and observable constraints on the interface can yield information difficult to obtain in ordinary martensitic transformations.

1.6.3.4 Precursor Phenomena

In many of the alloy systems exhibiting a martensitic transformation a characteristic so-called tweed pattern is observed in two-beam TEM images of the austenite as shown in Fig. 79, including the corresponding SAED pattern showing the diffuse streaks at the Bragg reflections. These patterns can exist up to several decades of degrees above the transition temperature M_S. Such patterns were first explained in detail by Tanner for the case of GP zones in Cu–Be [284]. An extensive study on the imaging characteristics of this tweed pattern in Ni–Al was conducted by Robertson and Wayman [285]. As this contrast appears under two-beam conditions, the actual choice of diffracting vector as well as the value of the extinction distance s play an important role in the

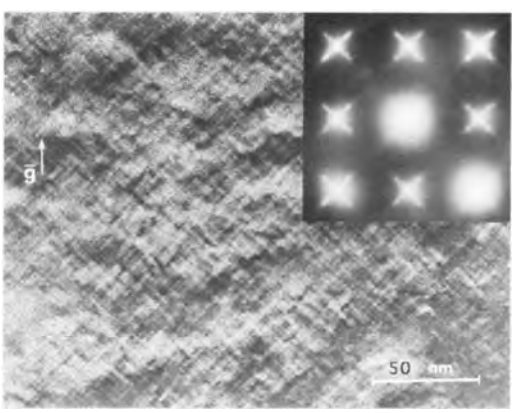

Figure 79. Conventional two-beam tweed pattern in Ni–Al showing ⟨110⟩ striations as a result of soft transverse modes in the matrix responding to local strain centers. The inset shows the corresponding diffuse intensity around the Bragg reflections.

final contrast, for example, affecting its orientation and coarseness. The origin of the image contrast is believed to lie in the existence of strain modulations of the matrix, appearing in more than one but usually equivalent crystallographic directions. Since then, tweed patterns have been found in many different systems including high-T_c superconductors and other ceramics [286]. The actual structural origin of the strain modulation will depend on the system under consideration. Valid candidates are point defect strain centers in rapidly quenched alloys, preliminary clustering in ordering systems, GP zones when decomposition occurs, and so forth.

In the case of Ni–Al, HREM provided some more detailed information on the atomic configurations underlying the tweed contrast. Two distinct but typical examples of such images are shown in Fig. 80 [287], obtained from thin but flat regions of a wedge-shaped foil. In Fig. 80a the local distortions are clearly recognized as patches in which the expected two-dimensional square white dot pattern corresponding with the undistorted ordered structure [238, 239] is changed into line patterns along two possible orientations. Optical diffractograms (ODs) of large areas from such HREM micrographs immediately reveal the static or dynamic nature of the tweed pattern. If the OD reveals the same diffuse intensity streaks as the SAED patterns, as seen in Fig. 80c, the corresponding distortions are recorded in the image (illumination time around 1 s), indicating static displacements [288]. In Fig. 80b, contrast modulations parallel with {110} b.c.c. planes and with a wavelength of ±1.3 nm are superposed onto the white dot pattern. In some domains a homogeneous shear could also be

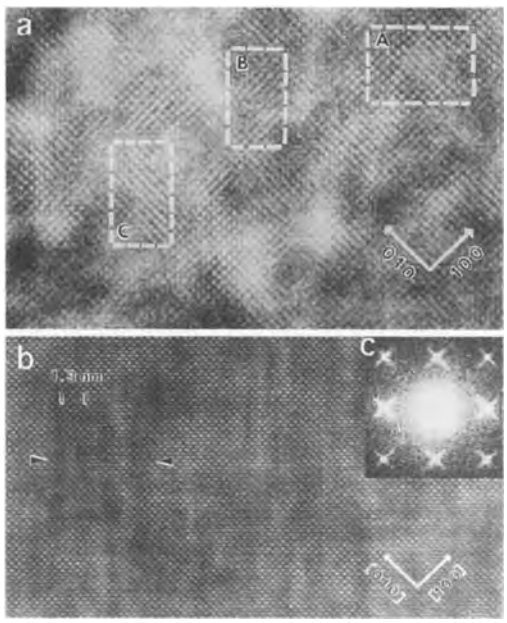

Figure 80. HREM image revealing domains of micromodulations observed above M_s in Ni–Al: (a) only homogeneous distortions of different variants are visible, (b) a 1.3 nm contrast modulation along ⟨110⟩ is superposed [287], and (c) OD from a HREM image of (b) showing diffuse intensity at the Bragg reflections indicating the static nature of the distortions [288].

measured. Each of these *micro*modulations has a correlation length of a few nanometers, as indicated by the arrows on one domain. Based on image simulations, these micromodulations were interpreted as due to transverse sine waves superposed onto a homogeneous shear [287]. Since in this multibeam imaging condition one is looking along a well-chosen zone axis, the observed micromodulations and shears are intrinsic to the material and not a result of the imaging conditions, as is the case in the conventional tweed images of Fig. 79. The phenomenon yielding the latter is thought to be correlated to the strains between the different domains. To what extent these

precursing micromodulations and shears influence or are necessary for the ensuing transformation is still a matter of debate [289].

Another example of a new insight into precursors as obtained by HREM is found in rapidly quenched Ti–8 at.% Mo where the primary direction of alignment in the precursors strongly deviates from the final ⟨111⟩ direction necessary to form the ω structure [290]. Although a valid suggestion for the atomic configuration underlying the HREM images could be presented, a proper explanation for the appearance of this deviation is still at large.

1.6.3.5 Nucleation and Transformation Characteristics

The above examples of the use of different microscopy techniques in the study of displacive transformations mainly refer to problems related to static situations. In order to understand the nucleation mechanisms and the actual behavior of the lattice during the transformation, however, in situ experiments have to be performed. In the case of structural transformations this implies the use of heating and cooling as well as straining stages or even, as recently developed for electron microscopy, a combination of both [291]. Unfortunately, working in situ still decreases the obtainable resolution of the entire set-up so that only conventional TEM and SAED are possible, except for some very specific cases.

A typical example of a conventional in situ TEM study is shown in the sequence of Fig. 81 where the nucleation of the R phase in cycled $Ti_{50}Ni_{48}Al_2$ material is followed [292]. It is seen that the dislocations in the B2 parent phase act as nucleation centers for the product phase, of which the structure was determined using SAED (see inset). It is interesting to see that a single R plate can form after the nucleation of different plates A and B

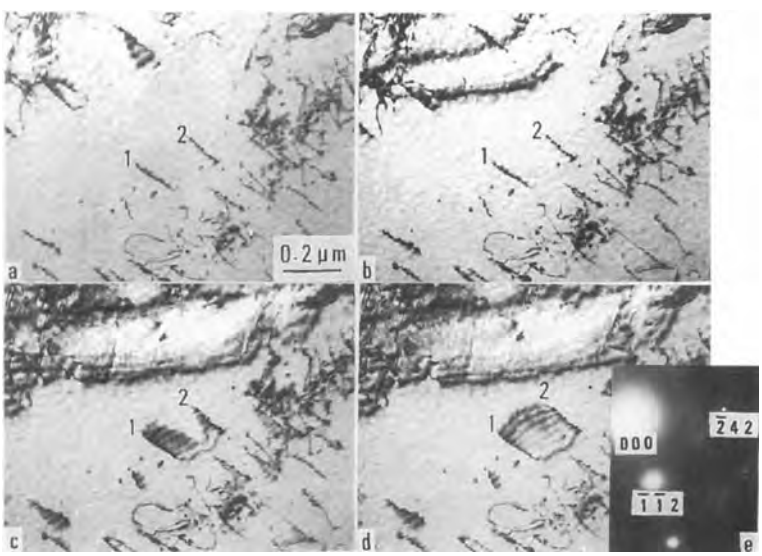

Figure 81. In situ cooling sequence showing the nucleation and growth of R phase plates in $Ti_{50}Ni_{48}Al_2$. Note the formation of a single plate between two separate dislocations. (Courtesy of T. Saburi [292].)

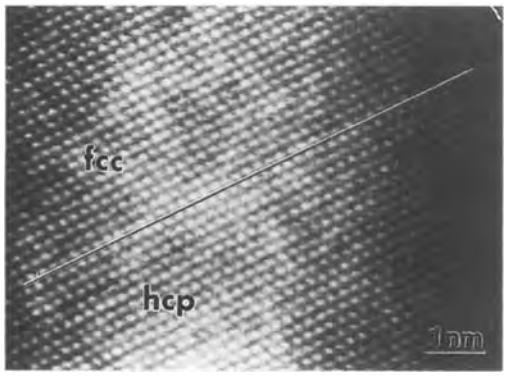

Figure 82. In situ HREM image of a coherent and atomically flat $\{111\}_{f.c.c.}//(0001)_{h.c.p.}$ interface observed in a $\langle 110\rangle_{f.c.c.}//\langle 11\bar{2}0\rangle_{h.c.p.}$ orientation in Co–32 wt.% Ni. (Courtesy of J. Howe [293, 294].)

(Fig. 81c) at separate dislocations 1 and 2 (Fig. 81a). In the present experiment the transformation was steered by reducing (cooling) or increasing (heating) the beam intensity, and the appearance and disappearance of the R phase plates proceed in the same manner on repeated cooling and heating, as long as the cycling does not influence the dislocations.

As mentioned above, the use of in situ techniques usually limits the attainable resolution of the experiment so that in most studies only conventional microscopy can be used. However, a few examples from dedicated HREM instruments equipped with special in situ holders do exist today. In Fig. 82 a $\{111\}_{f.c.c.}//(0001)_{h.c.p.}$ interface is shown observed in a single crystal of Co–32 wt.% Ni and taken during an in situ heating experiment at about 100°C in a JEOL 4000EX equipped with a UHP40X hot-stage pole piece [293, 294]. In the present case the martensitic f.c.c. to h.c.p. (hexagonal close packing) transformation has a strong hysteresis around room temperature, enabling one to trap the system halfway through the transition and to study the dynamics of the transformation in the in situ stage. As seen in the image the interface is perfectly coherent and atomically flat.

In some cases, a martensite transition can be trapped inside the hysteresis loop, or a temperature or stress gradient is observed along the edge of a thinned electron microscopic sample. An example of the latter is shown in Fig. 83 which was found at a $\langle 110\rangle$ crack automatically formed during the last stages of electropolishing to an extremely thin foil [276]. SAED (see insets) shows that the wings around the crack are martensite (14M with and 2M without microtwinning) while the rest of the matrix is still austenite. However, when zooming in at the austenite close to the crack a gradual change in distortion is observed in HREM as well as SAED, attributed to the stress gradient [276]. Thus although these images were again obtained from a static situation, the actual information can immediately yield atomic detail on the transformation process.

1.6.4 Some Other Transformations in Alloys

The mere fact that the remaining transformations include diffusion as well as displacement of the atoms makes them interesting study cases for which a combination of different microscopy techniques is appropriate. In a detailed HREM plus electron microdiffraction study, Muto et al. showed that in the formation of the metastable Ni_2Al structure local reordering as well as atomic shuffles are involved [295, 296]. The latter

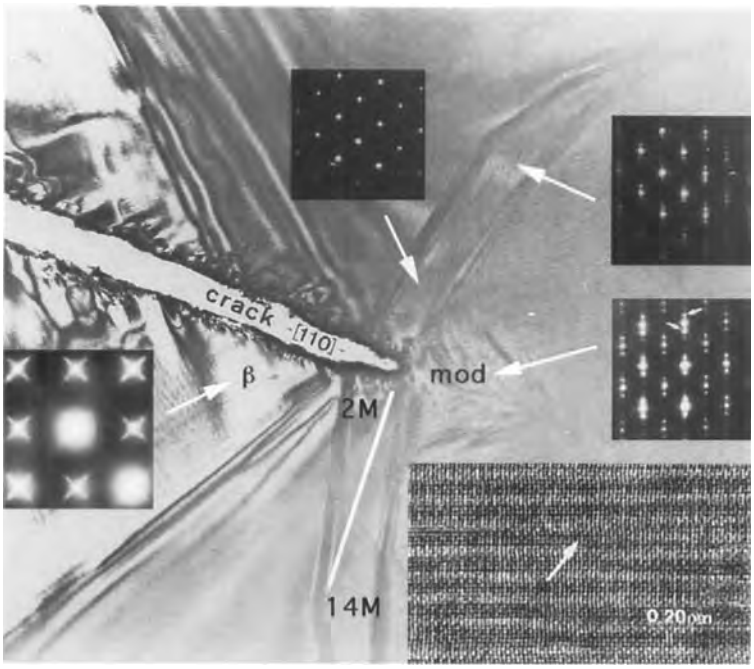

Figure 83. TEM image of a transformed matrix in the stress region surrounding a thin foil crack in $Ni_{62.5}Al_{37.5}$ [276]. HREM and SAED (insets) reveal 2M and 14M martensite in distinct regions as well as a broad area of decreasing strains and changing modulations between the martensite and austenite.

can be compared with ω-type shuffles, but appear to be only partial, that is, the collapse of $\{111\}_{B2}$ planes is incomplete ($z' < 0.083$). In Fig. 84 a comparison between experimental and calculated HREM images is shown, indicating that the shuffles cannot be larger than 50% of complete ω shuffles. On the other hand, the relative intensities of the super-reflections as measured by densitometry from electron microdiffraction patterns from single variants showed that these shuffles were at least 20% of complete ω shuffles. This is shown in Fig. 85. So although no exact atomic positions were obtained, the existence of a partial collapse was clearly established.

Another example of a combined transition is the precipitation of Ni_5Al_3 (5 : 3) by annealing the B2 Ni–Al matrix. One specific advantage of the usually slower transformation process of these coupled

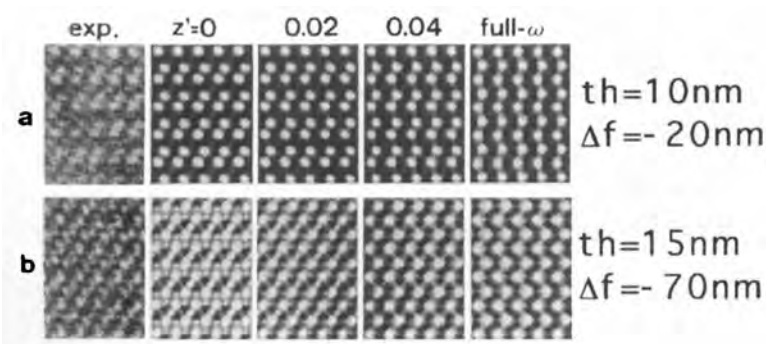

Figure 84. Experimental and simulated HREM of Ni_2Al showing the existence of a minimum amount of ω collapse [295].

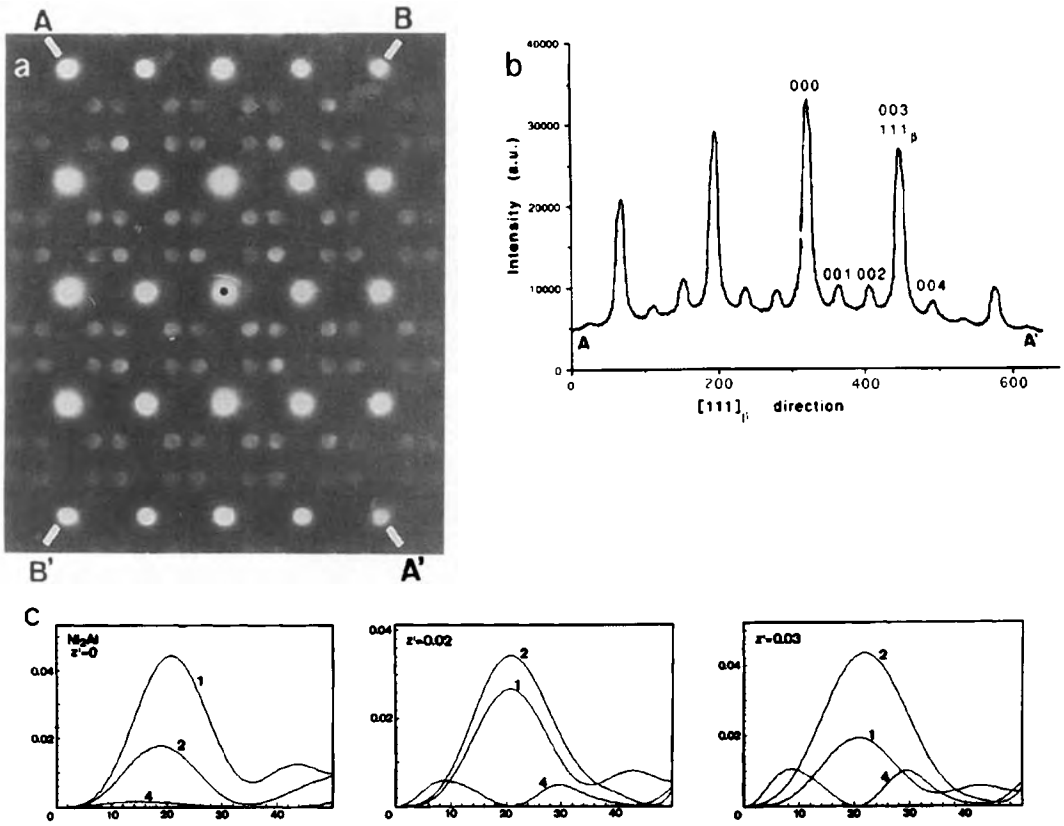

Figure 85. Comparison of (a) the microdiffraction pattern of a Ni_2Al precipitate and (b) its densitometry measurement with (c) corresponding simulations showing the incomplete nature of the ω collapse [295].

transformations when compared with pure displacive ones is the fact that intermediate transition stages are more readily observed. Due to the combination of the reordering process and the cubic to tetragonal distortion nanoscale star-shaped precipitates are formed as shown in Fig. 86 [297]. The internal atomic structure, the relative composition with respect to the matrix and the defect configuration of the interfaces can directly be investigated by HREM and nanoprobe EDX. Further on during the transformation these precipitates grow into twinned plates embedded in the matrix. From HREM images of the interface of such a plate with the matrix the orientation relationship as well as the lattice strain can be measured [298].

A classic case of coupled transformations is the class of Bainitic transformations in which martensite-like characteristics are combined with atom diffusion. Again, these transformations are usually much slower than pure martensitic ones, and intermediate situations are more easily retained in quenched samples. Moreover, in case the diffusion yields a decomposition, small-probe analytical microscopy will be of help to determine

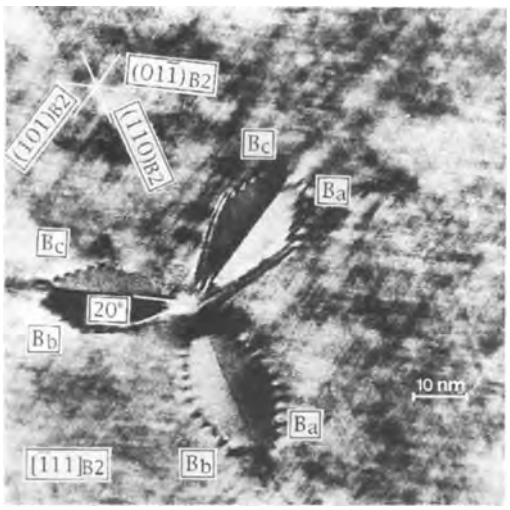

Figure 86. Ni_5Al_3 precipitate in a ⟨111⟩ B2 matrix formed by a twinning configuration of different variants indicated as B_a, B_b and B_c [297]. Due to severe distortions, dislocations still exist in the precipitate–matrix interface.

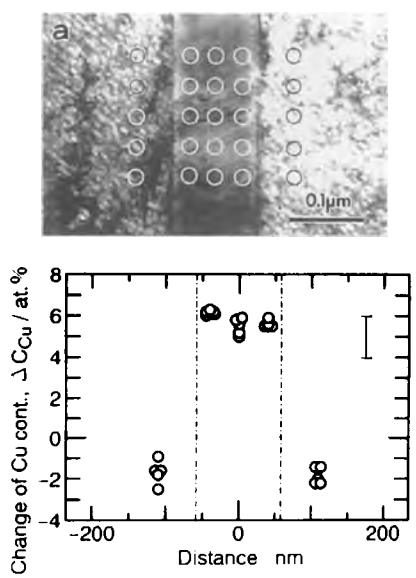

Figure 87. Relative copper content in a 100 nm thick Bainite plate in Cu–Zn–Au with respect to the surrounding matrix and obtained by EDX with a 20 nm diameter FEG probe. (Courtesy of T. Tadaki et al. [299].)

the nominal compositions of the Bainite and the surrounding matrix. An example is seen in Fig. 87, where a 100 nm thick Bainite plate in a Cu–Zn–Au alloy was analyzed with a 20 nm diameter probe from a field emission gun [299, 300]. The graph shows the relative increase of copper content in the plate with respect to the surrounding matrix and no differences between the central and edge regions of the plate. Although scanning TEM could provide a smaller probe, TEM was used since in this mode the exact location of the plate could best be observed.

1.6.5 Imaging Phase Transformations: Conclusions

In the present section we have selected some of the key contributions of microscopy techniques to the study of phase transformations in metals and alloys. Although it is of course impossible to give a complete survey of these in this extremely wide field of research, we have tried to cover most of the current topics of interest by showing examples from different materials and a variety of experimental techniques. Investigations on pretreated samples as well as in situ work are presented, and although the majority of cases were conducted using electron microscopy, from which different modes can yield information on different scales and of different type, some relevant results from other microscopy techniques have been presented.

With the further evolution of attainable resolution, the possibility to perform combined experiments and the improvements with new probe techniques, it is clear that

microscopy investigations on phase transformations in metals and alloys still have a bright future.

Handbook of Microscopy
S. Amelinckx, D. van Dyck, J. van Landuyt, G. van Tendeloo

2 Microscopy of Rocks and Minerals

2.1 Introduction

Many minerals have lower symmetry than cubic. In general, the nature of their bonding causes a large gap between the valence and conduction bands, so that the most minerals are excellent insulators and, correspondingly, transparent to visible light. Opaque minerals are either semiconducting or metallic. The particular physical properties of minerals, and the rocks that they form, dictate and somewhat limit the types of microscopy that can be applied. As a compensation, the anisotropy deriving from the noncubic symmetries of many minerals provides the basis for phase identification in optical petrology and the determination of crystal orientations.

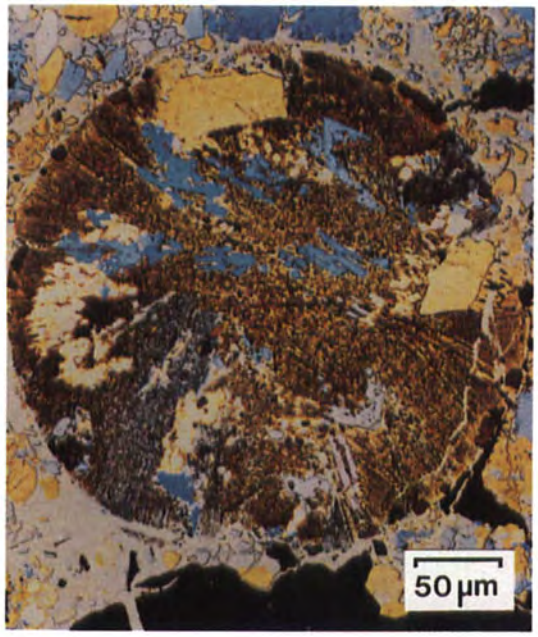
When minerals are irradiated with electrons or ions the problems of electrical charging preclude some techniques that provide abundant data about metals and semiconductors. For instance, no results have come from field ion microscopy, and Auger electron spectroscopy (AES) is severely limited in application. Spectroscopic methods in imaging mode, like Raman, FTIR and NMR, are at an early stage of application in the geosciences and there are relatively few examples. The range of spectroscopies that have been applied to problems in geoscience are discussed elsewhere [1, 2]. Apart from IR mapping and Raman imaging, only AES and XPS seem to merit a separate discussion at this stage.

In just one chapter it is impossible to discuss and reference all the excellent microscopy that has been carried out on rocks and minerals over many years. The material covered is inevitably very selective and the emphasis reflects a personal view. I have endeavored to emphasize the state of the art for the newer and less routine techniques, since the established methods are well documented elsewhere. I apologize in advance if my bias or ignorance has led to the omission of technical developments or findings that others consider to be important.

2.2 Optical Microscopy, Petrology, and Other Optical Methods

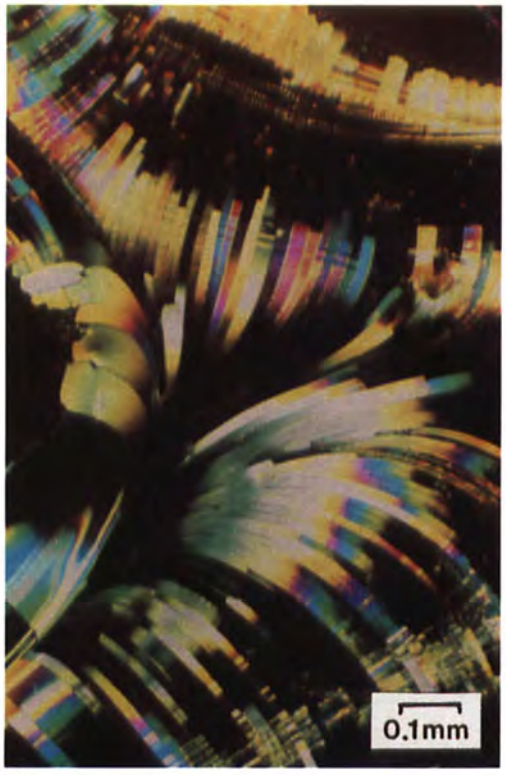
2.2.1 Transmitted Light Microscopy and Petrology

Light optical microscopy (LOM) has been a routine and essential tool of the earth scientist for many years. The theory of



(a)

(b)



(c)

(d)

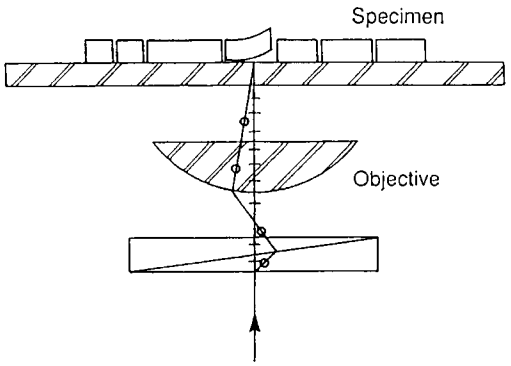


Figure 1. (e) Schematic diagram of an arrangement for producing inverted-type differential interference contrast images from thin translucent crystals, as in (c) and (d). Reproduced with permission from Bousfield [6] and reprinted by permission of John Wiley & Sons Ltd.

crystal optics enables analysis of individual crystals and mineral grains in transmission with the polarizing microscope [3]. The study of a polished thin section (PTS) with the polarizing microscope allows all the routine methods of petrography to be applied to the identification of minerals in a rock. These techniques, which include the study of the color and pleochroism of a mineral, its shape and habit (noting cleavages, twinning, relief, inclusions, etc.), followed by establishing its optical characteristics (refractive indices, optic sign, etc.), are applied routinely by earth scientists and will not be described here. Standard texts cover the theory of optical mineralogy and describe the methods of optical petrology [4].

The preparation of high quality PTSs reproducibly, is basic to effective optical petrology, which starts from cutting slices with a diamond saw, followed by lapping and polishing with progressively finer powders to a thickness of $\approx 30\,\mu m$. Techniques and materials used in the preparation of PTSs of geological materials are well covered in the literature [5, 6]. Examples of minerals and rocks in thin section are not illustrated here, since they are readily accessible [7, 8].

Ultrathin polished sections ($<30\,\mu m$ thick and usually $<10\,\mu m$) require special care in preparation [9]. They take best advantage of the resolution in LOM ($\approx 0.5\,\mu m$) and are invaluable for very fine-grained materials, since the superposition of grain-scale features is minimized. The better definition removes sources of ambiguity and gives very beautiful images [10]. Figures 1a and b show ultrathin sections of two stony meteorites in transmitted polarized light. Demountable polished thin sections (DPTSs) [5] and ultrathin versions [11] are a further development; their value is mainly as starting points for making specimens for transmission electron microscopy.

The universal stage (U-stage) and spindle stage were once essential for making precise crystallographic measurements on minerals and petrofabrics. The U-stage featured strongly in studies of carbonates [12] and deformed tectonites [13], works

Figure 1. Transmitted light images of ultrathin polished sections (2–4 μm thick) of stony meteorites viewed with partially light and quartz plate: (a) Allegan (H5) chrondritic meteorite, showing olivines (purple, blue, yellow) and chromites (brown) in a radiating fine-grained chondrule and some of the surrounding matrix; (b) Dhajala (H3) chondritic meteorite, showing a chondrule consisting almost entirely of extremely fine-grained pyroxene with additional Fe/Ni metal and troilite in the irregular core. Micrographs taken by R. Beauchamp [10]. Reprinted by permission of Meteorifics. Inverted differential interference contrast images of columnar sodium silicate crystals grown in colloidal silica solution, seen with (c) an extinguished background and (d) a red background obtained by adjusting the wedge position. 100×. Courtesy of Bousfield [6].

that are prime examples of the method. Electron microscopy, with its greater resolution and other advantages, has eclipsed the U-stage but its effectiveness at the submillimeter scale should not be overlooked [14].

The polarizing microscope has been used in texture analysis by a photometric method [15] but the method has not found favor. It is not so versatile and less attractive than automated analysis by EBSP (see this Volume, Chap. 2, Sec. 2.6.3). The photometric approach has greater merit for clays and soils, where it is quite widely used and the benefits of image analysis have been noted [16].

2.2.2 Reflected Light Microscopy and Opaque Minerals

For opaque minerals (sulfides, hematite, etc.), optical techniques are much more restricted than for transparent minerals. Color, lustre, cleavage, twins, and exsolved phases in crystallographic relationship to the host mineral are all features, visible in reflected light, that can assist in phase identification and crystallographic analysis. The reader should see texts on ore mineralogy for further information [17]. Polishing followed by etching, thermally or chemically, can be a valuable adjunct for particular minerals. Standard techniques used in the crystallographic analysis of deformed metals by LOM [18] (see also this Volume, Chap. 1, Sec. 1) are also applicable to the opaque minerals.

The use of differential interference contrast (DIC) microscopy and phase contrast (PC) microscopy is most evident in studies of mineral surfaces, and especially in relation to natural growth features, laboratory studies of crystal growth, impurity segregation, etc. Good examples of DIC and PC are given in references [19] and [20], respectively. Figures 1c and d are representative of some striking DIC images of thin minerals produced [6] using an inverted viewing arrangement, shown in Fig. 1e, which is sensitive to surface slope, surface interference, and dichroism. (For comparison, a normal DIC image of a crystal surface is shown in Sec. 2.5, Fig. 4d.)

2.2.3 Infrared Micro-spectroscopy, Laser Raman Microprobe and Micro-Raman Imaging

Infrared spectroscopy gives valuable information about organic species and elements like H, C and N which they incorporate. It can now be employed to map distributions, and to reveal zonations and inclusion chemistry in minerals. This is well illustrated in studies of diamond [21] which use mid-infrared micro-spectroscopy in combination with other techniques, including cathodoluminescence (see Sec. 2.8 of this Chapter). Software developments allow contour maps for various chemically-significant spectral lines to be generated relatively easily.

2.2.3.1 Phase Identification

Many minerals with absorption spectra in the middle and far infrared spectrum conveniently give Raman lines in the visible spectrum. Raman spectra offer an excellent analytical finger-printing technique,

the lines being relatively simple, but occurring in distinctive and unique patterns. Applications in mineralogy are assisted by a compilation of Raman spectra [22]. New instrumentation allows an image to be formed by selecting a single Raman line, providing a simple, nondestructive method of sequentially imaging different phases in a bulk sample, which may be useful when their optical characteristics are similar and where cathodoluminescence (CL) (Sec. 2.5 of this Chapter) does not work well. This micro-Raman method is also a means of detecting foreign matter that has been introduced artificially, for example, the impregnation or dyeing of inferior semiprecious minerals, to increase their value.

Micro-Raman is also very useful for in situ studies of minerals in high pressure cells. There are various examples of spectroscopy with diamond anvil cells, although, as yet, without imaging [23, 24]; it is, nevertheless, a growing field of activity.

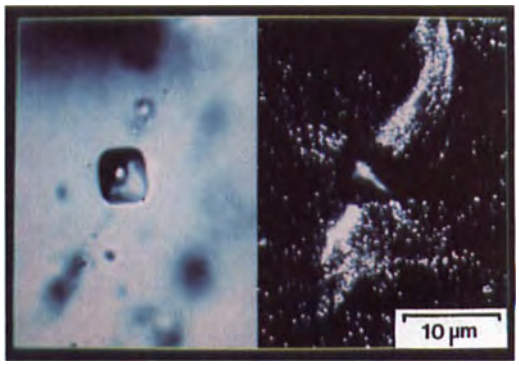

Figure 2. (a) Transmitted light image two-phase (water and gas) fluid inclusion in quartz. Scalebar: 10 µm, laser wavelength 488 nm; (b) reflected confocal scanning laser microscopy image made up of 80 optical sections taken at 0.3 µm increments, representing a depth of 24 µm. The fluid inclusion was located ≈60 µm below the surface. The confocal image reveals the existence of a large number of highly reflective, submicron inclusions not seen in the conventional image. Courtesy of Petford [27].

2.2.3.2 Fluid Inclusions

The majority of minerals form from fluids. Fluid inclusions are important because they are a record of the history of the host mineral. In principal, analysis of inclusion contents enables pressure, temperature, density, and compositional data to be established for geological fluids, present when a mineral formed or was altered. Results of fluid inclusion research from optical methods are summarized and listed by Roedder [25], a leader in the field for many years.

The use of microthermometry with LOM is common, and an excellent recent example is the combination of CL (see this Volume, Chap. 1, Sec. 6) with microscopy to obtain a fluid inclusion stratigraphy related to the authigenic minerals and cement zones within them [26]. Confocal scanning laser microscopy (CSLM) (see Sec. 2.2.4 of this Chapter) is also valuable in fluid inclusion research, since it can reveal the presence of features not seen by routine LOM [27]. Figures 2a and b illustrate this point very well.

The challenge today is to obtain quantitative analysis of a few cubic micrometers of fluid in an inclusion (often a supercritical liquid), typically containing dissolved gases and solids, the entity being isolated within a semitransparent solid. The laser Raman microprobe is an instrument well suited to this task [28–30]. The laser beam can be focused so that the contents of an inclusion can be analyzed from its spectra nondestructively and very valuable results

have been obtained. A theory for the scattering of light by fluids under pressure is still being developed, however, and calibration data for the interpretation of the resulting spectra still need to be acquired [31]. Proton-induced X-ray emission (PIXE) is another technique that has similar uses in the study of fluid inclusions [32] and can be a microscopic technique (see Sec. 2.12 of this Chapter).

2.2.4 Confocal Scanning Laser Microscopy

The confocal scanning laser microscope (CSLM) is a new tool which has so far found little application in the earth sciences, although its resolution and selectivity at depth makes it very suitable for some types of work. CSLM has been used by a few workers for improved imaging of microfractures and quantitative measurements of porosity. It has used it to characterize the fissure space of rocks [33]. Correlated studies of sections were carried out by several microscopic methods, including acoustic microscopy and fluorescence microscopy. CSLM was shown to be a superior technique for observing the fine detail of fractigraphic networks, facilitating stereology and digital image analysis.

Observations of etched fission tracks and the reliable counting of track densities are essential to the well-established fission-track method of age determination. For currently evolving methods of estimating paleotemperatures, both track lengths and track densities must be determined accurately. Conventional LOM does not work well for tracks at high angles to the plane of the section and, more generally, there are problems with distinguishing tracks from some other forms of defect. Both aspects are less problematical when CSLM is used. This is exemplified by the use of CSLM for imaging etched fission tracks [34]. The CSLM seems likely to revolutionize track analysis as software becomes available to permit the automated analysis of 3D binary images [35]. CSLM is now also being applied to fluid inclusions (see also Sec. 2.2.3 of this Chapter).

2.2.5 Ultraviolet Fluorescence Optical Microscopy

Ultraviolet fluorescence microscopy provides a good alternative to scanning acoustic microscopy or scanning electron microscopy (SEM) methods for the study of cracks and pores. Nishiyama and Kusuda [36] have demonstrated the identification of pores and microcracks in resin-impregnated sections of granite, weathered tuff, schist and marble by ultraviolet microscopy. Cyanoacrylate and methylmethacrylate are both good permeating agents since they readily penetrate pore spaces and cracks; they can be dyed with fluoresceine or loaded with fluorescent paints. Image processing and analysis techniques, respectively, (i) allow better discrimination of the resin-filled spaces, and (ii) facilitate quantitative measurements. Figures 3a and b are excellent illustrations of the method, which is an alternative to and may be a better way of quantifying cracks and pores than SEM methods [37].

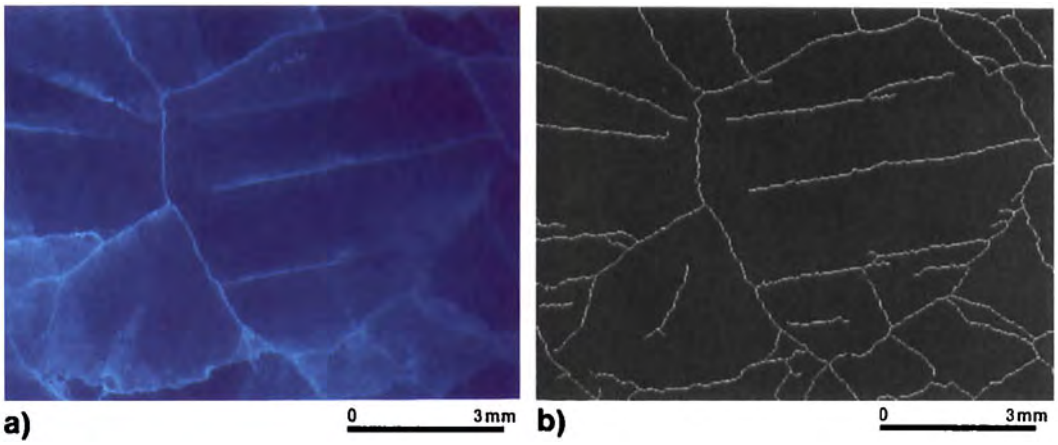

Figure 3. Ultraviolet fluorescence imaging: visualization and image analysis of microcracks in marble. (a) Visualization with fluorescent paint under ultraviolet light; (b) thinned binary image of the microcracks. Courtesy of Nishiyama and Kusuda [36].

2.3 X-Ray Methods

2.3.1 Computer-Aided Tomography

Computer-aided tomography (CT) with X-ray radiography is hardly within the scope of this book. However, it is worth noting that applications of CT in the earth sciences are increasing, although only one example will be given. This is the use of X-ray CT for investigating sediment cores, which are very important in geological prospecting. Normal X-ray radiography is of limited use with full-round cores because of defects at the core periphery, next to the sleeve. CT avoids destructive cutting and enables high resolution imaging of internal features without confusion [38]. CT also makes possible the generation of 3D images. Laser scattering CT, which can be used to detect and characterize defects near surfaces and in the bulk, is effective with hematite crystals [39] when using infrared wavelengths.

2.3.2 X-Ray Microtopography

X-ray topography has not been applied widely to minerals because of its inability to image very defective crystals. Most work has been done on diamond and quartz; this is described in this Volume, Chap. 1, Sec. 7. Both X-ray topographs and surface microtopographs have been used to study twinning and related impurity effects in hematite crystals [40].

Synchrotron radiation is being used increasingly for topographic studies of diamond and quartz. It has been used in conjunction with infrared absorption microscopy and CL topography to study the long-range imperfection of diamond [41, 42]. Greater use of in situ synchrotron X-ray radiation topography is also likely. For example, it has been employed to study

annealing processes in a sanidine feldspar with an unusually low Al/Si order–disorder transformation temperature [43].

2.4 Scanning Acoustic Microscopy

The technique of scanning acoustic microscopy is yet to be applied to rocks in a systematic way. Exploratory results are reported for granite [44] and comparisons of images of cracks in polished rock sections have been made with those from other imaging methods [45]. Continuing developments with time-resolved imaging [46] hold some promise for the study of microfracturing dynamics in laboratory studies of rock deformation.

2.5 Cathodoluminescence Microscopy

Few minerals are naturally photoluminescent, since their band gaps exceed 5 eV. Most respond to higher energy electron irradiation, luminescing with characteristic colors. This cathodoluminescence (CL) is very convenient for revealing the multiphase nature of rocks and natural cements, and compositional zoning in mineral grains and gemstones. CL is usually obtained using polished specimens, either in a dedicated instrument or an SEM.

The CL of geological materials, the influence of defects, temperature, etc., together with applications, are well described [47, 48]. CL reveals spatial distributions of minerals, distinguishing constituents with similar optical properties, for example, calcite (yellow–orange) and dolomite (crimson). Another strength is the display of significant textural features not seen by any other technique [49]. CL, however, is largely a qualitative analytical tool, since intensity and absolute concentration of the activated species are not well correlated.

Carbonates luminesce brightly and stably. Growth features that are difficult to see by LOM are readily resolved: zoning, fast and slow-growing sectors, veins, and authigenic overgrowths. Differing trace levels of divalent ions (Mg, Fe and Mn principally) reveal successive layers of void-filling cements in carbonate rocks. Figure 4a shows a CL image of zoned calcite crystals cementing a cavity formed by dissolution of a gypsum nodule [50], while in Fig. 4b CL reveals growth sector boundaries in another cementatious calcite crystal [51]. Figures 4c and d are CL and DIC images respectively of the (0 0 0 1) surface of an apatite crystal [52].

CL is especially valuable for provenance studies, since grain populations usually possess defining spectral 'fingerprints' deriving from their source rocks, whether carbonates or sandstones. Quartz minerals are damaged by electron irradiation; their luminescence is not stable and color changes are rapid. Authigenic overgrowths do not normally luminescence but hydrothermally-grown quartz shows zoning in CL, and so it is a sensitive indicator of growth processes.

Steele [53, 54] has used CL effectively with meteoritic minerals. Only some olivines in carbonaceous chondrites show CL, but for these it is very sensitive to composition, allowing classification into subgroups and defining stages in the

(c)

(d)

Figure 4. (a) CL image of zoned calcite crystals cementing a cavity formed by dissolution of a gypsum nodule within the Upper Permian Raisby Formation at an outcrop in north-east England. Prior to dissolution of gypsum, the nodule was partially replaced by fluorite, which luminesces blue. Long dimension is 2.25 mm. Courtesy of Lee. (b) CL image of a polished section through a calcite crystal occurring as a cement in a limestone. The crystal, having formed on a substrate (at bottom), exhibits well-developed concentric growth zoning that records the crystal habit. The luminescence is of Mn^{2+} activated, and the intensity reflects subtle variations in Mn^{2+} concentration introduced during growth. Growth on different faces resulted in differential Mn^{2+} incorporation (i.e., sector zoning). Sector boundaries are arrowed. Courtesy of Reeder [53]. (c) CL image of (0001) surface of apatite crystal (from Llallagua, Bolivia) with hexagonal growth hillocks. Differential luminescence corresponds directly to symmetrically nonequivalent regions of the hillocks. (d) DIC image of the (0001) surface of apatite shown in (c) at a slightly different magnification. Both (c) and (d) courtesy of Rakovan and Reeder [54].

formation of grains with complex textures and chemistries. Olivines with blue CL were deduced to be products of nebular condensation, whereas subsequent fluid-phase reactions create red CL.

Recent developments include an instrument designed for producing strong CL in minerals of low luminescent intensity [55]. CL can be used to image defects in minerals (e.g., [56]), although this is less common than with semiconductors. Improvements in defect imaging involve computer processing of CL maps [57].

Induced thermoluminescent emissions (TL) are used in archeological and meteorite research to characterize devitrification and low-grade metamorphism. For example, TL from feldspar derived by devitrification of glassy phases is a sensitive function of petrologic grade [58]. Microscopic imaging by means of TL is a recent development [59]; two-dimensional photon counting is achieved with a highly parallel processor array system. The formation of images by triboluminescence (emission caused by fracture or wear) appears to be possible with similar equipment.

2.6 Scanning Electron Microscopy

2.6.1 General Uses

The SEM is an important tool in the earth sciences. The large depth of field of the SEM makes it particularly effective in sedimentology, where fracture surfaces are used to elucidate diagenesis by examining rock texture, porosity, cements, and pore-filling materials. Stereo pairs are a useful adjunct and the heterogeneity of many sedimentary rocks favors the making of montages of images. Grains can be analyzed and identified in situ using EDS. Standard polishing methods are applicable when preparing SEM specimens of less porous rocks. All modes of SEM operation are then possible. Unconsolidated sediments can be infiltrated with resin, or prepared as scattered grain mounts and polished. Etching may assist to reveal microstructures and in deriving grain origins; for example, eroded grain surfaces may allow their transport history to be deduced. In particular, the SEM plays a pivotal role in the study of carbonate sediments, where porosity is not only characteristic of processes (e.g., dolomitization), but has important commercial implications for extraction from oil reservoirs. Figure 5 illustrates the use of the SEM in imaging to various forms of sedimentary materials [60].

Conditions in the SEM are less harsh than in TEM and even better in an environmental SEM (ESEM), where greater stability is traded for some loss of resolution. Thus, the SEM can give excellent morphological information of radiation-sensitive minerals. When clay minerals or wet sediments are involved, it is desirable to adopt special preparation methods that do not alter the grain morphologies. These methods include freeze-drying and critical point drying (CPD), the latter being slow but preferable, because of the removal of the damaging effects of surface tension. CPD is better for the preservation of delicate filamentary structures [61]. Smart and Tovey [62, 63] illustrate the value of SEM in clay mineralogy; many excellent micrographs are given in reference [62], and the techniques are described in reference [63].

Trewin [60] and by permission of Blackwell Science Ltd.

A more specific example of the power of SEM in clay mineralogy is given by Keller and Haenni [64], on the intimate mixing of kaolins.

Direct studies of cracks and pore spaces are somewhat under-represented in the earth sciences, reflecting the difficulty of obtaining three-dimensional and quantitative data. Indirect methods of investigating porosity are easier to use, but the data can be a cloak for a wide range of features whose individual identities and significance are hidden. SEM is useful for the study of cracks and similar extended features because of the instrument's large depth of focus; it performs well at a scale intermediate to LOM and TEM. It is also excellent for studying fracture surfaces but the recognition of cracks in such surfaces which penetrate into the bulk can be difficult. Flat, polished surfaces are better for seeing cracks and pores, but polishing may obscure detail and lead to erroneous results because of infilling and the distortion of surface layers. The ion bombardment of surfaces to erode damage produced by polishing is very effective [65]. It is an important, almost essential, approach when SEM is used for crack studies. Good examples exist of SEM in the study of micropores [66] and of surface channels on grains undergoing pressure solution, Fig. 6 [67].

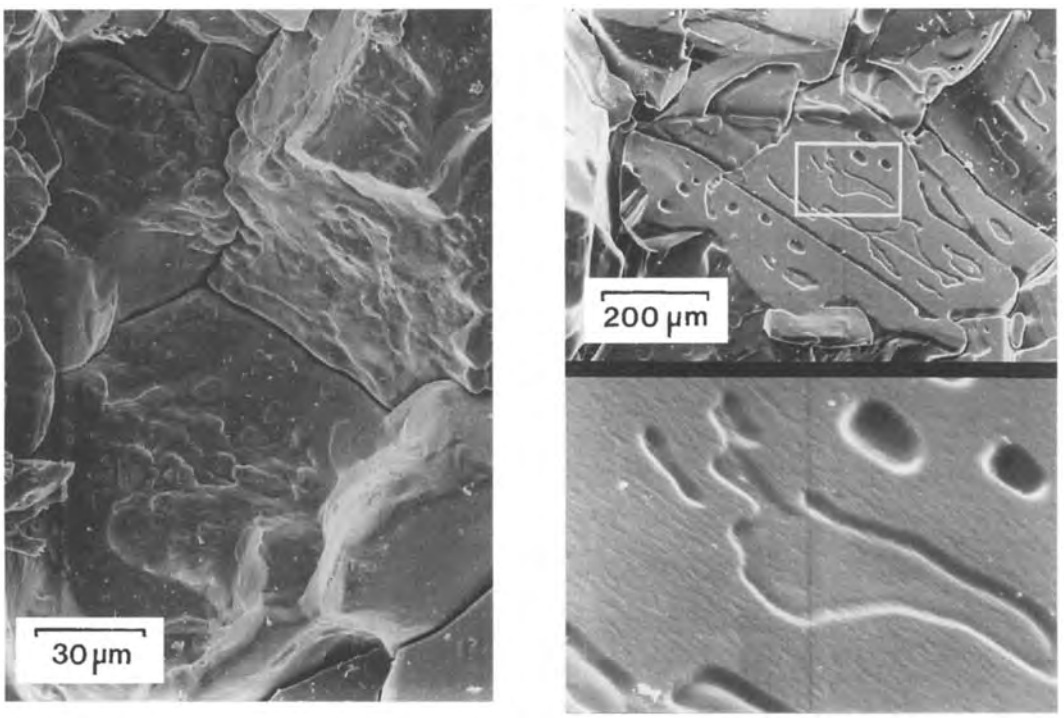

Figure 6. SEM secondary electron images showing two different forms of grain contact morphology on mechanically-parted crystals from wet-compacted samples of halite aggregate subjected to a volume strain of >25%, and undergoing pressure solution. (a) Irregularly-shaped tabular plateaus, or 'islands'; (b) (top) surfaces with an anastomozing pattern of channels, incizing into a more or less planar surface, arising from tubular structures; (bottom) enlargement of area outlined by white rectangle. Figure 7. SEM secondary electron images (20 kV) of uncoated specimens obtained with an environmental SEM fitted with a charge-free anticontamination system: (a) halite hopper crystal, bar mark 91 µm; (b) modern forminifera from N.E. Australia, bar mark 204 µm. The specimen in (b), which was mounted on cardboard, belongs to the Micropaleontology Collection, Natural History Museum (NHM), London. Courtesy of Jones, NHM.

ESEM (see Vol. 1, Chap. 4, Sec. 1), is still too new to have been applied widely, but it clearly has advantages in approaching the humidity conditions experienced by many natural samples. High quality imaging of uncoated, nonconducting specimens is possible, through the ionization of residual air in the chamber. The usefulness of ESEM is illustrated by Figs. 7a and b, which show a hopper crystal of halite (NaCl) and a foraminifer, respectively. The latter sample was imaged undisturbed on its cardboard museum display tray (it is good policy not to coat museum-type materials, because this precludes further study by LOM).

2.6.2 Electron Channeling Patterns

Electron channeling patterns (ECP) enable crystallographic orientation to be determined (see Vol. 1 of this Handbook). The method has been explored for the petrofabric analysis of quartzites [68]. More general applications to geological materials have also been discussed [69]. The ECP technique has also been applied to twinned quartz crystals [70], showing that left and right-handed Brazil twins cannot be distinguished because the twin plane coincides with the mirror plane in the ECP sphere (i.e., the twins have identical ECPs). Dauphiné twins are readily distinguished. The ECP technique is not widely used and it is being superseded by the following methodology.

2.6.3 Electron Backscattering Patterns

The use of electron backscattering diffraction patterns (EBSPs) in conjunction with SEM is a comparatively new technique for earth scientists. Like ECP it does not image the material in an exact sense, but it gives an 'orientation image'. The EBSP technique merits a brief mention on account of its growing importance.

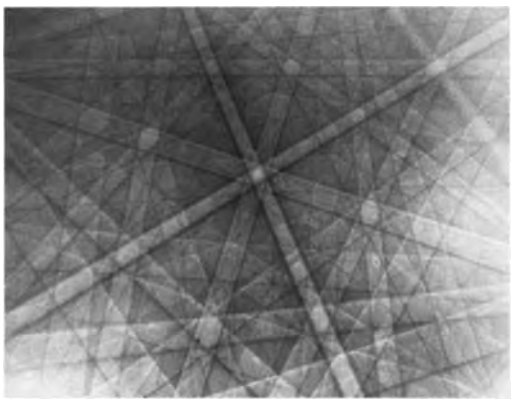

Figure 8. Wide angle backscattered electron Kikuchi diffraction pattern from chalcopyrite, illustrating the projection symmetry of the [0 0 1] axis, which has Laue group 2m. The pattern coverage along the diagonal is 70°. Courtesy of Baba-Kishi, Hong Kong Polytechnic University.

Because backscattered electrons only sample a very thin layer at the surface, it is necessary to use special specimen preparation techniques to prevent lattice distortion and 'smearing' of the surface. EBSPs are very useful for examining the symmetry of single crystals and individual mineral grains [71]. Figure 8 is the pattern for pyrite with a ⟨1 1 1⟩ pole at the center. An atlas of many patterns exists [72], including some for minerals.

More generally EBSPs are very valuable for the determination of preferred orientation, or texture, in combination with microstructural data. They also offer a means of studying plastic deformation and dislocation densities, but this approach has not yet been used for rocks. Current developments in instrumentation are much concerned with facilitating unambiguous orientational analysis by means of EBSP, and enabling orientations and textures to be measured automatically. Good examples of the power of automated systems are [73] on quartzite and [74] on calcite.

2.6.4 Microanalysis by Scanning Electron Microscopy and Electron Probe Microanalysis

Microanalysis with SEM, energy dispersive spectroscopy (EDS) and wavelength dispersive spectroscopy (WDS) (i.e., SEM/EDS, SEM/WDS) and the electron probe microanalyzer (EPMA) are essential tools of the earth scientist, generating detailed compositional data at a submillimeter level about suites of rock and minerals. Established texts and Vol. 2 of this Handbook discuss the particular problems of microanalysis and just a few points are made here.

The chemical complexity and the inhomogeneity of many geological samples outweighs that of the average metallurgical specimen. This poses particular problems when coupled with the difficulty of analyzing oxygen and other light elements quantitatively. Ideally, a complete analysis should list the phases present, the average and spread of compositions for each phase, the phases present, the average and spread of compositions for each phase, the amount of each phase, and the bulk composition of the sample. As described in Vol. 2 of this Handbook, ZAF-type computer programs are widely available to process raw WDS X-ray data so that accurate quantitative analyses result. Special programs exist for geological materials, of which the Bence–Albee correction procedure [75] for EPMA data from oxides and silicates is well known. With some modifications it is still one of the best, being rapid and easy to apply [76]. SEM/EDS is able to provide good analytical information about rock samples if data is treated by multivariate statistical

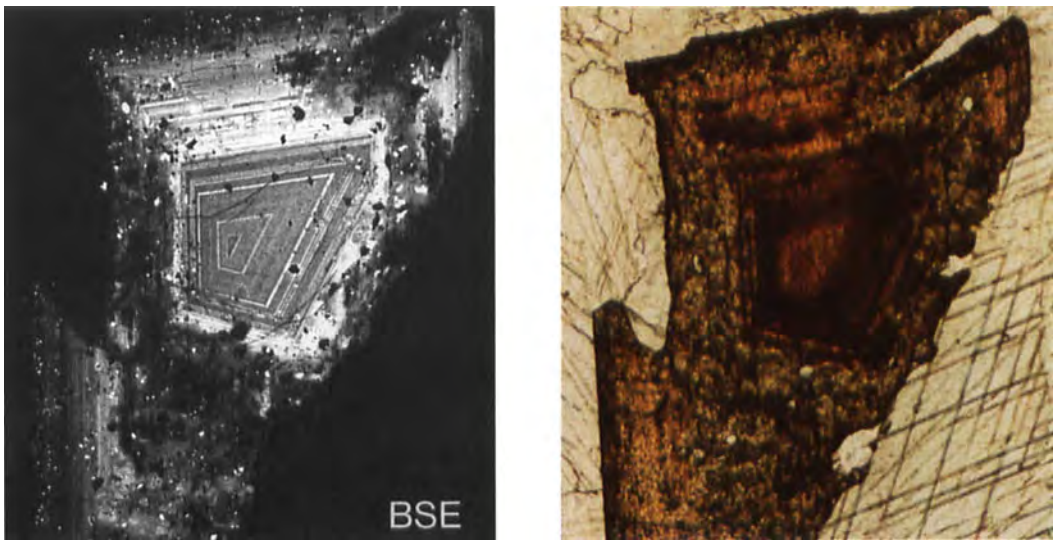

Figure 9. Pyrochlore crystal (30 μm polished section) from magnesiocarbonatite at Fen, Norway (sample from D. D. Hogarth, Ontario): (a) BSE image revealing overall compositional variation obtained with an SEM operating at 15 kV; (b) LOM (transmission) image; X-ray maps for (c) Ce(Lα); (d) Th(Mα); (e) Ta(Lα); and (f) Si(Kα), taken using an electron microprobe operating at 20 kV and 100 nA. Courtesy of Williams, Natural History Museum, London.

methods and ZAF correction; the value of applying the method of principal components analysis to sets of EDS image data is demonstrated elsewhere [77].

Several groups have automated EPMA or SEM analysis for particular mineralogical purposes. WDS detection for precious metals searching was an early development [78]; an improved system with BSE imaging and EDS detection for gold microprospecting is described by Harrowfield et al. [79].

X-ray mapping is useful for revealing major element distributions, compositional zoning, etc., although it lacks sensitivity and is only qualitative. Figures 9a–f show BSE, optical, and X-ray images for Ce, Th, Ta, and Si from a pyrochlore crystal from a carbonatite. The initial oscillatory zoning (Ce varies most strongly) is subsequently partially embayed and corroded. The altered pyrochlore is hydrated, generally richer in Th, and is associated with intergrown silicate phases. The BSE image (a) is a map of overall compositional variation, and being a surface effect, is much sharper than the optical image (b).

2.7 Transmission Electron Microscopy

2.7.1 General Uses

Transmission electron microscopy (TEM) was scarcely applied to geological materials until the 1970s. The use of TEM by relatively few groups has greatly advanced knowledge about natural processes at the grain, subgrain, and atomic scales. Drits [80] and McLaren [81] give good

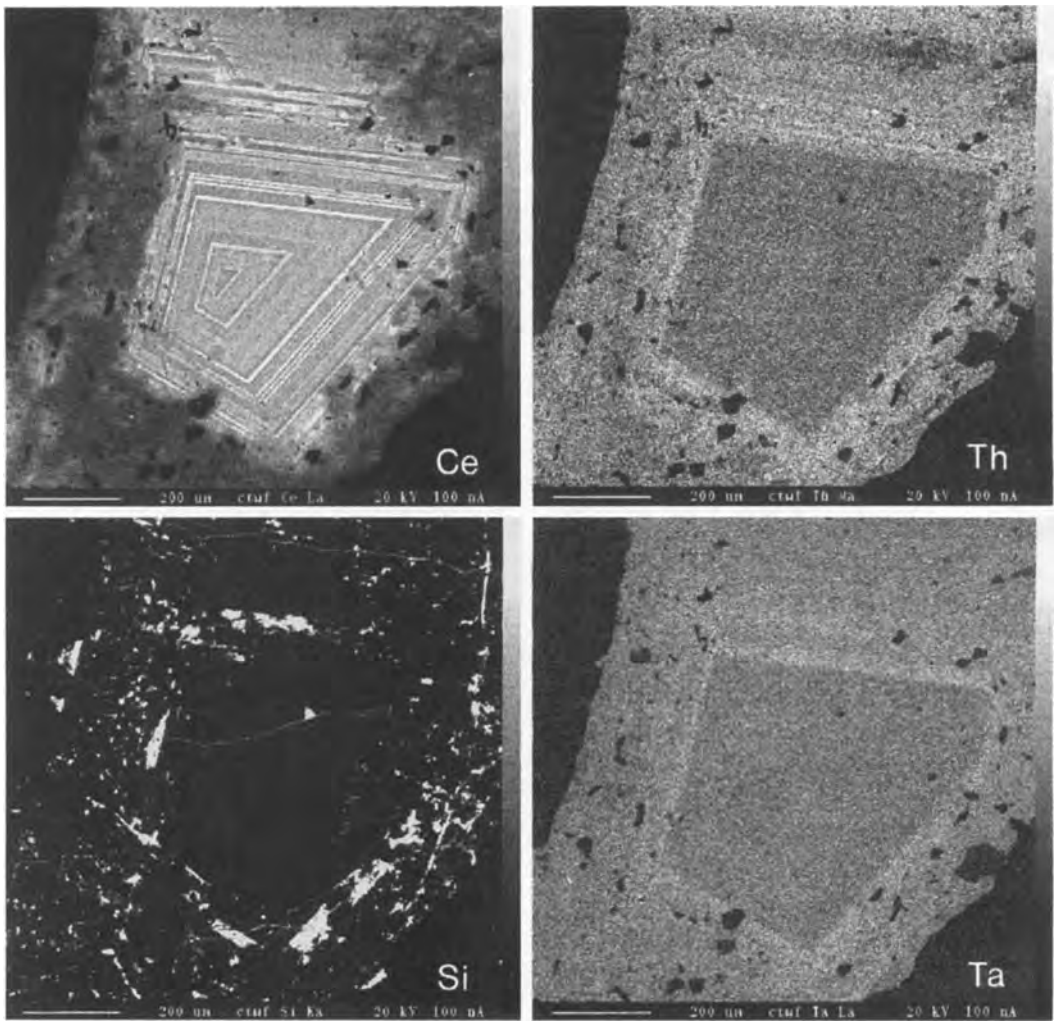

Figure 9. (c)–(f).

introductions to the field; two recent books [82, 83] present very different aspects of the present state-of-the-art.

The advantages of microanalysis in TEM (mainly improved spatial resolution and simpler correction procedures) have been promoted widely. The fine-grained nature of some geological samples makes thin film analysis essential. Currently there are too few examples of the acquisition of high quality TEM/EDS data, although qualitative analyses are common. Applications of ALCHEMI to minerals are discussed in the literature [84, 85]. Automated thin film analysis has been developed [86] for the rapid characterization and the classification of interplanetary dust particles.

Electron energy loss spectrometry (EELS) has not been widely applied to

mineralogical problems, despite its value for light element analysis, and the information it gives about bonding, [85, 87]. EELS data from meteorite residues rich in Cδ, a type of diamond, illustrate the last point [88]; another EELS study of interstellar diamonds from residues was carried out by Bernatowicz et al. [89].

Instrumentation for high resolution electron microscopy (HREM) is not yet sufficient to resolve anions of most oxides and many minerals. This should be possible with the next generation of instruments, where the resolution is expected to be 0.1 nm. Meanwhile, it is possible to determine structures at below the instrumental limit by using three-dimensional image information. This has been demonstrated with staurolite, a resolution of 0.16 nm being achieved [90].

2.7.2 Exsolution, Microstructures, Transformations, and Atomic Structures

Feldspars have played a pivotal role in the development of ideas about differentiation. An abundant and complex group with a wide range of compositions, the feldspars define well the stages of evolution of igneous rocks: crystallization, subsolidus transformation, and alteration. Brown and Parsons [91, 92] have variously addressed exsolution textures, coarsening kinetics, alteration reactions, and twinning in alkali, plagioclase and ternary feldspars. The results have greatly increased knowledge about feldspar microstructures, the mechanisms by which they form, and their relevance. Figure 10a, a micrograph of a cryptomesoperthite from an alkali feldspar rim in a zoned ternary feldspar is an example of the many beautiful TEM images deriving from the work. ALCHEMI and convergent beam electron diffraction (CBED) have been used to study symmetry and Al-Si order, respectively, for a tweed microstructure in an orthoclase (potassium–feldspar) [93]. Since the preparation of TEM specimens is always time-consuming, more rapid methods for revealing fine microstructures in feldspars are often needed. Figures 10b and c illustrate an etching method [94] which enables the scale and type of exsolution to be visualized by SEM. Figure 10b, a TEM image of a similar area from the same specimen, is included for comparison.

Microstructures in calcite and dolomite have been characterized by TEM [95]. Growth and alteration microstructures are considered in [96]. Notable are the elucidation of the nature of ribbon-like microstructures in impure calcites [97] and HREM imaging of various superstructures in calcian dolomite [98], ankerite [99], magnesian calcite [100], and in terms of proposed models [98]. Figure 11a shows the complexity of recent carbonate sediments revealed by HREM, while Fig. 11b shows comparison of simulated images with observed structures of host and a superstructure domain for a calcium ankerite.

TEM has greatly added to knowledge about phase transformations that derived from X-ray diffraction studies, and particularly on the evolution of microstructures with time and temperature. It has demonstrated the common occurrence of metastable, disordered phases outside their stability fields. Phase transformations and transformation-induced microstructures

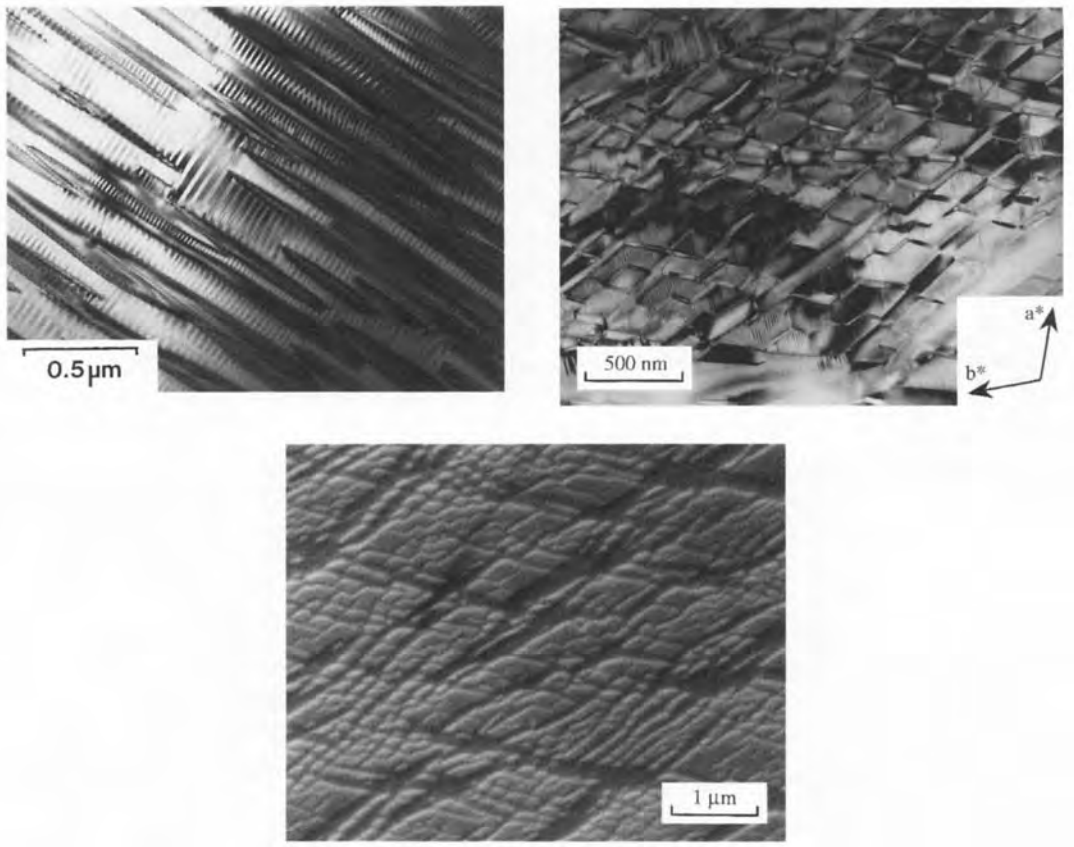

Figure 10. (a) TEM bright field image of cryptomesoperthite from alkali feldspar rims from zoned ternary feldspars. This image shows an orthoclase-poor area where low sanidine occurs in lenses parallel to $(\bar{6}\,0\,1)$. The periodicity of the Albite twinning (lamellae orthogonal to the darker lenses) varies at the ends of the lenses. Courtesy of Brown and Parsons [91]. (b) TEM bright field image and (c) SEM secondary electron image of coherent braid microperthitic alkali feldspar in which zig zag lamellae of low microcline outline lozenges of Albite-twinned low albite. In (b) the electron beam is approximately parallel to the *c*-axis. In (c), the (0 0 1) cleavage surface has been etched with hydrofluoric acid for ≈50 s, which has attacked the low albite lozenges more rapidly, so that they show in relief. Courtesy of Waldron, Lee and Parsons [93]. All three feldspar samples are from the Klokken layered syenite intrusion, South Greenland. Reproduced by permission of Springer Verlag.

in minerals are reviewed by Nord [101]; no summary is attempted here. In situ TEM studies (see also Chap. 2, Sec. 2 of this Volume) of phase transformations in minerals are quite rare. Those of the α–β quartz transformation [102, 103] and of the $P\bar{1}$–$I\bar{1}$ phase transition in anorthite [104] are notable. The first found an incommensurate phase when very close to the transition temperature T_c and produced striking images, as shown in Fig. 11c. The results on the $P\bar{1}$–$I\bar{1}$ transition led to models of the dynamics [105]. An investigation with different aims has shown that in quartzite rocks the Dauphiné twins formed at T_c interact strongly with dislocations and thus can be retained to low temperatures [106].

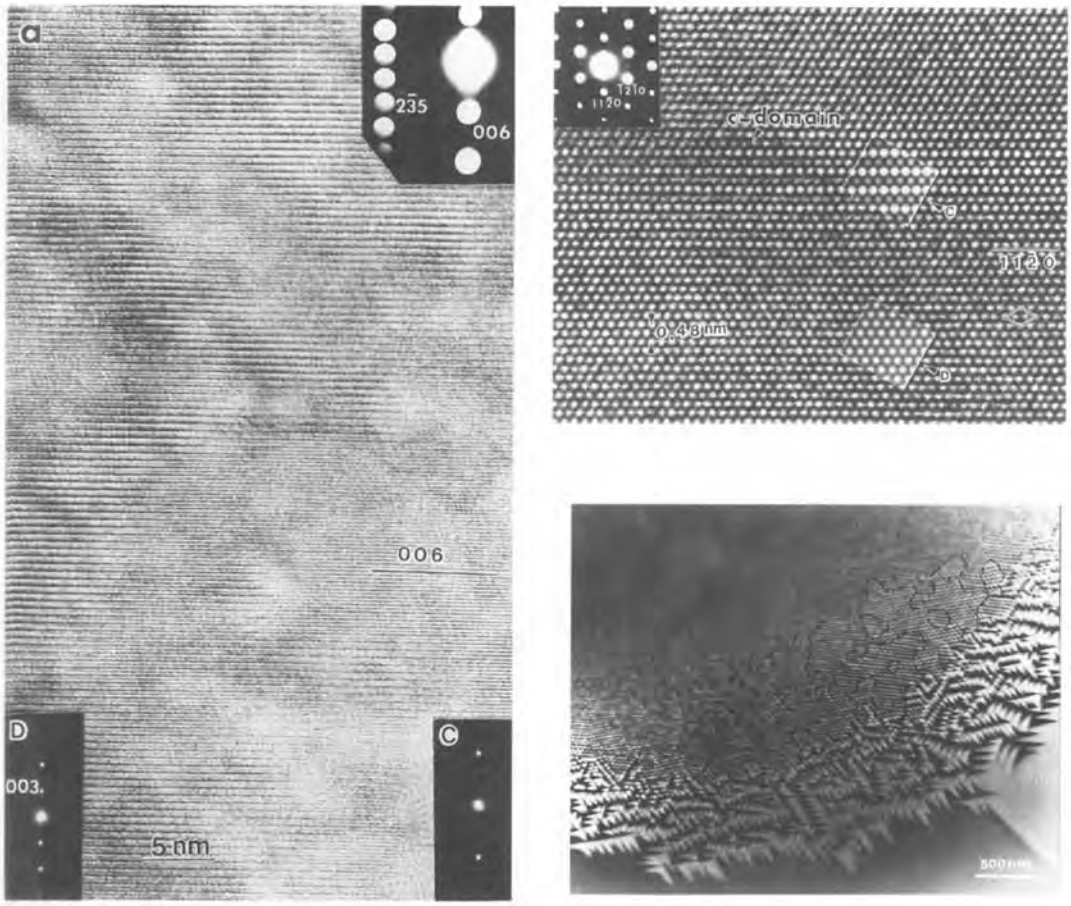

Figure 11. (a) HREM image of Recent Ca–Mg carbonate sediment from Abu Dhabi Sabkha. Spherical domains (within host Mg-calcite) showing fringes characteristic of dolomite ordering. Inset optical diffraction patterns (at bottom corners) from the image show order reflections for dolomite domains (D), but only fundamental reflections for host Mg-calcite (C). Courtesy of Wenk [100]. (b) Comparison of calculated multibeam image simulations with experimental HREM [0 0 0 1] zone images of calcian ankerite and **c** superstructure within it. Simulation at **c** corresponds to the superstructure model proposed in [98]. The simulation at **d** is for ideal dolomite; a hexagonal unit cell is shown for reference. Courtesy of Wenk [99]. (c) Dark field TEM image of the transition region from α-phase to the incommensurate phase close to the phase transition in a quartz specimen cut parallel to the basal plane; (3 0 $\bar{3}$ 1) reflection. The α-phase lies beyond the top left corner. The dark and light triangles are Dauphiné-twin-related prism-shaped domains, and the strong contrast is due to difference in the modulus of the structure factor for α_1 and α_2. Note the differently oriented macrodomains of the incommensurate phase. Courtesy of Van Landuyt [102]. Figures (a) and (b) reproduced by permission of Springer Verlag.

2.7.3 Phyllosilicates

Electron microscopy enables clay minerals to be characterized in three ways: grain texture (grainsize, morphology, by TEM), crystal structure (including stacking sequences, by HREM and diffraction), and chemical composition (by AEM). Most clay minerals present difficulties because they tend to lose bound water

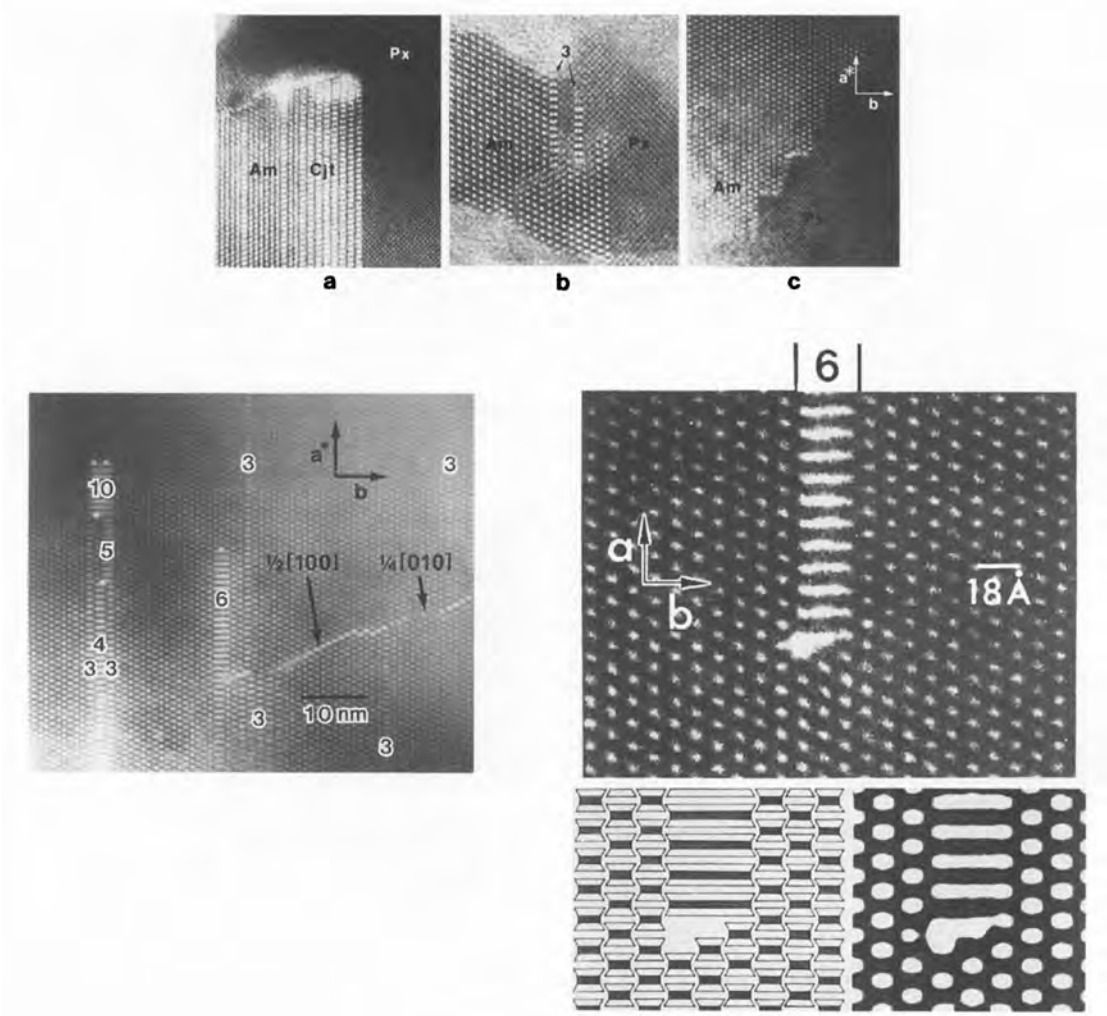

Figure 12. TEM images of replacement reactions in Palisades augite: (a) intergrown amphibole and triple-chain silicate (clinojimthompsonite–Cjt) replacing pyroxene near a fracture; (b) amphibole and augite together with only limited amounts of triple-chain structure (3); (c) the boundary between an amphibole bleb and host augite. The two pyriboles share common crystallographic axes, but the boundary is irregular; (d) part of an amphibole bleb showing wide-chain zippers and displacive faults typical of amphiboles undergoing reactions to sheet silicates. (e) A sextuple-chain defect terminating in the amphibole anthophyllite. TEM image, Jeol JEM 100B. under vacuum and when heated; they are also susceptible to damage by electron and ion irradiation [107]. Their preparation usually requires special techniques and some care.

Disaggregation and dispersal of a typical phyllosilicate onto carbon-coated grids produces platy or fibrous crystals with a small spread of orientations. To view the basal planes 'edge-on' is important, since

this provides greater distinguishing characteristics than when basal planes lie in the plane of the samples. Specimens are therefore prepared either by microtomy or by ion-milling of properly oriented materials. There is much excellent TEM work on phyllosilicates: on crystal structures and variants [108, 109], mixer layer structures [110], hydrothermal alteration and weathering [111], transformations [112], solid state reactions [113], and polytypism [114]. Veblen's work on polysomatism is especially notable. He has shown that reactions in which the reactant and the product belong to the same polysomatic series are common, with pyroxene being replaced by oriented amphibole, wide chain pyriboles, and sheet silicates during alteration and weathering [113]. Figures 12a–c illustrate the replacement of augite by amphibole and triple-chain silicate [115]. Alteration often appears to take place by the growth of lamellae of different chain width ('zippers') into the host. HREM combined with image simulation, Figs. 13a–d of reactions in the double-chain silicate anthophyllite, reveals the natures of the various displacement defects that can terminate zippers when rules governing replacement chain widths are not obeyed [116].

The identification of different phyllosilicate phases and layer sequences can be problematic because of closely similar *d*-spacings, for example, smectites and chlorites, collapsed smectite layers and illites. The utilization of overfocused lattice images and the simulation of images of various phases, Guthrie and Veblen [117, 118], has been influential. The approach has been successful with highly ordered interstratified illite/smectites, and with other mixed layer sequences [107]. Cryotransfer and HREM observation at liquid nitrogen temperatures to prevent collapse of layer spacings is one possible alternative [119]. Chemical treatments have also been developed to stabilize layers against collapse under intense irradiation and otherwise to assist in phase identification. Alkylammonium cations intercalated with phyllosilicate layers arrange themselves to satisfy the layer charge. Another benefit is greater resistance to electron beam heating. HREM measurements of the interlayer spacings of various alkylammonium-saturated phyllosilicates enable the interlayer charge to be estimated and the phases to be identified. This approach is valuable with extraterrestrial phyllosilicates [120], where complex mixtures and interlayering are common, and amounts of material are very small (see this Volume, Chap. 1, Sec. 8).

2.7.4 Deformation Mechanisms in Minerals and Rocks

Microscopy plays a pivotal role in the elucidation of rock deformation mechanisms and the processes giving rise to the observed macro- and micro-structures. The value of LOM for the analysis of petrofabrics, slip mechanisms, and twinning was established many years ago, and it is still valuable for the analysis of deformation in situ [121]. Now both SEM and TEM methods are frequently employed, but optical microscopy is a necessary complement. The scope of such studies ranges from the determination of deformation mechanisms using single crystals, through experimental deformation of rock samples, to the collection and analysis of field

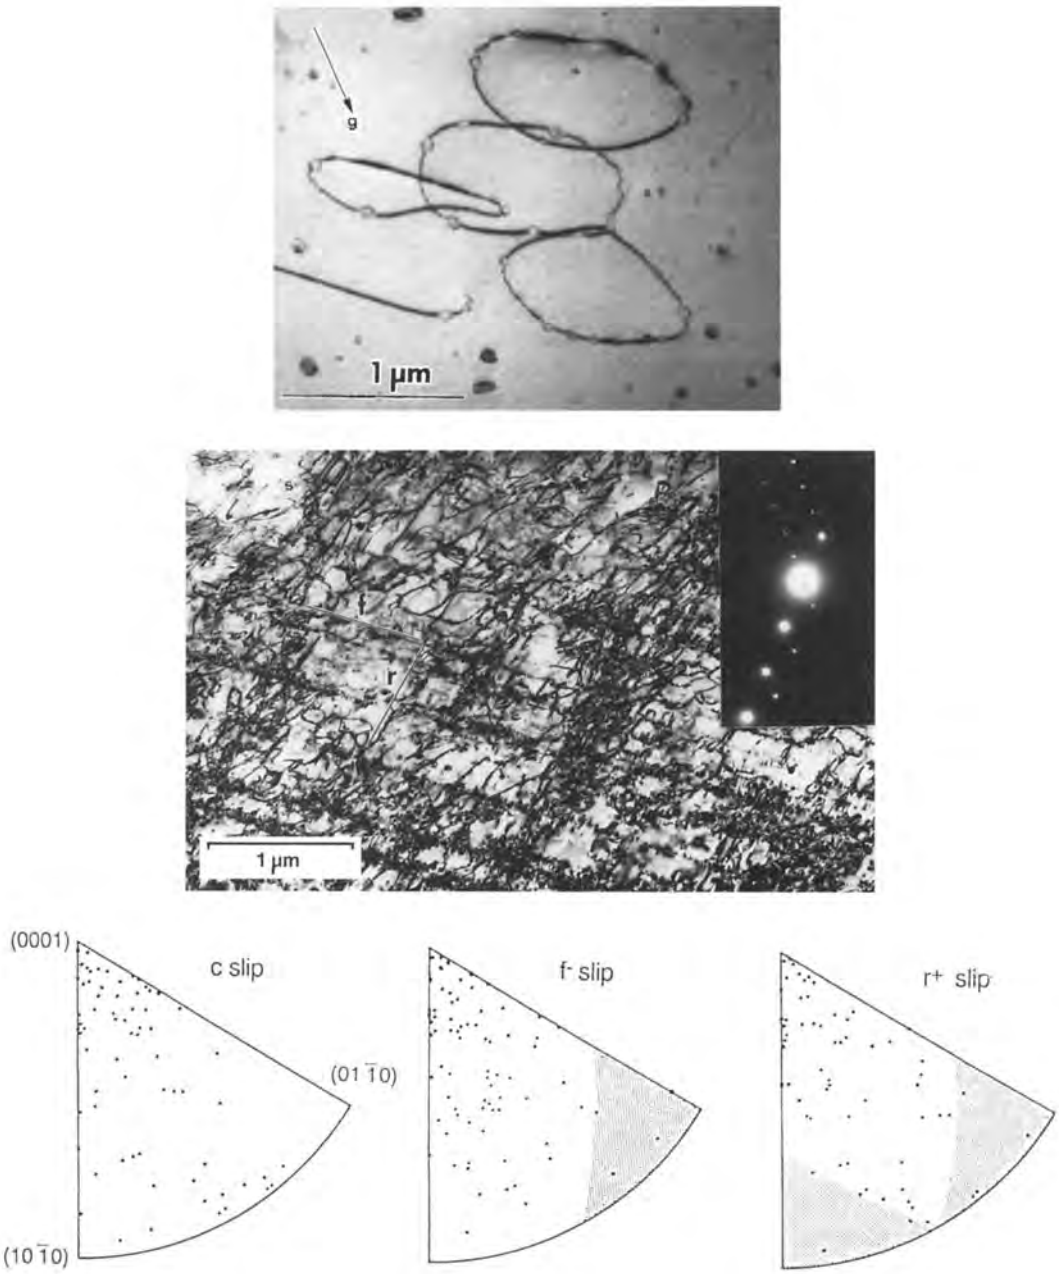

Figure 13. (a) Bright field transmission electron image showing bubbles on dislocation loops in a specimen of quartz heated at 600 °C for 90 min. Diffraction vector, $g = \bar{1}\,1\,0\,1$, the scale mark indicates 1 μm. Courtesy of McLaren [129]. (b) TEM image showing slip on the $(\bar{1}\,0\,1\,2) = f$ and $(1\,0\,\bar{1}\,4) = r$ planes in polycrystalline dolomite deformed in compression at 700 °C under confining pressure; $1\,0\,\bar{1}\,4$ systematic reflection. The slip systems operating and the distribution of deformation were analyzed in some 200 grains from samples deformed at different temperatures; (c) inverse pole figures (equal area projection) combining high and low temperature data representing the final orientations of compression axes for grains deforming by the labeled slip systems; shaded Schmid factor for the expected senses of $(\bar{1}\,0\,1\,2)$ and $(1\,0\,\bar{1}\,4)$ slip, respectively. Barber [132]. Figure (a) reproduced by permission of Springer Verlag and figures (b) and (c) reproduced by permission of Elsevier Science S.A.

samples leading to the interpretation of tectonic events.

Examples of the determination of slip mechanisms using TEM are papers on feldspars [122, 123], quartz [124], diopside [125], dolomite [126], etc. TEM has been very effective in studies of the experimental deformation of polycrystalline aggregates and rocks [127]. Green [128] reviews TEM results on deformation mechanisms in silicates and some high pressure silicate analogs.

Quartz and quartzites deserve special mention, for reasons of history and because TEM has illuminated the problem of hydrolytic weakening, that is, the low strength of 'wet' quartz. Experiments on quartz deformation under a confining pressure led to the earliest use of TEM to the study of mineral deformation. The discovery of hydrolytic weakening further stimulated studies of microstructural effects, often using synthetic quartz to give more control over variables. The results [129–131] from which Fig. 13a derives, are testament to the power of electron microscopy in solving problems in mineralogy.

Assumptions about deformation mechanisms and plasticity which are used in simulations of texture development have been the subject of TEM investigation using deformed dolomite [132]. Figures 13b and c are from this work, which enabled the construction pole figures of the distributions of final orientations of compression axes for grains yielding by particular mechanisms. The number of slip mechanisms active in each grain was always less than the number assumed for simulations and observed subgrain-scale heterogeneity of deformation is not built into current models.

TEM has not been applied widely to field samples of deformed rocks. Mylonitic rocks have received the most attention [133–135]. The work of Knipe [136] is proof that TEM, in combination with optical microscopy, can be a key to the understanding of the deformation within larger scale systems.

2.8 Electron Microscopy of Extraterrestrial Minerals and Rocks

Meteorites and more exotic particles like interplanetary dust particles (IDPs) are our only directly accessible evidence for solar system processes that have made life possible. Although such matter is abundant in space, only a small proportion of that which encounters the Earth's atmosphere is recovered. Consequently, starting with the samples returned by the Apollo missions, techniques requiring only small sample volumes have been pushed to their limits. Maximum information must be extracted from extraterrestrial materials because (i) they result from chance events, so that a given sample may be unique, and (ii) the most informative techniques (ion imaging, TEM) are destructive. Not surprisingly, cutting-edge microscopy is applied to tiny amounts of precious and rare extraterrestrial matter.

SEM/EDS/WDS and EPMA are used routinely in the investigation of the complex mineralogies of stony meteorites, enabling petrologic classifications based on optical microscopy to be extended and refined. Microanalysis has identified meteorites attributed to Martian and to

lunar origins. The differing chemistries of chondrules revealed by EPMA are now attributed mainly to differences in the composition of the solar nebula in various chondrule-forming regions [137]. Thus, electron probe results, together with isotopic data obtained by ion probes, now allow properties of the nebula to be inferred. The enigmatic Ca-Al rich refractory inclusions (CAIs) within chondrules in CV3 carbonaceous chondrites, generally argued to be very primitive [138, 139], have been another fertile field for state-of-the-art EPMA and SEM. Their microstructural complexities and extreme variations in microchemistry would remain undiscovered but for the spatial resolution of present-day electron probes. There are many exemplary papers on this topic, an obvious choice being the first systematic study of rim sequences on CAIs [140]. Later work confirmed their complexity, providing composition profiles, elucidating the reactions responsible [141].

TEM has proved particularly valuable in unraveling the very complex mineralogies of carbonaceous chondrites of low petrologic grade. These contain abundant phyllosilicates, sulfides, and some relict grains. The matrices of meteorites are generally too fine grained to be analyzed by LOM and EPMA methods, and for many years their natures and origins remained obscure. TEM has been crucial in several ways, for example, it shows that much of the layer-silicate matrix of CM chondrites is Fe-rich serpentine. SEM and TEM characterization together indicate that CM and CO matrices, although primitive, have undergone aqueous alteration in an asteroidal regolith [142].

Complex intergrown materials in the CM chondrites, revealed by LOM and SEM, were for some years called PCP (poorly characterized phases). Microanalysis narrowed their identity by showing PCP to be rich in iron, sulfur, silicon and oxygen. A major component was eventually identified as tochilinite [143], a dispersed terrestrial mineral among the first to have its structure determined by electron diffraction [144]. The presence of nierite (Si_3N_4) in four chondrites was discovered by TEM [145], while trace minerals and unsuspected phases in meteorite matrices, for example, saponite, has been identified by using HREM [146]. Small amounts of high melting point silicates in CAIs have been very elusive. One of these, a Ti-rich silicate, has been identified by combining several analytical methods, with convergent beam electron diffraction playing a decisive role [147].

Tiny grains of diamond, other forms of carbon, silicon carbide, and refractory carbides which formed before the solar system and which were incorporated, unmelted, into meteorites have been extracted and identified recently by TEM methods. Their presence was indicated by isotopic anomalies in residues from dissolved meteorites some twenty years ago, but their isolation and identification has proved difficult. The results [88, 148, 149] on such 'stardust' (dust from carbon-rich circumstellar clouds) are both unusual and of great value to the astrophysics community. Figure 14 is an image of the central section through interstellar graphite spherule extracted from the Murchison carbonaceous chondrite. The central crystal is TiC, which acted as a heterogeneous nucleation site for graphite condensation. The sequence TiC $\rightarrow$ graphite is predicted for equilibrium thermodynamics

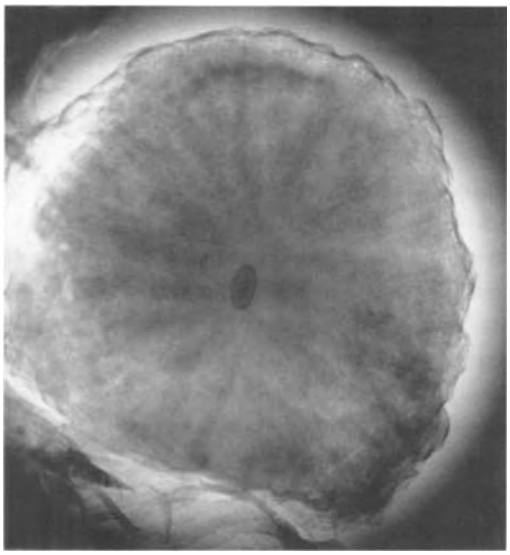

Figure 14. TEM image of an ultrathin section (≈100 nm thick) through an interstellar graphite spherule (≈0.7 μm dia.) extracted from the Murchison meteorite. The central crystal is TiC, which was a nucleation site for graphite condensation. Courtesy of Bernatowicz [149].

for stellar atmospheres with $C/O \approx 1.1$ [148]. TEM has also played a major role in the characterization of interplanetary dust particles [85, 150]. Magneli phases (Ti_nO_{2n-1}) and TiC have been identified within extraterrestrial particles separated from ancient Antarctic ice [151].

2.9 Electron Microscopy of Biogenic Minerals

Biominerals are very different from their geological counterparts in form and properties. The mechanisms of formation and of biological control of microstructure are complex and still somewhat obscure [152]. The microscopy of biominerals is a large subject with some outstanding technical achievements, and it cannot be covered comprehensively here. Much of the optical microscopy and SEM studies can be considered as standard methodology, but it would be a serious omission to mention some of the TEM-based research.

Much attention has naturally been given to hydroxyapatite (HA), the major mineral constituent of bone and teeth. For bone, dentin and mineralized tendon, TEM is essential since the crystals are tiny, typically with lengths and widths ≈10 nm and thicknesses ≈1 nm [153]. Dental enamel has larger HA crystals. Their assemblages and the process of demineralization have been widely studied by TEM and lattice imaging [154].

The mechanisms whereby biominerals form and their microstructures are controlled have also attracted much attention. SEM and TEM have laid the foundations for the present state of knowledge [150]. TEM has been used to analyze the structural complexities [155] and crossed lamellar structures [156, 157] which gives the high strength for weight of molluscan shells, partially inspired by the goal of designing new architectures in synthetic materials based on natural microstructures in biominerals (biomimetics). X-ray microanalysis does not feature much, since it cannot measure the nonstoichiometry and subtle compositional effects that undoubtedly contain many clues, but lattice imaging is used increasingly: for example, to show the single domain nature of magnetosomes of magnetite in magnetotactic bacteria [158] and that barium sulfate crystals in *desmids* are single crystals [159]. HREM plays a growing role in the study of interfaces [160] and in elucidating

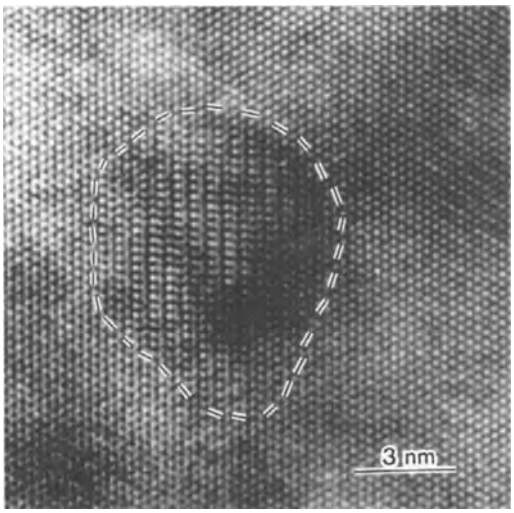

Figure 15. A 400 kV [0 0 *l*] HREM image from calcite from the spine of the deep water echinoderm *Stronglocentrotus franciscanus*. The outlined region is a domain that displays an ordered superstructure and is believed to originate during growth. Courtesy of Buseck [161].

subtle microstructural effects, for example, mosaicism and partially-ordered domains in the calcitic plates and spines of sea urchins [161]. Figure 15 shows a superstructure domain in calcite from the spine of a deep water *echinoderm* [161]. Such are apparently related to mosaicism, but the mechanisms for their formation are not yet understood.

2.10 Auger Electron Spectroscopy (AES) and X-Ray Photoelectron Spectroscopy (XPS)

AES and XPS have not been as widely applied to geological problems as in materials science generally. This may be attributed to a combination of lack of accessibility and exposure of earth scientists to the techniques, to less concern with surfaces as opposed to bulk, and to some technical difficulties (e.g., charging of mineral specimens with AES). Surface analysis has been applied to four main topics in the earth sciences: (i) the oxidation states of near-surface atoms; (ii) adsorption on mineral surfaces; (iii) alteration and weathering; (iv) atomic structures. Hochella [162] summarizes the techniques and reviews results.

The use of XPS and AES in mapping or 'imaging' modes are relatively new. The optimum spatial resolution of a dedicated scanning Auger microprobe, $\approx$70 nm, cannot be achieved with most minerals because they become charged. Effective charge neutralization of the scanning beam is difficult. The application of a *very* thin layer of a material with a low atomic number (e.g., carbon) is one approach, but it usually masks much of the desired information, since the surface specificity of AES is very high. Nonetheless, useful data on complex processes can be obtained by Auger microscopy, as illustrated by a study of the dissolution of labradorite [163].

XPS is generally favored over AES for minerals and XPS more easily provides information about the chemical state of the surface. However, imaging with XPS has much lower resolution than AES, since with XPS either the specimen or the detector must be scanned. A typical spatial resolution for an acceptable signal-to-noise ratio is 70 μm. This might be a tolerable resolution for studies of types (i) and (ii) above, but in general it is limiting.

2.11 Ion Microprobe Analysis and Ion Microscopy

The ion microprobe (dynamic secondary-ion mass spectrometry (SIMS)) is widely used by geologists. It can be employed to measure isotope ratios on very small volumes, and, like EPMA, to define grains of different compositions [164]. Both exploit the ion probe's excellent elemental sensitivity and good spatial resolution. An O^- primary beam is frequently used because rock samples are insulating.

Dynamic SIMS enables the sites of isotopes of particular significance to be identified and ion microscopy enables the spatial distribution of isotopes to be imaged. The discrimination of the sites and concentrations of different isotopes by secondary ion imaging (SII) is very important for investigations of processes which produce isotopic fractionation. Natural processes ranging from terrestrial weathering to stellar nucleosynthesis produce characteristic isotopic ratios. SII is also useful in laboratory studies on minerals where an isotopic tracer is employed, for example, ^{18}O can be a tracer in hydrothermal experiments and has been used to map microporosity and to study micropermeability in feldspars [165]. Ion imaging of ^{18}O after mineral-fluid exchange experiments allows quantification of the relative importance of solute-reprecipitation against solid-state migration and has further benefits in diffusion studies [166].

Equally revealing and state-of-the-art are SII results from the analysis of extraterrestrial materials. The ion probe has been instrumental in identifying mineral grains within primitive meteorites that have anomalous isotopic enrichments (e.g., of ^{26}Mg and ^{17}O [167]), or evidence of extinct radioactivities [168]. Other grains recognized by their isotopic signatures are various types of circumstellar grains that have survived incorporation into the solar system, for example, interstellar SiC has large enrichments of C and N and a nonsolar Si isotopic ratio. Figures 16a,b and c,d are ion images of aluminum oxide and silicon carbide grains, respectively, in residues from meteorite samples dissolved in acids. The oxide grains which show an enrichment of ^{17}O and a depleted ^{18}O (with respect to normal solar system abundances) are deduced to be interstellar grains. Similar arguments apply to silicon carbide grains that have high $^{28}Si/^{30}Si$ ratios [169].

2.12 The Scanning Proton Microprobe and Micro-Proton-Induced X-Ray Emission Spectroscopy

Proton-induced X-ray emission spectroscopy (PIXE) is recommended as a trace element tool, with a better sensitivity than EPMA by a factor of 10 or more [170]. The scanning proton microprobe facilitates X-ray emission analysis at a similar spatial resolution to EPMA. Micro-PIXE (μ-PIXE), as this is known, was pioneered for geological samples at Heidelberg. μ-PIXE has been used by the Heidelberg group both in isolation and to supplement EPMA data [170]. As with EPMA, there is a requirement for homogeneous mineralogical standards which can be a problem [171] in the absence of reliable synthetic ones.

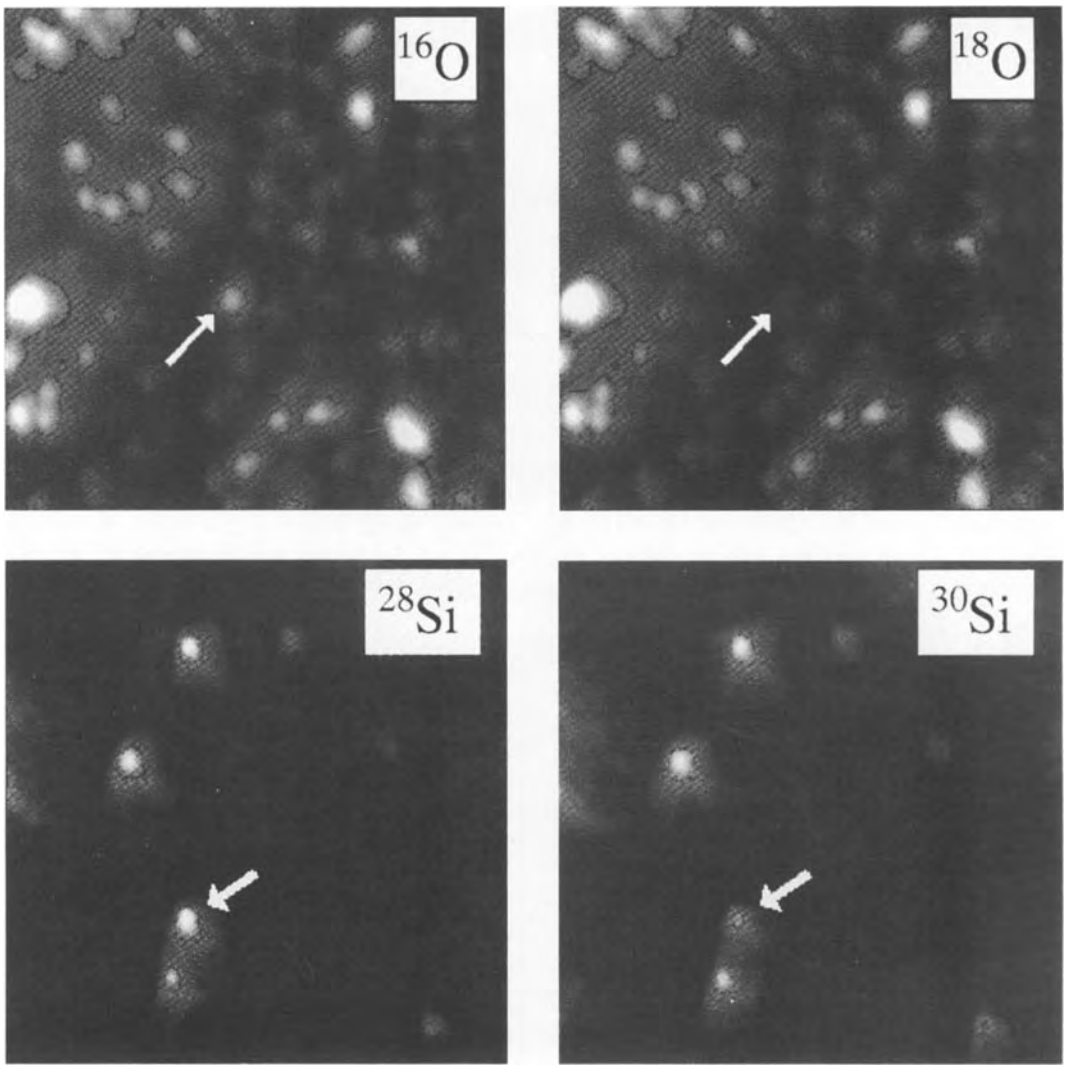

Figure 16. Secondary ion images of dust grains separated from acid residues of primitive meteorites: (a)(b) oxygen isotopes in 1–5 μm Al_2O_3 grains; (c)(d) silicon isotopes in 3 μm SiC grains. Exposure times are selected so that equal intensities reflect normal isotopic compositions. Such ion images allow the rapid identification of rare interstellar dust grains which survived the formation of the solar system, trapped in meteorites. The grains indicated by arrows have isotopic ratios completely different from materials of solar system origin, and they probably formed in the cool atmospheres around giant red stars. Courtesy of Nittler [169].

In addition to the application of μ-PIXE to fluid inclusions [32] (see also Sec. 2.2.3.2 of this Chapter) it has been used for the geothermometry of Ni-bearing garnets, used in assessing diamond-bearing formations [172]. Other geological uses of μ-PIXE are summarized in [173].

2.13 Scanning Tunneling Microscopy and Atomic Force Microscopy

Scanning tunneling microscopy (STM) is of limited use with geological materials because most are too insulating for a tunneling current to flow. STM has therefore mainly been applied to sulfides [174]. The cell of the (1 0 0) galena (PbS) cleavage plane is square with the same dimensions as the bulk unit cell [175]; Pb and S sites are distinguishable, with preferential imaging of the S sites [174]. Defects attributed to Ag and Sb impurity ions suggest that the images can be truly atomic [176]. The (0 0 1) surface cell of hematite is hexagonal, and corresponds closely to the bulk unit cell dimensions [175]. Other minerals imaged by STM include pyrite, stannite and magnetite. The observed atomic structures of the surfaces are in close agreement with those of the corresponding bulk minerals. STM is possible with clay minerals provided that they are ultrathin ($\approx$1 nm) [177].

STM images represent distributions of electron density and should be interpreted in conjunction with calculations about such distributions. STM gives little indication of the composition of imaged features when surfaces are topographically complex. Electron tunneling spectroscopy [178] gives additional information provided that the STM tip is stable (e.g., results on galena [179]).

Atomic force microscopy (AFM) is more versatile and it is increasingly used for the study of mineral surfaces, especially their dynamic processes. The first AFM images of insulators were of boron nitride [180]. AFM studies have to date mostly imaged the surfaces of minerals that cleave easily: graphite, molybdenum disulfide, other sulfide minerals, mica, and calcite. Albite, chlorite, hematite, gibbsite, hydroxyapatite, quartz, montmorillonite, and mixed-layer smectite/illite minerals have also been imaged. The results indicate that surface reconstruction, common with metals and semiconductors, is not prevalent in minerals. This conclusion may be misleading because the surfaces of minerals have been studied in air or under water, and not in ultraclean environments. Also AFM images may not be truly atomic in resolution, for example, the earliest images of calcite may show 'averaged' structures, since no defects were imaged. However, images at 'nearly' atomic resolution have shown a surface cell which is in agreement with both the bulk unit cell and the results from LEED [181]. Figure 17, showing the structure of a calcite cleavage surface, is

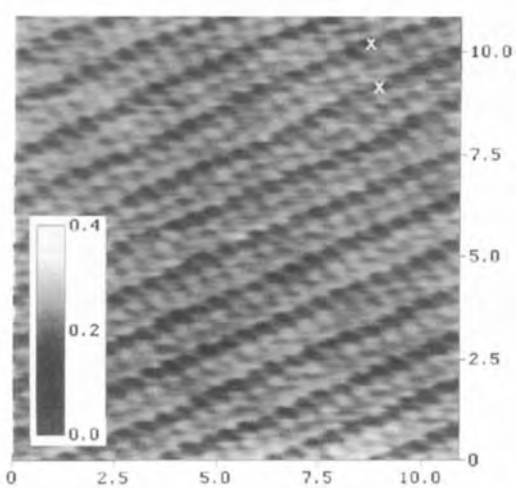

Figure 17. An AFM image of the calcite cleavage plane at atomic resolution showing surficial rows of oxygen atoms (light spots) of the carbonate group, with parallel dark rows (×) formed by the subsurface presence of calcium ions. The vertical inset in this figure provides a scale of surface roughness in nm. Courtesy of Xhie, Hong Kong University of Science and Technology.

believed to have such resolution.

AFM has been used to investigate the applicability of crystal growth theories to quartz and calcite. Sequential measurements have been made on quartz surfaces [182]. In situ AFM observations of surface dynamics have been made with fluid flowing over calcite cleavage surfaces. Surface diffusion is not rapid and step-site nucleation is thought to be the growth-controlling factor [183].

The effects of high energy particle irradiation on various materials have also been investigated by STM and AFM. AFM images the entry points of tracks of Kr ions on mica as depressions in the surface with disordered cores [184]. The application of STM and AFM techniques in the earth sciences is in its infancy. Their use and the breadth of applications will increase as suitable instruments become more widely available.

3 Semiconductors and Semiconductor Devices

3.1 Introduction

The impressive progress in microelectronics is based on silicon technology using MOS (metal oxide semiconductor) transistors. Since 1969, every three years a new generation of MOS technology emerges with four times as many transistors as the previous generation. At present the leading semiconductor fabrication lines are producing 4 Mbit and 16 Mbit dynamic random access memories (DRAMs) and logic integrated circuits (ICs) with critical dimensions of 0.7 and 0.5 μm, respectively. Sixty-four megabit DRAMs enter the production phase, and functional 256 Mbit samples are already available. Research and development is focusing on 1 Gbit/4 Gbit devices with 0.1 μm structures (theoretical and practical limits of gigascale integration are discussed by Meindl [1]). The scientific and industrial community feels convinced that progress in microelectronics will not encounter fundamental roadblocks for the next 15 years [2]. Apart from miniaturization, further progress will need material innovations, such as new metals and dielectrics. CMOS (complementary MOS) technology is dominating increasingly because of advantages in complexity, power consumption, and speed.

Silicon technology comprises the formation of active device areas in the silicon substrate by doping, the fabrication of dielectric layers, and the deposition of metallization layers. Of course, all regions and layers require patterning by photolithography and etching. For an introduction to silicon technology see, for example, Sze [3] and Ghandi [4]. The active device areas in MOS transistors are source and drain regions as well as the gate channel. Dielectric layers are either grown by thermal oxidation, resulting in thin (<10 nm) or thick (~1 μm) SiO_2 layers, or by chemical vapor deposition (CVD) of silicon dioxide or silicon nitride. The gate and metallization layers involve primarily the materials polycrystalline silicon ('polysilicon'), metal silicides, tungsten and aluminum.

With increasing miniaturization the complexity of the process technology also increases, which places higher demands on techniques for inspection, characterization, or analysis. Miniaturization of course calls for microscopic techniques providing high spatial resolution for both imaging and analysis. A large variety of optical, electron beam, and ion beam methods are employed for both materials characterization during technology development as well as for inspection and failure analysis during process optimization and process

control. Apart from microscopic techniques, methods for ultratrace analysis of inorganic and organic impurities in process media and on the wafer surfaces are also required. For example, metal contamination levels as low as 10^{10} atoms cm^{-2} have to be analyzed.

The main emphasis in microscopic techniques will be on the application of electron microscopy because of the excellent spatial resolution down to nanometers for scanning electron microscopy (SEM) and down to the atomic scale for transmission electron microscopy (TEM). Equally important is the possibility of obtaining reliable results within a short time during routine operation. SEM is most widely used for the imaging of device structures, and allows process control by nondestructive inspection within the fabrication line. Cross-sectional samples for SEM can be easily prepared by cleavage or polishing, and provide detailed information for technology assessment. The cross-section of Fig. 1 was prepared by focused ion beam (FIB) etching and shows two perpendicular section planes through a 16 Mbit DRAM. Prior to SEM imaging the section surface was selectively etched to delineate the various layers more clearly. TEM on the other hand allows more detailed materials characterization, as is visualized in the inserts of the cross-section through a 4 Mbit DRAM (Fig. 2): geometrical details, crystal defects, and material reactions at interfaces. TEM cross-sections in particular provide an understanding of material effects occurring in the various technology processes. In addition to imaging, additional analytical techniques such as energy-dispersive X-ray (EDX) spectroscopy are extremely valuable for both SEM and TEM. The various

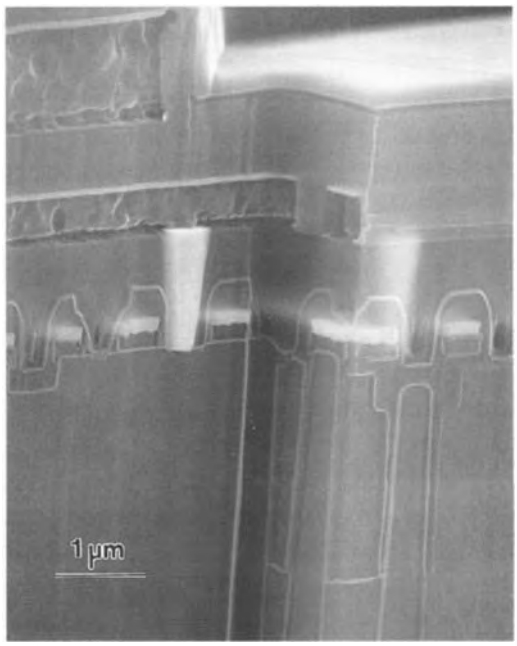

Figure 1. SEM image of a cross-section through a 16 Mbit memory chip (DRAM). Part of a trench capacitor is visible in the lower right corner. The bright 'needle' left of the center is a tungsten plug providing contact between the first aluminum metallization level and the silicon substrate.

scanning probe microscopy techniques, such as STM (scanning tunneling microscopy) and AFM (atomic force microscopy), of course provide superb resolution both laterally and vertically, but are still in an initial stage of routine application. Quantitative determination of surface roughness after cleaning and etching processes and the study of epitaxial growth mechanisms of silicon and compound semiconductors have been major fields of application. In many cases the methods of surface analysis are required. Both Auger electron spectroscopy (AES) and secondary ion mass spectroscopy (SIMS) offer the possibility of spatially resolved chemical analysis. An

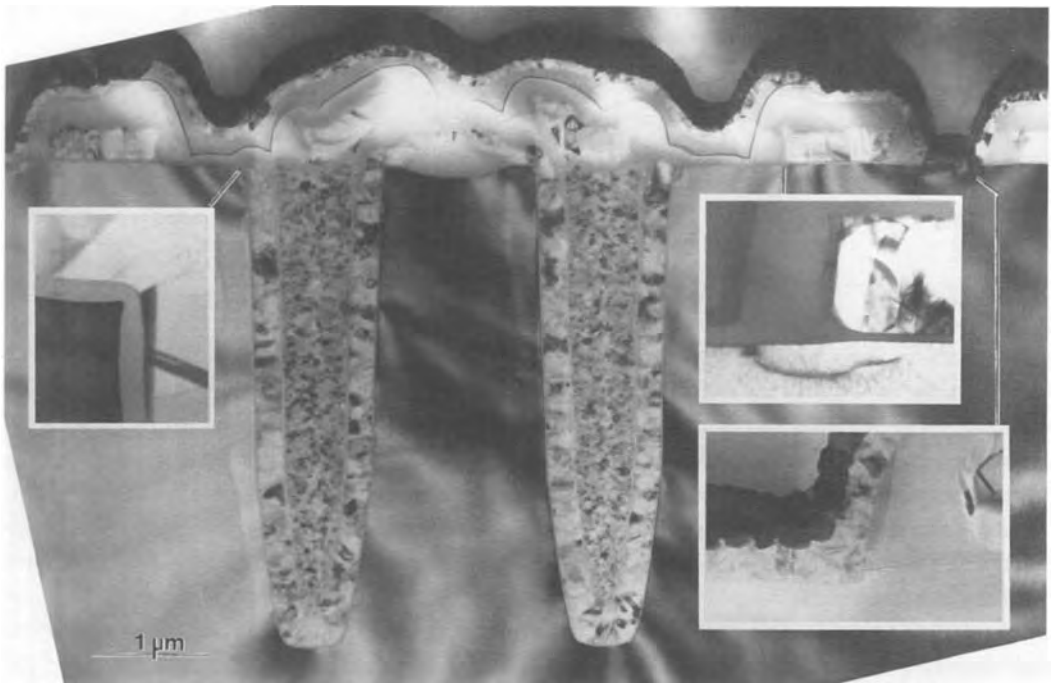

Figure 2. TEM image of a cross-section through the storage cell area in a 4 Mbit DRAM. The insets show magnifications of critical device features which require TEM inspection: oxide thinning at the trench edge (left), dislocations in the silicon substrate, and material reactions in contacts to the substrate (right).

introduction can be found in Fuchs et al. [5]. In failure analysis of electronic devices, various methods for defect localization such as electron beam testing (EBT) and emission microscopy are applied before physical failure analysis by SEM or TEM can be employed to identify the failure cause. Finally, special emphasis must be put on specimen preparation, which is extremely important for TEM. Advanced procedures for preparation of TEM cross-sections of semiconductor samples are described by, for example, Benedict et al. [6]. FIB systems offer the intriguing possibility of both local specimen preparation (e.g., etching of a cross-section, see Fig. 1) and imaging with good resolution. A wealth of detailed information on both microscopic methods and materials science problems may be found in the proceedings of the biannual Oxford conferences on the microscopy of semiconducting materials [7].

As indicated above, the main emphasis is on silicon technology. For compound semiconductors focus is put on characterization of heteroepitaxial layer structures. Such heterostructures are used for both electronic and optoelectronic devices. Since the thickness of the individual layers ranges down to a few nanometers, various methods of cross-sectional TEM imaging are discussed. In addition, examples of GaAs technology are described briefly.

3.2 Semiconductor Bulk Material

3.2.1 Silicon for Device Fabrication

Silicon single crystals for integrated circuit fabrication have been grown dislocation-free by float zone (FZ) and Czochralski (CZ) growth for almost three decades. In quantity, most of the silicon single-crystalline material is grown by the CZ technique, the rods now having a diameter of up to 300 mm. Though FZ and CZ grown silicon crystals are dislocation-free, they contain a variety of grown-in defects. These are agglomerations of self-point defects (silicon interstitials or vacancies) such as dislocation loops and stacking faults. Moreover, CZ silicon contains a very high concentration of oxygen, up to the solid solubility of oxygen in silicon, which arises from the oxygen from the SiO_2 crucible material dissolving into the silicon melt. Thus, CZ silicon contains SiO_x precipitates and their associated secondary defects, that is, dislocation loops and stacking faults. The density and distribution of all these grown-in defects depend strongly on the crystal growth parameters which influence the distribution and concentration of the self-point defects and impurities. In the starting silicon material for device manufacturing, that is, the silicon wafer, grown-in defects have to be avoided in the electrically active device areas.

Characterization of these microdefects involves first imaging of their distribution within the wafer on a larger scale, and second identifying their crystallographic nature in detail. For imaging of defect distributions defect etching using, for example, Secco or Wright–Jenkins etch [8] and optical microscopy is still an extremely sensitive and straight forward method. In addition, techniques based on infrared microscopy have been used successfully. Infrared microscopy at low magnification allows wafer mapping of inhomogeneities. Scanning infrared microscopy is more sensitive and can image individual microdefects much smaller than the resolution by using various imaging modes [9]. An analogous procedure is laser scanning tomography [10]. A narrow beam from an infrared laser is made to enter the edge of a wafer and to run within the wafer parallel to its surface. Light scattered through 90° from the beam is recorded with an infrared camera. Scanning the wafer parallel to the wafer surface in a direction perpendicular to the laser beam yields a two-dimensional (2D) image. Detailed characterization of the defect nature (dislocation, stacking fault, interstitial, or vacancy type) and distribution was originally obtained by X-ray topography of silicon slices cut from the crystal ingot [11]. A more precise analysis of the individual microdefects can be obtained by TEM, and a few examples will be discussed below.

In the periphery of FZ and CZ wafers the silicon self-interstitial concentration is enhanced, which may lead to particular microdefects—the so-called swirls. The A defect type of these swirls were identified by TEM to be interstitial dislocation loops having extensions of up to a few micrometers [12]. By controlling the impurities such as oxygen, carbon, and nitrogen as well as the growth parameters, swirls can be avoided. The demand for thinner gate oxides (<10 nm) makes the oxide more susceptible to degradation by grown-in

defects. Defect etching revealed so-called COPs (crystal originated particles) in the centre of CZ silicon, and FPDs (flow pattern defects) in the center of both FZ and CZ wafers. These defects cause severe problems for gate oxide integrity. TEM analysis revealed the FPDs to be tiny interstitial dislocation loops [13].

In CZ crystal growth, point defect clusters consisting of the impurities oxygen and carbon and the self-point defects are formed, acting as nucleation centers for SiO_x precipitation and stacking fault generation in the cooler parts of the just grown crystal. A homogenization procedure at high temperature dissolves the SiO_x precipitates before silicon wafers are cut from the ingot. In order to avoid oxygen precipitation in the active device area close to the silicon surface, a high-temperature annealing step is applied to diffuse out the oxygen and form an oxygen-denuded zone several micrometers wide below the wafer surface. Then, a low-temperature annealing follows to create a high density of nucleation centers for SiO_x precipitates. Succeeding high-temperature annealing causes the SiO_x precipitates to grow [14]. Extensive TEM analysis was carried out to document the precipitate and secondary defect morphology after the various annealing processes. A full compilation was given in a recent review [15]. The most predominant defects are SiO_x platelets and truncated SiO_x octahedra which are amorphous as revealed by high-resolution electron microscopy (HREM). The composition is substoichiometric SiO_2 as measured with electron energy loss spectroscopy (EELS) [16] and infrared absorption spectroscopy. Since an SiO_2 precipitate requires a 2.25 times larger volume than silicon, every precipitated oxygen atom generates 0.63 silicon interstitials which are released into the silicon bulk. The platelets lie on {1 0 0} planes and have ⟨1 1 0⟩ edges. As long as they are only a few nanometers thick their contrast in a bright-field image is dominated by the strain field (Fig. 3). A 'line of no contrast' appears where the atomic displacements associated with the strain field are perpendicular to the diffraction vector. According to the respective diffraction vectors, the line of no contrast lies along the platelet in Fig. 3a and normal to it in Fig. 3b. Further growth in thickness leads to the generation of punched out interstitial-type prismatic dislocation loops along four different ⟨1 1 0⟩ directions (Fig. 4). In this way the high strain is released by silicon interstitial emission. The characteristic bright-field image of a truncated octahedral precipitate is shown in Fig. 5. The octahedra have {1 0 0} and {1 1 1} faces and are almost strain-free. The silicon interstitials emitted from such a defect can nucleate an extrinsic stacking fault bordered by a Frank partial dislocation. The bright-field image in Fig. 6 shows such a stacking fault having nucleated at an octahedral precipitate. SiO_x precipitates and their secondary defects become harmful to device performance (gate oxide breakdown, and refresh-time killers in DRAMs) when they are generated in a denuded zone that has not been properly produced. The degree of precipitation also strongly determines the wafer warpage. The SiO_x precipitates and their secondary defects in the bulk of the wafer also have a beneficial effect: they serve as gettering sites for heavy metal impurities. In order to optimize this kind of gettering process the mechanism of 'intrinsic' gettering has to be understood. TEM analysis showed

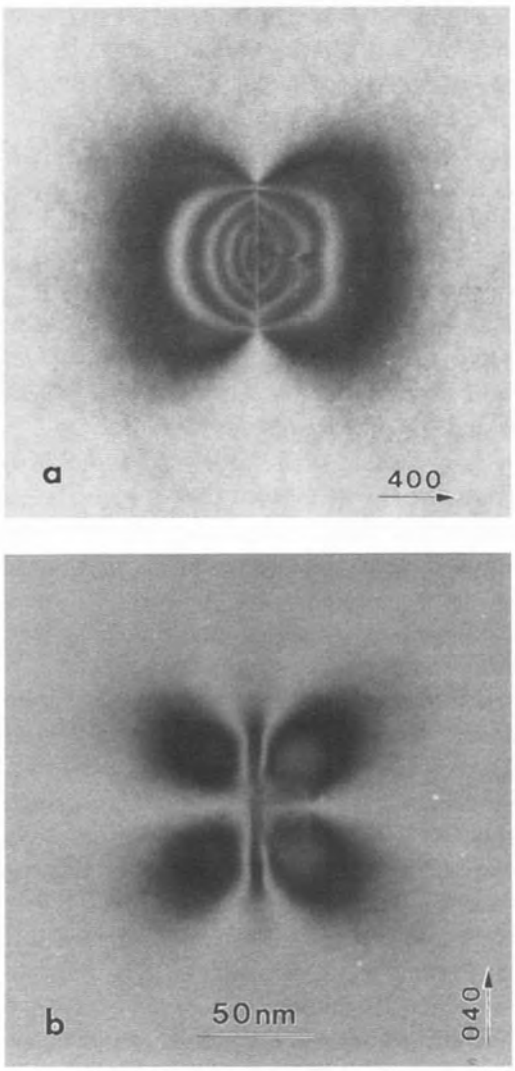

Figure 3. Strain contrast of a thin amorphous SiO_x precipitate in silicon lying on a {1 0 0} plane. Bright field TEM images of the same precipitate recorded with the (4 0 0) (a) and (0 4 0) (b) reflections perpendicular and parallel to the precipitate plane, respectively.

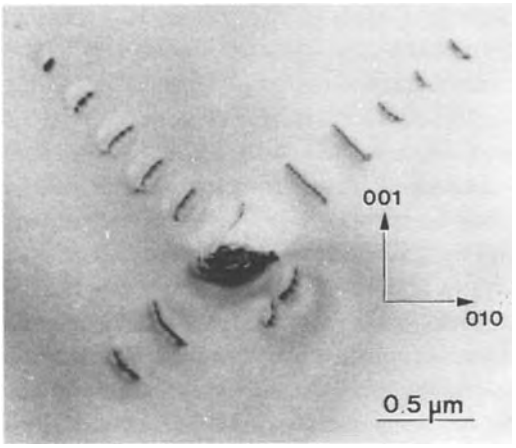

Figure 4. Extrinsic dislocation loops punched out on four equivalent glide systems from a platelike, amorphous SiO_x precipitate in the center of the image.

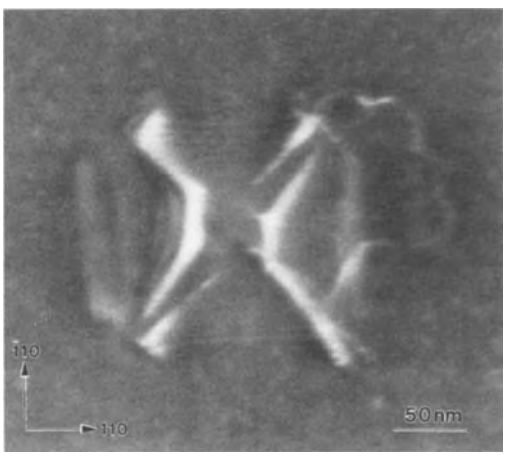

Figure 5. Weak-beam image of an amorphous SiO_x precipitate having the shape of a truncated octahedron with {1 1 1} and {1 0 0} faces.

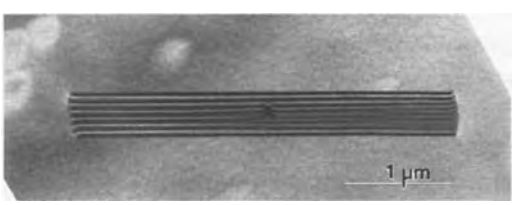

Figure 6. Extrinsic stacking fault accommodating the Si interstitials which were emitted by the SiO_x precipitate at its center.

that heavy metals (iron, nickel, and copper) precipitate as silicides at the SiO_x precipitates [17] or at the prismatic dislocation loops and Frank partial dislocations of the stacking faults [18, 19]. Which

kind of defect acts as a nucleation site depends strongly on the metal silicide, that is, whether it emits or absorbs silicon interstitials on precipitation, and on the strain field of the defect. The homogeneous nucleation of metal silicide precipitates in the bulk of silicon wafers has been studied in detail by Seibt [20–22].

3.2.2 Compound Semiconductors

From the numerous compound semiconductors only a few are used as single-crystal substrate material for semiconductor devices. III–V semiconductors, in particular gallium arsenide (GaAs) and to a lesser extent indium phosphide (InP), find broad application as substrates for both optoelectronic and electronic devices. Optoelectronic devices such as laser diodes and light-emitting diodes exploit the direct bandgap of GaAs and InP, allowing radiative recombination processes of charge carriers leading to light emission. Electronic devices for high frequencies (>10 GHz) such as microwave and millimeter wave power devices benefit from the higher mobility of charge carriers compared to silicon. Devices based on silicon carbide (SiC) hold promise for high-voltage and high-temperature applications but are still at an exploratory stage.

The requirements for GaAs substrate crystals used for optoelectronic devices differ notably from those for electronic devices. Fabrication of optoelectronic devices involves the growth of heteroepitaxial layer structures, the characterization of which will be described in Section 3.5.1 of this Chapter. The substrate crystals have to be highly doped since high currents flow from the back contact through the substrate to the pn junction in the layer structure on top of the wafer. Doping levels are 10^{18}–$10^{19}\,cm^{-3}$ with silicon for n-type and carbon or zinc for p-type GaAs. The dislocation density has to be extremely low since individual dislocations in the active layer of a laser diode enhance nonradiative recombination and the local increase in temperature may degrade the laser. For GaAs crystals grown by the horizontal Bridgman technique, dislocation densities of 1000–$2000\,cm^{-2}$ are usually obtained. Recently, the vertical gradient freeze technique has yielded GaAs wafers with even lower dislocation densities below $500\,cm^{-2}$ [4].

In contrast, for electronic devices, undoped semi-insulating GaAs substrate crystals are required to provide isolation between the active device areas. No useful thermal oxide which allows lateral isolation of active device structures in silicon technology can be grown on GaAs. Undoped, semi-insulating GaAs crystals are predominantly grown by the liquid encapsulated Czochralski (LEC) technique, and contain significant dislocation configurations. The average dislocation density is between 10^4 and $10^5\,cm^{-2}$ and is correlated to the thermal stress operating during crystal growth [23]. The dislocation distribution can be imaged by X-ray topography, infrared microscopy, and defect etching. Figure 7 shows an X-ray topograph of a 75 mm GaAs wafer. Because of the high absorption of the Mo-K_α radiation by the 0.5 mm thick GaAs wafer, only the X-ray wavefield anomalously transmitted through perfect crystal regions causes bright contrast. In regions of high defect density a larger angular width of the incoming X-ray

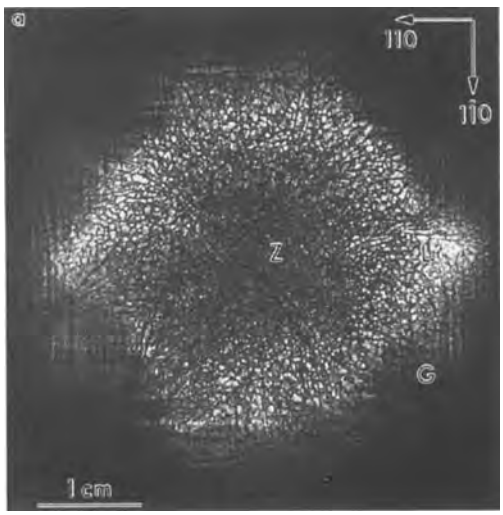

Figure 7. X-ray topograph of an undoped semi-insulating GaAs wafer showing dislocation cell walls in the center (Z), slip bands (G), and lineages (L).

beam is diffracted initially, but is subsequently absorbed in the crystal, and those regions, therefore, appear dark. In the center of the wafer (Z in Fig. 7) the dislocations are concentrated in dislocation cell walls, enclosing virtually dislocation-free material. The cell size is below 100 μm. In the wafer periphery, slip bands parallel to ⟨1 1 0⟩ directions (G in Fig. 7) and lineages develop. In a detailed analysis of defect configurations by TEM [24], it proved advantageous to mark the cell walls or glide bands by chemical etching in order to find individual dislocations by TEM. The DSL etch (diluted Sirtl etch applied with light) which is sensitive to the point defects surrounding the dislocations [25], was used for this purpose. Figure 8 shows a dislocation in a cell wall with two precipitates (P) associated with it. These precipitates exhibit an increased arsenic peak in the EDX spectrum, and were identified to consist of rhombohedral arsenic [26]. In the dark field image of a polycrystalline arsenic precipitate (Fig. 9a) only part of it appears bright. In the corresponding selected-area diffraction pattern (Fig. 9b) no orientation relationship between precipitate and the GaAs matrix can be detected. Analysis of the Burgers vector and the plane of the dislocation in Fig. 8 showed that the dislocation had moved by positive climb, that is, by the addition of vacancies or the emission of interstitials. While arsenic precipitation is assumed to occur soon after solidification at temperatures above 800°C, positive climb of dislocations is proposed to occur at lower temperatures with gallium vacancies providing the driving force for a climb process during which arsenic antisite defects, that is, arsenic atoms on gallium lattice sites, are created [24]. These antisite defects are widely agreed to correspond to the EL2 centers, the main electronic trap in semi-insulating GaAs.

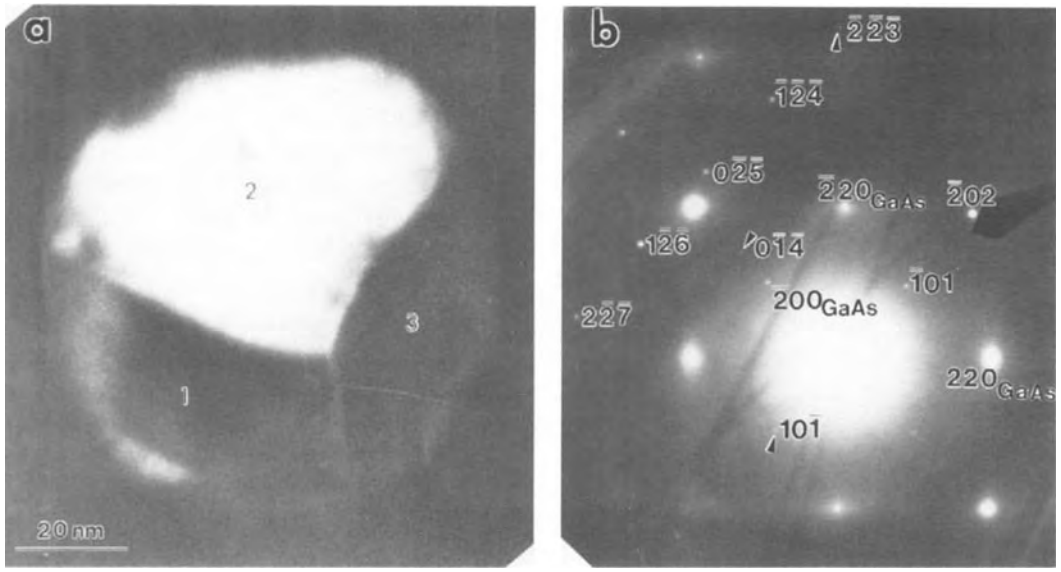

Figure 9. (a) Dark field image of a polycrystalline arsenic precipitate imaged in the $(\bar{2}02)$ reflection. (b) Corresponding selected-area diffraction pattern. Indices without the subscript GaAs refer to rhombohedric arsenic.

Progress in LEC crystal growth of semi-insulating GaAs has led to increased crystal diameters. Up to 100 mm diameter wafers are used in fabrication presently with up to 150 mm diameters in the future. Despite the increase in wafer diameter the dislocation density could be kept to levels of 10^4–10^5 cm^{-2}, which are not critical to performance and reliability of discrete GaAs devices.

3.3 Silicon Technology Processes

3.3.1 Dielectric Layers

Apart from the semiconducting properties of silicon, the possibility of growing high-quality dielectrics by thermal oxidation is a major benefit in silicon technology. The gate oxide of MOS transistors is usually grown by dry oxidation with a thickness of the order of 10 nm or even below. Thin dielectrics are also required for the capacitors in DRAMs. For lateral insulation between different device structures, thick oxides are grown by wet oxidation up to thicknesses around 1 μm (field oxides). In addition to thermal oxidation, chemical vapor deposition is used to fabricate silicon dioxide and silicon nitride layers. Such dielectrics are used for insulation between metallization layers and for passivation to protect devices from impurities, moisture, and scratches.

Since the interface between the gate oxide and the silicon substrate has an influence on device properties, for example via the interface trap density and the interface roughness, the structure and composition of this interface has been studied in

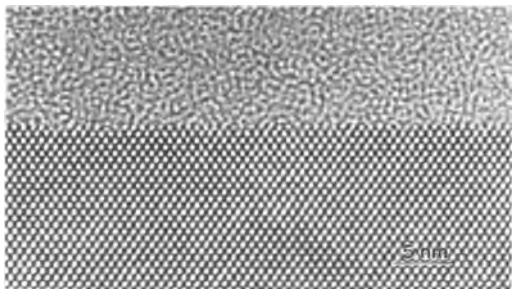

Figure 10. High-resolution image in ⟨110⟩ projection of the interface between thermal SiO_2 and (100) oriented silicon substrate.

detail by various analytical techniques. HREM of ⟨110⟩-oriented cross-sections was the first technique to reveal the (100)Si–SiO_2 interface on an atomic scale [27]. Figure 10 shows an HREM image in the ⟨110⟩ projection of a (100)Si–SiO_2 interface fabricated by a standard dry oxidation process. In the silicon crystal one set of {200} and two sets of {111} lattice fringes are visible. The dark dots in the crystalline part correspond to the position of two projected columns of silicon atoms being 0.136 nm apart, whereas the white dots are the tunnels in the crystal structure. The amorphous oxide shows a grainy contrast which does not reproduce the amorphous structure. Viewing the image parallel to the interface at an oblique angle reveals steps being one or two {200} lattice fringe spacings high. Characterization of irregular roughness by HREM of thin cross-sections suffers from the problem that even at very low specimen thickness (<10 nm) atomic elevations and depressions are projected on top of each other. Hence, simple visual inspection of the interface corrugation is bound to give the impression of too smooth interfaces. A quantitative approach by digitizing the image of the interface and calculating its covariance [28] yields values for the root mean square (r.m.s.) roughness and a correlation length. These parameters correspond to the peak-to-peak amplitude and the period of the roughness. The intentionally roughened (100)Si–SiO_2 interface oxidized in an ambient containing HCl was measured in this way [29], resulting in values of 0.3 and 2 nm for r.m.s. roughness and correlation length, respectively. This corrugation was found to explain well the decrease in carrier mobility in the inversion layer of a MOS transistor due to carrier scattering at the rough interface.

High-resolution microscopy of thermally oxidized, almost perfectly flat (100)Si surfaces, which were grown by molecular beam epitaxy (MBE), revealed a transition layer of 1 nm thickness at the (100)Si–SiO_2 interface with distinct crystalline contrast [30]. The contrast was found to be different in [011] and [0–11] projections and was interpreted as a thin layer of trimidite (high-temperature phase of quartz) epitaxially grown on (100)Si during thermal oxidation. It was argued that this crystalline layer might not be continuous on a less flat surface. In the ⟨100⟩ HREM images of thicker specimen areas a pronounced dot contrast with ⟨110⟩ spacings was found at the interface [31]. With the help of image simulation it was demonstrated that this contrast comes from the projection of small silicon pyramides with {111} facets which form at the (100)Si–SiO_2 interface.

An atomic model of the interface structure cannot be derived from HREM images only. X-ray photoelectron spectroscopy (XPS) measurements suggest some transition region between silicon and

SiO_2 since silicon atoms with one, two, and three bonds to oxygen were identified in addition to the tetrahedrally coordinated silicon atoms in the substrate as well as in the SiO_4^{2-} tetrahedra of the amorphous SiO_2 structure [32]. Information on the oxidation states of silicon with a spatial resolution at the atomic level may be obtained by using a 0.25 nm diameter electron probe in a scanning transmission electron microscope with a field emission gun for analyzing the near-edge structure of the Si $L_{2,3}$ ionization edge in an electron energy loss spectrometer [33]. The step height and their spacings on (1 0 0)Si–SiO_2 interfaces may also be evaluated from (1 0 0) plan view TEM specimens without removing the oxide [34]. In the [1 0 0] diffraction pattern, forbidden {0 1 1} reflections appear which are due to incomplete silicon unit cells terminating at the interface. From their diffracted intensity the mean step height and step separation may be extracted. More recently, STM and AFM have been widely applied to study the silicon surface after various chemical surface cleanings [35]. Good correlation between initial roughness and gate oxide breakdown was reported.

Apart from the gate oxide, thin dielectrics are also required for the cell capacitors in DRAMs. Reducing the size of the memory cell while maintaining its capacity was first achieved by reducing the thickness of the oxide. Since thermal oxides of thicknesses below 10 nm are difficult to fabricate with high yield and high reliability, the area of the capacitor was increased using different concepts: by fabricating trench capacitors, all the sidewalls of the trenches etched into the silicon substrate contribute to the capacitor area while keeping the required cell area small. Alternatively, the capacitor can be 'stacked' on top of the transistor using two polysilicon electrodes (stacked cell).

Various aspects during fabrication of the dielectrics for trench capacitors will be discussed in the following. While SEM cross-sections are well suited for the inspection of the shape of the trench after reactive ion etching, TEM cross-sections are required to image the detailed configuration of the trench dielectrics with sufficient resolution (about 0.5 nm in bright field images).

Figure 11 is a horizontal section through a trench capacitor of a 4 Mbit DRAM with a thermal oxide as the dielectric [36]. Reactive ion etching of the trench was followed by a wet chemical etching process to round the bottom of the trench. By this process, trenches were produced with sidewalls having a preferential orientation along {1 0 0} planes. The oxide is not of uniform thickness along the perimeter of the trench, due to differences in

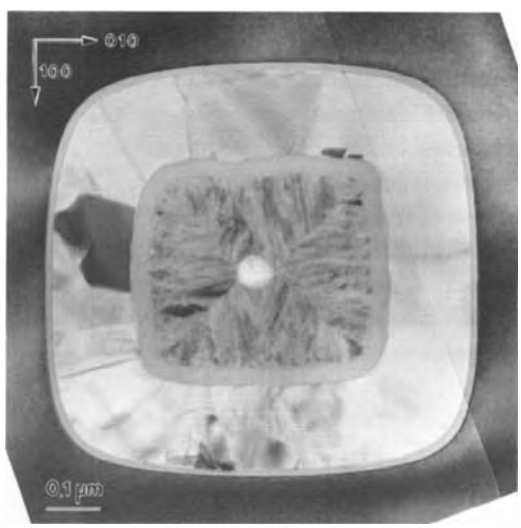

Figure 11. Horizontal section through a trench capacitor with a thin capacitor oxide.

the oxidation rate on the various crystallographic planes: oxidation on {1 1 0} planes is faster than on {1 0 0} planes. Whereas the oxide on the {1 0 0} sidewalls is approximately 13.5 nm thick, its thickness increases by about 30% to 17.5 nm in the rounded corners where the sidewalls are parallel to {1 1 0} planes.

The top and bottom edges of the trench are critical points with respect to thermal oxidation, because at temperatures below 1000°C the oxide thickness is reduced at the edges [37]. This effect always occurs at the upper edges of the trench, where patterning produces a sharp edge (Fig. 12a and b). Besides reducing the thickness of the oxide, this sharp-edged geometry impairs the breakdown strength of the oxide and forms a center of high mechanical stress which may nucleate dislocations [38]. At the bottom of the trench this problem can be avoided if well-rounded edges are produced by the etching process (Fig. 12c). In accordance with their different crystallographic orientations, the (1 0 0) trench bottom has a thinner oxide layer than the {1 1 0} trench sidewalls.

Because of the problem of oxide thinning at the upper trench edges, triple-layer dielectrics with an SiO_2–Si_3N_4–SiO_2 structure (ONO) are now employed as trench dielectrics. They benefit from the

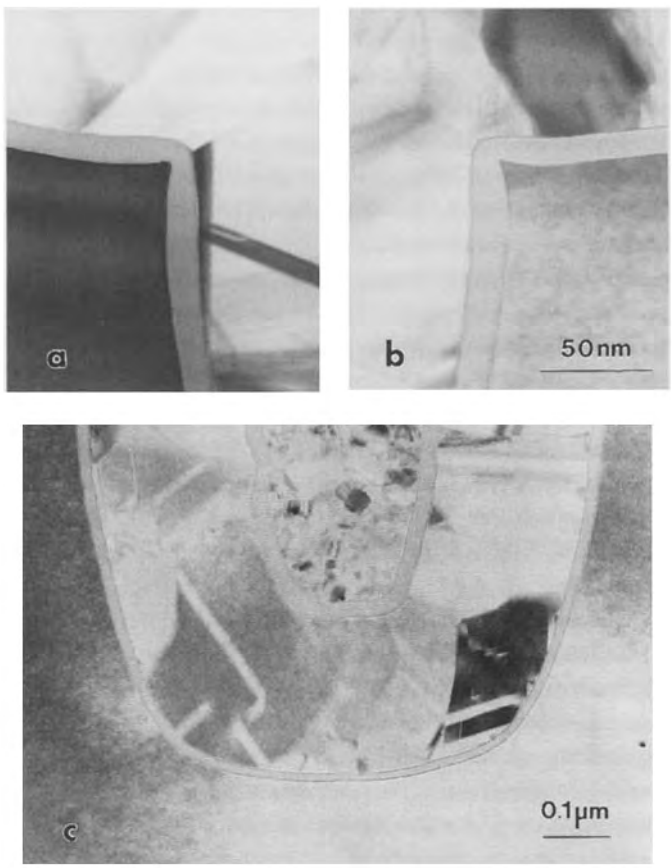

Figure 12. (a, b) Thinning of the thermally grown capacitor oxide at the top edges of a trench capacitor. (c) Cross-section of trench bottom. The center of the trench is filled with an additional thermal oxide and polysilicon.

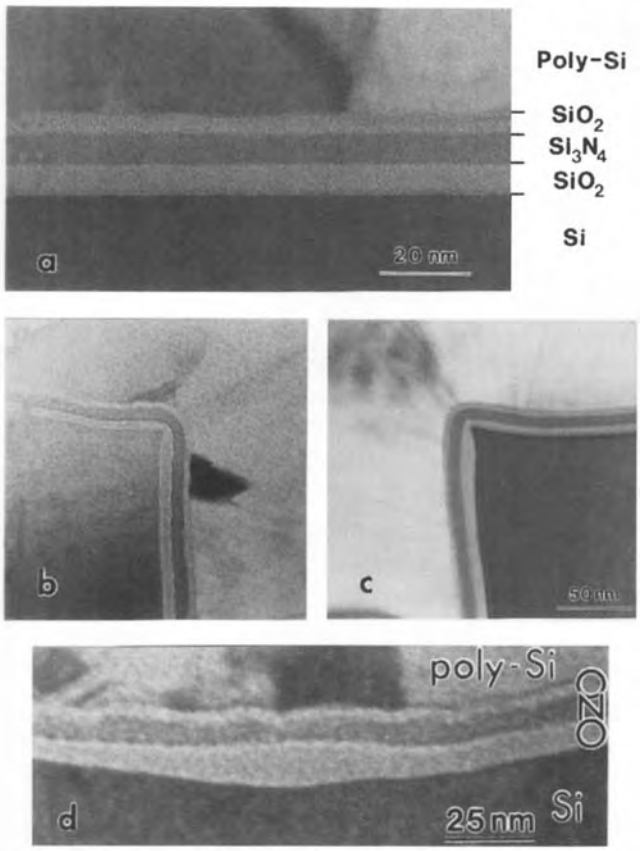

Figure 13. Bright field images of ONO triple layer dielectrics in the planar region (a) and at the upper trench edges (b, c). (d) Increased local oxidation of the bottom oxide at pores in the nitride layer.

fact that the nitride exhibits a higher dielectric constant ($\epsilon \approx 7$) as compared to SiO_2 ($\epsilon \approx 4$). Thus, reliable ONO dielectrics may be fabricated yielding the same capacitance as an effective ultrathin oxide. The oxide layers are needed to maintain well-defined Si–SiO_2 interface properties. The nitride of the ONO dielectric in Fig. 13a appears darker than the oxide layers because of its higher density resulting in enhanced scattering contrast. The configuration of an ONO dielectric at the upper edges of trenches is shown in Fig. 13b and c [36]. Again, the thermal bottom oxide is thinner at the edge. The nitride, in contrast, coats the edge with uniform thickness, because it was deposited from the vapor phase. The top oxide is best produced by thermal oxidation of the nitride. In this case, its thickness cannot be determined by ellipsometry, and TEM cross-sections represent the only means of measurement. The upper interface of the nitride layer is often slightly rough (Fig. 13d). This roughness is related to the nucleation of Si_3N_4 islands during the initial stage of deposition and may lead to the formation of pores in the nitride during oxidation. Since the oxidation rate of silicon is much higher than that of Si_3N_4, the bottom oxide tends to form lens-shaped areas at the pores (Fig. 13d) [39]. Besides the uniform step coverage of the nitride at the edges, this self-healing

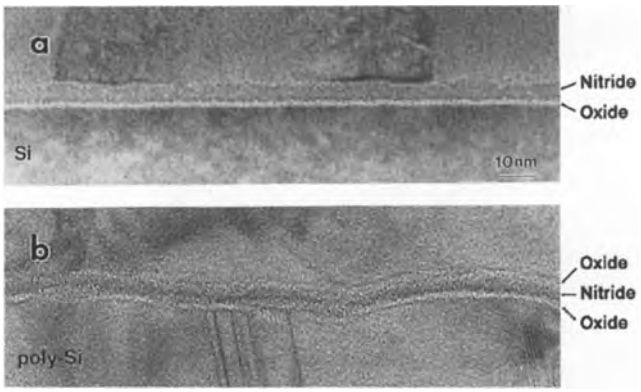

Figure 14. (a) Thin nitride/oxide layer on silicon substrate. (b) ONO layer on a rough polysilicon electrode.

effect, that is, the repair of local defects in the nitride during thermal oxidation, represents another advantage of ONO dielectrics.

For the capacitors in 16 Mbit and 64 Mbit DRAMs, progressively lower thicknesses of the dielectric are required. For the 64 Mbit DRAM, thicknesses will be as low as about 2 nm for the oxides and 5 nm for the nitride. Figure 14a shows an SiO_2–Si_3N_4 film on a silicon substrate. The nitride again shows a fine surface roughness. If such dielectrics lie between two polysilicon electrodes, the interfaces will not be planar, and TEM imaging in projection is only possible in limited regions (Fig. 14b) [39]. Recently, oxynitrides have drawn attention as possible gate dielectrics for submicrometer devices because they act as diffusion barriers for dopants from the polysilicon gate into the channel and have a low density of oxide charges and interface traps [40]. Future memory devices will employ novel perovskite-related materials, such as barium strontium titanate (BST) providing extremely high dielectric constants (up to 1000) or strontium bismuth tantalate (SBT) whose ferroelectric properties can be exploited for nonvolatile memory devices [41].

Using a high-intensity electron beam in the analysis of oxide and nitride layers may produce problems during TEM and also AES analysis. High-dose irradiation has shown that two effects occur with thermal oxides under the electron beam in the transmission electron microscope: (i) swelling of the oxide if there is no covering layer [42] and (ii) a thickness reduction if the oxide is covered by a polycrystalline silicon layer [43]. AES depth profiling of ONO layers with high electron current density leads to a pile-up of nitrogen at the Si–SiO_2 interface, whereas electron irradiation during TEM imaging of thin cross-sections induces nitrogen diffusion from the nitride layer to both Si–SiO_2 and polysilicon–SiO_2 interfaces [44]. Also ion beam milling may cause atomic mixing within the ONO layers [45].

3.3.2 Polysilicon and Metallizations

Modern CMOS circuits such as memory devices generally require three polysilicon levels for the gate and capacitor electrodes and for the first level of interconnections.

Since the conductivity of polysilicon is limited, primarily by the solubility limit of dopants in silicon, double layers of a refractory metal silicide and polysilicon—so-called polycides—are used for the gate and the first interconnection level. For additional interconnections, three or more metallization levels are required. Layers of aluminum alloys are used for this purpose, sandwiched between barrier layers, preventing interdiffusion at the contact interfaces and serving as anti-reflective coating for lithography. Since the conductivity of the interconnection layers depends strongly on their microstructure, and contact resistance is influenced by interface reactions, TEM cross-sections are used predominantly in the following to describe various materials effects.

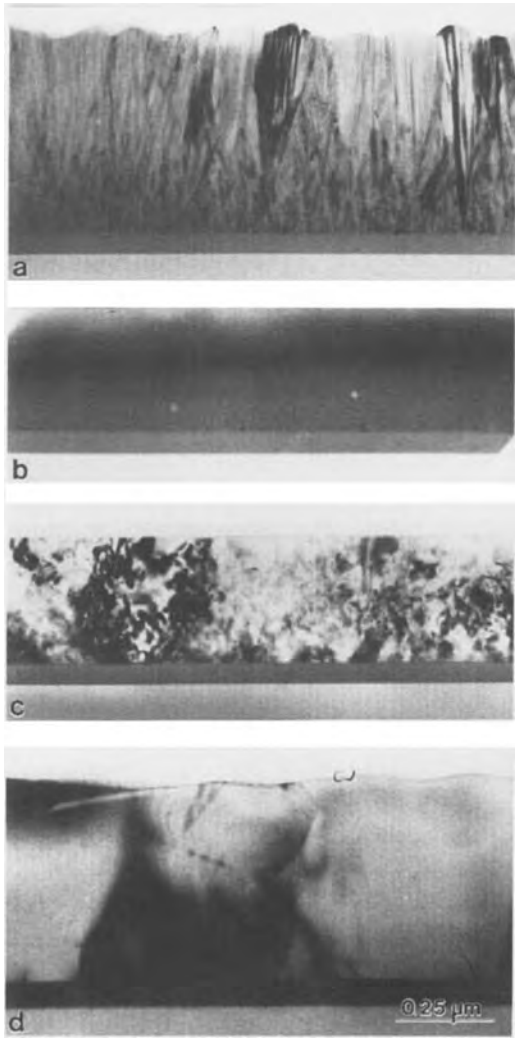

Figure 15. TEM cross-sections of polysilicon films deposited by LPCVD on SiO_2. (a) Crystalline deposition at 620°C. (b) Amorphous deposition at 560°C. (c) Crystallization during annealing (950°C) of an amorphously deposited film. (d) Grain growth due to high arsenic doping.

3.3.2.1 Polysilicon

Polycrystalline silicon (polysilicon) films are fabricated by LPCVD (low-pressure chemical vapor deposition) through the thermal decomposition of silane at temperatures between 550 and 630°C. Polysilicon technology is described in detail by Kamins [46]. The microstructure of polysilicon is strongly influenced by deposition and doping parameters; an overview is given by Cerva and Oppolzer [47]. Deposition at 620°C results in the growth of polycrystalline films (Fig. 15a) with a grain size of a few nanometers at the bottom interface. Conical grains start to grow at this interface with a cone angle of about 20°. Consequently, their grain diameter parallel to the film plane increases almost linearly from the bottom to the top interface and reaches about 120 nm at the top of a 0.5 µm thick film. The conical grains contain a high density of microtwins having a width of only a few nanometers. At the film surface, the microroughness of about 10 nm differences in height is determined by the grain structure,

with each grain forming a small hillock. Analysis by X-ray diffraction or RHEED (reflection high-energy electron diffraction) yields a preferred orientation of ⟨1 1 0⟩.

During deposition at 560°C, amorphous films are grown (Fig. 15b) with planar surfaces. At the bottom interface, small crystallites have nucleated. By an additional annealing step the amorphous film is crystallized which results in randomly oriented grains extending from the bottom to the top of the film (Fig. 15c). The film surface remains planar during crystallization. Since the silicon grains contain numerous microtwins the grain boundaries are not clearly visible in Fig. 15c, and grain size can best be determined by TEM dark-field images of plan view specimens. The shape of the grains is elliptical with the long axis parallel to a prominent microtwin running in the ⟨1 1 2⟩ direction. The growth of such grains may be explained by a specific mechanism [48]. Under standard annealing conditions of 800–900°C, crystallization takes place during heating up to the annealing temperature, since crystallization starts below 600°C. Therefore, the grain size depends on the process details, and larger grains grow at lower temperatures due to a reduced number of nuclei. Once crystallization is complete, no further grain growth occurs up to temperatures of about 1000°C. This almost holds also for polycrystalline deposited films: only the very small grains at the film bottom start to grow at 1000°C.

For application as gate or interconnect material the polysilicon films must be doped either by ion implantation, from the gas phase ($POCl_3$) or by the addition of doping gases during deposition (in situ doping). To obtain low sheet resistances, high doping levels up to the solubility limit (around $10^{20}\,cm^{-3}$) have to be applied. Boron doping has only a minor effect on the microstructure of polysilicon films. Large grains are only obtained by doping the amorphously deposited film prior to crystallization. Arsenic and phosphorus doping to produce highly n-doped polysilicon, on the other hand, causes strong grain growth, especially in polycrystalline deposited films. Grain growth stops when the grain size is of the order of the film thickness (Fig. 15d). All defects within the grains, that is, mostly the microtwins, disappear. When the doping level and/or the annealing temperature is not sufficiently high to cause pronounced grain growth the sheet resistance is especially sensitive to the microstructure, since the dopant atoms may segregate to the grain boundaries where their electrical activity is reduced. Strong segregation in combination with small grain size, that is, a large area of grain boundaries, results in unexpected high sheet resistances [49].

The segregation of arsenic to grain boundaries in highly arsenic-doped samples was measured directly by X-ray microanalysis in a scanning transmission electron microscope (STEM) equipped with a field emission gun [50, 51]. In a sample implanted with a dose of $2 \times 10^{16}\,cm^{-2}$ and annealed at 950°C for 30 min, arsenic profiles were recorded across grain boundaries which were parallel to the electron beam. Such a grain boundary is shown in Fig. 16a between A and B. The profile in Fig. 16b was obtained with a distance between the measurement points of 5 nm, and shows that the arsenic concentration is enhanced at the grain boundary by a factor of

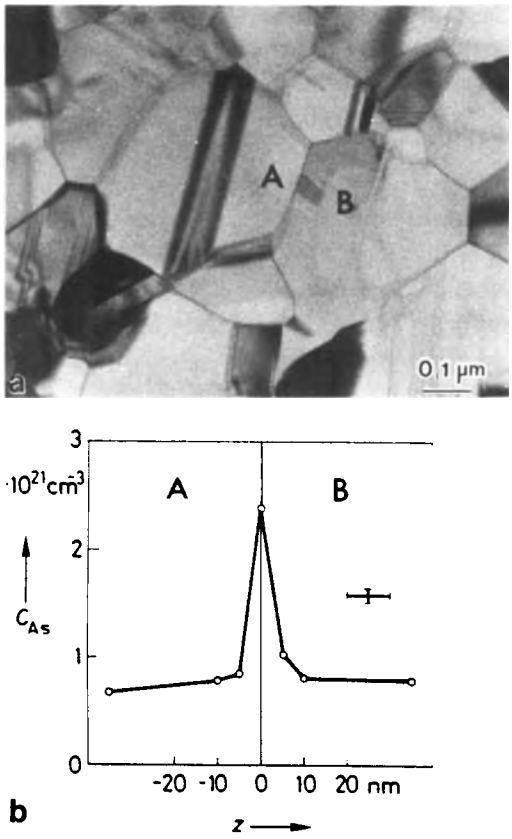

Figure 16. Arsenic segregation to grain boundaries in polysilicon. (a) Bright field image of the microstructure. (b) Arsenic concentration profile across the grain boundary between A and B in (a) measured by X-ray microanalysis with a 1 nm electron probe in a field emission STEM.

about 3. The arsenic concentration at 5 nm distance from the grain boundary is slightly higher than in the grain interior. Since this is due to beam spreading of the probing electron beam the width of the zone with increased arsenic concentration must be smaller than 5 nm, probably only a few monolayers [51]. The amount of arsenic atoms segregated to the grain boundaries was found to correspond approximately to one monolayer. From the grain size of 0.3 μm and the mean arsenic concentration of $8 \times 10^{20}\,cm^{-3}$, it follows that about 30% of the total arsenic atoms are segregated to the grain boundaries.

3.3.2.2 Refractory Metal Silicides

Double layers of polysilicon and silicides provide sheet resistances of only about one-tenth that of highly doped polysilicon single layers. The silicides of refractory metals such as titanium, molybdenum, tungsten, and tantalum have the advantage of being compatible with standard process technology: they are stable at temperatures as high as 900°C and are resistant to chemical wafer cleaning and etching solutions containing HF. The polysilicon is still needed along with the silicide, firstly because the well-defined interface with the SiO_2 is retained and secondly because it acts as a silicon source or drain during the annealing process, thus assuring reproducible manufacturing of stoichiometric disilicides. An overview on the application of silicides in silicon technology was given by Murarka [52].

The polycide of Fig. 17 contains a tantalum disilicide layer which appears dark due to increased scattering contrast caused by the high atomic number of tantalum. The polycide is shown after sputter deposition, annealing to form crystalline $TaSi_2$, and thermal oxidation. The roughness of the $TaSi_2$–polysilicon interface is determined by the globular shape of the $TaSi_2$ grains and indicates some interface reaction. During thermal oxidation an SiO_2 film grows on top of the polycide. Silicon diffusion through the $TaSi_2$ layer is so fast that it does not restrict the oxidation rate. The oxide film contains

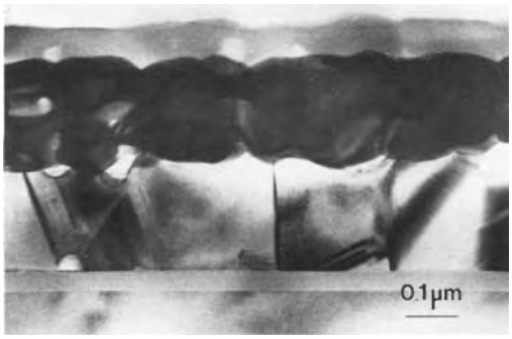

Figure 17. TEM cross-section of $TaSi_2$-polysilicon layer after thermal oxidation producing an SiO_2 layer on top.

numerous pores which are assumed to be responsible for the poor breakdown strength of such oxides as compared to SiO_2 on (1 0 0) silicon, like gate oxides [53].

In the case of a specific sputtering process for molybdenum silicide, a fine columnar structure was found in the amorphous material only at the steep sidewalls of contact holes (Fig. 18a) [39]. The bright lines represent low-density material forming channels with a honeycomb structure. If annealing (900°C) is performed in an oxidizing ambient, oxidation proceeds fast along the fine channels between the columns (Fig. 18b). The $MoSi_2$ no longer forms a continuous film, since the individual grains are surrounded by SiO_2. It is obvious that this effect, which does not occur in the planar film regions, increases the sheet resistance of such interconnections crossing contact holes or surface steps drastically. By changing the annealing conditions such that the initial annealing is performed in nitrogen, $MoSi_2$ films with a continuous microstructure and low sheet resistance were obtained.

In the 'salicide' process, a self-aligned silicide is grown in a contact hole, for example, without additional patterning

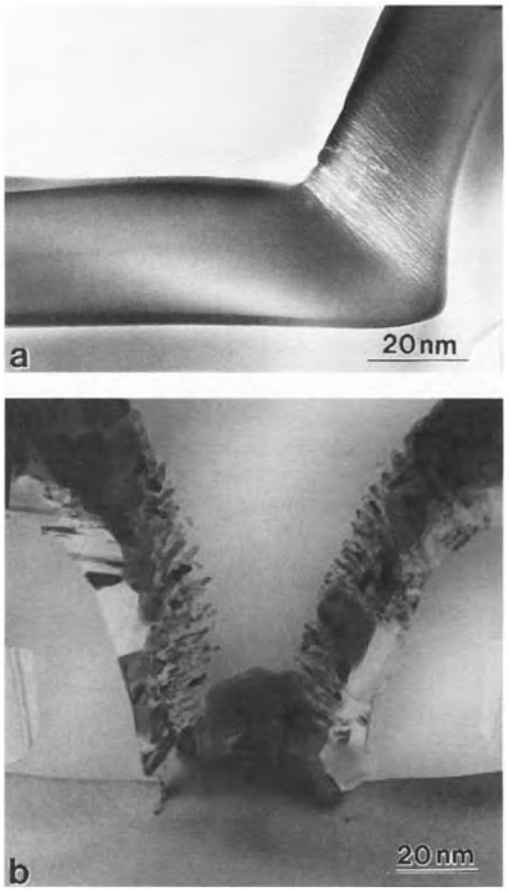

Figure 18. (a) Amorphous molybdenum silicide in a contact hole after sputtering. (b) Annealing (900°C) in an oxidizing ambient leads to a discontinuous $MoSi_2$ film at the sidewalls.

[52]. This process starts with depositing a thin metal layer on top of the patterned oxide on the silicon wafer. During annealing at a moderate temperature (<700°C), the metal reacts with the silicon substrate only in the oxide windows. When the metal which has not reacted is removed from the oxide by selective wet chemical etching, a silicide is left that has grown only in the oxide windows. Since the silicide–silicon interface was produced by a chemical reaction, it is free of contaminants and

has a low contact resistance. If the salicide process is applied to an MOS transistor structure in which the sidewalls of the polysilicon gate are masked by oxide spacers, a silicide is grown on the polysilicon at the same time as growth proceeds in the source/drain regions. As a result, sheet resistivity is reduced both in the polycide and in the source/drain regions. Figure 19a shows such a transistor structure with a titanium 'salicide'. Titanium silicide exhibits the highest thermal stability [52] but requires two-stage annealing. During the first step under a nitrogen atmosphere at a temperature below 700°C, the selective reaction produces the high-resistive C49 phase of $TiSi_2$. Following selective etching of the reacted TiN, the second annealing step is carried out at a higher temperature (e.g., 900°C) to form the low-resistive $TiSi_2$ of the desired phase (C54) [54].

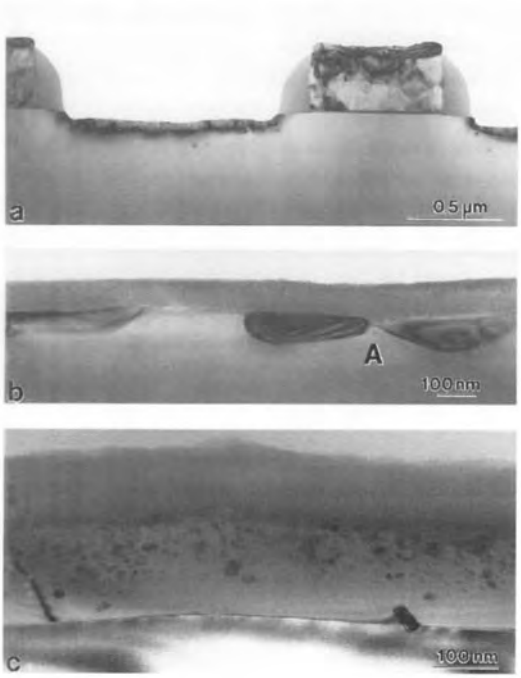

Figure 19. TEM cross-section of $TiSi_2$ films ('salicide' process). (a) MOS transitor with $TiSi_2$ on both the polysilicon gate and the source/drain regions. (b) Breaking up of $TiSi_2$ layer after high-temperature annealing. (c) TiB_2 precipitates at the interface to the substrate after boron implantation ($10^{16}\,cm^{-2}$) and annealing (950°C).

Prolonged annealing at 900°C, necessary for the reflow of borophosphosilicate glass (BPSG) to achieve planarization, however, increases the sheet resistance of $TiSi_2$ layers. This increase is due to morphological degradation of the $TiSi_2$ layers. Irregularities in film thickness due to nonuniform reaction are enhanced. Especially at grain boundaries the film thickness decreases strongly (at A in Fig. 19b) since the grains tend to form a globular shape in order to reduce their surface energy. In the end this process leads to breaking up of the silicide layer with the holes filled by epitaxially regrown silicon (Fig. 19b). A titanium salicide process with increased titanium thickness and an in situ cleaning step by back-sputtering prior to metal deposition proved to withstand the temperature of a BPSG reflow step (900°C for 40 min) without severe morphological degradation [55].

Apart from the decrease in sheet resistance, the contact resistance of $TiSi_2$ to highly doped silicon also increases during high-temperature treatment. This is due to a decrease in dopant concentration at the interface since the dopants diffuse from the silicon into the undoped silicide, where they are easily distributed because of their high diffusion coefficient in the silicide. Dopants in the silicides are also trapped by the formation of metal–dopant compounds. A detailed study [56] showed that in the case of boron doping, TiB_2 precipitates are formed at the interface (Fig. 19c). Their phase could be identified

by both lattice imaging (HREM) and X-ray diffraction after selective removal of the silicide leaving the precipitates at the surface. In the case of contacts to arsenic-doped silicon, TiAs precipitates are formed. To keep the increase in contact resistance at an acceptable low level, the thermal budget after silicide formation has to be minimized.

3.3.2.3 Aluminum Metallization

In the past aluminum–silicon alloys were the most widely used metallization system in silicon technology [52]. The addition of a weight fraction of about 1% silicon inhibits the dissolution of silicon from the substrate within the contact hole into the aluminum layer during annealing, a process that is usually carried out at temperatures around 450°C. The solid solubility of silicon in aluminum at 450°C is about 0.8% by weight fraction. If the silicon content is below the solubility limit because of local silicon depletion or excessive temperatures, interdiffusion takes place during contact sintering: silicon diffuses from the substrate into the aluminum and vice versa. A feature known as an aluminum spike then is formed in the contact hole. If all the technology layers are removed by etching, the spikes can be seen as pyramid-like pits in the silicon substrate (Fig. 20a). The formation of spikes results in pn junction leakage or shorting. On the other hand, the excess silicon in the Al (1% Si) metallization precipitates during cooling and forms silicon particles. Silicon precipitation may also take place in the contact hole, in which case the silicon grows epitaxially on the substrate. In Fig. 20b most of the

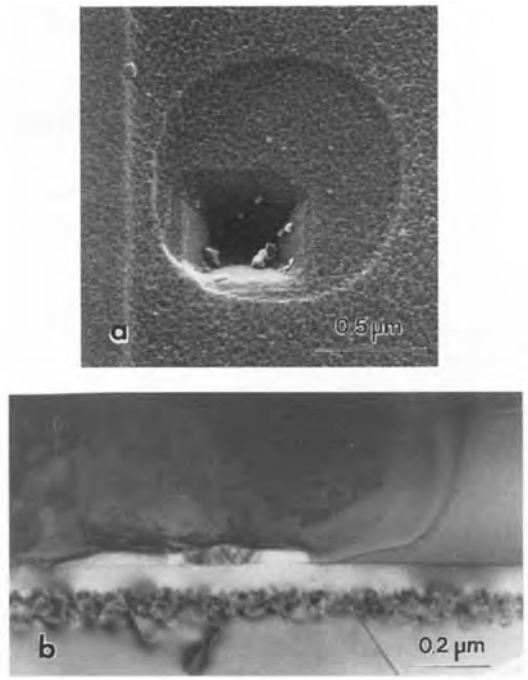

Figure 20. (a) Aluminum spike in a contact hole imaged in the SEM after etching off all device layers. (b) TEM cross-section of a contact hole with epitaxial silicon islands in an Al(1% Si) contact to the silicon substrate.

contact hole is covered by epitaxial silicon. The interfacial oxide layer is broken up into small oxide particles, which make the original interface show up weakly as a dark line. The epitaxial islands contain microtwins. Since the epitaxial silicon precipitates from the aluminum, it is p conductive and produces regions with nonohmic contact behavior for contacts to n-type silicon. The contact resistance of contacts to p-type silicon is increased. Both problems, spiking and epitaxial precipitation, can be overcome by barrier layers.

With shrinking device dimensions the width of both interconnect lines and contact holes decreases. The increased current density in narrower aluminum lines

enhances the risk of failure due to electromigration, that is, current-induced material transport leading eventually to the interruption of lines. Adding about 0.5% copper, for example, to aluminum minimizes this risk but requires the use of additional diffusion barriers, since copper contamination in the active device regions reduces the lifetime of charge carriers and generates crystal defects causing leakage currents. As mentioned above, diffusion barriers are also required to inhibit interdiffusion effects such as spiking and epitaxial regrowth, which are critical for small contact holes in particular. On account of its high thermal stability and good electrical conductivity, TiN is one of the best suited materials. To improve adhesion on SiO_2 and obtain a low contact resistance on p- and n-type silicon, a thin layer of pure titanium is deposited before the TiN. Both layers are deposited in one run with the TiN layer being produced by reactive sputtering from a titanium target in an $Ar–N_2$ gas atmosphere. The composition of the TiN_x layer is controlled by the $Ar–N_2$ flow ratio. Since only TiN_x layers with $x \approx 1$ exhibit favorable properties, their composition must be analyzed quantitatively with high accuracy. Based on calibration by RBS (Rutherford backscattering spectroscopy), this can be achieved by AES. AES with a small electron probe (<0.1 µm diameter) even allows local analysis of the TiN_x composition, for example at the sidewalls of contact holes.

For investigation of the thermal stability of the Ti–TiN barrier, specimens annealed at 450 and 550°C were examined by TEM (Fig. 21). The TiN has a pronounced columnar microstructure. Crystallites with a diameter of 5–10 nm extend almost throughout the entire film. The bright lines indicate voids or narrow regions of low density at the grain boundaries which, however, are probably 'stuffed' with oxygen due to exposure to air after film deposition. Auger analysis showed the TiN to indeed contain several

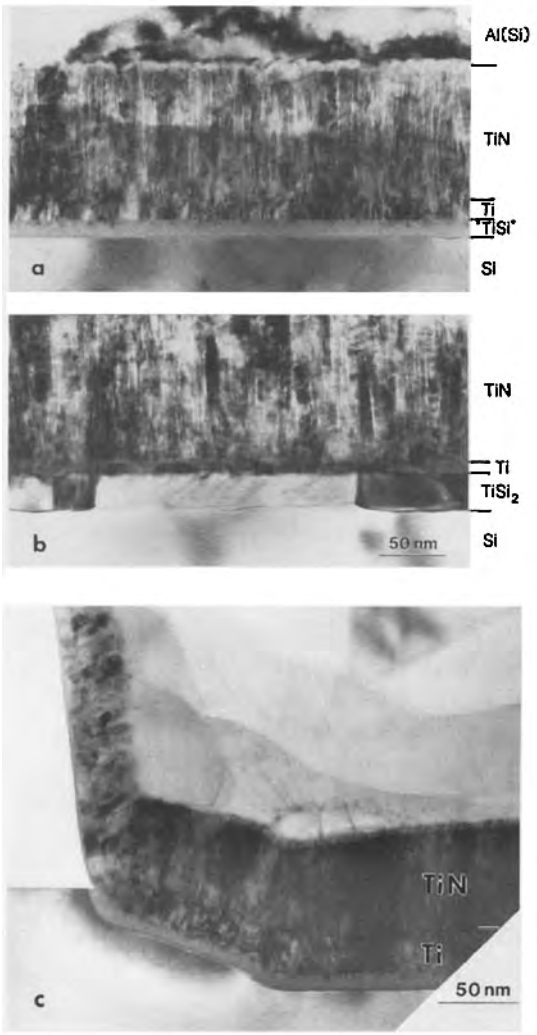

Figure 21. (a, b) Ti/TiN barrier layer between aluminum metallization and silicon substrate after annealing at 450°C (a) and 550°C (b). Ti/TiN layer at the bottom corner of a contact hole with reduced thicknesses, especially at the sidewall.

percent of oxygen. The titanium layer reacted with the silicon substrate in both specimens. Whereas the reaction zone is amorphous in the specimen annealed at 450°C (Fig. 21a), it is crystalline with grains some 100 nm in size after annealing at 550°C (Fig. 21b). The composition of this zone was measured by X-ray microanalysis of the thin cross-sections using a scanning transmission electron microscope equipped with a field emission gun. The measurements revealed that the amorphous layer has a composition close to TiSi, whereas the crystalline layer consists of $TiSi_2$ [36].

While the contact holes become smaller, the thickness of the insulating dielectric layers remains largely constant. Hence, small contact holes have a high aspect ratio, defined as the ratio of depth to diameter. To ensure reliable contacts, a certain step coverage much be achieved during deposition of the metallization. Step coverage is the ratio of layer thickness on a vertical sidewall to the nominal layer thickness, and is a function of the aspect ratio and the deposition process. Sputter deposition suffers from shadowing effects that reduce film thickness at the bottom and on the sidewalls of the contact hole. Figure 21c shows a Ti–TiN barrier at the bottom corner of a small contact hole. The titanium and TiN thicknesses of 50 and 100 nm besides the contact are reduced to 8 and 23 nm at the sidewall, and 11 and 28 nm at the bottom of the hole, respectively, not taking into account the amorphous reaction zones. At the sidewall the TiN layer can be distinguished from the titanium by its columnar microstructure. Besides this poor step coverage, the detailed shape of the sidewall is critical since protruding parts, such as of an additional nitride layer, lead to interruptions of the barrier and possibly allow direct contact between the aluminum alloy and silicon. Collimated sputtering of TiN increases the barrier thickness at the bottom of the contact hole, and CVD deposition provides uniform coverage.

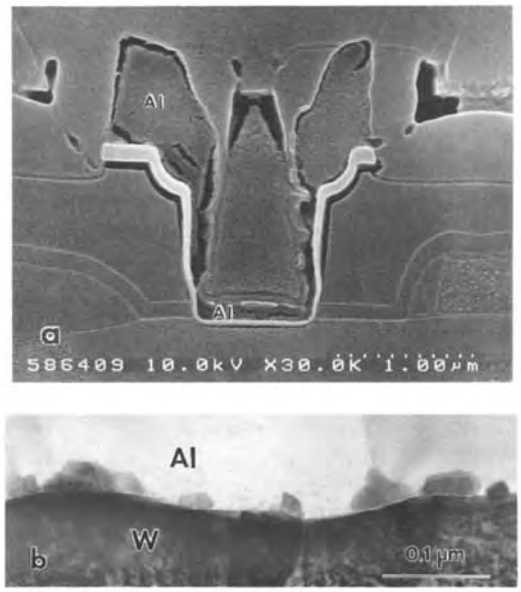

Figure 22. (a) SEM cross-section of a contact hole showing poor step coverage of the aluminum film. (b) Grains of the additional phase $W(Si,Al)_2$ at the tungsten–aluminum interface.

Also, the sputter deposition of the aluminum metallizations suffers from poor step coverage. The SEM cross-section of Fig. 22a shows that the aluminum thickness of 0.8 µm outside of the contact hole is reduced to only 0.1 µm in the contact hole bottom. At the sidewalls the thickness is locally even lower. When the step coverage becomes unacceptably low, the problem can be solved by a different approach, that is, filling the contact holes with tungsten plugs. This requires a two-stage process. First, tungsten is deposited uniformly by CVD on the patterned wafer covered by

a Ti–TiN barrier layer. Second, the tungsten in the planar regions is etched back until the etch-back stops at the TiN layer. When the tungsten film thickness is sufficiently high, the contact holes remain well filled by tungsten after the etch-back. Such tungsten plugs are used for both contacts to silicon and for 'vias', that are contacts between different aluminum metallization levels. In Fig. 1 such a tungsten plug can be seen between two gates, appearing as a bright needle because of its high atomic number. At the interface between tungsten and an AlSiCu metallization (1% Si and 0.5% Cu) a reaction was observed after annealing at 450°C [57]. Grains of an additional phase are formed at the interface within the AlSiCu layer (Fig. 22b). These grains—about 30 nm in size—were identified by microdiffraction in the transmission electron microscope to consist of hexagonal $W(Si,Al)_2$. No detrimental effect on contact resistance, however, was observed.

3.3.3. Lithography and Etching

In combination with the fabrication of dielectric and conductive layers and forming the active device areas by doping, generation of the device patterns is the main task in IC manufacturing. Patterning comprises both the generation of a resist pattern on the wafer by optical lithography and transferring this pattern into the underlying layer by an etching process. During fabrication of ICs, patterning is performed many times for the various regions and layers such as implantation regions, contact windows, interconnections, and so forth. In lithography the photoresist is exposed with the pattern of the mask using a projection system reducing the mask (reticle) size by a factor of usually 5. The whole wafer is exposed in a 'stepping' procedure. After development the resist pattern resembles that of the mask (reticle) for a positive resist. Using deep ultraviolet light, optical lithography is able to generate patterns with dimensions below 0.2 μm and therefore will dominate in the near future. Dry etching is predominantly employed for pattern transfer since its high anisotropy produces steep sidewalls. The proper choice of reactive ions in combination with optimized etching parameters provides high selectivity when the plasma-assisted etching process reaches the underlying material.

To solve specific problems during the development of lithography or etching processes, the detailed information provided by cross-sections is frequently necessary to measure features, such as step coverages or the exact shape and angle of sidewalls. Since the preparation of cross-sections by cleavage fracture or polishing destroys the processed wafer, this type of SEM characterization is performed outside the fabrication line. The detailed procedures, such as slight selective etching of the cross-sections to obtain a better contrast between the various layers, are identical to those used in failure analysis, and will be discussed in Sec. 3.4.2 of this Chapter. Process control of lithographic and etching processes, however, requires nondestructive assessment within the fabrication line with a short turnaround time. This topic will be discussed separately in Sec. 3.4.1 of this Chapter.

After reactive ion etching (RIE), residual surface films can be formed on both the sidewalls and at the bottom of contact

holes. During RIE of a $TaSi_2$–polysilicon (polycide) layer using chlorine-based chemicals a film of about 20 nm thickness was found at the sidewalls [58]. Anisotropic etching during RIE is assumed to be due to protective polymer films at the sidewalls stemming from residues of the photoresist. Cross-sectional TEM and AES, however, showed this film to consist of SiO_2 sputtered from the oxide lying under the etched polycide. Sputtering of the oxide takes place after the polycide is etched through.

After etching of contact holes in CVD oxides, thin insulating layers may be present at the bottom of the contact holes, degrading the contact resistance seriously. Figure 23a shows a TEM cross-section of an aluminum contact to polysilicon. A thin layer of about 5 nm thickness is clearly seen between the silicon substrate and the polysilicon (Fig. 23b). From the very high resistance of this contact the layer was assumed to consist of SiO_2. Because RIE is assisted by ion bombardment, a considerable amount of lattice damage is introduced in the underlying material once the contact hole is etched through, and native oxide growth is enhanced when the etched wafer is brought back into the air. To avoid excessive oxide growth, the etching process must be optimized by appropriate post-treatment steps in order to remove the damage zone without introducing new damage. During RIE process development the thickness of the thin oxide layer at the bottom of contact holes had to be determined with a short turnaround time. Since cross-sectional TEM is too elaborate for this purpose, a method was developed [59] based on AES which provides both sufficient lateral resolution and surface

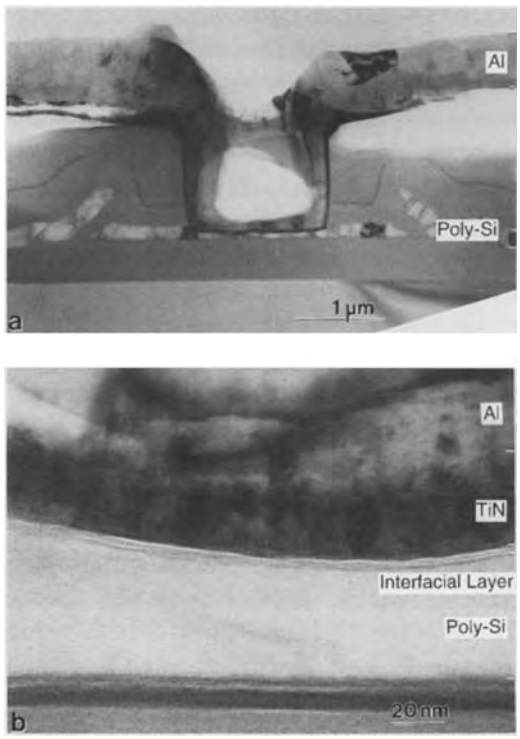

Figure 23. (a) TEM cross-section through an aluminum contact with high contact resistance to a polysilicon interconnection. (b) Higher magnification of the contact region revealing a 5 nm thick interfacial layer.

sensitivity. Application of AES to this problem of contact holes, however, is not straightforward. Conventional sputter depth profiling cannot be applied in such narrow holes because material sputtered off from the sidewalls will be redeposited at the bottom. To avoid any sputtering, the Auger electron lineshape was utilized to monitor the film thickness, which was below 10 nm. The peak shapes of the silicon KLL Auger transitions differ in a characteristic way between elemental and oxidized silicon (Fig. 24a and b). Since the Auger spectrum of the contact hole is a superposition of the spectra from bulk silicon and SiO_2, it can be fitted with the

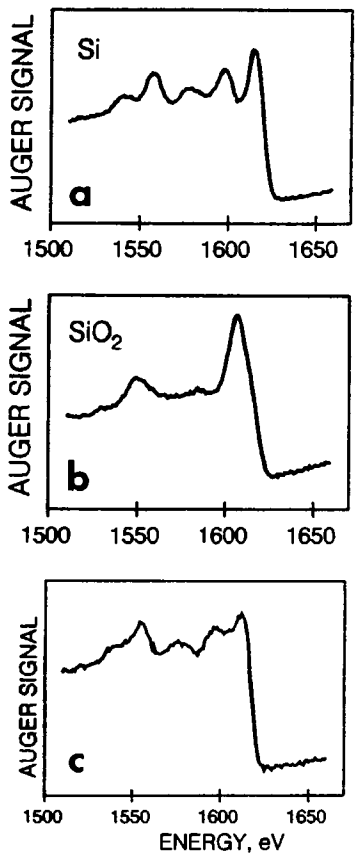

Figure 24. (a, b) Auger spectra (silicon KLL transition) of silicon and SiO_2. (c) Auger spectrum of a thin oxide film in a contact hole representing a superposition of spectra (a) and (b).

respective reference spectra. The oxide thickness follows from the fitting parameters [59]. Figure 24c shows the spectrum from a thin oxide film in a contact hole, the thickness of which was determined to be 1.7 nm. Process optimization resulted in a reduction of the oxide thickness to a level of the native oxide which is not critical for contact failure. Shadowing of the Auger electrons emitted from the bottom of the contact hole by the sidewalls, however, restricts this method to contact holes with an aspect ratio of about 1. For higher aspect ratios, appropriate sample preparation is necessary, for example, by cleavage fracture through the holes.

3.3.4 Doping

To produce the active device areas, dopant atoms have to be introduced into the silicon substrate within selected regions defined by a mask. Compared to diffusion from the gas phase or doped-oxide sources, the most commonly used method of doping is ion implantation with boron for p doping and arsenic or phosphorus for n doping. Ion implantation allows the doping depth and concentration to be varied within wide limits by selecting the acceleration voltage and the dose. The wells for CMOS devices, for example, are only lightly doped ($\sim 10^{16}\,cm^{-3}$) and may extend up to several micrometers into the substrate. Highly doped regions ($>10^{19}\,cm^{-3}$) with pn junctions below 100 nm depth are required for the source and drain regions of MOS transistors or the emitter of bipolar transistors, for example. Since the nuclear collisions that occur during implantation damage the crystal lattice, the defects produced by this damage have to be annealed by heat treatment. Only after annealing are the dopant atoms located on substitutional sites and electrically active. Characterization of the lattice damage after ion implantation and of the residual defects after annealing will be discussed in Sec. 3.3.5 of this Chapter on process-induced defects. Since the electrical device parameters depend critically on the depth distribution of the dopant atoms, the dopant depth profiles have to be accurately

measured by SIMS. SIMS is the method of choice since it combines sufficient sensitivity (down to dopant concentrations of $10^{14}\,cm^{-3}$) with good depth resolution (down to <10 nm). An introduction to SIMS can be found in Fuchs et al. [5], and a more detailed description in Benninghoven et al. [60].

SIMS profiles are usually measured on test patterns, for example $100 \times 100\,\mu m$ in size. Although the primary ion beam is scanned across the silicon surface to provide uniform erosion, no lateral information is required in general. In specific cases, however, SIMS profiles have to be measured within actual device structures. This calls for spatially resolved SIMS (micro-area SIMS). As an example, the analysis of the dopant depth profile at the sidewalls of trench capacitors in 4 Mbit DRAMs [61] will be discussed. One electrode of this capacitor is formed by highly n-doped polysilicon and the other by the wall of the trench doped by diffusion from a CVD oxide which contains arsenic. Since systematic differences were observed between the capacity of the trench cells and analogous planar structures, indicating geometrical influences of the CVD process, it was important to determine the actual dopant depth distribution at the sidewalls of the trenches directly. For this purpose cross-sections were prepared (Fig. 25a) and analyzed by micro-area SIMS with a primary ion beam diameter of only 0.3 μm. To obtain high sensitivity the 'useful ion yield', that is, the ratio of detected ions and the atoms sputtered from the sample, must be optimized. In this case of arsenic in silicon an optimum useful yield of 2×10^{-2} was found for $AsSi^-$ secondary ions under cesium bombardment. During each scan of the

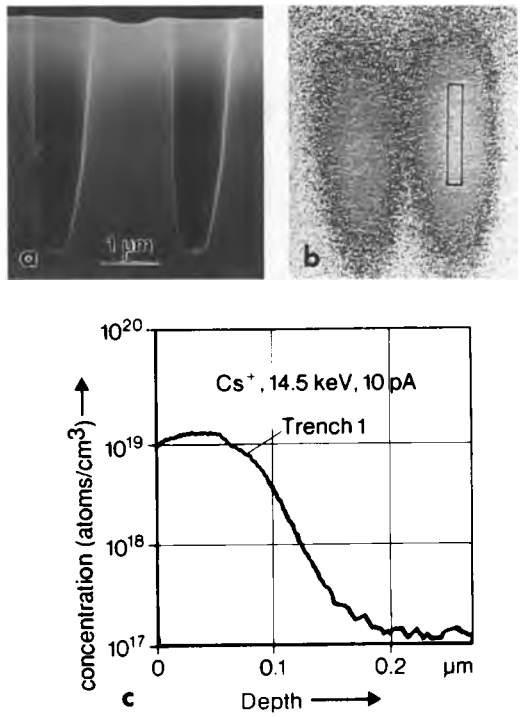

Figure 25. Micro-area SIMS of the arsenic depth profile at the sidewalls of trench capacitors in a 4 Mbit DRAM. (a) SEM image of a cross-section through two trenches. (b) Arsenic distribution using the $AsSi^-$ signal. (c) Arsenic depth profile from the selected area indicated in (b).

analyzed area the intensity of the $AsSi^-$ ions was stored in a digital image storage system, allowing the area of interest to be selected retrospectively from the stored data. The area that contributes to the profile can thus be optimally matched to the size of the trench wall. Figure 25b shows such an $AsSi^-$ image with the area selected for the profile. The resulting dopant profile is shown in Fig. 25c. Despite the high efficiency for secondary ion detection of the SIMS system used, only a limited number of dopant atoms are available in the analyzed microvolume. This restricts the detection limit to about $10^{17}\,cm^{-3}$ in this case. Compared to planar

structures, both maximum concentration and the dose (total area below the curve) of arsenic were found to be lower at the trench sidewall. This difference was thought to be due to the oxide acting as a diffusion source being thicker on the planar surface than in the trench.

With decreasing device dimensions the lateral extension of dopants below mask edges is becoming more important, calling for an accurate determination of 2D dopant profiles with a resolution of 10–50 nm and a sensitivity range of 10^{16}–$10^{21}\,cm^{-3}$. This places serious demands on techniques to be applied to the characterization of 2D profiles. The easiest way to obtain 2D information of doped regions is selective (concentration-dependent) etching of vertical cross-sections and imaging of the etched surface topography by SEM, TEM, or STM, and AFM. SEM cross-sections are most widely used for technology characterization, and selective etching in addition provides junction delineation. Most etching solutions are mixtures of HNO_3, which oxidizes silicon, and HF, which removes the oxide. The addition of acetic acid controls the etch rate. The cross-section of an MOS transistor structure in Fig. 26a was etched in a solution of 0.5% HF in HNO_3. The highly arsenic-doped source and drain regions are preferentially etched and are bordered by a sharp contour because of the steep concentration gradient typical for arsenic depth profiles. This contour represents an isoconcentration line, and by comparison to SIMS profiles was found to correspond to a concentration of about $10^{19}\,cm^{-3}$ when applied to TEM cross-sections [62]. The contours reach about 100 nm underneath the oxide spacers on both sides of the gate. The so-called lightly doped drain

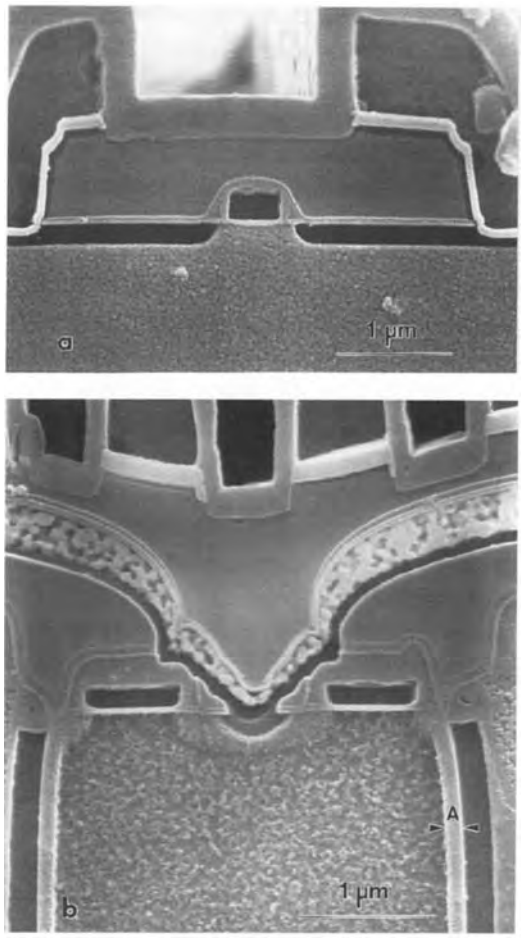

Figure 26. Delineation of pn junctions by selective etching of SEM cross-sections. (a) Highly arsenic doped source/drain regions of MOS transistor. (b) Bit line contact in a 16 Mbit DRAM.

(LDD) and source regions, which extend from the highly doped regions just below the gate, were not delineated. Since their maximum concentration is typically below $10^{18}\,cm^{-3}$ they were not attacked by this chemical etch. Figure 26b shows an SEM cross-section of the bit line contact of a 16 Mbit DRAM etched in a solution of 2% HF in HNO_3. The bit line consists of a polycide, the n-doped polysilicon of which is strongly etched and therefore appears

dark due to reduced secondary electron (SE) collection from regions lying deeper than the other surface. The highly arsenic doped contact region in the silicon substrate is also strongly etched. The source and drain regions extending from the bit line contact to the gates on both sides can be identified since they are attacked less than the silicon substrate despite higher doping. On the far side of both gates the doped sidewalls of the trench (region between the two arrows at A in Fig. 26b) are visible because of the same etching behavior. The highly n-doped polysilicon within the trenches is strongly attacked, similar to the gates. No quantitative comparison with SIMS profiles was made in this case. In Fig. 26a only one isoconcentration line was delineated. Other etching solutions yield up to three different isoconcentration lines for boron which can be quantified by SIMS [63].

When TEM cross-sections are selectively etched, these specimens are attacked from both sides. The solution of only 0.5% HF in HNO_3 [62] exhibits a reduced etching rate at 5°C [64]. When imaged in bright field under two-beam conditions, thickness fringes appear in the preferentially etched regions. They mark lines of equal specimen thickness and correspond to isoconcentration lines, provided the specimen has uniform thickness after ion milling prior to etching. In Fig. 27 five thickness fringes may clearly be discerned. The n-doped region was produced by arsenic implantation at an energy of 50 keV and a dose of $5 \times 10^{15}\,cm^{-2}$, followed by annealing at 900°C for 1 h [65]. Comparison with the SIMS depth profile showed the deepest thickness fringe to correspond to a concentration of about $5 \times 10^{17}\,cm^{-3}$. The contours corresponding to concentrations

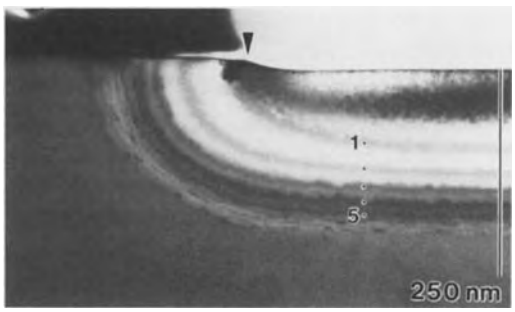

Figure 27. Thickness fringes in the n^+-doped region of a selectively etched TEM cross-section.

of 10^{19} and $10^{18}\,cm^{-3}$ at depths of 160 and 215 nm, respectively, were found to extend laterally 100 and 130 nm beyond the mask edge. The ratios of lateral extension and vertical depth are 0.63 and 0.61, respectively. Since the reproducibility of selective etching is limited, the accuracy and quantification of this method are restricted, and reference to SIMS profiles is necessary. Furthermore, when selective etching is applied to SEM cross-sections of actual device structures, identical transistors may yield different results if they are connected to different parts of the circuit having, for example, different capacities.

Various other microscopic techniques have been applied to characterize 2D dopant profiles [66], and were reviewed by Diebold et al. [67]. STM allows delineation of pn junctions by detecting differences in the tunneling characteristics for p-type and n-type semiconductor material [68]. Since the tunneling current depends on the Fermi level rather than on the carrier concentration, the application of this approach for profiling is restricted. Recently, a sharp conductive AFM tip was used to perform local resistance measurements between the tip and the back contact of the sample. When the tip is

scanned across a vertical cross-section the lateral carrier distribution can be determined [69], extending spreading resistance profiling (SRP) to nano-SRP. A metallized probe tip can also be used for scanning capacitance microscopy (SCM) when the tip is brought in contact with the oxidized semiconductor surface. The resulting MOS capacitance varies with carrier concentration. Recently, by calibration with SIMS, SCM was successfully applied to measure a 2D dopant profile quantitatively [70].

In the scanning electron microscope pn junctions can also be delineated by using the electron beam-induced current (EBIC) as a signal for imaging. When the electron beam strikes a pn junction the holes and electrons generated by the primary electrons are separated by the electric field of the pn junction, and a charge collection current, that is, the EBIC signal, can be recorded in a closed circuit. Only the minority charge carriers diffusing to the pn junction contribute to the EBIC signal when the electron beam generates electrons and holes at some distance from the junction. Therefore, the pn junction appears as a bright line, and its 2D shape is displayed directly when a cross-section is imaged. In the cross-section of a bipolar transistor in Fig. 28 all pn junctions between emitter (E), base (B), collector (C), and substrate (S) are visible [71]. In asymmetrically doped junctions (n^+p or p^+n) the EBIC maximum deviates considerably from the location of the junction. In addition, the finite size of the generation volume for charge carriers, which depends on the primary electron energy, limits the resolution of this method to above 0.1 μm. An introduction to junction delineation by EBIC is given by Fuchs et al. [5], and a more detailed review, also covering other applications of EBIC, by Leamy [72].

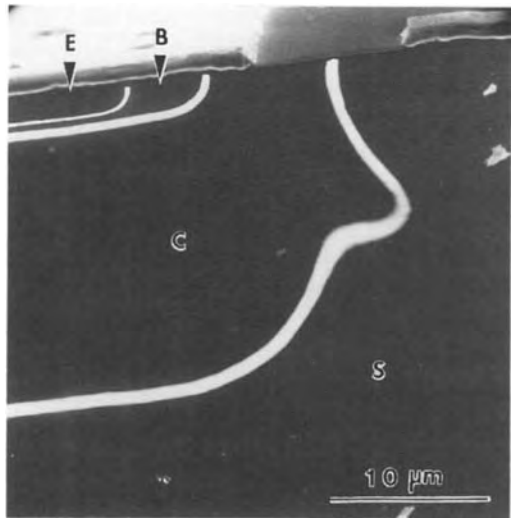

Figure 28. EBIC image (superimposed on SE image) of an integrated bipolar transistor showing all pn junctions between emitter (E), base (B), collector (C), and substrate (S).

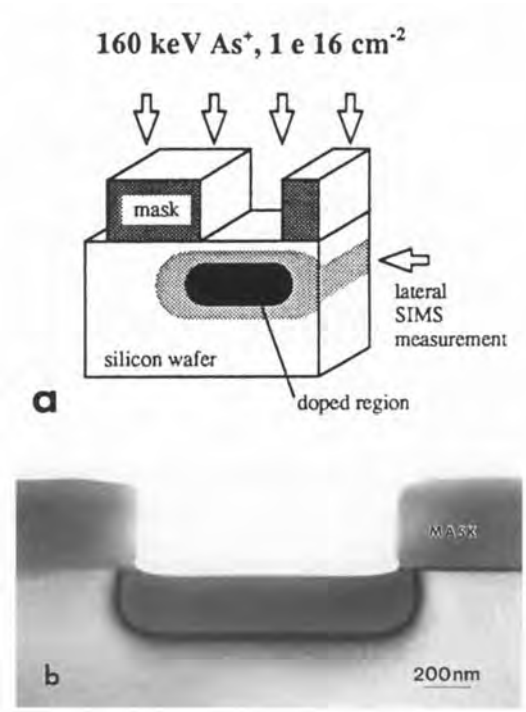
The resolution and sensitivity of SIMS are not sufficient to measure the true 2D dopant distribution on a vertical cross-section directly. The lateral extension of doped regions underneath a mask edge, however, can be measured by SIMS, when a vertical cross-section parallel to the mask edge is analyzed as shown in Fig. 29a [73]. By selecting only the narrow, doped zone at the wafer surface for micro-area SIMS, the lateral dose distribution of the dopant atoms is measured with high lateral resolution. In this 'lateral SIMS' method the high lateral resolution is achieved by the good depth resolution (typically 10 nm) of SIMS profiling. Figure 29b shows the TEM cross-section of a test structure studied by lateral SIMS. A pattern of oxide stripes was implanted with 160 keV As^+ ions ($10^{16}\,cm^{-2}$ dose). The zone

amorphized by arsenic implantation appears dark (see Sec. 3.3.5). The lateral dopant distribution after ion implantation as measured by lateral SIMS is shown in Fig. 29c [74]. At a distance of about 50 nm from the mask edge, a maximum in the dose distribution is observed. To support the experimental results, Monte Carlo simulations of the implantation process were performed, taking into account the precise shape of the mask edge as displayed in Fig. 29b. The very good agreement is evident. The maximum in the dose distribution stems from ions which were implanted into the mask close to its edge but after several scattering events could leave the mask through the sidewall and reach the silicon substrate [74].



3.3.5 Process-Induced Defects

Crystallographic defects such as dislocations, stacking faults, and precipitates may form during particular steps in device processing, and have a direct influence on device performance and yield. Several reviews with a strong emphasis on TEM have been published [75–79]. There are several sources for defect generation in the various technology processes, and mutual interaction of the sources is possible.

Figure 29. 'Lateral-SIMS' method. (a) Principle: micro-area SIMS measurement on vertical cross-section. (b) TEM cross-section of test structure with oxide stripes and amorphized implanted regions. (c) Lateral dopant distribution with respect to mask edge.

3.3.5.1 Thermal Stresses

During high-temperature processes in a furnace the silicon wafers are positioned in a row with constant spacings. This leads to large radial temperature gradients between the wafer center and periphery because heat is dissipated differently during the cooling down procedure [75]. The temperature gradient increases with increasing wafer diameter, cooling rate, and furnace temperature. The stresses are highest at the wafer edge and cause dislocation generation when the stress exceeds the critical resolved shear stress. Generation of dislocations strongly depends on the availability of nucleation sources (e.g., microscratches, film edges, and precipitates). Impurities such as dissolved oxygen reduce the mobility of dislocations and impair their propagation. Precipitation of oxygen drastically reduces the yield strength and the critical resolved shear stress [75]. Hence, high-temperature steps after precipitation which cause large temperature gradients should not be applied. The stresses due to temperature gradients may be avoided by slowly inserting and withdrawing the wafers into/from the furnace at moderate temperatures (ramping procedures). Moreover, a minimum of grown-in bulk microdefects, or doping the silicon with nitrogen, reduces the generation of dislocations. X-ray topography allows nondestructive imaging of the distribution of stress-induced dislocations such as glide bands across the entire wafer.

3.3.5.2 Metal Precipitates

Heavy metals may contaminate the silicon wafer during processes such as wet cleans, dry etching, ion implantation, and furnace annealings, and through wafer handling and transport [80]. In particular iron, nickel, and copper are fast diffusers in silicon and have a relatively high solubility which declines steeply with decreasing temperature. Therefore, metal contamination on the wafer surface is dissolved at high temperatures and distributed in the silicon lattice. Upon cooling the metals precipitate as metal silicides when their concentration exceeds the solid solubility. Pre-existing defects—such as oxidation-induced stacking faults or implantation damage—and the $Si–SiO_2$ interface can act as heterogeneous nucleation sites for the precipitates, and dislocations may become decorated and electrically active. Precipitates at the gate oxide or the capacitor oxide reduce the dielectric breakdown field [81]. TEM investigations on intentionally contaminated silicon wafers revealed the different precipitation behaviors of copper and nickel and thus can explain their different impacts on oxide integrity [82, 83]. Nickel precipitates coherently as $NiSi_2$ with the CaF_2 structure, causing almost no volume expansion in the silicon lattice. Figure 30a shows a thin and long $NiSi_2$ platelet at the $Si–SiO_2$ interface penetrating into the oxide only slightly. The enlarged view in the high-resolution image (Fig. 30b) reveals that the $NiSi_2$ lattice is in a twin orientation to the silicon lattice and the $NiSi_2–Si–SiO_2$ interface exhibits notches. The cusp of the $NiSi_2$ platelet might alter the strength of the electric field across the oxide and lead to oxide failure. Copper silicides reduce the oxide breakdown field much more strongly than $NiSi_2$ [81]. According to structural and EDX analysis in TEM, copper silicide precipitates are

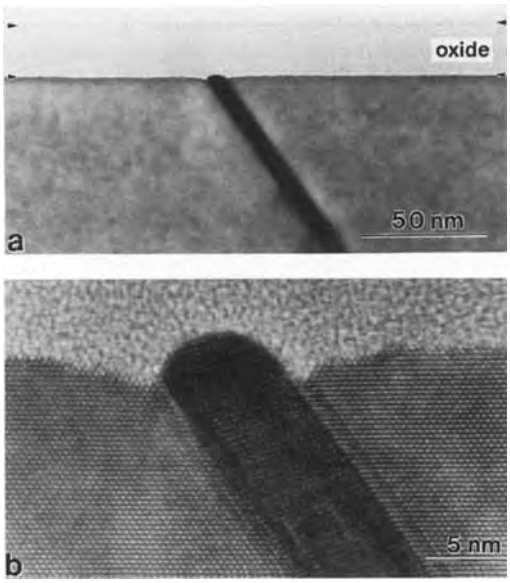


Figure 30. Precipitation of a $NiSi_2$-micrometer-platelet at the (1 0 0)Si-SiO_2 interface. (a) Bright field image of the top portion of a several-micrometer-long precipitate lying on a {1 1 1} plane. (b) HREM image of the top of the precipitate penetrating the oxide layer only slightly.

reported to be copper-rich [82, 84]. In any case, the volume required by the copper silicide precipitate contains a lower silicon concentration than the same silicon volume. Hence, copper silicide precipitation causes volume expansion and is accompanied by silicon interstitial emission or vacancy absorption. Figure 31a shows a copper silicide precipitate at the Si–SiO_2 interface. The oxide layer on top of the precipitate is clearly bent upwards with the reduction in oxide thickness being negligible. If there is, however, a polysilicon layer on top of the oxide, clear oxide thinning occurs (Fig. 31b). The copper silicide precipitates penetrate into the oxide, and the released silicon interstitials grow epitaxially at the silicon interface in between the precipitates. The arrows in Fig. 31b indicate the silicon regions which lie clearly above the original Si–SiO_2 interface.

3.3.5.3 Stress Fields Induced by Film Edges and Silicon Trenches

The silicon surface is exposed to local stress fields induced by (a) edges of patterned thin films, (b) the oxidation of nonplanar silicon surfaces such as convex and concave trench edges, or (c) filling a trench in the silicon substrate with a material exerting an intrinsic or thermal stress. A review of stress-related problems in silicon technology is given by Hu [38]. Thin films exhibit intrinsic stress due to

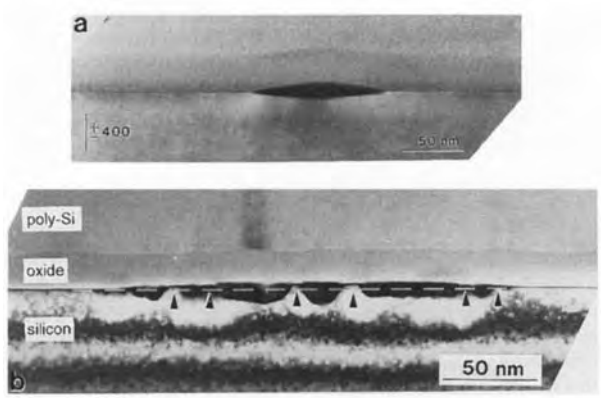

Figure 31. Precipitation of copper-silicide at the (1 0 0)Si-SiO_2 interface. (a) The precipitate bends up the oxide layer. (b) Thinning of the oxide layer by the precipitates in the case of a polysilicon top layer.

their particular microstructure, which is characteristic of the deposition process and the material. Stress in thin films also arises due to the difference in thermal expansion coefficients of the film and substrate. Stress in uniform planar films causes wafer bending. After patterning, however, local stress fields arise at the film edges which may surpass the critical yield stress for dislocation generation. Typical examples are thin Si_3N_4 layers which are used as diffusion barriers for oxygen or as an auxiliary layer acting as a selective etch stop in, for example, contact etching. The local oxidation of silicon (LOCOS) process, which is used to isolate different device areas, uses a nitride layer as a mask, with oxide growth occurring in the mask windows. Due to lateral oxidation below the nitride edge the LOCOS edge assumes the form of a wedge or a 'bird's beak', which causes the nitride mask to bend upwards. If the nitride layer thickness as well as the temperature, time, and ambient atmosphere for oxidation are not chosen carefully, dislocations are generated which glide deeply into the silicon substrate. Detailed TEM work on the dislocation type and their configuration with respect to the nitride edge position is described by Vanhellemont and coworkers [85, 86]. Another example is the dislocation generation in the salicide process (see Sec. 3.3.2 of this Chapter) at the edge of the $TiSi_2$ layer when it exceeds a critical thickness [87].

Silicon trenches are used for device isolation when filled with oxide, or as trench capacitors, and for vertical MOS transistors when covered with a thin dielectric and a highly doped polysilicon layer. Stress fields at concave and convex trench edges develop during thermal oxidation or are generated by the trench filling material due to its intrinsic stress or because of the difference in the thermal expansion coefficients. Typical examples from DRAM technology are given in the literature [76, 79, 88]. The thin dielectric layer at the top edge of capacitor trenches is often accessible to oxygen during various high-temperature processes. This can lead to local oxidation of this area, resulting in a small vertical 'bird's beak'. The additional stress field induced by this wedge may finally cause the nucleation of dislocations. Trench-induced dislocations may be rapidly visualized by defect etching [89]. The local stress fields can be measured by micro-Raman spectroscopy with a resolution of about 1 μm [90]. A higher spatial resolution is offered by simulating the diffraction contrast arising from stress fields in the TEM image or using a fine electron probe ($\leqslant$20 nm) to record convergent beam electron diffraction (CBED) patterns [91]. The CBED methods, however, suffer from the drawback that they are very slow, and at present can barely give timely feedback during technology development.

3.3.5.4 Damage Produced by Ion Implantation and Reactive Ion Etching

Ion bombardment of the silicon surface and subsequent annealing causes residual lattice defects which degrade device performance or act as nucleation sites for secondary defects. Ion implantation for doping of silicon areas operates in the several kiloelectronvolt to megaelectronvolt energy range. The various categories of implantation damage have been described exhaustively [92, 93]. The defects

most frequently encountered are the so-called end-of-range (EOR) dislocation loops, which are of interstitial type. They are formed by the agglomeration of the silicon interstitials, which are generated by displacing silicon atoms from lattice sites and which are driven beyond the projected ion range. The position of these loops with respect to the position of the pn junction is of utmost importance because they may enhance junction leakage. Here we will focus on a special defect which occurs under the mask edge after high-dose implantations of silicon, phosphorus, germanium, or arsenic, which amorphize the silicon substrate above a critical dose [94]. Figure 32a shows a schematic cross-section of a typical MOS transistor with the lightly n-doped drain and source regions (2) extending below the polysilicon gate (cf. Sec. 3.3.4 of this Chapter). The areas denoted by 1 are the high-dose arsenic-implanted source/drain regions. They are completely amorphized after implantation, as can be seen in Fig. 32b at A. The amorphous–crystalline interface smoothly bends to the silicon surface below the spacer oxide mask. Annealing at 500°C for 30 min recrystallizes the amorphous layer epitaxially on the silicon substrate (Fig. 32c). Since the regrowth process is incomplete it becomes obvious that the crystallization front does not follow the original amorphous–crystalline interface but forms a notch under the mask edge. Complete recrystallization as shown in Fig. 32d after 900°C/60 min annealing reveals that a defect has formed at the position of the notch. High-resolution TEM has identified this defect to be a vacancy-type dislocation half loop [94]. Figure 33 gives a schematic explanation of the defect formation. The tangents to

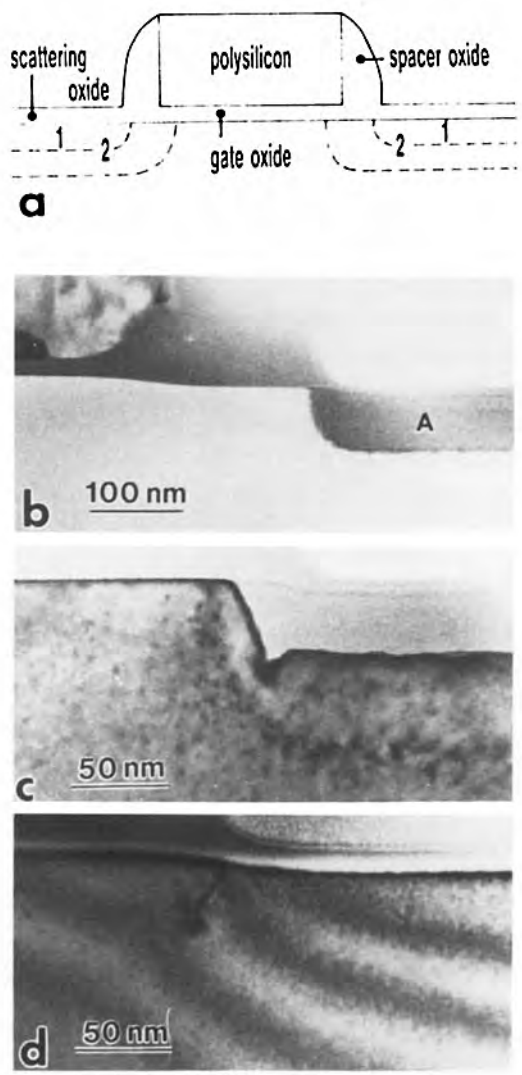

Figure 32. Formation of mask edge implantation defects below the spacer oxide of an MOS transistor due to amorphization of the silicon substrate by a high-dose arsenic implantation. (a) Schematic cross-section of an MOS transistor with source/drain implantations of $5 \times 10^{15}\,cm^{-2}$ arsenic in region 1, and $2 \times 10^{13}\,cm^{-2}$ phosphorus in region 2. (b) After implantation. (c) Partial recrystallization after annealing at 500°C for 30 min. (d) After annealing at 900°C for 60 min.

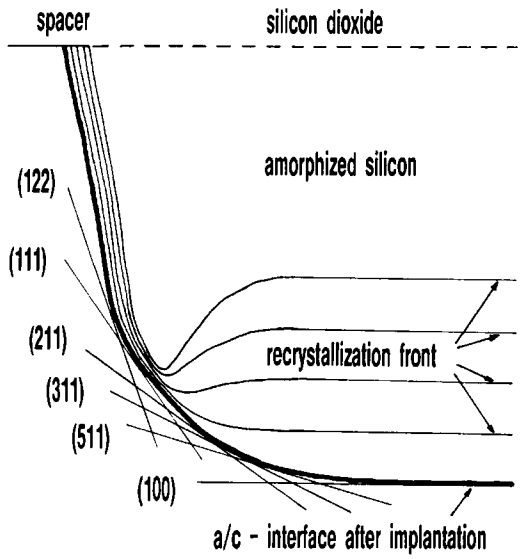

Figure 33. Schematic drawing showing the regrowth at the curved amorphous-crystalline interface which was formed by implantation below the mask edge (cf. Fig. 32b). The recrystallization fronts after isochronal anneals reveal the formation of a notch due to the different regrowth rates on the various lattice planes.

the curved amorphous–crystalline interface below the mask edge visualize the various lattice planes forming this interface. They all have different regrowth rates in the following order: (100) > (110) > (111). The schematic in Fig. 33 shows that a notch must form after isochronal annealings. The mask edge defects have received much attention because high-dose arsenic source/drain implantations are a worldwide standard for n-MOS transistors, and it has been realized [95] that these defects are preferred nucleation sites for secondary defects, such as glide dislocations or metal precipitates, which degrade device performance. It is interesting to note that the amorphizing BF_2 implantation for p-MOS transistors does not produce such defects. The crystallization front produced in the BF_2-implanted area consists of tiny pyramids with {1 1 1} facets. This appearance was attributed to the segregation of fluor at the regrowth front [96]. Thus, the regrowth rate is the same everywhere on this front, and no notch is formed.

Reactive ion etching (RIE) is a dry etching process which allows highly anisotropic pattern transfer with high etch selectivity (see Sec. 3.3.3 of this Chapter). RIE combines physical sputtering with chemically reactive plasma etching. During etching, volatile reaction products are formed by an ion-supported chemical reaction between the attacked material and reactive radicals as well as ions produced in the plasma. Due to the selectivity of the process the etching process stops at the silicon surface once the material above is etched away. However, to ensure complete successful etching, prolonged etching on the bare silicon surface (over-etching) is necessary. Low-energy ions (100–1000 eV) are therefore implanted into the silicon surface during over-etching. A typical patterning step is to open thick oxide layers to form a contact to the silicon substrate. This process requires a CHF_3–O_2 chemistry [97, 98]. An approximately 50 nm thick surface layer is damaged for 600 eV ion energy and 100% over-etching (Fig. 34). The defects consist of platelets on (1 1 1) and (1 0 0) planes being about 20 nm in diameter. High-resolution imaging and Fresnel imaging shows that they contain both silicon atoms and atom species lighter than silicon (carbon and hydrogen from the plasma) [99, 100]. This damage layer has to be removed by an additional dry etching process, for example with NF_3 chemistry, because the RIE-induced defects are nucleation sites for oxidation-induced stacking faults and metal precipitates.

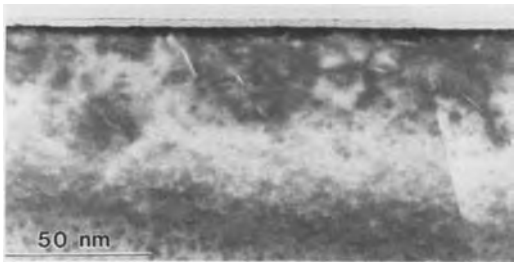

Figure 34. ⟨1 1 0⟩ aligned bright field image of the damage formed by reactive ion etching with CHF_3 near the silicon surface. Platelike defects on {1 1 1} and {1 0 0} planes are visible.

3.4 Silicon Device Structures

3.4.1 In-Line Wafer Assessment by Scanning Electron Microscopy

As pointed out above, fabrication of ICs consists of a complex sequence of all the processing steps described in Sec. 3.3 of this Chapter as well as several others not described such as cleaning steps which call for control of contamination levels. Here, two topics of microscopic characterization will be discussed, that is, application of SEM within the fabrication line and the methods used for failure analysis (see Sec. 3.4.2 of this Chapter). Process control of lithographic and etching processes requires nondestructive assessment within the fabrication line with a short turn-around time. Highly specialized equipment based on optical microscopy and SEM has been developed for this purpose. Optical tools have the advantage of higher throughput. Since the minimum device dimensions are approaching 0.2 μm, the higher resolution of SEM-based tools will further increase their use, and therefore their application will be emphasized here. Detailed contributions to both light and electron optical methods can be found in the literature [101, 102].

In-line wafer assessment by SEM has three main tasks:

- *Inspection*: evaluation of pattern fidelity by, for example, checking for resist and etching residues and monitoring the shape of the sidewalls.
- *Metrology*: measurement of *critical dimensions* (CDs), for example linewidth and pitch (period of regular patterns) as well as placement accuracy, of both resist patterns and etched film structures.
- *Defect review*: First, defects in patterns induced by, for example, particles are detected and localized by automated optical methods. They use either image-processing techniques to compare a certain area with a neighboring area of identical pattern, or detect defects from the scattered light intensity in the scanning laser system. Both methods provide the defect coordinates necessary for detailed characterization (defect review) in the second step. Optical defect review stations are based on, for example, scanning laser microscopes with confocal imaging providing three-dimensional information and allow the operator to classify defect types and perform statistical tracking. SEM-based systems, of course, yield much higher resolution, and thus from the particle shape more easily allow identification of the origin of defects. In addition, EDX spectroscopy can be employed by the operator to obtain elemental analysis.

Special requirements have to be met by scanning electron microscopes for in-line application. Besides clean-room compatibility and oil-free vacuum systems to

minimize contamination of the wafer during imaging, automated wafer-loading systems with cassette-to-cassette operation and wafer stages for 200 mm diameter wafers are required. Of crucial importance is low-voltage operation with electron energies between 0.5 and 2 keV, since standard imaging conditions with high-energy electrons (10–30 keV) lead to charging of the dielectric layers and beam damage of the photoresist patterns, and coating with a conductive film is prohibitive. Recent progress in SEM technology has been summarized by Peters [103]. To obtain good resolution at low beam voltages, field emission (FE) electron sources are required, including either a cold FE cathode or a Schottky emitter, that is, a thermally assisted FE source. Besides the high brightness, FE sources also offer the long service life (up to several thousands of hours) needed for production environment. Also, the lens design has been vastly improved. In virtual immersion lenses (Snorkel lens) the magnetic field extends beyond the lens structure and as such allows a shorter focal length, providing better resolution. In a novel design of a combined magnetic and electrostatic lens, especially low lens aberrations were obtained [104]. This lens yields a resolution of 5 nm even at a 0.6 kV beam voltage. The conical shape of the pole piece allows wafer tilt without loss of resolution due to an increased working distance. In contrast to standard SE detection by their collection at one side of the pole piece, SEs can be extracted through the bore of the final lens and deflected towards a detector. This through-the-lens detection provides symmetric contrast of both sidewalls in CD measurements and allows the bottom of deep holes to be imaged since SEs generated there are also collected. In addition to SEs, back-scattered electrons (BSEs) are also used for imaging since BSEs are less sensitive to charging and can also image the bottom of deep holes [105]. Since in-line scanning electron microscopes play a pivotal role in manufacturing yield improvement, automated operation and wafer throughput are very important. For CD measurements with five sites per 200 mm wafer, a throughput of more than 20 wafers per hour has been achieved.

CD measurements and defect review will be explained in more detail with the aid of two examples each. The photoresist lines in Fig. 35a are 1.5 μm thick and nominally 0.4 μm wide. In the SE image with a 0.6 kV beam voltage they appear as bright regions because SE collection from the trenches between the lines is restricted. The sidewalls are brighter than the center because SE emission is increased at inclined surfaces. Both sidewalls show similar contrast since the CD scanning electron microscope used employs through-the-lens SE detection. For CD measurements the SE signal is recorded across the resist pattern (line scan profiles). Two profiles are shown in Fig. 35a, since the SE detector is split into four sectors, and either the right or the left part was used to record the upper and lower profiles, respectively. Therefore, the profiles are no longer symmetrical, but nevertheless show an increased SE signal at both sidewalls. The splitting of the detector allows automatic distinguishing between holes and elevations. The line scans were not derived from the SE image information but recorded in separate electron scans. This explains the slight lateral shift of the profiles with respect to the SE

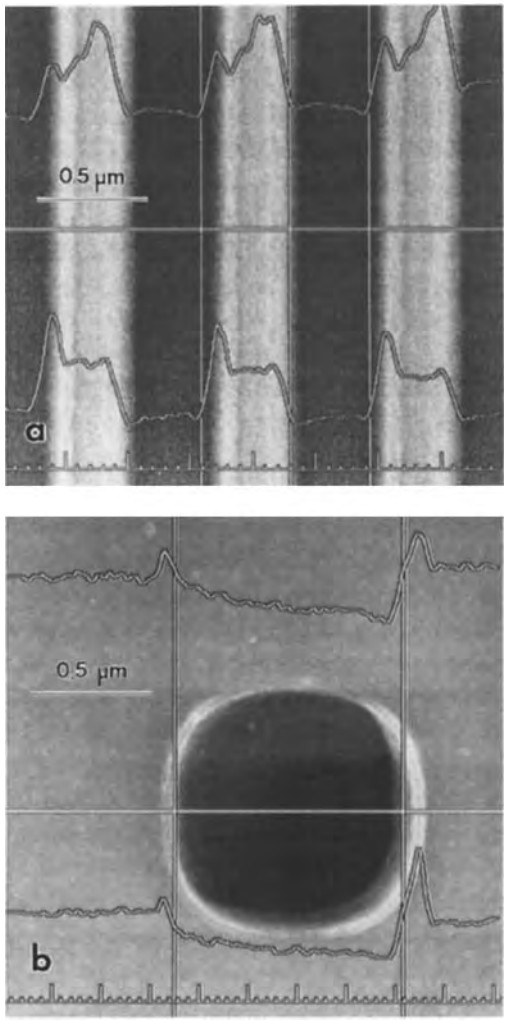

Figure 35. Critical dimension measurements of photoresist lines (a) and contact hole in a BPSG layer (b). Superimposed on the SE images are line scan profiles using the right or left part of a split SE detector.

image. Various algorithms can be applied for automatic SE profile evaluation. Here, the linear regression method was used since the bottom width is of main interest for photoresist lines. Both the baseline and the profile edge are approximated by straight lines, and their intersection defines the position of the bottom edge of the resist. A bottom width of 421 nm was measured in Fig. 35a and a separation of 336 nm between two lines.

Figure 35b shows a contact hole in a BPSG layer of 1.4 µm thickness. With the low beam voltage of 0.8 kV a sharp image of this oxide structure not disturbed by charging effects was obtained. Because of through-the-lens SE collection the bottom of the contact hole can be inspected, and is found to show residual oxide in the upper left part. The sidewalls of the contact hole are not symmetric. Therefore, the increase in SE signal is higher at the right sidewall in both profiles, recorded with the right (upper) or left part of the SE detector (lower profile). For measuring the width of contact holes from the SE profile, different algorithms are applied, for example setting a threshold level for the signal or using the inflexion point. Here, the midpoint between the maximum and minimum of the slope representing the sidewall was chosen. Thus, a value of 0.93 µm was obtained for the width of this hole.

As an example of defect review, Fig. 36a shows a defect found after deposition and patterning of polysilicon lines. The particle in the center of the image has led to an increased polysilicon thickness in its surrounding. After etching, the particle remains, and part of the polysilicon is not removed. This shows that this particle must have originated prior to or at the beginning of polysilicon deposition. A defect embedded in the top layer like this one cannot be classified by optical defect review. In contrast to this defect, the particle of Fig. 36b clearly lies on top of the wafer, with aluminum interconnections forming the top layer. EDX analysis showing chlorine, and the cubic shape of the particles imply that they consist of NaCl.

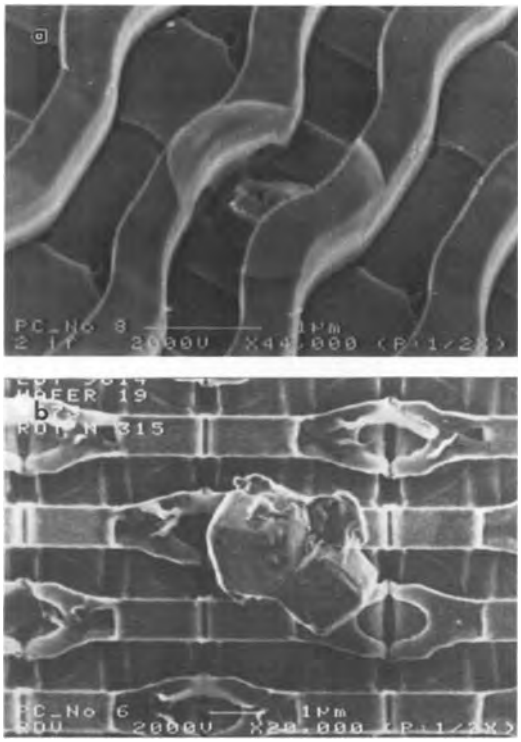

Figure 36. Defect review by scanning electron microscopy. (a) Particle leading to an increased thickness of polysilicon lines. (b) NaCl particles on top of the wafer surface.

3.4.2 Failure Analysis

Due to progress in dimensional miniaturization the physical and logical sophistication of highly integrated circuits increases. Therefore, failure analysis has become more important since precise knowledge of the failure mechanism is necessary first for quick improvement of yield in a fabrication line. Second, improvement of reliability requires clarification of failures after burn-in or failures that occur during operation of ICs. In both cases, failures are traced to incompletely mastered single processes, unreliable, nonoptimized technological parameters, or problems with topography and materials, and so forth. Thus, failure analysis helps to maximize the efficiency of the learning cycle and to transfer the knowledge gained directly into the current fabrication process. A systematic approach for failure analysis after electrical testing first involves localization of the failure site and, second, physical analysis to clarify the failure mechanism. A success rate of more than 90% has been achieved by employing the various techniques systematically for logic ICs with 0.5 μm design rules [106]. Detailed information on all type of techniques for both localization and physical analysis of failures can be found in recent conference proceedings of ISTFA [107] and ESREF [108].

3.4.2.1 Localization of Failure Sites

In special cases the failure site can be derived directly from electrical tests. In refresh analysis of DRAMs, for example, the time after which the first memory cell loses its information is determined. When refresh analysis is performed for a certain block of the cell array, the address of the initially failed cell is obtained. An example of further analysis of the physical cause via TEM characterization of the associated crystal defect is given below. Generally, however, the failure sites have to be located by special techniques depending on the failure type, that is, whether or not the devices show functional failure and/or excessively high total current consumption (I_{cc}) stemming from leakage currents. Functional failures can be located by EBT. I_{cc} leaking produces local heating at the failure site which necessitates, for example, thermal imaging techniques.

EBT is based on the voltage contrast for SE imaging in the scanning electron microscope. When an IC under electrical operation is imaged, SE collection is influenced by the local electric fields prevailing above the surface of the IC. Thus, interconnections with negative voltage appear bright since SE collection is facilitated by these fields. Interconnections with positive voltage on the other hand appear dark: part of the emitted SEs cannot be collected because the local electric fields deflect them back to the surface. Apart from voltage contrast imaging, voltages can be measured locally with an electron spectrometer for SE collection. Furthermore, stroboscopic techniques allow waveform measurements of electric signals on internal nodes in a circuit and mapping of logic states as function of time. An introduction to EBT is given by Fuchs et al. [5], an overview on application by Wolfgang [109], and more detailed information can be found in reference [110]. When EBT is applied to failure localization, major faults often can be identified by comparing static voltage contrast images of the nonfunctional device to those of a functional device. Alternatively, internal electrical signals have to be traced by waveform measurements until the critical fault site is located. In addition to failure analysis, EBT is also employed for design verification of ICs, providing localization and quantification of design weaknesses.

The source points of leakage currents on an IC can be located by thermal imaging (hot spot detection) since electrical energy is converted into heat at these points. In many cases, hot spots indicate technology defects such as short circuits in aluminum or polysilicon levels, substrate leaks around contact holes, gate oxide breakthroughs, and floating gates. They may also indicate design weaknesses such as increased current paths, faults in the layout, or latch-up regions in CMOS circuits [111]. A recent overview on thermal imaging techniques is given by Kölzer et al. [112]. In liquid crystal thermography (LCT), which is widely used for hot spot detection, a thin layer of a liquid crystal (LC) is applied onto the surface of an IC [113]. The device is then examined under operation in an optical microscope using polarized light with the polarizer and analyzer crossed. Areas without the LC appear dark. The optical properties of the LC depend on the temperature. Below the clearing-point temperature T_c the LC exhibits crystalline order since nematic LCs are used as a rule. Birefringence in the LC causes the polarization plane of the light to rotate, resulting in some brightening of the image. On IC areas with a local temperature above T_c, the LC transforms into the optically isotrope phase. Here, the polarization plane remains unchanged and the relevant area appears dark (hot spot). By controlling the temperature of the device with a heating stage to be just below T_c, hot spots with low power dissipation can also be detected. In practical operation, temperature differences of approximately 0.1°C can be resolved. Depending, for example, on their depth below the surface of the IC, failures with a power dissipation of 50–500 μW can then be detected [114]. The spatial resolution of the method is about 1 μm. Not every detectable hot spot represents a failure site, since specific parts of an IC may have an increased temperature during standard operation.

LCT allows quick detection of hot spots but provides only a binary response, indi-

cating whether or not the hot area is above the transition temperature. In fluorescent microthermography (FMT), on the other hand, the temperature behavior of a device can be studied with improved temperature resolution (<0.01°C) and spatial resolution (0.3 μm) [115, 116]. FMT involves applying a thin film of europium thenoyltrifluoroacetonate (EuTTA) and polymethyl methacrylate (PMMA) dissolved in acetone onto the surface of the IC. Illumination with ultraviolet light in a wavelength band of 340–380 nm stimulates fluorescence in the film at 612 nm. No significant absorption occurs in the film above a wavelength of 500 nm causing secondary fluorescence. Thus, a clear separation between excitation source and fluorescent light is possible. The quantum efficiency of the 612 nm fluorescence decreases exponentially with temperature, thereby providing information on the temperature distribution of the operating IC. The fluorescence radiation is acquired by a charge-coupled device camera.

In addition to local heating, the excessive currents at failure sites may lead to the emission of light. By combining optical microscopy with the superb amplification of night-vision technology, very faint light emission in the visible and near-infrared region is detected, and the location of emission pinpointed. An overview of emission microscopy is given by Kölzer et al. [117]. Light emission is induced mainly by three phenomena:

- Recombination of minority carriers injected into the pn junction, which enables the analysis of forward-based bipolar devices as well as parasitic bipolar effects such as latch-up phenomena in CMOS devices.
- Field-accelerated carriers, which are generated by high local electric fields, allow the investigation of, for example, saturated MOS transistors, hot electron degradation, effects of electrostatic discharge events, or of leakage currents due to microplasma discharge at dielectric breakdown.
- Tunneling (Fowler–Nordheim) currents flowing through thin dielectrics offer the potential to study gate oxide quality.

Emission microscopy goes beyond the mere localization of failures since the emission spectrum provides information on the defect mechanism [117]. Since light emission is easily detected if the leakage current flowing at the source point is more than 10 μA, emission microscopy is the most useful technique for quick localization of leakage current sources in the substrate or related to thin dielectrics [106]. Of course, the application of emission microscopy is hindered when large areas of metallization cover the failure site. Failures within the various metallization levels are located by hot spot detection.

3.4.2.2 Physical Failure Analysis

To identify the cause of a failure after its localization, detailed physical analysis is required involving various procedures of destructive specimen preparation. Usually, the first step is 'delayering', that is, selective removal of technology layers down to the level of failure by wet chemical etching, RIE, or mechanical polishing. In many cases the origin of the failure can be clarified by SEM inspection. If this is not possible, cross-sections provide additional information. Precision cross-sectioning, that is, preparation of a cross-section

through the preselected area of the failure site, is achieved by well-controlled polishing for SEM and TEM samples, but is also possible without polishing by focussed ion beam (FIB) techniques.

For polishing of SEM cross-sections the sample is not embedded but mounted on a fixture allowing observation of both the surface and the cross-section of the IC in an optical microscope [118]. Thus, the polishing process can be controlled to an accuracy of less than 0.2 μm for the position of the section plane. The cross-sections can be imaged without further preparation when low beam voltages of a few kilovolts are used in the scanning electron microscope. Alternatively, slight etching delineates the various layers more clearly by creating contrast-enhancing steps at the interfaces between the layers. The etching solutions used either attack SiO_2 or silicon [119, 120]. Sputter coating with a conductive gold–palladium film facilitates imaging of dielectrics but slightly degrades the resolution.

A failure causing high standby currents in a 16 Mbit DRAM was located by LCT and analyzed in detail [121]. In Fig. 37a the operator marked the area by a circle where the dark 'hot spot' occurred first when the IC temperature was increased. No indication of any defect could be found on the chip surface (Fig. 37b). The technology layers were successively removed by face lapping with the polishing procedure being controlled by microscopic inspection. Only when the bit line material was removed was a defect covered by an oxide layer detected. After slight etching of the oxide a protrusion is clearly seen in the SEM image (Fig. 37c, arrow). A precision cross-section allows identification of the failure origin (Fig. 37d). The protrusion was caused by a local increase in polysilicon thickness. It is well known that particles can cause such defects during polysilicon deposition. Since the region of increased polysilicon thickness was not removed during pattering of this level, the polysilicon residue formed a connection to the silicon substrate and thus led to an increased standby current.

When crystal defects are expected to cause the failure, TEM cross-sections or plan view specimens may be used for their identification. This applies to defects reducing the retention time of memory cells during refresh analysis of DRAMs. Defect-induced leakage currents through the substrate diminish the charge stored on the substrate node of the trench capacitor. For preparation of a precision cross-section, the defective trench capacitor has to be marked by, for example, laser shots or FIB in the surroundings. Polishing from one side is analogous to the procedure for SEM cross-sectioning using the laser shots to identify the defective trench. After polishing from the other side, final ion milling has to be controlled to obtain electron transparency at the selected site. In the example of Fig. 38a small precipitates were indeed found in the vicinity of a trench capacitor with reduced retention time. Figure 38b shows that these defects are platelets on {1 1 1} planes with a diameter of up to 40 nm exhibiting strong strain contrast [122]. After additional ion milling a ⟨1 1 0⟩ lattice image of the same precipitate could be obtained (Fig. 38c) showing two additional {1 1 1} planes inserted into the silicon matrix. In EDX analysis a small copper peak was found (Fig. 38d), providing evidence for copper precipitates stemming from metal contamination during device processing.

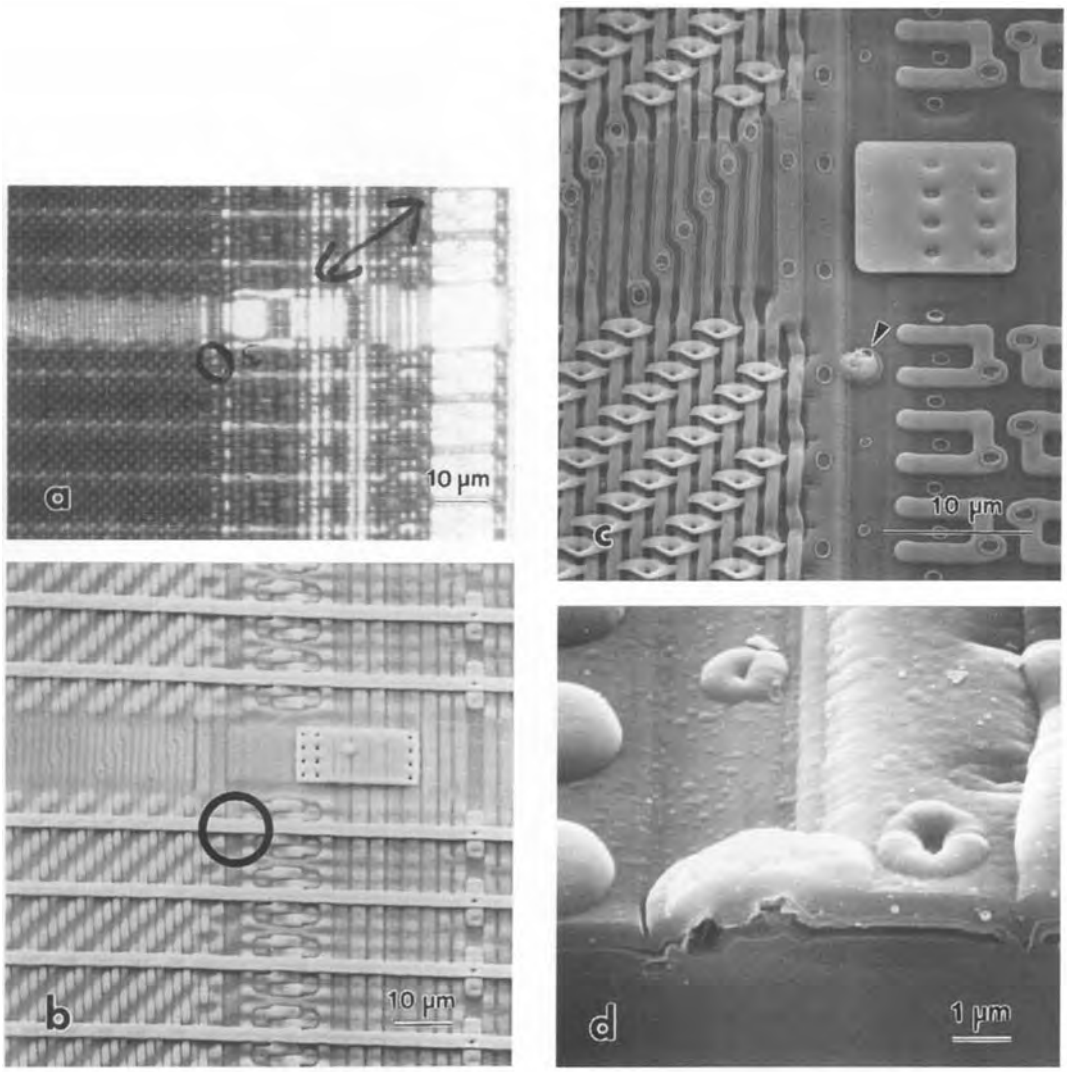

Figure 37. Failure analysis of a 16 Mbit DRAM with a high standby current. (a) Optical micrograph with the 'hot spot' marked by a circle after detection by LCT. (b, c) SEM images of the same area as in (a). Only after removal of several technology layers is the defect visible (c). (d) Precision cross-section through the defect.

FIB systems have advanced to a stage where they are now routinely applied for both circuit modification and failure analysis. Liquid metal ion sources employing Ga^+ ions with an energy of 20–30 keV provide beam diameters well below 50 nm and high current densities ($>10\,A\,cm^{-2}$) [123]. Analogous to SEM, the ion beam is scanned across the specimen surface for imaging and the SEs released by the Ga^+ ions serve as the image signal. Beams with a diameter below 10 nm and a current of only ~1 pA are employed for imaging presently, and change the sample only slightly. When much higher currents (several nanoamps) are used, local sputtering with high rates

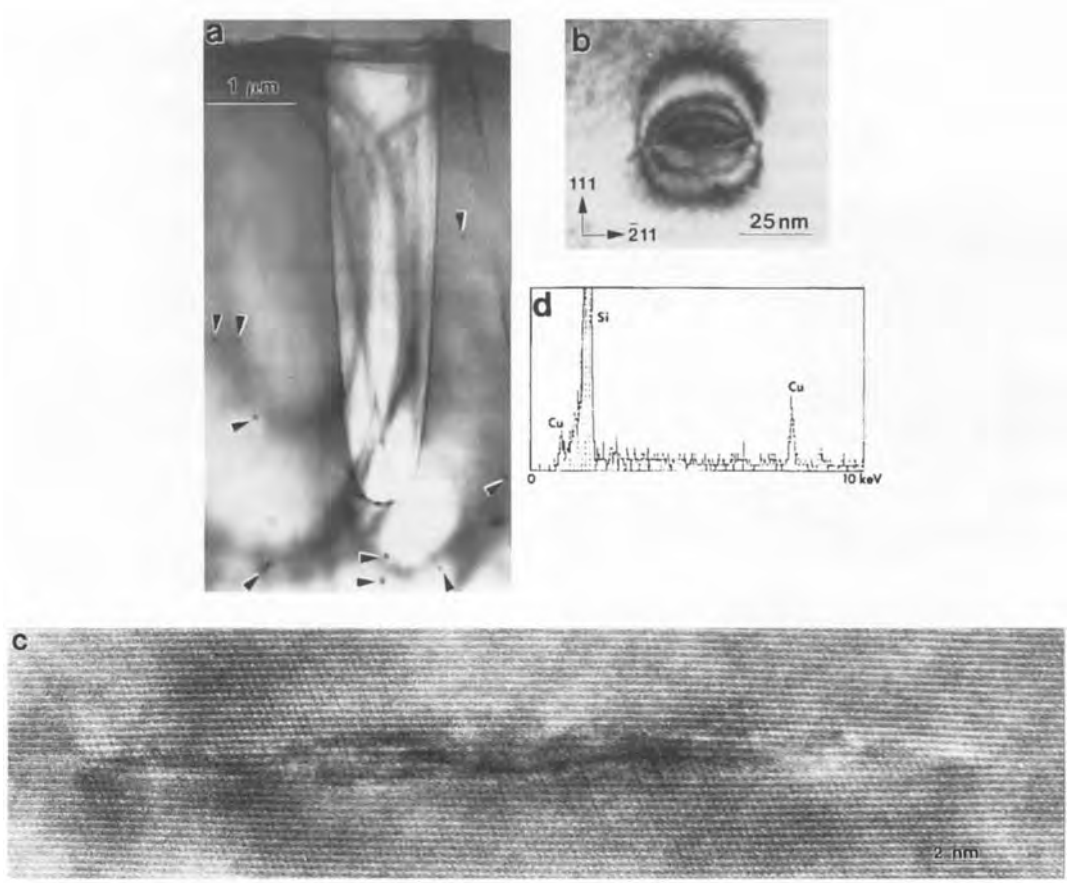

Figure 38. TEM failure analysis of a specific defective storage cell in a 4 Mbit DRAM device. (a) Bright field image of the defective storage capacitor. The arrows mark precipitates. (b) Bright field image of a single precipitate. (c) ⟨1 1 0⟩ HREM image of a precipitate having two additional {1 1 1} planes. (d) EDX spectrum of the precipitate showing copper.

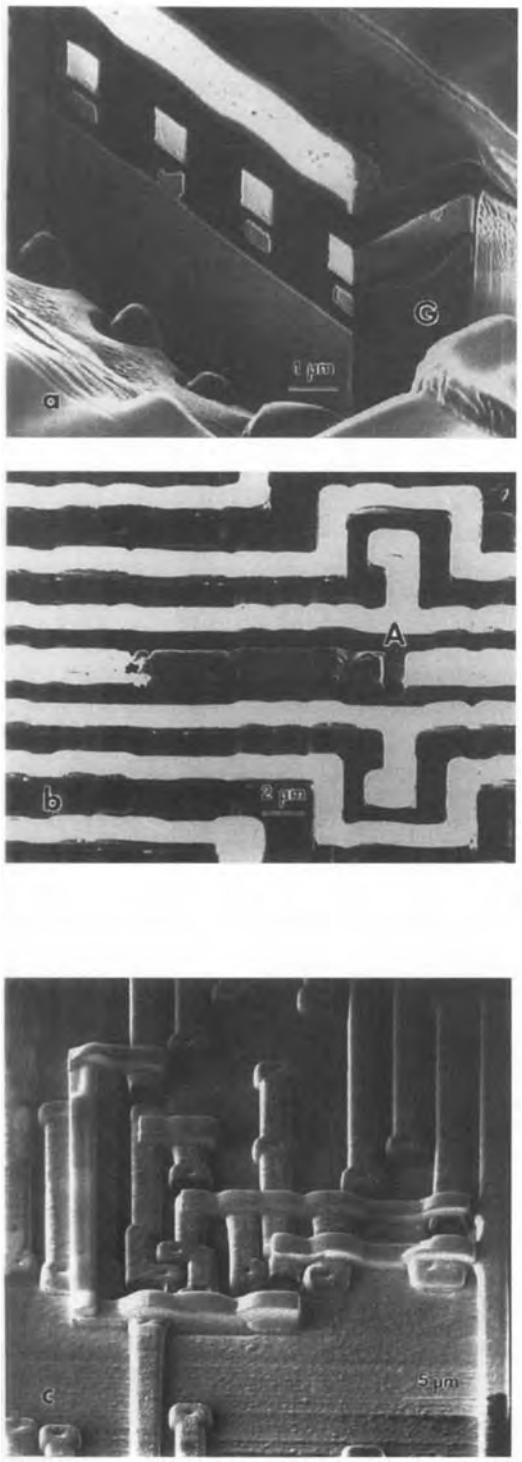
yields the possibility of micromachining, such as for etching a cross-section at a location selected from the image. This combination of micromachining and high-resolution imaging allows very quick physical failure analysis, and FIB workstations are therefore increasingly being used for this purpose [124].

In the FIB image of Fig. 39a, cross-sections along two perpendicular planes were etched into an IC. The narrow section cuts through a polysilicon gate extending over the field oxide on both sides of the gate region (G). The fault in this device was located at the gate in the middle of the longer section plane. It is clearly seen that the field oxide below the polysilicon is missing here, probably because of a mask defect. The microscopic cross-sections prepared by FIB can also be imaged in the SEM when superior resolution is required (see Fig. 1).

FIB image contrast is different from SE images recorded by SEM. Since the SE yield, that is, the number of SEs emitted per incident primary ion, is larger than



unity, dielectrics such as oxides always charge up positively and therefore appear dark. Positive charging restricts the SE collection analogously to the voltage contrast used in EBT. This charging, however, usually does not degrade image quality since the positively charged areas can attract SEs emitted from other parts of the specimen, and the much higher mass of the Ga^+ ions compared to electrons makes them less sensitive to local electric fields. The SE signal generated by primary ions is very surface sensitive since the ions penetrate into the specimen only a few tens of nanometers and the emitted SEs have low energy (<10 eV) [123]. Furthermore, the SE signal exhibits no 'material contrast' as in SEM because the fraction of backscattered electrons contributing to the SE signal in the SEM is missing in FIB systems. Since the penetration of the primary ions depends sensitively on crystal orientation (channeling), the SE contrast also varies. This effect allows imaging of the grain structure of metallization layers, such as for aluminum interconnections. In Fig. 39b charging was used intentionally to locate the interruption of an aluminum interconnection. After cutting the aluminum line (at A in Fig. 39b), the part between the cut and the interruption is disconnected from the next contact and therefore charges up positively during ion bombardment. This part thus appears dark and allows easy location of the failure.

The capability of FIB for micromachining also allows the preparation of precision

Figure 39. Focused ion beam application in failure analysis. (a) FIB image of precision cross-section etched by FIB. (b) FIB image of aluminum interconnections. The interruption is visible because of local charging. (c) Ion-beam-induced deposition of metal interconnections (horizontal lines).

cross-sections for TEM inspection [125]. The thin slice in the FIB image of Fig. 40a represents the electron transparent part of the sample. To protect the surface, a narrow tungsten line was deposited (see below) prior to FIB etching. The TEM image of this specimen (Fig. 40b) shows the section plane to cut through the trenches of the 4 Mbit DRAM.

Besides failure analysis, FIB systems are widely applied for circuit modification using two operations: cutting of unwanted interconnections and depositing new ones. This possibility allows designers to test modified circuits with short cycle times and without the need to generate new mask sets and silicon. An example of cutting was shown in Fig. 39b. Redeposition during etching of deep holes with high aspect ratios can be avoided by gas-assisted etching. Reactive gases such as halogens volatilize the sputtered material and enhance the FIB milling rate [126]. For deposition of interconnections, organometallic gases are injected near the area of interest. During ion beam-induced deposition, gas molecules adsorbed at the surface are decomposed by the ion beam with the metal remaining in the areas scanned by the ion beam. All the horizontal platinum interconnections in Fig. 39c were deposited in a FIB system.

3.5 Compound Semiconductor Devices

3.5.1 Heteroepitaxial Layer Structures

Modern compound semiconductor devices employ heteroepitaxial layer structures which are grown by metal–organic vapor phase epitaxy (MOVPE) or MBE [127]. Both electronic and optoelectronic devices make use of single and multiple quantum well structures with layer thicknesses being typically in the range of several nanometers. The 2D electron gas confinement achieved with $Al_xGa_{1-x}As/GaAs$ and $Al_xGa_{1-x}As/In_xGa_{1-x}As/GaAs$ layers finds application in high electron mobility transistors (HEMTs, see Sec. 3.5.2 of this Chapter).

Binary (AB), ternary ($A_xB_{1-x}C$), and quaternary ($A_xB_{1-x}C_yD_{1-y}$) III–V compounds with the sphalerite structure are used with high success for layer structures in optoelectronic devices (e.g., light-emitting diodes and lasers), because the band gap varies with composition. However, in most cases a change in composition causes the lattice constant to change too. Thus, band gap engineering not only requires adjustment of the width of the band gap by composition but also exact matching of the lattice constant of the layer to that of the GaAs or InP substrate. For optimum device characteristics layer growth has to be controlled precisely with respect to thickness and uniformity of the layers, abruptness of the hetero-interfaces, composition and lattice match, and layer doping.

Analysis of heteroepitaxial semiconductor layers first of all involves X-ray diffraction to examine whether the correct lattice match was obtained in the case of unstrained layers or to determine the lattice distortions in the case of strained layers. Multiple crystal diffractometers provide the high angular resolution required for this purpose. Accurate determination of layer thicknesses and compositions is achieved by simulation of the diffraction profiles using the dynamic theory of diffraction [128]. This procedure is usually more straightforward for superlattice systems than for single layers or aperiodic layer structures. Also, photoluminescence (PL) is frequently used to assess heterostructure layer systems [127], but in the case of quantum wells often relies on accurate layer thickness determination by other methods in order to separate, for example, effects of layer composition and thickness on the spectral position of the PL lines. Both techniques have in common that they usually measure averages over an area of some hundred micrometers across, and/or they form the average over several periods in a multiple quantum well structure. The depth profile of dopants can be measured by SIMS, as in silicon technology [5, 60].

Cross-sectional TEM imaging is currently the only technique which offers valuable information with high spatial resolution both in the vertical and lateral directions. The points of interest for TEM analysis comprise determination of layer thicknesses (even below 1 nm), interface abruptness, layer composition, and uniformity of the layers. The assessment of the interface abruptness requires chemical and/or structural information down to the atomic level. This is the case for compositionally sharp or graded interfaces and for the detection of interface steps. Moreover, imperfect growth conditions stemming from too high lattice mismatch, surface steps, or growth disturbances as well as relaxation mechanisms in strained layer systems may give rise to the formation of crystal defects such as dislocations, stacking faults, antiphase domains, and precipitates. Microscopy of lattice defects is not discussed further here, and selective reference is made to Mahajan [129] and Ueda [130]. Basically, three approaches exist to characterize heteroepitaxial layer structures: (a) the {200} dark field imaging of thin cross-sections, (b) imaging of cleaved wedges, and (c) high-resolution imaging.

3.5.1.1 {200} Dark Field Imaging of Thin Cross-sections

The preparation of thin cross-sections for TEM has become a routine method within

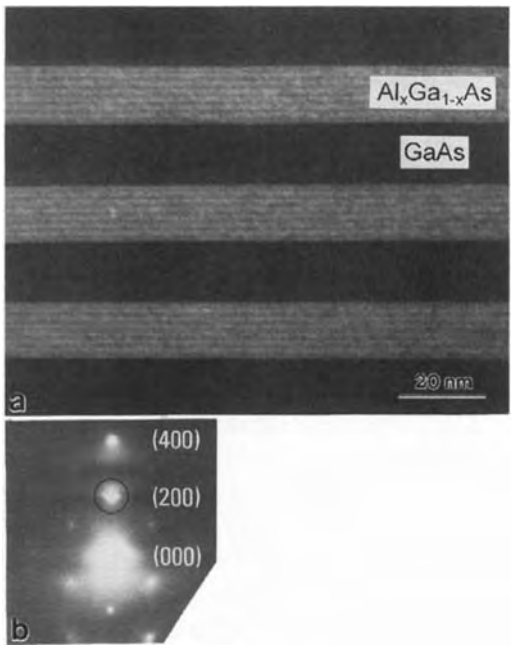

Figure 41. (a) {200} dark field image of an $Al_xGa_{1-x}As$/GaAs multi-quantum-well structure. The bright and dark stripes in the $Al_xGa_{1-x}As$ layers reveal a fluctuation in the aluminum content. (b) Diffraction pattern. The (200) reflection used for the dark field image (a) is encircled.

the last decade, and a description may be found for example in Cerva and Oppolzer [131]. The cross-sectional specimen has to be oriented to the electron beam such that the layer interfaces are viewed end-on. A {200} dark field image is obtained by allowing only the {200} reflection to pass through the objective aperture, as indicated in Fig. 41b. The resolution of this technique of approximately 0.5 nm is limited by the aperture cutting off electrons with larger scattering angles. Also, the apparent interface width increases with specimen thickness because of tilting to the Bragg angle necessary for exciting the {200} reflection. In the {200} dark field image of Fig. 41a the $Al_xGa_{1-x}As$ barriers and GaAs wells of a multiple quantum well structure appear bright and dark, respectively. This may be understood by considering that the kinematic intensity is proportional to the square of the structure factor F, which for the {200} reflection of a binary compound having the sphalerite structure is proportional to the difference between the atomic scattering amplitudes f of the cation and anion. The structure factor F_{200} for GaAs is almost zero because $f_{Ga} \approx f_{As}$, whereas in the case of AlAs there is a large difference. For the ternary compound $Al_xGa_{1-x}As$ the structure factor is given by $F_{200} \approx 4x(f_{Al} - f_{Ga})$. The contrast between layers of different composition is best described by the (200) kinematic intensity ratio $R(x)$ of a ternary and a binary compound ($A_xB_{1-x}C$ and BC, respectively). $R(x)$ is given by

$$R(x) = I(A_xB_{1-x}C)/I(BC)$$
$$= \{1 + [x(f_A - f_B)/(f_B - f_C)]\}^2$$

yielding

$$R(x) = (1 + 2.91x^2)$$

for $Al_xGa_{1-x}As$/GaAs at 200 kV. $R(x)$ increases monotonically with increasing aluminum content x for the system $Al_xGa_{1-x}As$/GaAs. Thus, $Al_xGa_{1-x}As$ layers always appear brighter than GaAs layers, and a qualitative interpretation of the {200} dark field image contrast is possible. For example, the $Al_xGa_{1-x}As$ barriers in Fig. 41a show fine alternating bright and dark fringes in the $Al_xGa_{1-x}As$ barriers. This modulation in the aluminum content is attributed to small variations in the flux profile of the group III elements over the substrate surface [131]. Differences in the aluminum content of $\Delta x > 0.05$ can be recognized from such images [132], and by quantification of the

contrast using densitometry the aluminum content x may be determined with an accuracy of about 3% [133]. The $In_xGa_{1-x}As/GaAs$ system is an example where the contrast does not change unambiguously with the indium content x [134], and hence compositional variations have to be identified by analytical TEM. In general, imaging of conventional cross-sections has the advantage that the layers may be inspected along a relatively large distance (a few tens of micrometers). This is especially useful when assessing wavy interfaces, layer inhomogeneities, and crystal defects. Further examples of the application of this technique may be found in Cerva and Oppolzer [131].

3.5.1.2 Imaging of Cleaved Wedge Specimens

Conventional TEM cross-sections are particularly useful for studying laterally nonuniform effects. In most instances, however, only depth information is required, which can also be obtained by imaging the edge of a cleaved wedge specimen [135]. Since specimen preparation by cleavage is much faster than the conventional procedure, this technique has become very popular. It exploits the property of compound semiconductors such as GaAs and InP to cleave precisely along {1 1 0} planes. A wedge-shaped specimen with a sharp 90° edge (Fig. 42a) can be produced by cleaving a [0 0 1]-oriented wafer along two {1 1 0} planes which are normal to each other. This preparation procedure takes approximately 10 min, and the specimen can then be transferred immediately into the microscope. If the cleaved edge is viewed in transmission after orienting it perpendicular to the electron beam, a cross-sectional image of the heterostructure is obtained.

Just as with thin cross-sections, the wedge-shaped specimens (Fig. 42b) can be imaged with the {2 0 0} dark field method when the sample is tilted slightly away from the [1 0 0] zone axis. For the dark field image, however, that type of {2 0 0} reflection has to be selected which has its diffraction vector parallel to the edge of the sample. Otherwise the layer interfaces are not viewed in projection. In Fig. 42b, the cleaved edge is on the left of the image (arrowed) and is not directly visible. The thickness increases towards the right in accordance with the geometry of the specimen (Fig. 42d). In the thin regions immediately beside the cleaved edge, the intensity in the $Al_xGa_{1-x}As$ layers increases with thickness. Thickness fringes, however, do not appear in thicker regions because the extinction distance of the {2 0 0} reflection is very large. As the result of increased electron scattering and 'absorption' by the objective aperture, intensity drops again at distances of more than approximately 60 nm from the cleaved edge.

In addition to displaying the layer structure, another imaging method allows compositional analysis [135]. This entails tilting the wedge specimen exactly into the [1 0 0] zone axis and recording a bright-field image, that is, the small objective aperture allows only the directly transmitted beam to pass through. The precise orientation is again controlled with the aid of the diffraction pattern. Multiple beam conditions result, because numerous reflections are excited. Figure 42c shows such a bright field image of the $Al_xGa_{1-x}As/GaAs$ layer structure of

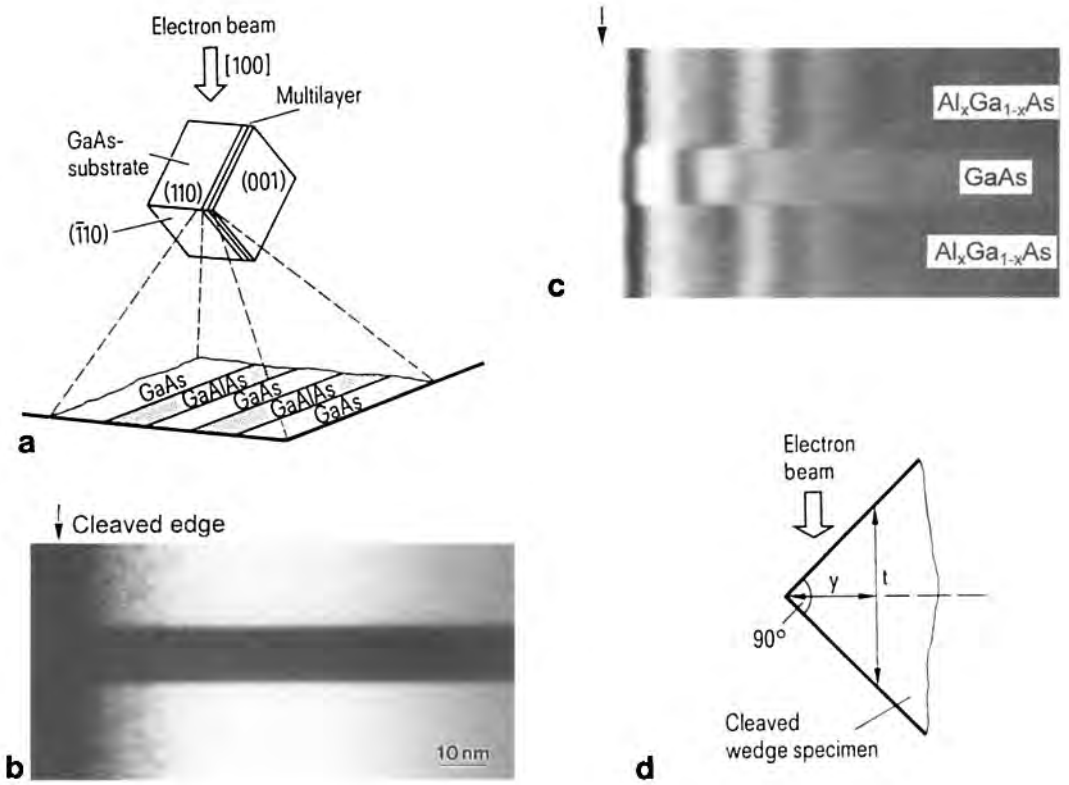

Figure 42. TEM analysis of cleaved wedge specimens. (a) Schematic showing the geometry of the specimen with respect to the electron beam and the cross-sectional image of the multilayer. (b) {2 0 0} dark field image of an $Al_xGa_{1-x}As/GaAs$ quantum well structure. (c) ⟨1 0 0⟩ aligned bright field image of the same quantum well structure as in (b). (d) Geometric relationship between transmitted sample thickness t and distance y from the cleaved edge.

Fig. 42b. Thickness fringes parallel to the cleaved edge can now be seen in the layers. The defined geometry of the 90° wedge means that the position of the thickness fringes (distance y from the cleaved edge) correlates unambiguously with specimen thickness t: $y = t/2$ (Fig. 42d). The periodicity of the depth oscillations and hence the position of the thickness fringes depends on the structure factor, which in turn varies with the aluminum content of the layer. The fringes in layers of different aluminum content are thus displaced with respect to each other. When the position of the thickness fringes is calculated with the aid of the dynamic theory of electron diffraction, the aluminum content can be quantitatively determined [135, 136]. As with the {2 0 0} dark field images, the abruptness of the interfaces can be assessed with a resolution of about 0.5 nm. Bending of the thickness fringes within a layer or at an interface is indicative of a change in the aluminum content or a transition region at the interface.

The two $Al_xGa_{1-x}As/GaAs$ multiple quantum well structures in Fig. 43 were grown by MOVPE within the same

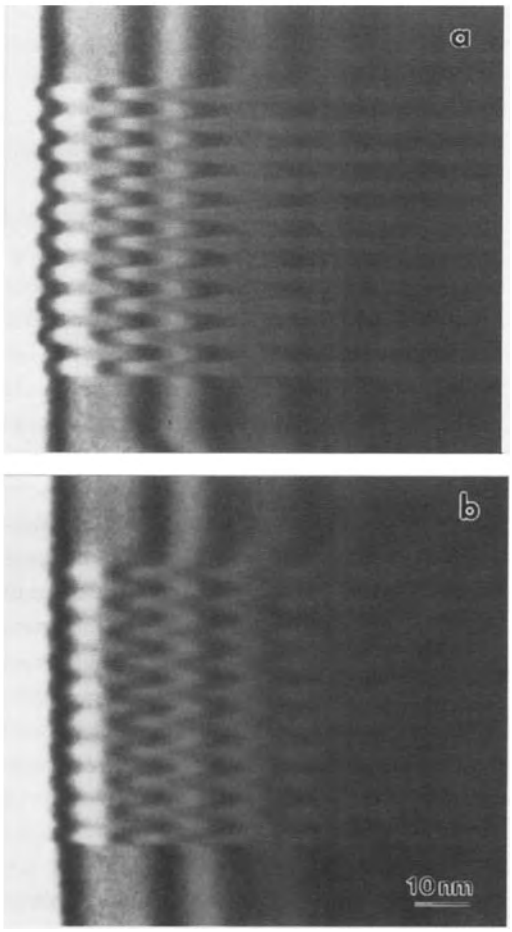

Figure 43. ⟨1 0 0⟩ aligned bright field images of cleaved wedge specimens. The $Al_xGa_{1-x}As/GaAs$ multi-quantum-well structure was grown by MOVPE with growth interruptions at the interfaces (a), and without interruptions (b).

specimen so that they could be imaged by TEM at the same time and under the same conditions. The multilayer in 'Fig. 43a was deposited with growth interruptions at the interfaces, and exhibits abrupt interfaces. In contrast, the multilayer in Fig. 43b exhibits transition zones at the interfaces approximately 1.5 nm in width, because growth was not interrupted. A variety of further examples making use of the cleaved wedge preparation can be found in the literature [131, 134, 137].

3.5.1.3 High-Resolution Imaging

HREM can be applied to both thin cross-sections and wedge specimens, and provides not only structural but also quantitative chemical information on layer interfaces at atomic or near-atomic scale. This requires the HREM image intensities in the dot pattern of the lattice to be related to the chemical composition. Then, by comparing the image intensities in the specifically different contrast patterns at the interface and on both sides of the interface, the chemical variation across the interface can be derived. An algorithm was developed to extract the chemical signal quantitatively under suitable imaging conditions [138]. Over the last few years this real-space algorithm has been extensively used on images projected in the ⟨1 0 0⟩ orientation for various systems such as $Al_xGa_{1-x}As/GaAs$ and $Hg_xCd_{1-x}Te/CdTe$ to study structural and chemical interface properties and point defects. A theoretical and experimental treatment of the image contrast in ⟨1 0 0⟩ projection based on the nonlinear imaging theory was described for the $Al_xGa_{1-x}As/GaAs$ system [139, 140] and silicon/germanium system [141]. The algorithm described by Thoma and Cerva [140] was used to verify the different abruptness of AlAs/GaAs and the GaAs/AlAs interfaces [142], and an example is given below. Recently, a general approach to the measurement of the projected potential in crystalline solids in any projection without knowledge of the imaging conditions has been given [143, 144].

As an example, the HREM assessment of the interfaces in an AlAs/GaAs double-barrier quantum well (DBQW) structure will be described in more detail. The interface quality of DBQWs used in resonant tunneling structures determines their electrical properties and, therefore, the interface quality is of decisive importance. Figure 44a shows a ⟨1 0 0⟩ HREM image of a conventional thin cross-section from an AlAs/GaAs DBQW structure grown by MBE [142]. In order to analyze the interface abruptness quantitatively with the algorithm described by Thoma and Cerva [140], the specimen thickness and focus have to be within the optimum range ($7\,\text{nm} < t < 13\,\text{nm}$ and $\Delta f = -25 \pm 5\,\text{nm}$ at 400 kV) so that a clear difference in contrast between the GaAs and AlAs layers appears, just as in Fig. 44a. The AlAs layer is characterized by a strong (2 0 0) pattern contrast, with the white dots corresponding to aluminum atom columns and black dots to arsenic atom columns, whereas in GaAs a (2 2 0) pattern contrast prevails, where white dots represent the positions of gallium or arsenic atom columns and black dots are tunnels in the structure. When crossing the interface, one type of contrast pattern changes into the other gradually. Under the given imaging conditions, this change in contrast with the aluminum content can be described by those Fourier components of the image intensity which contain the linear beam interactions between the transmitted and the (2 0 0) beams as well as the nonlinear interactions between (2 0 0) and (2 2 0) beams [139, 140]. This behavior stems from the fact that in the ⟨1 0 0⟩ projection the amplitudes of the (2 0 0) beams in $Al_xGa_{1-x}As$ increase with the aluminum content x whereas those of the (2 2 0) beams remain almost constant for the chosen imaging conditions. For determination of the local composition the contrast pattern is divided into unit cells which contain all the chemical information for the quantification procedure. In the case of $Al_xGa_{1-x}As$ in the ⟨1 0 0⟩ projection, the smallest cell has a size of $0.28 \times 0.28\,\text{nm}^2$ and is square shaped [138, 140] because the chemical

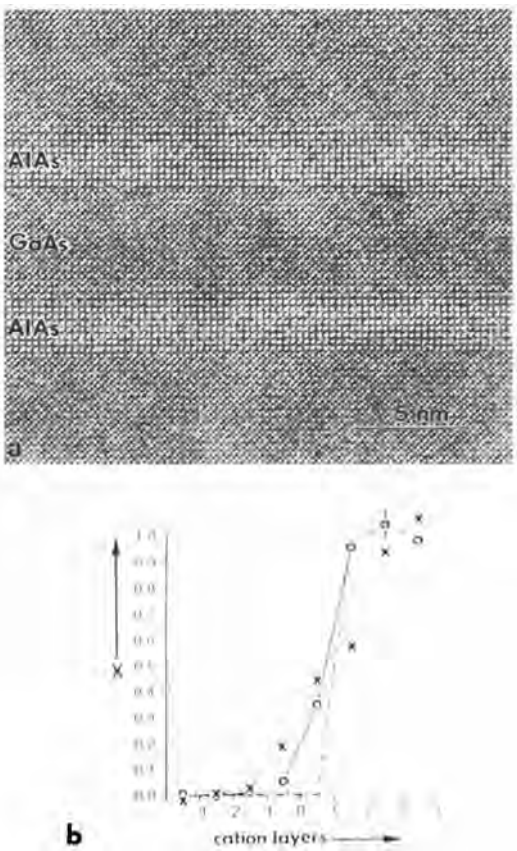

Figure 44. (a) ⟨1 0 0⟩ HREM image of an AlAs/GaAs double barrier quantum well structure grown by MBE showing characteristic dot patterns for AlAs and GaAs. (b) Aluminum concentration profiles across the interfaces obtained by quantitative evaluation of the dot pattern contrast. Sharp normal (AlAs on GaAs) interface (⊙), diffuse inverted (GaAs on AlAs) interface (×), and ideal interface (· – · – ·).

information is contained in the (200) beams which have diffraction vectors corresponding to real-space distances of 0.28 nm. In the $Al_xGa_{1-x}As/GaAs$ system the experimental accuracy of the method to determine the aluminum content in one individual cell of the contrast pattern was shown to be ± 0.1 [140]. Averaging over many cells along an interface improves this value drastically. Specimen preparation is an important issue for quantitative HREM imaging because it determines the signal-to-noise ratio in the image. Our laboratory experience confirms that the highest signal-to-noise ratio is found in chemically etched $Al_xGa_{1-x}As/GaAs$ samples, and the lowest in argon ion beam-thinned specimens [138]. The quality of cleaved wedge samples lies inbetween, and benefits from the simple preparation procedure. Layers with very low aluminum content ($x \approx 0.3$) are better imaged in chemically etched samples.

The clear difference in interface abruptness between normal (AlAs on GaAs) and inverted interfaces (GaAs on AlAs) can already been seen by visual inspection of the HREM image in Fig. 44a: the normal interfaces appear abrupt and the inverted ones diffuse. To quantify this impression, the composition profiles across the interfaces were determined using the algorithm described above (Fig. 44b). By averaging over 64 cells along the individual interfaces, the statistical error for the aluminum content x in the atomic layers of the transition region was reduced to $\Delta x = \pm 0.04$. The normal interface exhibits a transition region extending over one atomic layer, whereas the diffuse inverted interface extends over three layers. This difference between normal and inverted interfaces can be explained by the higher surface mobility of gallium atoms on the GaAs surface compared to that of the aluminum atoms on the $Al_xGa_{1-x}As$ surface during MBE growth. These results are in perfect agreement with electrical transport measurements [142].

A drastic improvement of HREM imaging in the ⟨1 1 0⟩ projection was obtained by removing the ion milling damage by chemical etching. Then, $Al_xGa_{1-x}As/GaAs$ and SiGe short-period superlattices can be imaged under certain conditions with high contrast [145], revealing interface steps and ordering effects clearly. This method was recently compared to the quantitative imaging method in the [1 0 0] projection by using the same samples and was found to yield the same results [146].

3.5.1.4 High-Resolution Chemical Analysis

High-resolution Z-contrast imaging combines very high compositional sensitivity with atomic resolution and has been applied to various semiconductor interface problems [147]. A high-current electron beam with a diameter of 0.2 nm or less generated by a field emission gun is scanned across a cross-sectional sample oriented in, for example, the ⟨1 1 0⟩ or ⟨1 0 0⟩ direction. The electrons scattered incoherently to high angles are collected below the specimen by an angular dark-field detector. This allows HREM images to be produced with strong differences in image intensity for elements with different atomic number Z, because the high-angle scattering cross-section depends closely on Z^2. Atomic interfacial ordering effects in SiGe superlattices and $CoSi_2/Si$ interfaces could be directly imaged [147].

Chemical composition profiles across III–V compound layers were successfully obtained with nanometer resolution by EDX analysis using a high-current 1 nm electron probe provided by a scanning transmission electron microscope with a field emission gun [148, 149]. However, it was realized that quantitative analysis can be severely influenced by electron channeling effects due to localization of the incident electron wave onto specific lattice sites. Then, the k factors used in the Cliff–Lorimer analysis change with orientation of the beam to the crystal, and with specimen composition and thickness. Moreover, phosphorus is lost from ternary and quaternary layers by a knock-on process when the electron beam energy of, for example, 200 keV is above the threshold energy of 110 keV for phosphorus displacement in InP [150]. Therefore, considerable care must be taken to ensure that a consistent method is adopted when performing such experiments.

3.5.2 Electronic Gallium Arsenide Device Structures

Electronic GaAs devices are based on FETs (field effect transistors), exploiting the higher electron mobility and drift velocity as compared to silicon, both of which improve device speed. In addition, use of semi-insulating GaAs substrate material minimizes parasitic capacitances. Disadvantages are the lack of a stable passivating native oxide (like thermally grown SiO_2 in silicon technology) and the higher defect density in the substrate (see Sec. 3.2.2 of this Chapter). Since both CMOS and, especially, bipolar transistors in silicon technology have improved drastically in speed in recent years, complex digital circuits on GaAs are not of general industrial interest. Analog ICs based on GaAs technology find their application at gigahertz frequencies. Microwave and millimeter wave power devices or low-noise amplifiers provide performance not obtainable with silicon. MESFETs (metal–semiconductor FETs) employ Schottky contacts as gate and ohmic contacts for source and drain metallization [151]. Process technology is in principle analogous to silicon IC technology with ion implantation for doping, lithography plus reactive ion etching for patterning, and silicon nitride layers deposited by CVD for passivation. All processes, however, have to be optimized according to the specific requirements of GaAs technology which—as with silicon technology—calls for detailed characterization during process development. Again, SEM and TEM cross-sections play a major part.

As an example, GaAs HEMTs are described which find wide application as, for example, low-noise transistors in receiver front ends for television satellite broadcasting. A HEMT is a modified form of a MESFET employing a heteroepitaxial layer structure grown by MBE [151]. At the interface of a low band gap material (GaAs) and a high band gap material ($Al_xGa_{1-x}As$) a thin inversion layer (minority charge carriers dominate) is formed, providing a very high mobility for the 2D electron gas. The cross-section through a GaAs HEMT device shows two gate fingers at A and B in Fig. 45a. Their sources are connected by an air bridge consisting of plated gold. This air bridge was deposited on a resist, which was dissolved afterwards, and

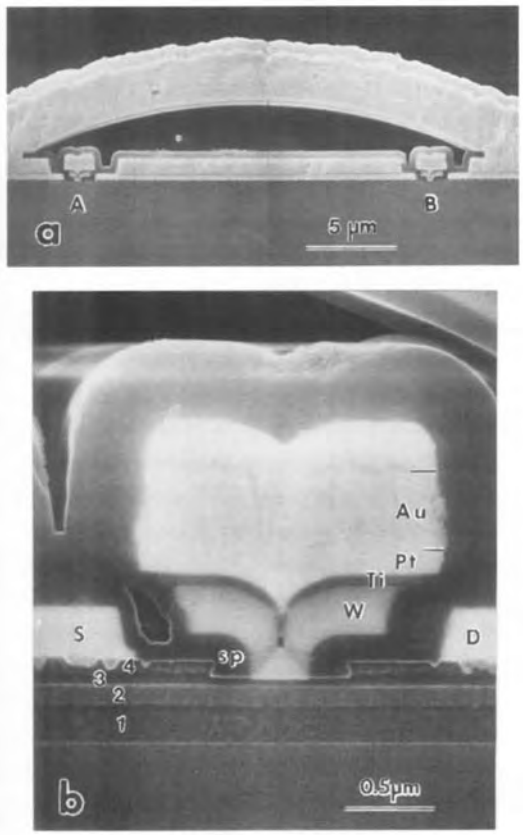

Figure 45. SEM cross-sections of GaAs HEMT device. (a) Overview with two gate fingers at A and B, and gold air bridge. (b) Gate region, for description see text.

provides a low-resistive and low-capacitance connection. The gate region is more clearly displayed in Fig. 45b. On top of the GaAs substrate, four heteroepitaxial layers can be discerned after selective etching of the SEM cross-section. Layer 1 is a $GaAs/Al_xGa_{1-x}As$ superlattice acting as a buffer layer, and the fringe pattern of the superlattice is just visible in Fig. 45b. At the interface of the undoped GaAs (layer 2) and the n-doped $Al_xGa_{1-x}As$ (layer 3) the inversion layer is formed. Using an additional strained pseudomorphic $In_xGa_{1-x}As$ layer at this interface for the channel enhances the charge carrier transport and the carrier density due to a decreased band gap, and thus improves the device properties [152]. The n^+-doped GaAs (layer 4) on top serves as the contact layer. To achieve a small gate length a self-aligned process was used for gate fabrication. First, the gate recess is etched into the contact layer using a mask of plasma silicon nitride. Then, Si_3N_4 sidewall spacers (sp in Fig. 45b) are produced by Si_3N_4 deposition and anisotropic RIE. Both RIE processes have to be optimized regarding lattice damage (see Sec. 3.3.5 of this Chapter). Using optical lithography for defining the 0.5 µm wide windows for the gate recess, the spacers narrow this window in a well-controlled way and provide a gate length of about 200 nm [153]. Tungsten is used as the gate material because of the high-temperature stability of refractory metals. To increase the conductivity of the gate, its cross-section is enhanced by additional titanium, platinum, and gold layers vapor deposited on top of the tungsten and patterned by the lift-off technique [151]. The various metal layers are indicated in Fig. 45b. All heavy elements show bright contrast in the SE image because a larger number of BSEs contribute to the SE signal. This stack of titanium, platinum, and gold is used as a mask to etch the tungsten gate. Over-etching reduces the gate width to less than that of the aforementioned stack. Then, this gate structure with a T shape ('T gate') allows self-aligned deposition of the ohmic metallization for the source and drain (S and D in Fig. 45b). The ohmic metallization further increases the thickness of the gate structure. Since ohmic metallizations involve alloying at a temperature of around 400°C (see below), a

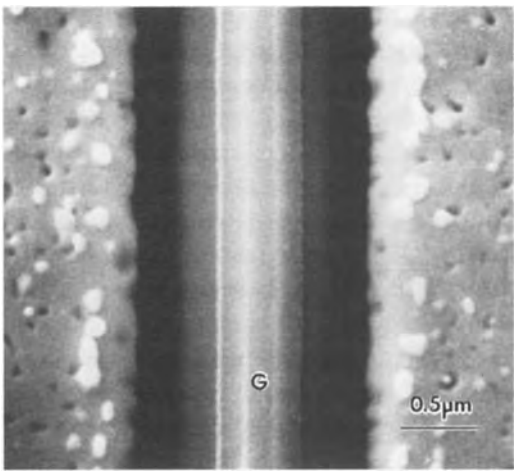

Figure 46. SEM image of the metallization-semiconductor interfaces in a GaAs HEMT after removal of the GaAs substrate by selective etching.

rough interface is formed at the source and drain contacts.

SEM cross-sections provide detailed information but only for one section plane. Since the gate fingers extend over, typically, 100 μm, assessment of uniformity along the gate requires additional information. This can be achieved by glueing the device upside down on a support and removing the semiconductor substrate and heteroepitaxial layers by selective etching. An etching solution of H_3PO_4, H_2O_2, and H_2O (13:20:5) provides high selectivity to both gate and ohmic metallization. Figure 46 shows the uniformly smooth interface of the tungsten gate (G) in the center and the rough interface of the ohmic metallization of the source and drain to the left and right.

In contrast to silicon, complex metallization systems are needed to attain ohmic contacts to GaAs. The gold–nickel–germanium system is the most widely used contact metallization for this purpose [154]. Because of its higher thermal stability, another metallization system made up of a germanium–gold–chromium–gold sequence of layers has been used successfully [155]. The complex metallurgical reactions that occur during the alloying process were studied in detail by TEM cross-sections and Auger depth profiles [156], and will be described briefly below. After vapor deposition of layers of 10 nm of germanium, 140 nm of gold, 40 nm of chromium, and 200 nm of gold, alloying was carried out at a temperature of 390°C for 12 min in a nitrogen atmosphere. The TEM cross-sections of Fig. 47 reveal the details of the alloying reaction. The morphology of the upper gold layer did not change during alloying, but the grain size has increased. Since the Auger depth profile showed the chromium layer to contain a considerable amount of oxygen, this film probably consists of chromium oxide, which also explains its very small grain size (Fig. 47b). The position of the original GaAs surface can be identified by a row of bright dots, representing oxide particles (arrows in Fig. 47b). These particles were formed when the interfacial oxide film balled up at the beginning of the alloying reaction. The grains in the vicinity of the original GaAs surface appear brighter than the gold grains, which, apart from diffraction effects, are usually darker due to their high atomic number. Individual grains were analyzed by EDX in a scanning transmission electron microscope in order to identify the various phases in the alloying zone (Fig. 47b). Only chromium and arsenic could be detected in the bright grains around the original interface with a ratio of the chromium and arsenic mole fractions close to one. The conclusion that this phase is indeed CrAs was supported by

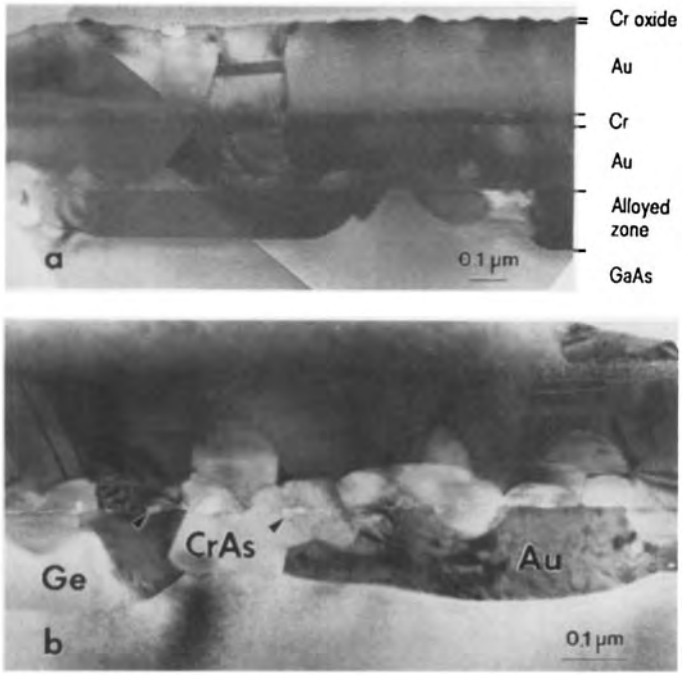

Figure 47. TEM cross-sections of ohmic metallization on GaAs after alloying. (a) Overall layer sequence. (b) The various phases in the reaction zone are indicated.

selected-area diffraction. Some grains in the alloying zone that exhibited only a slight difference in contrast from the GaAs substrate were found to consist entirely of pure germanium. These grains precipitated epitaxially onto the GaAs substrate (Fig. 47b). No significant variation was found in the composition of the gold grains in the various layers. Apart from gold, some gallium and arsenic was measured. To some extent at least, however, the X-ray intensities of arsenic and gallium stem from secondary excitation (e.g., by electrons scattered in the specimen). Since the intensity ratio of gallium to arsenic was about twice that in the GaAs substrate, we conclude that the grains of gold do in fact contain several percent of gallium. To obtain better quantitative results the upper gold layer was analyzed by electron probe microanalysis (wavelength-dispersive X-ray spectroscopy) using beam voltages low enough to confine the excitation volume to within this gold layer. No arsenic could be detected whereas the gallium mole fraction was about 7%. Furthermore, germanium was detected with a mole fraction of the order of 0.5–1%, which could not be detected by X-ray analysis in the scanning transmission electron microscope.

The line of oxide particles at the original metallization–GaAs interface (Fig. 47b) indicates that no melting occurred and alloying took place by solid state diffusion. Gold certainly provides the major driving force for the alloying reaction, supported by chromium. Gold penetrates the metal–GaAs interface and dissolves gallium, while arsenic reacts with chromium to form the CrAs phase. No compounds of germanium with other elements were found here, in contrast to the Ni_2GeAs phase described by Kuan

et al. [157]. Germanium forms a separate phase but is also dissolved in the Au(Ga) grains. Precise knowledge of the alloying reaction allows conclusions to be drawn about the conduction mechanism. During the formation of the Au(Ga) phase, gallium vacancies are produced in the adjacent GaAs crystal. The in-diffusing germanium atoms will populate gallium sites and therefore act as donors. This highly doped n^+ zone allows enhanced electron transport via tunneling. Consequently, the Au(Ga) phase that forms the major part of the contact interface is responsible for the current transport, to which neither the CrAs nor the germanium phases contribute [155, 156].

4 Optoelectronic Materials

4.1 Introduction

Most optoelectronic devices are based on semiconducting materials that can emit light efficiently under electrical excitation, converting electrical to optical energy (e.g. light emitting diode, semiconductor laser). Conversely, they can detect optical signals through electronic processes (e.g. photodetector) or convert light to electrical energy (e.g. photovoltaic device, solar cell).

Conventional optoelectronic devices are manufactured separately as individually packaged components, but numerous research activities have been performed recently on optoelectronic integrated circuits (OEIC) which incorporate optical and electronic devices monolithically on a single chip. This OEIC development is mainly due to a tremendous increase of semiconductor laser applications and to the progress in the very large scale integration technology (VLSI). As examples of technologies spawned by the semiconductor laser advent, there are: optical communications (long distance systems, local area networks or data transmission between satellites), laser radar and laser gyroscope, optical recording (video disks and audio disks), laser printers or displays, laser-micromachining (welding and soldering), bar code reading, medical technology (surgery and diagnostics).

Numerous industrial advantages may be attributed to OEIC including higher reliability, lower cost, higher performances and easier packaging [1, 2]. However, a difficult challenge faced by the technology is to interconnect electrically and optically various types of devices based on different materials with dissimilar structures. An illustration of this sort of problem is given by a communication system structure. The incoming electrical signal is modulated by a light source and then channeled as efficiently as possible into an optical fiber. At the end of the fiber, a detector converts the light signal back into an electrical signal. The coupling of the fiber both to the light source and to the detector is of major importance to minimize the optical losses. The transmission spectral window of the most common optical fibers presents a very low absorption at about 0.85, 1.1, and 1.5 μm and a minimum of the optical signal dispersion at 1.3 μm. The emitted wavelengths and the spectral width of the light source are thus imposed by the optical fiber properties to obtain a long distance and low cost optical communication system. In the same manner, the detectors should be designed to match their maximum sensitivity to these same wavelengths. Great

attention should be paid to the choice of the semiconductors used in such a system and to the compatibility in their mutual connection.

To date, silicon emerges as the most important material in microelectronic technology for electronic signal processing and transmission. However, due to its indirect gap nature, it cannot be intrinsically used as an efficient and universal light emitter. Concerning optoelectronic applications, the semiconductor compounds have been chosen as optoelectronic materials for their high quantum efficiency, their radiative carrier lifetime, their high surface-recombination-speed, their direct gap and the possibility of n or p-type doping to introduce efficient radiative recombination centers.

Table 1 summarizes the energy bandgaps (E_g) of various materials currently used in optoelectronic applications. III–V compounds are intrinsically good optoelectronic materials. However, their integration on silicon chips (used in microelectronic technology) is not yet fully achieved. Due to their larger bandgaps, II–VI materials offer the possibility of creating structures which operate in the visible region of the spectrum. The promise of these materials has not yet been realized because of the difficulties in producing defect-free structures with controlled doping. However, some II–VI heterojunction systems have been successfully fabricated for photodetection applications and solar cell energy conversion. Various silicon based compounds and heterojunctions have been recently studied and potential applications appear to be numerous. They are not yet developed at the industrial level because of difficulties in achieving high quality heterolayers.

It appears that most of the drawbacks listed above originate from the heteroepitaxy of active optoelectronic semiconductors on foreign substrates (e.g., silicon). Such process often causes deteriorations in epitaxial layers (high density

Table 1. Bandgap value of semiconductors most commonly used in OEIC

class	element	bandgap (eV)	direct (D) or indirect (I) gap	
IV	C	5.47	(I)	
	Si	1.12	(I)	
	Ge	0.67	(I)	
IV–VI	SiC	3.00	(I)	
III–V	GaP	2.26	(I)	
	AlAs	2.16	(I)	
	$GaAs_{1-x}P_x$	3.1 ($x = 0.45$)	(D)	$x < 0.45$
			(I)	$x > 0.45$
	GaAs	1.43	(D)	
	InP	1.35	(D)	
	InSb	0.18	(D)	
II–VI	ZnS(α) hexagonal	3.8	(D)	
	ZnS(β) cubic	3.6	(D)	
	ZnTe	2.58	(D)	
	CdS	2.53	(D)	
	CdTe	1.5	(D)	

of defects and stresses) and at the interface (misfit dislocations, etc.) due to the coupling of nonmatching lattice materials. These effects are especially detrimental for optical devices which function as minority carrier devices very sensitive to the material quality. A wide range of growth techniques has been developed in order to realize high quality heteroepitaxy including molecular beam epitaxy (MBE), chemical beam epitaxy (CBE), liquid phase epitaxy (LPE), various methods of vapor phase epitaxy (VPE) and physical vapor deposition (such as evaporation and sputtering). Concurrently performing electronic and structural techniques have also emerged in the heterolayer characterizations. Among them microscopic methods are particularly suited to the study of microstructures and their defects in very thin epitaxial layers and interfaces. This obviously covers: (i) conventional microscopy techniques such as transmission electron microscopy (TEM) and scanning electron microscopy (SEM); (ii) atomic microscopy, including scanning tunneling microscopy (STM) and atomic force microscopy (AFM); and (iii) chemical imaging techniques using ions (secondary ion mass spectroscopy), electrons (scanning Auger microscopy and electron energy loss spectrometry) and X-ray (energy dispersive X-ray spectrometry).

When specifically applied to optoelectronic materials, these microscopic techniques can provide information of the following kind:

- local composition (dopant and impurities)
- epitaxial relationships and misfit defects
- strain concentration
- morphology and microstructure.

Obviously this information should be strongly correlated to the optoelectronic properties of the materials investigated.

In this chapter, we first discuss some of the materials used as active components in the most common optoelectronic devices. The contribution of different microscopic techniques in the study of those materials is then detailed. Finally, we provide some examples of microscopic studies performed on heterojunctions or nanostructures based on III–V, II–VI and Si compounds.

4.2 Materials for Optoelectronic Devices

Materials used for optoelectronic devices can be schematically separated into two groups, depending on the physical interaction process between a radiation and the carriers of the semiconductor [3–6].

4.2.1 Luminescent Materials

Devices which convert electrical energy into optical energy are fabricated from those materials. The electrical energy applied to the semiconductor excites carriers (electrons) into the conduction band. Those electrons can fall down in free states (holes) of the valence band with '**spontaneous emission**' of a photon in the ultraviolet, visible, or infrared regions of the electromagnetic spectrum. Typical devices based on this electroluminescence phenomenon are light emitting diodes (LEDs).

The photon present in the semiconductor could also induce a transition of an

Table 2. Emission wavelength of some LED materials

material	dopant	emission wavelength (μm)	color
GaAs	Si or Zn	0.9–1.02	infrared
$GaAs_{1-x}P_x$	N	0.55–0.69	green–red
GaP	Zn or O or N	0.57–0.7	red
ZnS			blue
SiC			blue
$Ga_xIn_{1-x}As_{1-y}P_y$			infrared
$GaAs/Ga_{1-x}Al_xAs$ heterojunction			infrared

electron in the conduction band to a free state of the valence band with emission of a second photon of similar energy. This process is called '**stimulated emission**' and is used in semiconductor lasers.

The transition of carriers between the conduction and valence band is called an intrinsic band-to-band transition. The emitted light frequency corresponds then to the semiconductor gap value ($h\nu \sim E_g$). There are also other possibilities for extrinsic transitions involving carriers from one energy band to impurity levels near the opposite band (conduction band to acceptor levels, or donor levels to valence band) leading to a shorter emitted frequency ($h\nu < E_g$).

The main applications of LEDs and lasers are focused in optical coupling, optical display, and illumination.

The main requirements for a suitable LED material are: (i) a direct bandgap of appropriate width, (ii) low resistivity, (iii) efficient radiative pathway, and finally, (iv) the ease of fabrication of the material into a complete device. The most important materials used in LEDs are GaAs, GaP and ternary alloys $GaAs_{1-x}P_x$ whose characteristics are given in Table 2.

Basic principles of semiconductor lasers are quite similar to LEDs; therefore direct bandgap compound semiconductors are also required. GaAs was the first luminescent material to lase, but today most III–V compounds are extensively studied and developed in laser applications. Since the wavelength of the emitted light is very close to the width of the bandgap, wide range bandgap materials must be chosen to produce lasers which emit light in a large visible spectral width. Ternary III–V alloys of the form $A_xB_{1-x}C$ are currently used since their bandgaps vary monotonically with the value of x and lie between the AC and BC compound alloys. However, their lattice matching with the substrate is very poor. It is thus preferable to use quaternary III–V alloys which match much more closely the substrate material. Moreover, it is possible to select such alloys which are luminescent at any given wavelength from about 7 μm down to 0.55 μm. Although the two currently employed systems are $Ga_xIn_{1-x}As_{1-x}P_y/InP$ and $Al_xGa_{1-x}As_ySb_{1-y}/InP$, considerable use has also been made of the ternary IV–VI alloys PbSnTe and PbSSe, since their luminescence range varies from about 5 μm to 34 μm.

4.2.2 Photoconducting Materials

When radiation falls on the surface of a semiconducting material it can be

absorbed and carriers are generated either by a band-to-band process (intrinsic transitions) leading to the fundamental absorption or by extrinsic transitions involving impurity levels. Devices which convert optical signals into electronic processes are based on those materials. Typical examples are photodetectors and photovoltaic devices such as solar cells.

The two most common photodetectors are the photoconductive cell and the photodiode. Each type of these photodetecting devices uses specific semiconducting materials: (i) II–VI compounds under the form of polycrystalline layers are generally used for the realization of low cost photoconductive cells sensible to the visible range. CdS is conventionally used in the near infrared range but small bandgap (InSb, PbS) semiconductor compounds and Ge crystals doped with either gold or nickel are also good candidates. The $Hg_xCd_{1-x}Te$ ternary compound with a bandgap varying with x allows to realize devices with maximum sensitivity between 5 and 15 μm very useful for military applications. Table 3 compares the wavelength range for peak sensitivity of different photoconducting materials. (ii) So far, a wide range of photodiodes are fabricated with semiconductors, operating with different principles (p–i–n photodiode, avalanche photodiode, phototransistor, Schottky photodiode and heterojunction photodiode). Silicon is the major semiconducting material used in photodiode thanks to various extrinsic transitions. It provides devices with 80% quantum efficiency at wavelengths between 0.8 and 0.9 μm. Some other materials used also in photodiode technology are listed in Table 4.

Table 3. Wavelength range for peak sensitivity of different photoconducting materials

materials	wavelength (μm)
CdS, CdSe	0.3–0.7 μm
Ge (Au, Ni)	1–1.5 μm
PbS, PbSe, InSb	2 μm
$Hg_xCd_{1-x}Te$	5–15 μm (depending on x)

The simplest solar cell is based on a p–n homojunction. Incident photons pass through the thin n-type layer (called the collector) and are absorbed by the thick underlying p-type layer (called the absorber) generating carrier pairs which diffuse separately through the p–n homojunction. The solar cell performance depends on the creation efficiency of electron–hole pair and on the separation speed of these carriers across the p–n junction. Some calculated values of solar efficiency are given for various semiconductors (Table 5).

Table 4. Wavelength range for peak sensitivity of different photodiode materials

device	material	wavelength (μm)
metal–semiconductor photodiode	Ag/ZnS, Au/Si	0.3–0.7
heterojunction photodiode	$Al_xGa_{1-x}As/GaAs$	1.1–1.5
avalanche photodiode	Si	0.6–1
	Ge	1–1.6
n–i–p photodiode	Si	0.6–1
	Ge, GaAs, GaInAs, CdTe	1.1–1.5
	HgCdTe, PbSnTe	10

Table 5. Characteristics of some solar cell materials

material	bandgap (eV)	solar efficiency (%)
$CuInSe_2$	1.01	26
Si	1.12	27
Cu_2S	1.2	23
InP	1.35	29
GaAs	1.43	28
CdTe	1.56	27

4.3 Microscopic Techniques

The strong dependence of OEIC properties on the morphological and microstructural features of the used crystalline materials (and of the interfaces between layers), implies the necessity of using microcharacterization methods. These are important for checking the heterostructure quality: epitaxial relationships, crystalline defect and impurity density, interface grading, segregation of dopants, volume distribution of the chemical elements, level of strain, etc. Considering the low density level of defects (or impurities) demanded in OEIC devices, extremely high sensitivity techniques are needed. Conventional microscopic techniques (TEM and SEM) as well as atomic microscopy (AFM and STM) or chemical imaging (ionic, electronic, and X-ray mapping) are well suited for local microcharacterization of OEIC. Moreover, a correlation between atomic level information and optoelectronic device properties should be highly beneficial. For instance, cathodoluminescence (CL), electron beam induced current (EBIC) and scanning deep level transient spectroscopy (SDLTS) performed in TEM and STEM instruments are available to obtain this type of correlation.

We should point out that TEM studies necessitate difficult and tedious preparation of the samples mostly realized by mechanical thinning followed by either chemical etching or Ar^+ ion milling. The degradation possibly induced by this preparation process is one of the main drawbacks of TEM studies.

Some of the relevant questions that can be elucidated by the microscopic techniques are now discussed in detail.

4.3.1 Epitaxial relationships

At interfaces between OEIC layers, the carrier behavior is strongly dominated by interfacial states and/or electrical dipoles arising from the local chemical bonding. Therefore, the epitaxial relationships between the heterolayer and the substrate have to be well controlled. These relations, expressed as a pair of parallel directions in a pair of parallel planes, are easily determined by selected area diffraction (SAD). The comparison of diffraction patterns obtained along three orthogonal crystallographic axes gives the three-dimensional relations. One of these axes is taken parallel to the growth direction and corresponds to a plane view of the sample. The other two axes are perpendicular and correspond to transversal views.

Two cases should be distinguished depending on the constitution of the deposited layer, either large epitaxial grains with the same orientation relation or smaller grains with different orientations. In the first long-range-order case, various global diffraction techniques are available to determine the epitaxial relationships and the microscopy contribution is redundant. By contrast, the second case needs local structure determination which

can only be performed by TEM methods, by selecting very small area to obtain SAD pattern on a single grain [7]. Concurrently, local direct information is obtained by Moiré patterns (the parallel, rotational and mixed Moiré fringes can be distinguished by their relative orientation with the substrate planes) which allow the determination of the reflecting planes overlapping with a resolution of 1 nm (for a detailed description of SAD and Moiré patterns see Vol. 1 of this Handbook, Sec. 4.1.1).

4.3.2 Strain in the Heterolayer

Heterostructures are constituted by the combination of various semiconductor layers which have an artificial periodicity and structure. In such systems, the overlayers are usually limited in thickness in the range of few atomic monolayers. The epitaxial growth most often proceeds by building an overlayer strained in the growth plane to fit the substrate lattice constant. This phenomenon, known as pseudomorphism, allows buildup of strained-layer superlattices in which the thickness is small enough to accommodate the strain without creating misfit dislocations. An elastic deformation of the lattice is then observed. Quantum mechanical effects combined with strain effects drastically change the electronic band structures and can induce original optical properties of such layers [8–10].

For instance, it has been shown that the use of strained pseudomorphic heterojunctions in semiconductor lasers induces higher speed, higher modulation frequency, and lower threshold current density [11]. These characteristics are extremely sensitive to the amount of strain in the heterolayers. Two microscopic techniques are particularly well suited to determine precisely the strain content in thin layers: (i) convergent beam electron diffraction (CBED) and (ii) quantitative high resolution electron microscopy (Quanti-TEM).

Since a complete description of CBED has been presented in Vol. 1 of this Handbook, Sec. 4.1.5, we only briefly recall the advantages of this technique with regard to the strain analysis. The geometry of the High Order Laue Zone (HOLZ) lines (present inside the diffracted beams) is very sensitive to the variation of the lattice parameter and hence HOLZ patterns should be used to determine the local lattice parameter [12, 13]. Some lattice parameter variations have been measured with a precision down to $\sim 10^{-3}$. This precision in conjunction with the low diameter of the electron beam used in this technique makes it a unique means to determine local parameter changes due to elastic strains.

Quanti-TEM technique (for detailed description see Vol. 1 of this Handbook, Sec. 4.1.1) consists in measuring the variations of the projected potential over the interface area from lattice images of a heterojunction. The experimental conditions thickness/defocus are first determined using a set of calculated images. Then the intensity distribution of the experimental image is mapped. The maxima are precisely localized and related to the projection of the real structure of the sample. The measure of the exact positions of the maxima gives access to different phenomena and in particular to local elastic deformations [14–16].

4.3.3 Dopant and Impurity Volume Distribution

To modulate their extrinsic properties semiconductor materials are doped during their growth, but they may also be contaminated inadvertently with other impurities. To understand the electrical and optical properties of crystals it is necessary to control the impurity and dopant nature, their concentration, and their distribution within the layered structures. A broad range of local chemical analysis techniques have been developed and systematically applied to the new optoelectronic materials in order to gain a clearer insight into their chemical properties. Four main techniques should be cited here: microprofiling secondary ion mass spectrometry (SIMS), Auger electron spectrometry (AES), electron dispersive X-ray spectrometry (EDX) and electron energy loss spectrometry (EELS). They provide complementary information in specific areas.

For high sensitivity profiling, SIMS is the first choice method since concentration limits of $\sim 10^{13}$ atoms cm^{-3} are attainable and thus homogeneously distributed surface impurities in low concentration can be detected [17, 18]. Two types of instrumentation are used in depth profile imaging: (i) ion microprobe and (ii) ion microscope (Vol. 2 of this Handbook, Sec. 4.2.6). These techniques allow localization of chemical elements with a lateral resolution of 0.2–0.5 μm. Probing a very flat crater performed in the multilayer sample and a depth profiling image of the crater walls can be obtained and informs on the spatial distribution of the extracted secondary ions across the heterostructure thickness. For example, the electrical contacts of a transistor have been visualized by the SIMS image of Al^+ ions [19].

Higher lateral resolution in the range of 50 nm can be achieved with scanning Auger microscopy (SAM) (Sec. 2.3 of this Chapter) which is mainly limited by the incident beam diameter and the escape depth of backscattered electrons. Ultimate resolution of 10 nm has been reached with a beam energy of 5 keV and a beam intensity of 1 nA [20]. SAM is ideally suited for identifying small particulates and impurities on the wafer surface, since one can focus the electron beam on the particulate and record its Auger spectrum. Surface chemical imaging can be obtained. It is also possible to perform concentration depth profiles on a very small depth scale (nanometer range) [21].

A lateral resolution of approximately 1 nm (about the incident beam electron diameter) is obtained by EELS in TEM or STEM equipment (details in Sec. 1.3 of this Chapter). This electron spectrometry can also be used in the filtered imaging mode. This consists in integrating all the electrons which have lost an amount of energy ΔE selected by slits at the exit of the spectrometer. A procedure of background subtraction (similar to that used for SAM) allows a three-dimensional map to be obtained which informs directly on the localization of a given element. Line scan can also be performed across the interface of cross-sectional samples informing on the depth distribution of one element across the interface for example [22]. A severe limitation of the technique is in the preparation of very thin samples.

EDX can be performed in TEM or SEM apparatus. One of the advantages of using TEM is to enable a chemical map of cross-sectional thin samples to be

obtained. In this case, since beam spreading can be neglected, the spatial resolution of EDX spectrometry is approximately equal to the electron beam diameter (about 1 nm). The basic principle of the X-ray emission is detailed in Vol. 1 of this Handbook, Sec. 2.1. Briefly, the target atom ionized by the microscope electron beam produces X-ray emission associated to the inner shell level electronic transitions during the recombination process. By selecting an energy window one can obtain an elemental map of intensity. On the same sample area it is then possible to correlate the morphological characteristics of an optoelectronic structure with the spatial distribution of the chemical constituents. EDX is a quick, convenient and, at least, semiquantitative technique. However, the detection limit is very poor concerning light elements. Thus it can be used to check the presence of metallic impurities but not to detect oxides or hydrocarbon contaminants or even some kind of dopants.

4.3.4 Morphological Characterization

Morphological characterization includes the determination of layer thickness, interface and surface roughness, crystalline defect density, segregation and diffusion processes, intermediate phases at interfaces and their transitions, etc.

These morphological features are introduced during various steps of the heterolayer growth. First, for example, the clean substrate surface, which is obtained by etching of an oxidized wafer, may present structural defects like steps, vacancies, nonuniformity, and impurities capable of generating surface states. At the initial stages of deposition, the energy released by the chemisorption of adsorbed atoms can induce new reaction products and dissociate the substrate surface, generating new defects which govern the subsequent growth. Second, if now we assume that the starting substrate is perfectly flat, during the first stages of growth, surface roughening may appear because of dynamical roughness or transition from the layer-by-layer growth model to island growth mode, depending on various growth parameters.

Another important mechanism which induces grading of the interface is the segregation phenomenon. This mechanism brings substrate atoms to the topmost surface, while overlayer atoms are driven underneath, inside the substrate. This process, which takes place during the growth and sometimes at temperatures where bulk diffusion may be negligible, leads to a diffuse and intermixed interface. The interface grading can extend, even in perfectly matched layers, over several monolayers. This creates mixed chemical bonds between the interfacial atoms and their nearest neighbors in each layer and may induce significant changes in the energy levels of the heterojunction.

Furthermore, interfaces always contain interfacial defects which scatter and trap electrons, holes or excitons. These defects greatly affect the properties of optical components. In particular intrinsic defects give rise to a series of localized states well visualized in photoluminescence experiments [23]. Quanti-TEM and EELS are the most available microscopic techniques to yield information on the interface grading. EELS spectra of GaAs/AlGaAs heterostructures are given for instance in [24] and an example of Quanti-TEM

applies to Si/SiGe interface grading will be presented in the following section. The analysis of defects is commonly performed by transmission election diffraction (TED) coupled with HRTEM.

STM and AFM (detailed in Vol. 2, Sec. 7.1. and 7.2 respectively) give a direct mapping of the overlayer topography deduced from spatial variations of the electronic and atomic properties. Information on the geometry and dynamics of adsorbates can thus be easily recorded. STM (and AFM) studies mainly concern the surface reconstructions and initial stages of growth and allow the detection of local surface state defects. These surface states are of first importance for a full understanding of the growth mechanisms but they are generally not directly correlated to the optical properties of the heterostructures. However, some researchers have developed cross-sectional STM to study semiconductor heterostructures. Such studies have reported results on the local determination of band offsets, measurements of electronic transition widths at the interfaces and detailed mapping of multiple-valley conduction band structures [25].

4.3.5 Recombination Centers

We have reviewed above most microscopic techniques used for the characterization of optoelectronic materials. However, all these techniques do not allow characterization of the individual optoelectronic behavior of the chemical elements or components involved. Of particular interest is the determination of radiative/nonradiative centers in a semiconductor sample and of the wavelength of the emitted radiation. The optoelectronic properties of defects (point, line or planar) are also investigated extensively since defects play an important role in the degradation of the device optical properties.

With the advent of optoelectronic applications, new microscopic techniques have been developed. It is now possible to probe simultaneously the microstructural and the optoelectronic properties of materials with TEM or STEM microscopes equipped with cathodoluminescence (CL) systems [26–28]. Since the CL technique is introduced in Vol. 2 of this Handbook, Sec. 4.2.1 we only briefly recall the physical principle. Under the microscope primary electron beam, excitation of the target electrons from a ground state to an ionization state is followed by a relaxation process back to the ground state. During this relaxation different recombination processes take place, some of them leading to photon emission (radiative recombination). Measurements of the radiative process, which is very efficient in the case of direct bandgap materials, form the basis of CL.

Intrinsic emission results from the direct band-to-band recombination of carriers. The intrinsic emitted luminescence spectrum is often called near-band-edge radiation because of both free excitons and excitons bound to shallow recombination centers may contribute to this emission. Extrinsic emission arises from carrier transitions on shallow or deep energy states localized in the forbidden bandgap. These states associated with donor–acceptor centers result, for example, from the presence of impurities.

STEM–CL allows the measurement of the spectrum of light emitted by the sample, the display at a microscopic scale of the radiative defect centers, and the study (e.g.,

their properties) as a function of temperature. In CL spectroscopy implemented in a STEM instrument, the CL signal is collected through a very small elliptical mirror (or a lens) mounted inside the STEM polar pieces very close to the sample surface, guided by an optical fiber and detected by a photomultiplier. The signal is then analyzed by a spectrometer and sent into the video chain of the STEM microscope to obtain monochromatic CL images [20]. Some other spectroscopic techniques can be associated to CL, particularly with (i) the electron beam induced current (EBIC), which determines the recombination properties of the defects, and (ii) the scanning deep level transient spectroscopy (SDLTS), which measures the defect energy level in the gap [30].

All these spectroscopic techniques have been applied to defects and interfaces characterization in direct bandgap materials. Although unique information can be gained by a straightforward comparison of localized nanostructures observed in TEM micrographs with their radiative/nonradiative behavior, (CL) spectroscopy has not been very developed. This is mainly due to instrumental difficulties but also to the importance of the surface recombination effects. Indeed, for very thin samples there are numerous surface states with nonradiative high recombination rate that reduce the photon flux intensity.

4.4 Applications to Optoelectronic Materials

Examples of applications now follow to illustrate the contribution of some microscopic techniques for studying the different parameters, listed above, of paramount effect on the optical properties of the devices.

4.4.1 Applications to III–V Compounds

Under various growth conditions (cleaning, substrate nature, growth temperature, growth rate, etc.) III–V compound heterolayers prove to be high-efficiency luminescent materials. It is then important to clearly determine diverse origins of their light emission. These problems have been solved by microscopic cathodoluminescence techniques.

The first example [31] concerns GaAs/$Ga_{1-x}AL_xAs$ heterostructures. It compares the luminescence efficiency of two structures, a multiple quantum well (MQW) and an undoped double heterostructure (DH). The samples were grown by MBE on (1 0 0) GaAs substrates. Both photoluminescence (PL) and cathodoluminescence (CL) were measured on free-standing samples and quite similar spectra were obtained. The representative CL spectrum (Fig. 1a) obtained on a DH sample shows:

(i) a main luminescence peak at 1.513 eV which is associated with a neutral donor bound exciton (D°, X). This luminescence originates from the whole sample surface and is thus representative of an intrinsic phenomenon since nonradiative centers (at a density range of 10^4–$10^5\,cm^{-2}$) are observed in the corresponding monochromatic micrograph (Fig. 2a).

(ii) two luminescence lines associated to impurities; the carbon acceptor

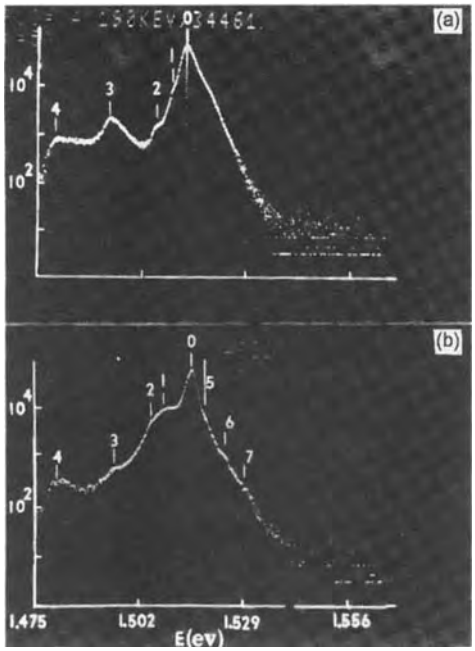

Figure 1. CL spectrum of (a) DH sample and (b) MQW sample. $E_0 = 100\,\text{keV}$. Sample temperature is 20 K. Reproduced by permission of P. M. Petroff et al. [31].

recombination (e, C°) at 1.493 eV and the germanium acceptor recombination (e, Ge°) at 1.480 eV.

(iii) two unidentified CL lines at 1.510 and 1.506 eV which seem to be associated to defects appearing during the MBE growth process. A series of CL monochromatic images in this energy range reveal that some of the discrete centers appear radiative at the energies of 1.510 and 1.506 eV (Fig. 2b), even in the highest quality areas of the sample. Concurrently, dislocation clusters or single isolated dislocation are pointed out by TEM analysis in the areas showing these discrete luminescence centers. Moreover, the disappearance of the luminescence at 4 K confirms that the defect bound exciton or

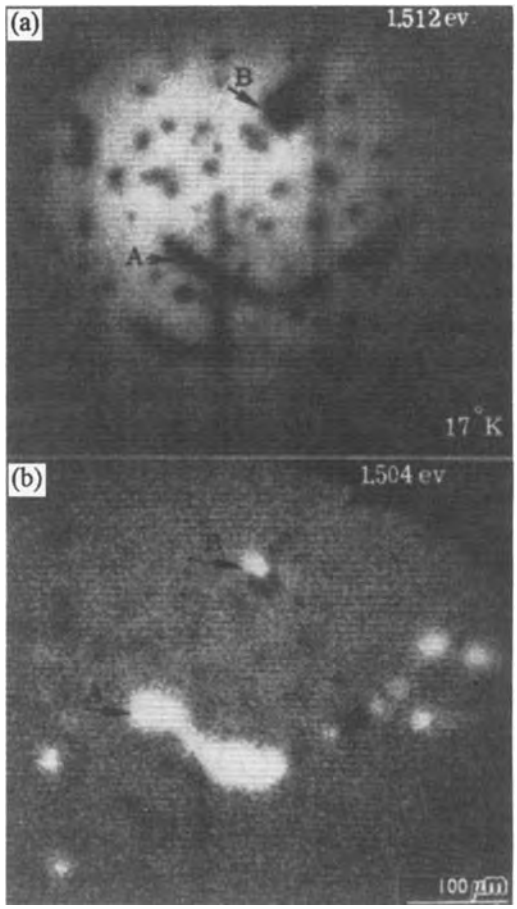

Figure 2. CL monochromatic micrograph of the DH sample at (a) 1.512 eV and at (b) 1.504 eV. Sample temperature is 17 K. Reproduced by permission of P. M. Petroff et al. [31].

electron is at the origin of this luminescence. Therefore it can be easily concluded that the 1.510 and 1.506 eV CL lines are related to the observed dislocations.

By comparison, the representative CL spectrum of a MQW structure (Fig. 1b) shows:

(i) a main luminescent line (at 1.516 eV) corresponding to the recombination energy of the free exciton attributed

to the electron–heavy hole (e–hh) $n = 1$ transition.

(ii) three emission lines at 1.519, 1.524 and 1.530 eV, respectively, attributed to the electron–light hole (e–lh) $n = 1$ transition, to the forbidden transition and to the (e–hh) $n = 2$ transition.

(iii) the below band gap luminescence which is identical to that of the DH structure. Even if the origin of the 1.513 and 1.508 eV emission lines is interpreted in the same manner than for the DH structure, it should be noticed that their intensity is much lower. Therefore, since a dislocation density of 10^4–$10^5\,cm^{-2}$ has been revealed by TEM, these are mainly inactive dislocations. Furthermore, by contrast with the DH structure, the monochromatic micrographs reveal a perfect uniformity of luminescence and the absence of nonradiative discrete centers. This result explains the higher luminescence efficiency observed in the MQW superlattices over that of the DH structures.

The second example of STEM–CL technique [32] analyzes degradations induced by the etching process on free-standing quantum dots fabricated from GaAs/AlGaAs quantum well heterolayers. The structure studied contained four single quantum wells with nominal GaAs well-widths of 5, 10, 20 and 80 nm separated by AlGaAs barrier thicknesses of 34 nm. The quantum dots were produced by a combination of electron beam lithography and reactive ion etching using CH_4/H_2 ambient. The etching depth was large enough to ensure that the 5 and 10 nm wells formed into dots. An array of dots 500 nm in diameter and 2 μm spacing was produced.

A representative spectrum recorded on unetched areas of the sample (Fig. 3a) shows peaks at 1.591, 1.543 and 1.521 eV that correspond to the quantum well excitonic emission from the 5, 10 and 20 nm

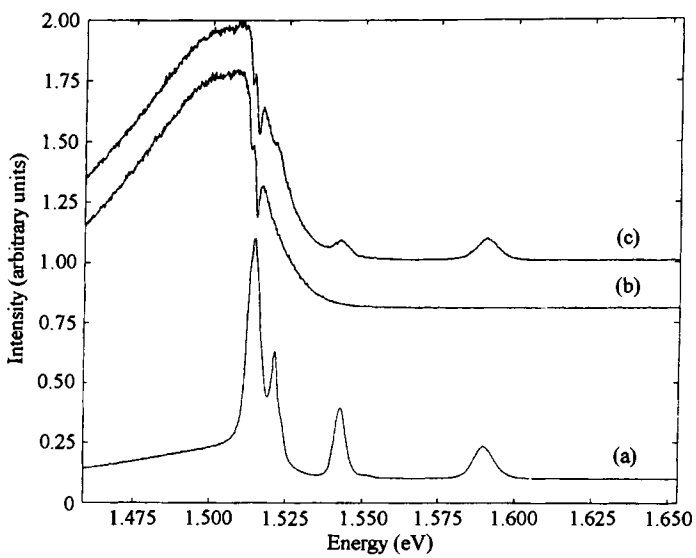

Figure 3. CL spectra from (a) unetched area, (b) etched area, and (c) individual quantum-dot. Reproduced by permission of J. Wang et al. [32].

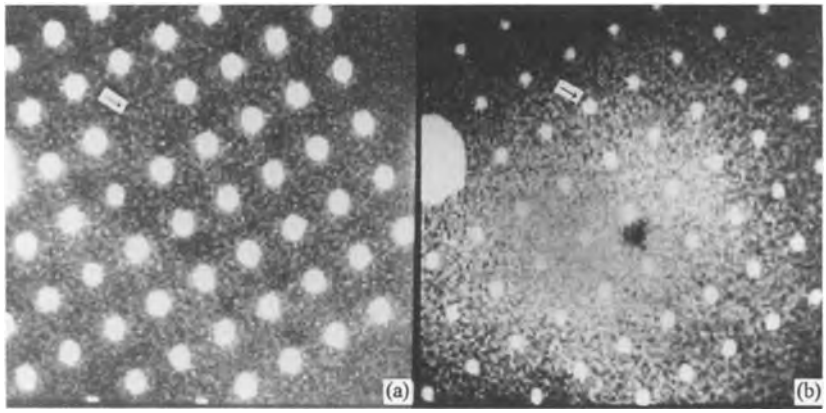

Figure 4. CL monochromatic image of the quantum dots at the emission energy of the quantum dots formed from (a) 5 nm (1.591 eV) and (b) 10 nm (1.543 eV) quantum wells. Reproduced by permission of J. Wang et al. [32].

wells respectively. A broad peak appears at 1.514 eV, which results from the emission of both the bulk substrate and the 80 nm well. The low energy tail of this peak is relative to impurities in the substrate. In spectra recorded on etched areas, only this low energy tail of the 1.514 eV peak dominates the curve (Fig. 3b); the emission lines from 5 and 10 nm wells disappear and those from the 20 and 80 nm are greatly reduced in intensity. This result shows that a high degradation of the quantum well side walls is induced by the etching process, leading to a high non-radiative surface recombination velocity.

By contrast, the representative spectrum of an individual 500 nm diameter quantum dot (Fig. 3c) shows the individual signal corresponding to the 5 and 10 nm quantum wells. The change of the effective energy gap caused by a lateral carrier confinement is unobservable in the spectrum. This result confirms the calculations which show that for quantum dots larger than 120 nm the energy shift should be lower than 1 meV. Two CL micrographs were taken at the energy corresponding to the 5 nm (Fig. 4a) and to the 10 nm (Fig. 4b) quantum wells, respectively. The dot-image/background intensity ratio is much higher for the dots formed by the 5 nm well than that for the 10 nm well. This difference can be explained by a lower carrier diffusion coefficient for the narrower quantum wells, resulting in a weaker sidewall-surface non-radiative effect. A higher degradation of a 5 nm depth dot (missing dot indicated by an arrow) should be noticed as compared to its corresponding 10 nm depth dot.

These two studies reveal the advantages of the microscopic CL technique to correlate structural-optical properties of nanostructures.

4.4.2 Applications to Si Based Compounds

About 95% of the microelectronic circuits rely on silicon chips. However, because its relatively small indirect bandgap, the band-to-band luminescence of bulk

crystalline silicon occurs in the near infrared wavelength with a very small efficiency. This is the reason for the quest of other optoelectronic semiconducting materials with higher efficiency and preferably compatible with the VLSI Si technology. The most common optoelectronic devices such as electroluminescent diodes for instance are fabricated from other semiconductors (GaAs and related compounds) but their integration in Si microcircuits still remains imperfectly resolved. Alternatively, luminescent Si based materials are also recently investigated in order to benefit all advantages of the digital Si advanced technology. Few studies of silicon based structures, with the use of microscopic techniques will be described here. The examples concern (i) luminescent porous silicon, (ii) Si/SiGe, and (iii) $FeSi_2$/Si heterostructures.

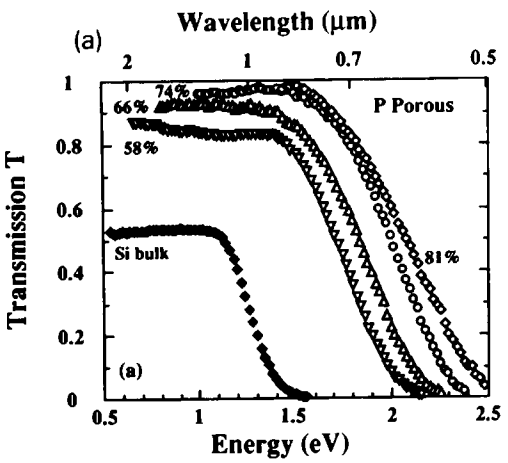
4.4.2.1 Luminescent Porous Silicon

The recent discovery that porous silicon (PS) layers can emit efficiently visible light at room temperature has boosted numerous investigations due to its potential applications. The generic name of PS includes various and complex materials whose properties (structural, optical, electrical, etc.) strongly depend on many different parameters. Generally PS is obtained by anodic dissolution of silicon in hydrofluoric acid solutions in an electrochemical cell with the silicon substrate biased as the cell anode [33]. The process results in a sponge-like sample constituted with an Si nanostructure skeleton (wires, dots, etc.) surrounded by empty pores.

The PS layers analyzed here were formed on (1 0 0) silicon wafers, either light (p^-) or highly (p^+) doped p-type. It has been shown that when the porosity of PS exceeds about 50% the samples display visible luminescence. Although the exact origin of this phenomenon is still controversial, the proposed mechanisms prevalent in the literature are centered around quantum size effects and surface passivation. This study compares both the photoluminescence and the microstructure of high porosity p^- and p^+ luminescent PS (LPS).

Optical transmission values of different porosity LPS samples (p^- or p^+ doped) are presented in Fig. 5. The increase in the bandgap energy E_g for the 80% porosity samples (p^- and p^+) can be explained by quantum confinement effect in the small silicon crystallites which constitute the silicon skeleton. The calculated values of the crystallites dimensions (L) are given simply by $E_g = h^2/4m^*L^2$ where h is the Planck's constant, m^* the effective electron or hole mass. L is in the range 2–4 nm in the case of lightly doped samples and 7–9 nm in the case of highly doped samples. Photoluminescence (PL) spectra of p^+ and p^- LPS are shown in Fig. 6. Results of a detailed comparative study reveal that spectra of both samples present a maximum at about the same wavelength. PL intensity of p^+ samples is however much less intense. When the porosity of the layer increases (L decreases) one observes a blue shift of the PL peak, which is in agreement with the quantum confinement estimation.

Concurrently, TEM analysis has been performed on those LPS samples ([34] and references therein). Although the preparation process for TEM analysis partly degrades the samples, valuable morphological and microstructural information can be gained. A detailed description of



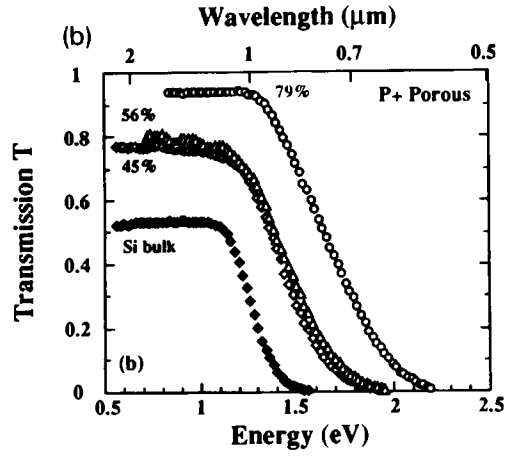


Figure 5. Transmission coefficient versus photon energy for 40 μm thick free-standing PS and substrate doping (a) p^- and (b) p^+ samples. Reproduced by permission of G. Bomchil et al. [33].

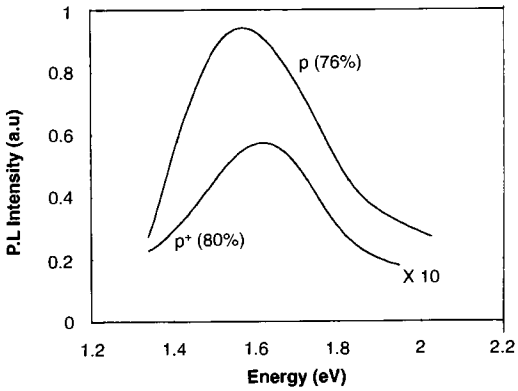

Figure 6. Photoluminescence intensity versus wavelength for p^- and p^+ samples. Reproduced by permission of G. Bomchil et al. [33].

information provided by different TEM associated techniques can be found in [35]. When the porosity is increased from 60 to 65% a decrease of the crystallite size from the 10–15 nm range to the 5–8 nm range is observed on the TEM micrographs. Moreover, HRTEM images show that the 80% (p^-) PS is formed with an array of fine holes and crystallites, while TED exhibits large spot streaking and diffuse scattering (Fig. 7). Two phases are clearly seen: (i) crystalline clusters with dimensions ranging from 1.5 to 4 nm. Various degradations (undulations and distortions) of the crystalline lattice of these clusters are observed (Fig. 8); (ii) an amorphous like contrast giving rise to broad diffuse rings. Clusters misoriented from each other with less than three superimposed planes or amorphous silicon could explain this contrast.

By contrast, 85% (p^+) LPS layers exhibit very different morphology. They rather display an anisotropic structure of a longitudinal-branched network of pores/silicon rods (Fig. 9). From HRTEM analysis two crystalline components should be distinguished (Fig. 10): (i) long monocrystalline rods with 10 nm or more diameter, and (ii) small rotated silicon crystallites with size ranging from 2 to 6 nm.

A quantitative estimation of the clusters density is rather difficult. However, a direct comparison between p^- and p^+ PS samples proves that many fewer crystallites with size in the range 2–4 nm are

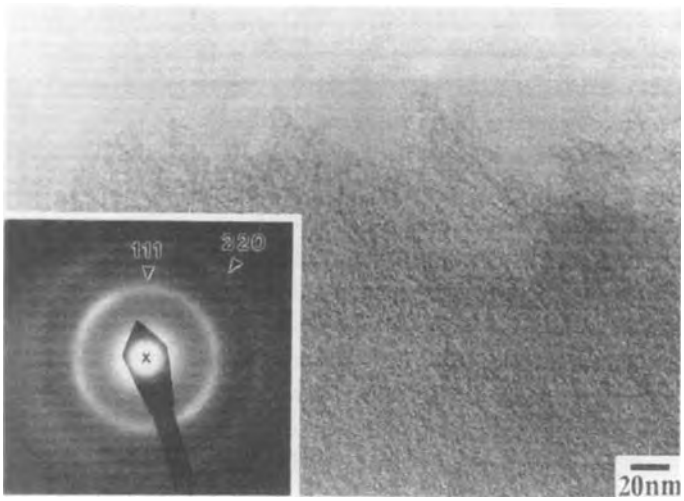

Figure 7. Overall view of 85% LPS p^- doped and corresponding TED pattern. Selected area diaphragm diameter: ~10 μm. Reproduced by permission of I. Berbezier et al. [34].

present in the latter case leading to a less intense PL signal. This result shows the influence of crystallites of very small size on the luminescence properties of LPS.

Since the various LPS microstructures generally observed should lead to different optical properties, the origins of the luminescence could be elucidated by systematic comparative TEM/PL studies.

Characterization at the atomic level could also be performed by EELS (together with HRTEM) which offers higher spatial resolution chemical analysis using a STEM. These techniques have been applied to investigate the chemical bonding of n^+-type LPS [36]. Samples were formed by electrochemical oxidation under anodic polarization of silicon in aqueous HF electrolyte assisted by illumination (photoelectrochemical etching). As shown by HRTEM, n^+-type LPS presents quite different morphology than a p-type

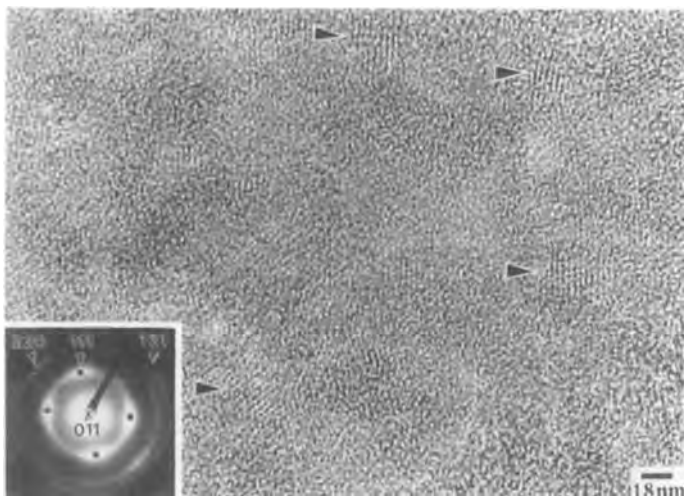

Figure 8. HRTEM and corresponding TED pattern of 85% LPS p^- doped sample. Selected area diaphragm diameter: 0.5 μm. Reproduced by permission of I. Berbezier et al. [34].

one. n^+-type LPS consists in wires composed of a crystalline core surrounded by a layer exhibiting typical granular contrast of noncrystalline material. The thickness of this surrounding layer was estimated to 1.5–2 nm. The core of the tangled silicon wire exhibited various diameter sizes ranging from 3 to 20 nm which often undulated in width. The determination of the nature of the amorphous coverage has been performed by EELS. Two energy loss regions of interest were scanned to obtain information on the electronic structure of the silicon wire: the low loss region and the fine structure occurring over the 10–30 eV above the Si L_{23} ionization edge.

Data acquisition consisted in a set of spectra recorded at given positions separated by a distance of about 0.5 nm across the silicon wire. Data for the L_{23} ionization edge region are displayed as three dimensional intensity plot along two axes (Fig. 11a), one corresponding to the position on the sample and the other to the energy loss scale. This perspective of the spectra reveals clearly the similar shape of all the L_{23} ionization edge whatever was the probe position. A selection of different spectra is extracted from the above sequence: (i) close to the surrounding amorphous layer (Fig. 11b) and (ii) within the silicon wire, between the crystalline core and the amorphous layer (Fig. 11c). It can be seen that the shape of the L_{23} ionization edge remains constant, and that no detectable chemical shift can be observed across the whole wire.

Similar sets of data acquisition performed in the low loss region show: (i) that the energy position of the volume plasmon does not shift noticeably, as long as it can be identified, (ii) that the

two first structures at the onset of interband transitions are also quite identical across the whole wire.

In conclusion, EELS results [36] demonstrate the absence of foreign species (SiO_2 and SiH) in the surrounding amorphous layer and thus support the quantum confinement model to explain the luminescence of n^+-type porous silicon.

4.4.2.2 $Si_{1-x}Ge_x$/Si Strained Superlattice Structure

Similar to the III–V or II–VI related compounds, $Si_{1-x}Ge_x$ alloys display at least two attractive features. By controlling the chemical composition x [37] one can play: (i) with the lattice mismatch δ, as compared to the Si substrate ($x \in (0, 1)$,

$\delta \in (0, \sim 4\%)$) and then control the strain in pseudomorphic heterolayers and their critical thicknesses and hence the optoelectronic properties; and (ii) with the fundamental energy gap E_g ($x \in (0, 1)$, $E_g \in (1.12\text{–}0.67\,\text{eV})$).

Other advantages include the Si technology compatibility, quantum effects with intersubband transitions allowing far infra red applications, non linear optical properties. For example it would be very attractive to use $Si_{1-x}Ge_x/Si$ strained layer superlattices (SLS) for light emitting diodes or photodetectors. However, one should notice that the $Si_{1-x}Ge_x$ alloy remains an indirect gap semiconductor at all values of x and a low absorption coefficient is predicted [38]. The comparison of photoluminescence efficiency and spectra recorded on strained and relaxed layers is shown for instance in [39]. Some basic ideas on the calculations of the strain and on the critical thickness are given in [40]. Many microscopic studies have been applied to the $Si_{1-x}Ge_x/Si$ system to determine its epitaxial relationships, its dopant distribution in volume and at interfaces, its strain and dislocation density, its morphology, etc. Here we will only detail a determination of the interface roughness by Quanti-TEM. This morphological detail is of great interest in the heterostructure buildup since it governs most of the optoelectronic properties of the material. This image analysis can also be applied to the strain determination.

In Quanti-TEM, the variation of the potential in crystalline solids is measured in any projection, without knowledge of the imaging conditions (detailed description in [41]). Image analysis [42] is then applied to determine the chemical composition mapping from an experimental image. The latter is divided into unit cells, corresponding to the lattice cells, the intensity distribution of which is digitized and represented by a vector R^i. The experimental image potential is then related to the projected crystalline potential of the material under specific imaging conditions (defocus, thickness of the sample). The R^i vectors are determined over a region of the sample with a chemical composition of reference. Changes in composition induce changes in the path of R^i and also in the rate at which the path is traversed in each material. Figure 12 shows the HRTEM image of a $Si_{0.75}Ge_{0.25}/Si$ interface and Fig. 13 is the composition map across the quantum well obtained by Quanti-TEM after thickness normalization. This quantitative microscopic map of the compositional change reveals the large extent of intermixing over the interface not visible on the HRTEM image. All these results should be taken

into account during the optical properties calculation.

4.4.2.3 $FeSi_2$/Si Interface

Recently the semiconducting silicide phase β-$FeSi_2$, which displays an optical gap close to 0.87 eV, has been extensively studied since it may be a very attractive material for novel integrated optoelectronic devices [43].

Due to the crystallographic properties it is possible to epitaxially grow orthorhombic β-$FeSi_2$ phase on silicon (0 0 1) and (1 1 1) surfaces and indeed numerous experimental studies achieved thin β-$FeSi_2$ epitaxial layers by different deposition modes [43].

Beside the stable β-$FeSi_2$ phase grown so far with solid phase epitaxy (SPE) and reactive deposition epitaxy (RDE), surprising results have been obtained. In particular, the appearance of various and unexpected $FeSi_2$ phases preceding the formation of the stable β-$FeSi_2$ has been observed. Among these 'new' $FeSi_2$ phases, two cubic metastable phases (not present in the thermodynamic phase diagram) strained and stabilized by epitaxy on silicon substrate have been identified by different groups of researchers (hereafter call CsCl- and γ-$FeSi_2$ phase). Moreover, during the RDE growth experiments at low temperature (~550°C), the metallic tetragonal α-$FeSi_2$ phase has been revealed. This phase thermodynamically stable only at high temperature (above 940°C) has been surprisingly stabilized during the deposition process at low temperature [44]. The appearance of all these metastable phases, not thermodynamically foreseen, leads to a rather confusing situation in the literature. Their identification is a rather difficult problem for at least two reasons: (i) they are observed only at very low thicknesses (a few nanometers), and (ii) when they grow on Si substrates their crystallographic structures are very close and give rise to similar diffraction pattern. Therefore, they call for a thorough knowledge of each phase in order to make sure their distinction.

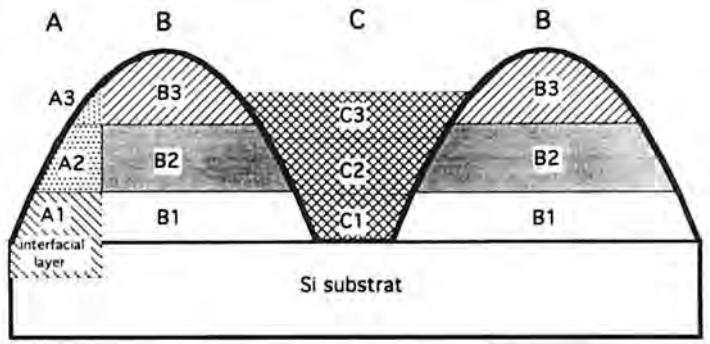

Figure 14. Schematization of the areas scanned and analyzed by image analysis. Reproduced by permission of I. Berbezier et al. [45].

Taking into account these remarks we have presented [45] a complete transmission electron microscopy (TEM) and transmission electron diffraction (TED) characterization of thin α-$FeSi_2$ films obtained by RDE deposition mode, on top of Si(1 1 1) surface. As an illustration of a complex multiphase-interface we reproduce, in Fig. 14, a HRTEM image of an iron disilicide/silicon interface.

The interface is atomically plane on a 20 nm mean averaged length. Macrosteps with spacing to each other of about 20–30 nm are observed with interfacial dislocations confined at the edge of these steps in agreement with the calculated distance between misfit dislocations (only due to the mismatch between the (2 2 0) Si and the (1 1 0) α-$FeSi_2$).

More quantitative information can be provided by performing a careful analysis of HR images. The (2 2 0) silicon planes separated 0.192 nm, are used to calibrate the distances on each image. The interplanar distances are averaged over a hundred planes leading to a measurement accuracy of ± 0.001 nm.

About twenty islands have been studied and, for each island, different areas are systematically scanned along a line perpendicular to the interface. Three regions have been probed: (i) in the near vicinity of the interface (within 1 nm from the interface), (ii) at approximately 2 nm from the interface, and (iii) on the top of the $\sim$500°C grown α-$FeSi_2$ film.

Parallel to the silicon surface three typical interfacial growths (A, B, and C) are observed (Fig. 15). The (1 1 0) α-$FeSi_2$ interplanar distances measured for each growth (A, B, and C) along the line normal to the silicon substrate surface are noted A_1, A_2, A_3, B_1, B_2, B_3 etc. starting from the

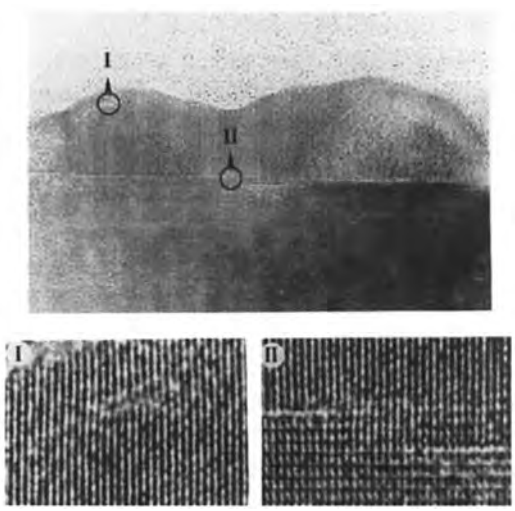

Figure 15. Cross-sectional analysis of an $FeSi_2$ grain along the ⟨1 1 2⟩ Si axis. Dislocations have been observed close to the silicide surface (area I) and at the interface (area II). Reproduced by permission of I. Berbezier et al. [45].

Table 6. Interplanar distances measured in different areas of the epitaxial film

area	measured (nm)	crystallographic data
A_1	0.192	(2 2 0) Si
A_2	0.189	(1 1 0) relaxed α-$FeSi_2$
A_3	~0.196	(0 0 1) or (0 1 0) β-$FeSi_2$
B_1	0.192	(2 2 0) Si
B_2	0.189	(1 1 0) relaxed α-$FeSi_2$
B_3	~0.196	(0 0 1) or (0 1 0) β-$FeSi_2$
C_1–C_3	0.189–0.196	From relaxed α and β-$FeSi_2$ phase

interface towards the topmost surface of the α-$FeSi_2$ layer. These are reported in Table 6 and compared to the crystallographic data of the relevant silicide and silicon interplanar distances in order to identify them.

Our HR measurements may be summarized as follows. In areas A (Fig. 15) at the Si substrate interface one first observes a very thin cubic $FeSi_2$ layer totally coherent with the Si substrate ($d \approx 0.192$ nm measured at A_1). It evolves to a relaxed tetragonal α-$FeSi_2$ phase ($d \approx 0.188$ nm measured at A_2) which, at its turn, transforms to the stable orthorhombic β-$FeSi_2$ phase ($d \approx 0.196$ nm measured at A_3). One remarks that the cubic/α-$FeSi_2$ interface is atomically abrupt while the relaxed α/β-$FeSi_2$ interface is usually broad, containing dislocations and disordered areas, reflecting faithfully the similarity of the interfacial structures between cubic and α-phases and in contrast the difference between the α and β-$FeSi_2$ ones.

An alternative of the $FeSi_2$ epitaxial growth is also observed (areas B, Fig. 15). In this case another strained α-$FeSi_2$ layer coherently covers the Si substrate ($d \approx 0.192$ nm measured at B_1). It replaces and plays the role of the cubic strained layer of the first case. This strained α-layer evolves towards a relaxed α-phase ($d \approx 0.188$ nm measured at B_2) and then towards the β-$FeSi_2$ phase ($d \approx 0.196$ nm at B_3). In those B areas at the Si interface, macrosteps are observed with interfacial dislocations, even though the α-layer at intimate contact with the Si substrate is not relaxed but still coherently strained (areas B_1). It only relaxes a little bit further from the interface (areas B_2). We believe that our observations are reflecting the initial stages of a strained–relaxed layer growth mediated through an interfacial dislocation formation.

Some areas called C in Fig. 15 display a quasicontinuous variation of lattice parameter which increases gradually from 0.188 nm (measured at C_1) corresponding to the relaxed α-phase, and towards 0.193 nm (measured at C_3) close to β-$FeSi_2$.

Our results shed light on the $FeSi_2$ epitaxy mechanisms. At the very intimate contact with the Si substrate coherent ultrathin $FeSi_2$ films should grow. This leads to either a pseudomorphic cubic phase or to a strained α-$FeSi_2$ phase. The following transformation of these phases to the stable orthorhombic β-$FeSi_2$ passes through a fully relaxed tetragonal α-$FeSi_2$ phase. Obviously, the growth is strongly dependent on uncontrolled factors since at

least two kinetic paths have been shown. The above mentioned uncontrolled factors may include mainly kinetic factors (depending on the growth technique, the growth temperature and the initial substrate morphology). The reasons why cubic or/and strained tetragonal $FeSi_2$ phase can easily grow on top of silicon might be attributed to the influence of the strains exerted by the silicon substrate during the epitaxial growth.

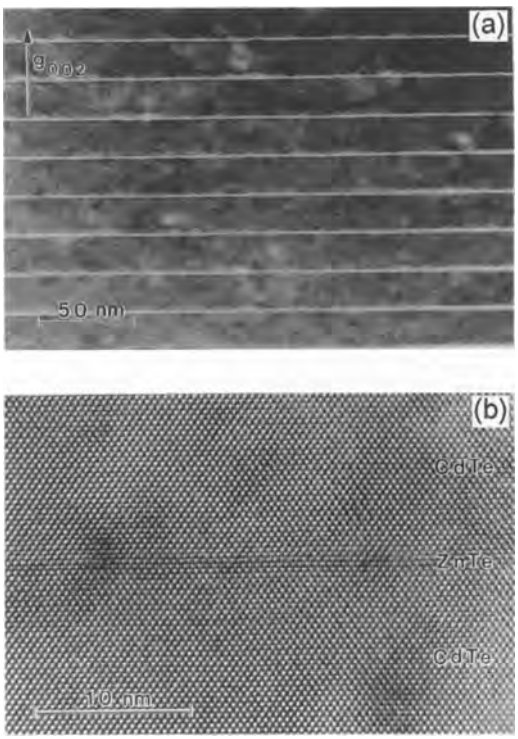

Figure 16. (a) Dark field imaging and (b) HRTEM of 57/2 CdTe/ZnTe samples. Reproduced by permission of P. H. Jouneau et al. [46].

4.4.3 Application to II–VI Compounds

$CdTe/Cd_{1-x}Zn_xTe$ is one of the most interesting II–VI heterostructures because of the valence band discontinuity induced by strain. Strained multiquantum wells (MQW), with strain orientated along polar crystalline direction present a high piezoelectric field. This field modifies the band structure and thus the radiative recombination energy. Since the strain distribution determines the localization and the intensity of the piezoelectric field, its characterization with TEM is of utmost importance as demonstrated below [46].

The $CdTe/Cd_{1-x}Zn_xTe$ MQW were grown by MBE with experimental conditions adjusted to avoid the strain relaxation of the well layers and to keep the average strain of the MQW close to zero (strain symmetrization). TEM analysis reveals the absence of misfit dislocations attesting the pseudomorphic growth and allows to determine the MQW period. Illustration of the 57CdTe/2ZnTe structure is given in Fig. 16 for which (a) displays a bright-field micrograph and (b) the corresponding HRTEM image. By digitizing HRTEM and with the use of an image processing software, local distortions can be measured. Figure 17 shows values of local distortion measured on three different samples (27/1, 57/2, and 88/3 periods, respectively) and by comparison the distortion calculated from the continuum elastic theory. It can be seen that the calculated values do not fit exactly the experimental curves. Other adapted models are proposed by the authors. About 70% of the strain is accommodated in the ZnTe layer and that residual strain extends over 3–5 ML after the last ZnTe plane location. Zn segregation, revealed by the asymetric strain profile, induces this residual strain.

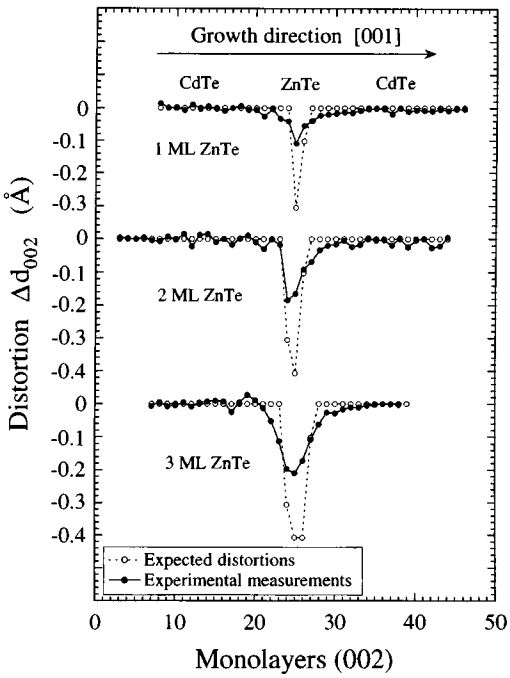

Figure 17. Distorsion analysis results deduced from HRTEM of 27/1, 57/2 and 88/3 CdTe/ZnTe samples. Reproduced by permission of P. H. Jouneau et al. [46].

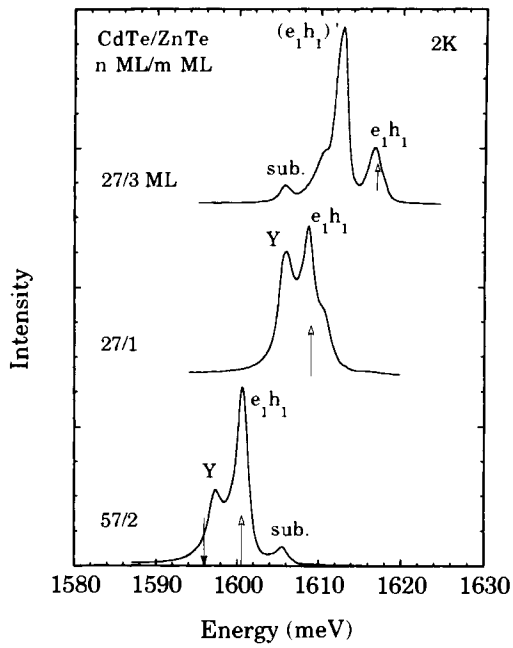

Figure 18. PL spectra of 27/1, 27/3 and 57/2 CdTe/ZnTe samples. Reproduced by permission of N.T. Pelekanos et al. [47].

Figure 18 shows the PL spectra of three strained MQW [47]. The e_1h_1 lines correspond to an intrinsic free HH-exciton transition, Y lines correspond to the transitions of extrinsic character and sub lines to the substrate contribution. The good optical properties of the samples are demonstrated: (i) by the major contribution of the intrinsic free-exciton recombination, and (ii) by the sharpness of the e_1h_1 lines. These are probably due to the fact that no strain relaxation has occurred in the samples as demonstrated by TEM. Upward white arrows indicate the calculated e_1h_1 position with a model taking into account the strain distribution measured by HRTEM. A good agreement between experimental and theoretical values is obtained.

4.5 Conclusion

Microscopic techniques are quintessential to modern materials science. Through the few selected examples in this chapter one can be convinced that most of the microstructural features which govern the optical quality of optoelectronic materials can be currently determined. In particular, the epitaxial relationships, strain features in heterolayers, dopant and impurity bulk and surface distribution, recombination centers, morphology are exposed. It is hoped that further detailed investigations in materials science will be achieved concurrently with the increasing development and progress of microscopic techniques.

5 Domain Structures in Ferroic Materials

5.1 Ferroic Phase Transitions

A crystal may transform from one crystal structure into another when the thermodynamic environment (temperature, pressure, and chemical composition) is changed. In many cases it is observed that these structural changes are subtle enough so that the crystal is not destroyed during the transformation and that the process is reversible. Much research has concentrated over the last three decades on the investigation of structural phase transitions in which the structural changes maintain the general topology of the crystal and all structural changes occur continuously (or nearly so).

In this case one finds that most phase transitions are correlated with a simple change of the symmetry of the structure: a crystal structure with a certain symmetry described by a space group G_0 (the 'high-symmetry phase') transforms into another structure in which at least one symmetry element of G_0 is missing. The new space group is now called G and the phase is called the 'low-symmetry phase'. Such symmetry conditions curtail significantly the possible atomic movements which lead to the phase transition. In the context of this section, the symmetry conditions are even more severe: we will only consider phase transitions with changes of symmetry elements of rotations, mirror planes, and inversion centers but no changes of any translational symmetries shall occur. Such transitions which maintain translational symmetries are called 'ferroic'. The two most important types of ferroic phase transitions are ferroelastic and ferroelectric ones, which are now discussed exclusively. In fact, most ferroelastic materials show phase transitions in which translational symmetries are also broken (so that the transition is not, strictly speaking, 'ferroic') but still maintain their ferroelastic fingerprint, namely the ferroelastic hysteresis. We will include these materials in the discussion. Details of the symmetry properties and the role of long-ranging strain interactions are given by Salje [1] and Khatchaturyan [2]. We will concentrate here on ferroelastic and ferroelectric phase transitions which are continuous in nature (or nearly so), but not stepwise transitions such as found in martensitic alloys and so forth.

5.2 Ferroelastic Phase Transitions

Ferroelastic materials have an unusual, but technologically most welcome property:

when they are subjected to external stress they first react elastically in a classic manner but when the stress surpasses a certain threshold, the structure suddenly becomes 'soft' and rearranges its atoms in a way which is better adapted to the external stress. This process is reversible. In fact, one finds that there are two or more structural states which are all energy ground states with the possibility to switch the crystal between these states via applied elastic stress. A typical ferroelastic hysteresis is shown in Fig. 1. In this figure the effect of the hysteresis is shown on three different length scales. On an atomistic scale, the relevant part of the crystal structure of $Pb_3(PO_4)_2$ is shown (top). Lead atoms are indicated as black ellipsoids which are surrounded by PO_4 tetrahedra. Around each lead position there are three tetrahedra with their apical oxygens pointing upwards and three tetrahedra with their apical oxygens pointing downwards. The lead position has, thus, topologically a high symmetry coordination with a trigonal space group. At sufficiently low temperatures the energy minimum 'seen' by lead is not on the triad, however, because it is energetically favorable to form some shorter bond distances Pb–O at the expense of elongating others. There are six possibilities to achieve such local distortions, namely by shifting lead positions (in a positive or negative direction) along one of the three channels indicated by arrows. The shifts are very small and can be reversed by external stress, that is, the lead positions can be switched collectively from one such energy minimum to another. Macroscopically, this switching is seen as the ferroelastic hysteresis which relates the angle between two macroscopic directions in the plane shown in the crystal structure, and the external shear stress. The coercive stress is rather small (1.6 bar) and the energy dissipated per switching cycle ($\int e \, d\sigma$, where e is the macroscopic strain and σ is the stress) is much smaller than the excess energy gained by the structural deformation. This observation leads to the question: Why is energy dissipated in a hysteresis much smaller than the total energy needed to displace all atoms via an excited state? The answer lies in the development of the microstructure shown at the bottom of Fig. 1. This figure shows a crystal placed between crossed optical polarizers, so that variations in the optical birefringence are seen as light or dark areas in the crystal. A crystal is shown for three phases of the switching process. Different orientations of the lead displacement appear as black and white areas in this figure. These areas are twins related to twin walls as domain boundaries between them. Only the atoms in these domain boundaries are, at any time, in the excited state between the potential minima of the lead positions of a stress-free crystal. All other atoms are in the equilibrium positions and do not contribute to the energy of the hysteresis. The mechanism by which switching is now achieved is by movement of the domain boundaries. The energy related to the movement of the domain boundary is a virtual energy in the case of lateral movements in an ideal crystal. In real materials, the movement of domain boundaries is hampered by pinning to defects, tilt of domain boundaries, and so forth (Fig. 2). The reversible lateral movement of such a ferroelastic domain boundary (twin wall) can be seen on a fine scale in Fig. 3. In this case, the wall movement is induced by local stresses generated by heating the

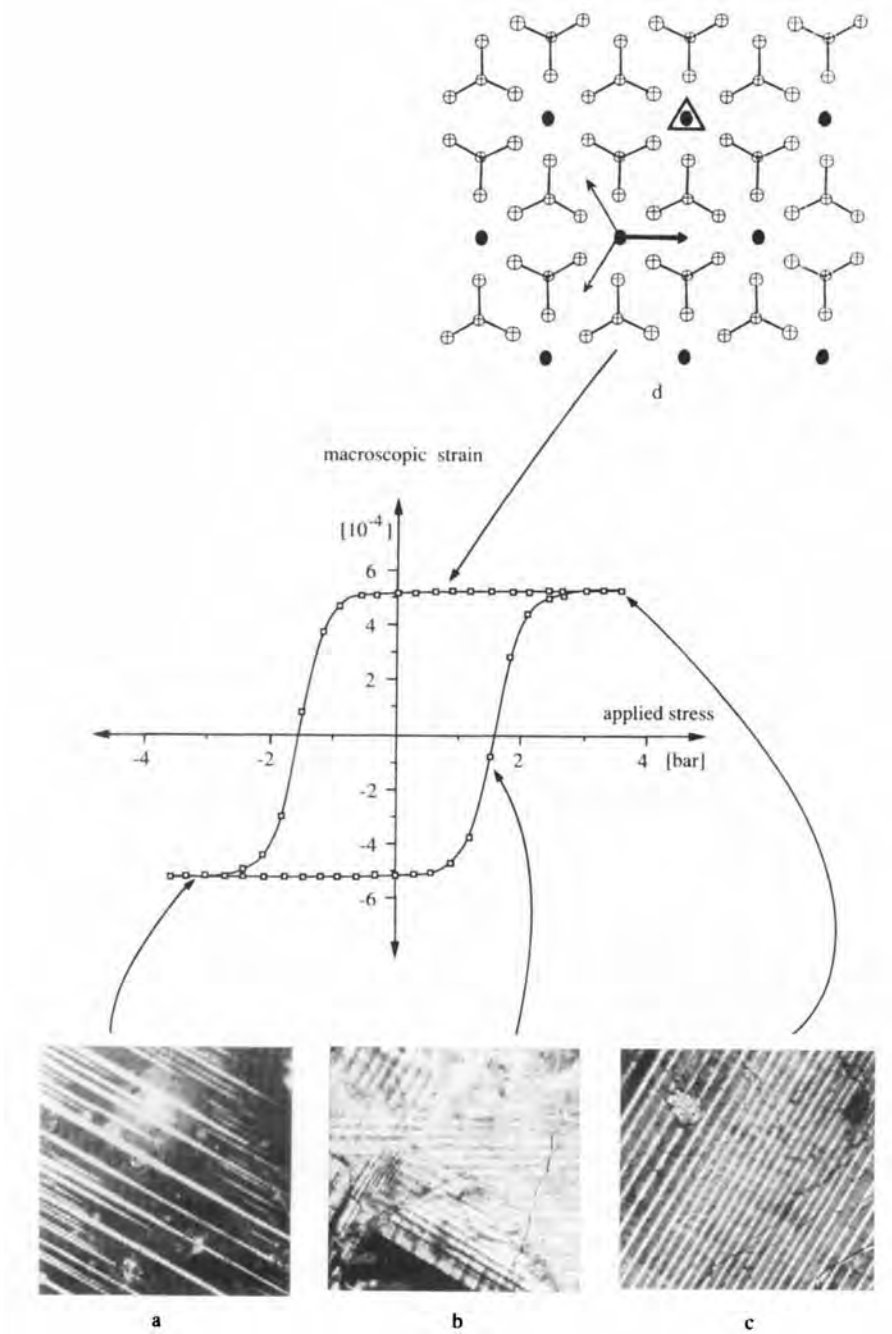

Figure 1. Crystal structure, ferroelastic hysteresis, and optically observed microstructures of $Pb_3(PO_4)_2$ [1]. The black lead atoms are displaced parallel or antiparallel to one of the three axes indicated by errors. The ferroelastic switching involves the reorientation of this displacement, and resulting twin structures are clearly seen under the optical microscope. Twin-free samples can be produced by appropriate external stress.

Figure 2. Observation of twin structures in $Pb_3(PO_4)_2$ with stranded needle domains as observed in the optical microscope using crossed polarizers. The dark and light areas represent the two twin-related domain orientations. The crystal has been slightly sheared, so that the dark domains dominate. The light domains form needle twins with needle tips pinned by defects (stranded needles). Further shear stress will overcome the pinning forces, so that the crystal will become a single domain (i.e., the light domains will vanish completely by retraction and annihilation of the two tips of each needle domain).

sample nonuniformly under the electron beam in a transmission electron microscope. In both ferroelectric and ferroelastic materials the width of the hysteresis, and hence the dissipated switching energy, is mainly determined by the structure and movement of domain boundaries.

Besides the limitation of boundary movements by extrinsic defects, boundary pinning can also occur as a consequence of the interactions between the domain walls. An example is shown in Fig. 4 where a multitude of domains form a complex pattern. The movement of any single domain boundary is hindered by some other domain boundaries. In a more typical situation (Fig. 5), domain boundaries form patterns with two dominant wall orientations. The major interaction is now due to the high strain energy of wall junctions and the consequent repulsion of wall tips. The repelled walls usually form needle domains (comb pattern) which can easily be moved by external stress in the case of most ferroelastic materials.

Before we return to the discussion of the internal structure of domain boundaries, we first introduce the relevant measure for the ferroelastic lattice distortion, namely the spontaneous strain. This strain is generated by the phase transition

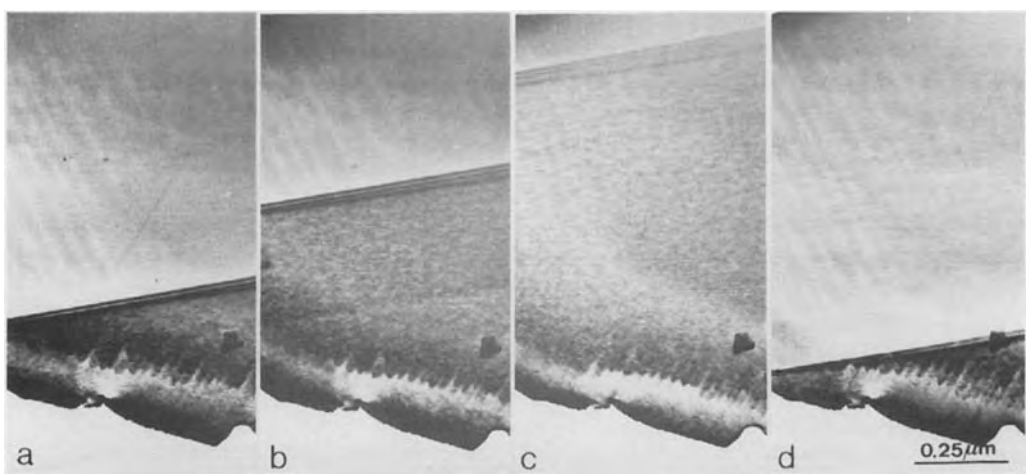

Figure 3. Motion of ferroelastic domain walls in lead vanadate under the influence of beam-induced stress. (Courtesy of EMAT Laboratory, Antwerp; see also Manolikas and Amelinckx [3].)

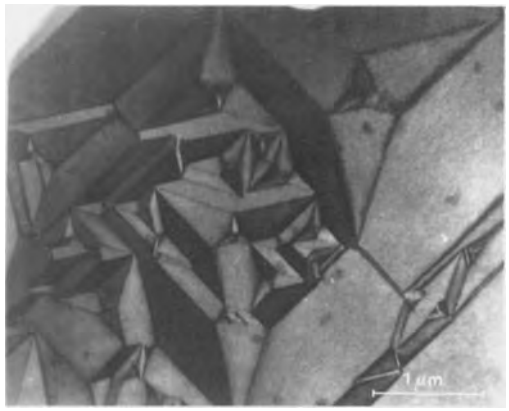

Figure 4. Ferroelastic domain structures with a high number of junctions. Such domain structures can often be aligned in external stress field. (After Manolikas and Amelinckx [3].)

without any external stress applied to the sample.

The ferroelastic strain can be expressed via the size and shape of the crystallographic unit cell (lattice parameters a, b, c, α, β, and γ; reciprocal lattice parameter a^*, b^*, c^*, α^*, β^*, and γ^*) relative to that of the undistorted (i.e., paraelastic) structure. The components of the spontaneous strain are

$$e_{11} = e_1 = \frac{a \sin \gamma}{a_0 \sin \gamma_0} - 1 \tag{1}$$

$$e_{22} = e_2 = \frac{b}{b_0} - 1 \tag{2}$$

$$e_{33} = e_3 = \frac{c \sin \alpha \sin \beta_0^*}{c_0 \sin \alpha_0 \sin \beta_0^*} - 1 \tag{3}$$

$$\begin{aligned} e_{23} &= \frac{1}{2} e_4 \\ &= \frac{1}{2}\left[\frac{c \cos \alpha}{c_0 \sin \alpha_0 \sin \beta_0^*} + \frac{\cos \beta_0^*}{\sin \beta_0^* \sin \gamma_0} \right. \\ &\quad \left. \times \left(\frac{a \cos \gamma}{a_0} - \frac{b \cos \gamma_0}{b_0}\right)\right] \\ &\quad - \frac{b \cos \alpha_0}{b_0 \sin \alpha_0 \sin \beta_0^*} \end{aligned} \tag{4}$$

$$\begin{aligned} e_{13} &= \frac{1}{2} e_5 \\ &= \frac{1}{2}\left(\frac{a \sin \gamma \cos \beta_0^*}{a_0 \sin \gamma_0 \sin \beta_0^*} - \frac{c \sin \alpha \cos \beta^*}{c_0 \sin \alpha_0 \sin \beta_0^*}\right) \end{aligned} \tag{5}$$

$$e_{12} = \frac{1}{2} e_6 = \frac{1}{2}\left(\frac{a \cos \gamma}{a_0 \sin \gamma_0} - \frac{b \cos \gamma_0}{b_0 \sin \gamma_0}\right) \tag{6}$$

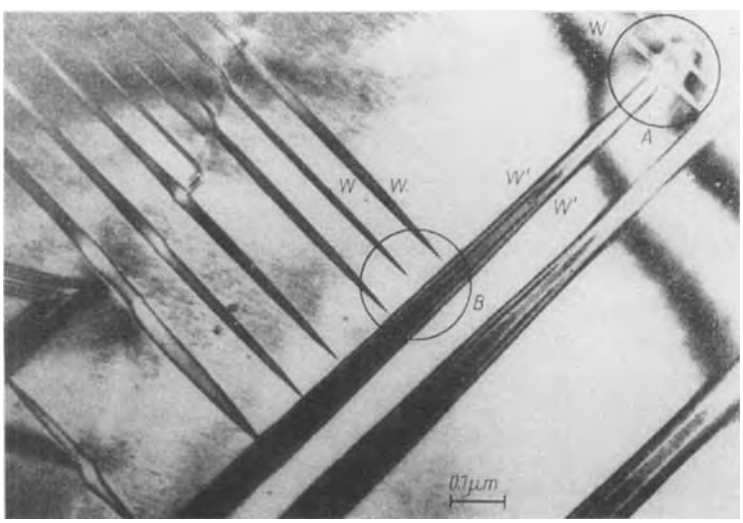

Figure 5. Needle domains with walls W and W′ in $Pb_3(PO_4)_2$. (Courtesy of J. Torres.)

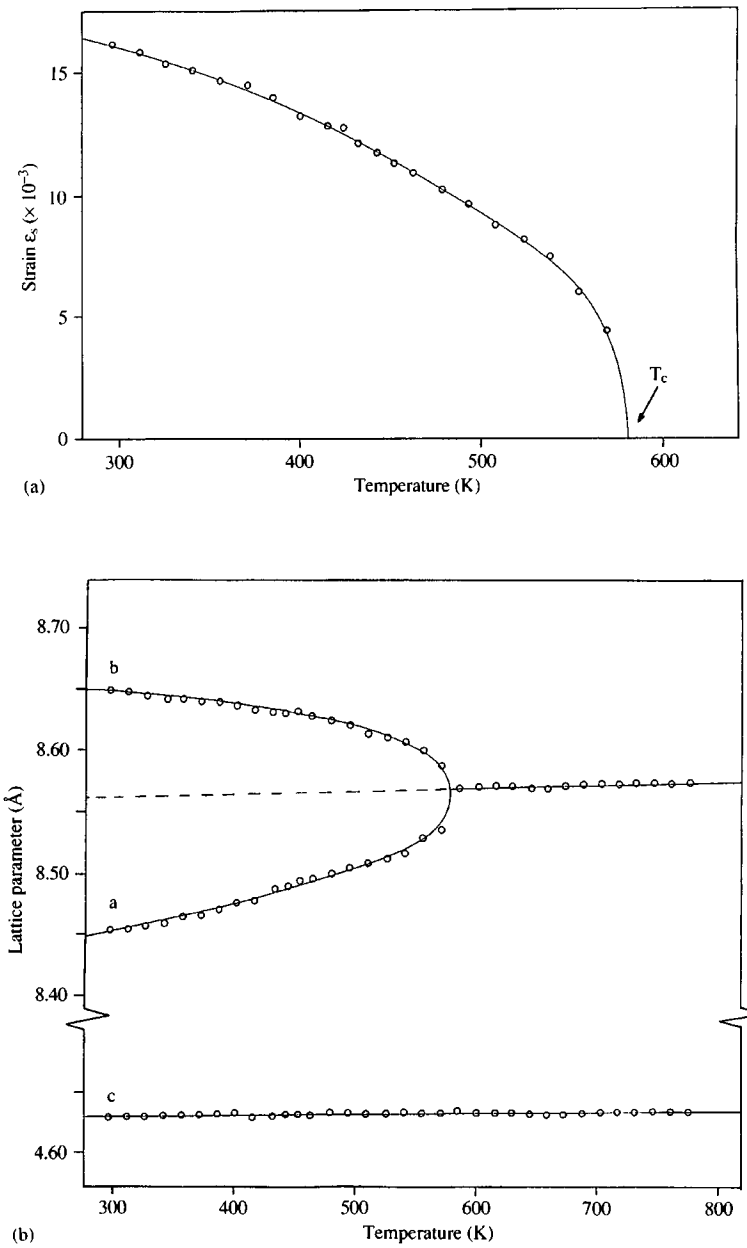

Figure 6. (a) Temperature evolution of the lattice parameters of ferroelastic As_2O_5. The crystal has tetragonal symmetry at $T > T_c$ with $a = b$. At $T < T_c$ the crystal symmetry is orthorhombic. (b) Temperature dependence of the spontaneous strain e_s. The line corresponds to the predicted behavior of a second-order phase transition using Landau theory.

and $e_s = \sqrt{\sum e_i^2}$ is the 'scalar spontaneous strain'. The index '0' indicates the lattice parameter of the high-symmetry phase as extrapolated to the thermodynamic conditions of the low-symmetry phase (for details of the relevant procedures, see Salje [1]). Several of the lattice parameters may assume specific values (e.g. $\alpha = \alpha^* = \gamma = \gamma^* = 90°$ in monoclinic symmetry), so that these equations may

simplify dramatically. A typical example for the temperature evolution of lattice parameters and the scalar spontaneous strain is shown in Fig. 6.

When a ferroelastic crystal is driven through a hysteresis or when the crystal is cooled through the phase transition without the application of external stress, the number of possible domain orientations is predicted by simple symmetry rules. The number N of domain orientations in the low-symmetry form is

$$N = \frac{\text{number of symmetry elements in the high-symmetry phase}}{\text{number of symmetry elements in the low-symmetry phase}} \quad (7)$$

Let us illustrate this rule with the example of the ferroelastic phase transition in NdP_5O_{14} at $T_c = 419\,K$. The high-symmetry form has the point group symmetry *mmm* and the low-symmetry form is ferroelastic with the monoclinic point group $2/m$. The total number of elements in *mmm* is eight, the total number of elements in $2/m$ is four, so that $N = 8/4 = 2$, that is, there are only two different domains and, consequently, two types of wall between them.

Let us now ask what the orientations of twin walls between ferroelastic domains are. If we assume that in some approximation the volume of the crystal is not changed during the phase transition, we find the simple condition of stress free walls:

$$\sum_{i,k=1,2,3} (e_{ik}(S_1) - e_{ik}(S_2)) X_i X_k = 0 \quad (8)$$

where S_1 and S_2 denote the two domains 1 and 2 and X_i are coordinates on the orthonormal axes of the spontaneous strain (e.g. $X_1 = X$, $X_2 = Y$, $X_3 = Z$). As an example, consider the transition $2/m \rightarrow \bar{1}$ with

$$e_{ik}(S) = \begin{pmatrix} 0 & e_{12} & 0 \\ e_{12} & 0 & e_{23} \\ 0 & e_{23} & 0 \end{pmatrix} e_{ik}(S_2)$$
$$= -e_{ik}(S_1) \quad (9)$$

which leads to the solution for the walls $Y = 0$ (i.e., the (010) plane) and $Z = (e_{12}/e_{23})X$ which is a plane perpendicular to (010). Twin walls which are fully determined by symmetry are called W walls (here (010)), and other twin walls are denoted W′. For a pioneering study of ferroelastic structures see, for example, Manolikas and Amelinckx [3].

5.3 Wall Energies and Wall Profiles

Although twin walls are rather thin on a macroscopic length scale, they can be described approximately in continuum theory. In fact, it is a misconception to assume that domain boundaries are thin on a level of atomic diameters. Typical wall structures can be seen in Fig. 7 with (a) a 'wide' domain boundary with $w \approx 7\,nm$ and (b) a 'thin' domain boundary with $w \approx 0.7\,nm$. Both domain boundaries occur typically in ferroelastic $YBa_2Cu_3O_{7-\delta}$ where wide boundaries are often related to oxygen deficit or impurity atoms such as cobalt or aluminum replacing copper [1, 5]. Wide domain boundaries also occur for antiphase boundaries such as in $Pb_3(VO_4)_2$ (Fig. 8) or titanite $CaTiSiO_4$. In the example of Fig. 8 the width w of the antiphase boundary is $\sim 4\,nm$. The most commonly adopted

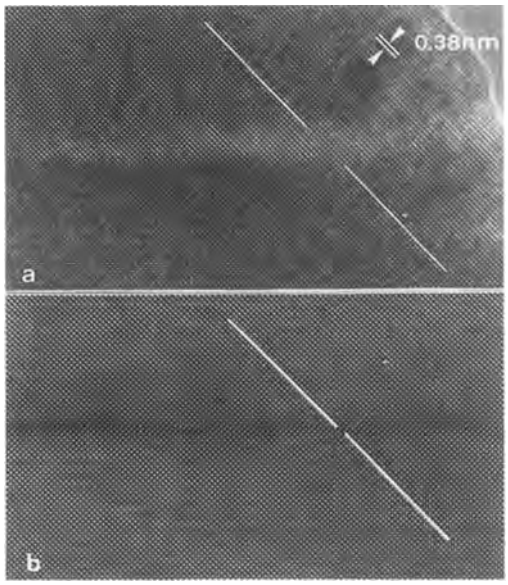

Figure 7. High-resolution transmission electron microscope image of (a) wide and (b) narrow twin boundaries in $YBa_2CU_3O_{7-\delta}$. (Courtesy of EMAT Laboratories, Antwerp.)

approach to analyze domain boundaries theoretically stems from the analysis of displacive phase transitions using an expression for the macroscopic excess Gibbs free energy of the low-symmetry phase with respect to the high-symmetry phase:

$$\Delta G = \tfrac{1}{2}A(T - T_c)Q^2 + \tfrac{1}{4}BQ^4 + \cdots + \tfrac{1}{2}g(\nabla Q)^2 \qquad (10)$$

where we generalize the strain e_{ik} to the relevant thermodynamic quantity which is the order parameter Q. The first part of this Landau–Ginzburg potential describes the thermodynamic behavior of the uniform crystal, and the last term is the energy related to variations of the order parameter in space (∇ is the gradient operator $\partial/\partial r$). The equilibrium condition $\partial G/\partial Q$ has besides the uniform solution in the ferroelastic phase $Q = Q_0 = \sqrt{(A/B)(T_c - T)}$ at $(T < T_c)$ also the solution for a single twin wall,

$$Q = Q_0 \tanh \frac{X}{w} \qquad (11)$$

where

$$w = \frac{1}{2}\left(\frac{g}{A(T_c - T)}\right)^{1/2} \qquad (12)$$

is the thickness of the twin wall (e.g., the width of the strain field around the wall). The energy E_w of the wall is directly proportional to its thickness, so that the fundamental physical parameter which determines both w and E_w at sufficiently low temperatures is the ratio g/AT_c. In a first conjecture, it was commonly assumed that g/AT_c is equal to d^2 where d is the lattice repetition length normal to the twin wall. More careful experimental work using X-ray diffraction analysis has revealed that g/AT_c may be substantially greater, with resulting wall thicknesses in framework structures ranging from 0.5 to 10 nm [4, 5]. As the precise knowledge of

g/AT_c is central to the theoretical treatment of domain structure, the experimental determination of the thickness of twin wall is tantamount for progress in this field of research.

5.4 The Internal Structure of Twin Walls

Ferroelastic and ferroelectric framework structures often show a multitude of phase transitions. In fact, it meant a breakthrough for the quantitative analysis of ferroelastic transitions when it was discovered that virtually all phase transitions (i.e., their relevant order parameters Q_i) influence each other even when the actual transition temperatures are far apart. This mutual interdependence is analyzed via energies which represent the coupling between various order parameters. In a most simple expansion of the energy expression, we find

$$\begin{aligned} G = {} & \tfrac{1}{2}A_1(T - T_c^1)Q_1^2 + \tfrac{1}{4}B_1Q_1^4 \\ & + \tfrac{1}{2}g_1(\nabla Q_1)^2 + \tfrac{1}{2}A_2(T - T_c^2)Q_2^2 \\ & + \tfrac{1}{4}B_2Q_2^4 + \tfrac{1}{2}g_2(\nabla Q_2)^2 \\ & + \lambda_1 Q_1 Q_2 + \lambda_2 Q_1^2 Q_2^2 \end{aligned} \tag{13}$$

There are strong symmetry constraints for $\lambda_1 \neq 0$ but none for $\lambda_2 \neq 0$. What is the internal structure of a domain wall of Q_1 for $\lambda_1 = 0$ and $\lambda_2 \neq 0$? It is obvious that for sufficiently weak coupling the equilibrium conditions $\partial G/\partial Q_1 = 0$ will lead to practically the same wall profile as before. This situation is rather unphysical, however, and cases with strong coupling may well be more realistic. In this case, wall profiles are significantly changed. The reason is that $\lambda_2 > 0$ means that the order parameters tend to suppress each other, that is, if a structure is distorted according to Q_1 it will not allow much distortion with respect to Q_2 and vice versa. A special situation occurs in the wall: Q_1 becomes zero so that the suppression vanishes and Q_2 can appear. This effect can be visualized if the wall profiles are plotted in the vector space of the two order parameters (Fig. 9). The bulk of the material is dominated by Q_1, and Q_2 appears in the wall. There are two solutions, however. In the first solution Q_2 is maximal in the middle of the wall with either $+Q_2$ or $-Q_2$ at the center. The state parameter is then a vector (Q_1, Q_2) which rotates positively or negatively. The wall now has a chirality + or −. In the second solution, Q_2 appears at the edges of the wall but also disappears at the center. In this case the vector (Q_1, Q_2) rotates twice, and the wall is called bichiral. Theoretical work has predicted a multitude of novel phenomena related to structural states inside twin walls which have no equivalent state in the bulk of the crystal [6].

5.5 Bending of Domain Walls and the Compatibility Relationship

The orientation of ferroelastic twin walls (W, W′) is determined by the condition that adjacent domains can match coherently. Any deviation from this orientation could, in principle, result in the creation of topological defects, and the crystal structure would cease to be coherent. In

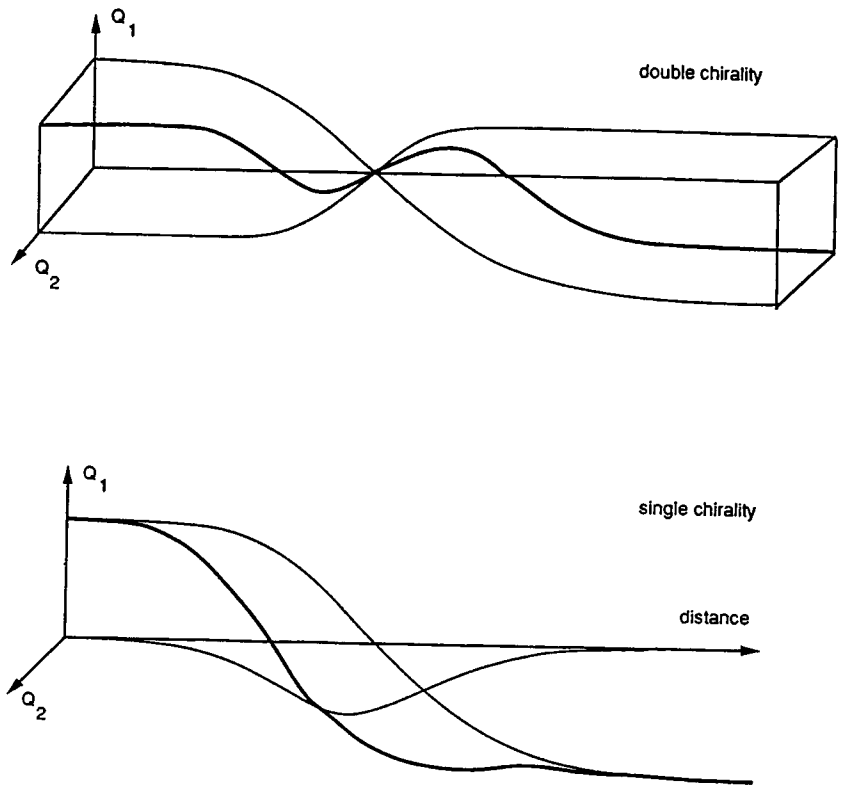

Figure 9. Wall profiles for twin domains with two coupled order parameters ($\lambda_2 Q_1^2 Q_2^2$). The relevant order parameter Q is plotted (thick line) as a vector sum of Q_1 and Q_2. The interaction between the two order parameters may lead to single or double rotation of Q, so that the internal wall structure becomes chiral with respect to the relationship between Q_1 and Q_3.

framework structures with sufficiently large unit cells this does not, in general, happen because the required energy to form dislocations is too large. As a result, the defect is compensated by internal adjustments of the atomic positions inside the unit cell. The penalty for such adjustments is paid for in terms of lattice strain, which is not identical with the spontaneous strain. Let us consider wiggled walls and wall corners, which are commonly observed in ferroelastic materials (Fig. 10). The quantitative description of the strain fields is based on the compatibility relationship, which allows us to calculate the strain components necessary to maintain the coherency of the lattice when a twin wall bends. If no dislocation is generated, the displacement of any atomic position u_i has to be continuous with respect to spatial variations up to second order. In this case the compatibility conditions mean that mixed second spatial derivatives of the displacement field cannot depend on the order in which the derivatives are taken:

$$\frac{\partial^2 u_i}{\partial x_j \partial x_k} = \frac{\partial^2 u_i}{\partial x_k \partial x_j} (j \neq k) \tag{14}$$

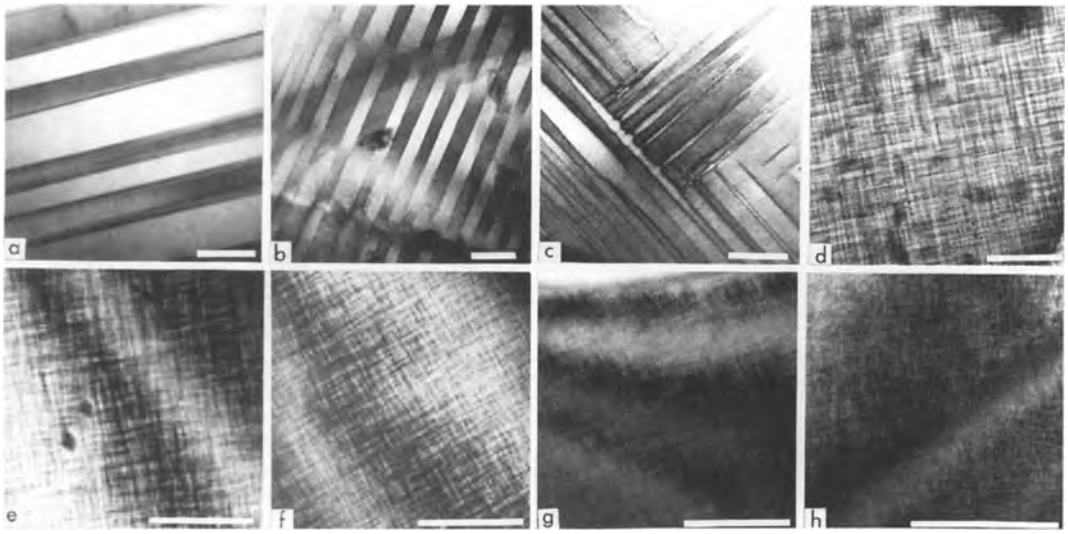

Figure 10. Characteristic microstructures in ferroelastic $YBa_2Cu_{3(1-x)}Co_{3x}O_7$ with $x = 0$ (a), 0.01 (b), 0.02 (c), 0.025 (d), 0.028 (e), 0.03 (f), 0.05 (g), and 0.07 (f). The scale bar is 0.1 μm. Twinning occurs for (a)–(c), and a tweed pattern is seen for all other compositions. Wall junctions, needle domains, and "wiggled' walls are seen in (c). (Courtesy of A. Putnis, Cambridge.)

This condition has substantial consequences when reformulated in terms of strain components e_{ik} rather than the displacements u_i. Let us consider a case in which we consider a trace of a twin wall in the xy plane, assuming that the wall does not bend in the z direction (e.g., the direction of the electron beam). In this case the compatibility relation becomes

$$\frac{\partial^2}{\partial x^2} e_{yy} + \frac{\partial^2}{\partial y^2} e_{xx} = 2 \frac{\partial^2}{\partial x \, \partial y} e_{xy} \qquad (15)$$

Let us now consider a spontaneous strain e_{xy}. For a planar wall along the xy direction (e.g., the (110) plane) the derivative $\partial^2 e_{xy}/\partial x \, \partial y$ vanishes, and there are no strain components e_{xx} or e_{yy}. As soon as the wall wiggles, the second derivative $\partial^2/\partial x \, \partial y$ measures the curvature of the wall. In order to fulfill the compatibility relation (Eq. (15)), spatial variations of e_{xx} and e_{yy} must exist, that is, these strain components can no longer vanish. This simple result implies that walls generated by the primary (i.e., spontaneous) strain will automatically generate secondary strain fields if they bend. These secondary strains are, indeed, the most sensitive indicators of wall deformations and largely determine their orientational fluctuations. A typical example is shown in Fig. 11, where pairs of domain walls join in order to form needle domain close to orthogonal domain walls. This image was taken in diffraction contrast so that the strain fields become observable. No or little strain variation is seen near the part of the domain structure with straight domain walls (top and bottom). Increasing strain modulation appears as contrast inside the needle domains and between the needles related to wall bending. Maximum strain contrast is seen at the needle tips. This strong contrast is similar to (but not

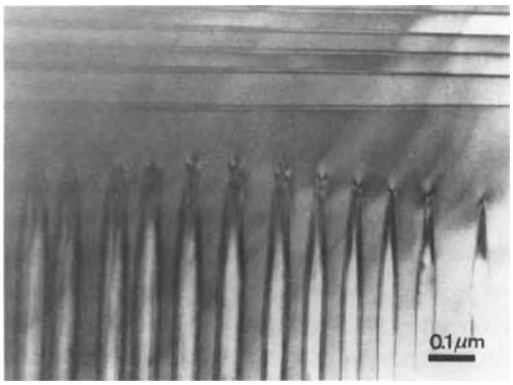

Figure 11. Comb pattern of needle domains in $YBa_2Cu_3O_{7-\delta}$, seen in diffraction contrast. Large strain fields can be seen near the tip of the needles. (Courtesy of EMAT Laboratories, Antwerp.)

necessarily generated by) dislocations at the needle tips. The similarly between strain fields from curved domain walls (without topological defects) and those generated by dislocations has led to the notion of 'pseudo-dislocations' for the theoretical description of strain fields [1]. Care should be taken not to confuse actual dislocations and 'pseudo-dislocations', which are only an elegant mathematical trick for the evaluation of the relevant strain fields of bent domain walls in terms of an equivalent behavior of hypothetical walls with in-built dislocations.

5.6 Wall–Wall Interactions in Ferroelastic Materials

Ferroelastic twin walls interact weakly for parallel walls at large distances $L \gg w$ (with predominantly attractive forces when surface effects are ignored). Strong repulsion occurs for distances of a few w, and it appears that interwall spacings smaller than some $5w$ have never been observed experimentally. Another predominant interaction occurs between walls which may form intersections. Typical examples are W and W′ walls with angles of $\pi/2 \pm \omega$ between each other. The angle ω measures the spontaneous strain. This situation is illustrated in Fig. 12. Here two walls are aligned along planes which were orthogonal in the high-symmetry phase but are sheared against each other in the low-symmetry phase. If we now measure the angle around the junction, we find that this angle is either $2\pi + \omega$ or $2\pi - \omega$, depending on the orientation of the twin planes. The compatibility condition now requires that the crystal is macroscopically sheared in order to compensate for the over- or unoccupied wedges near the junction.

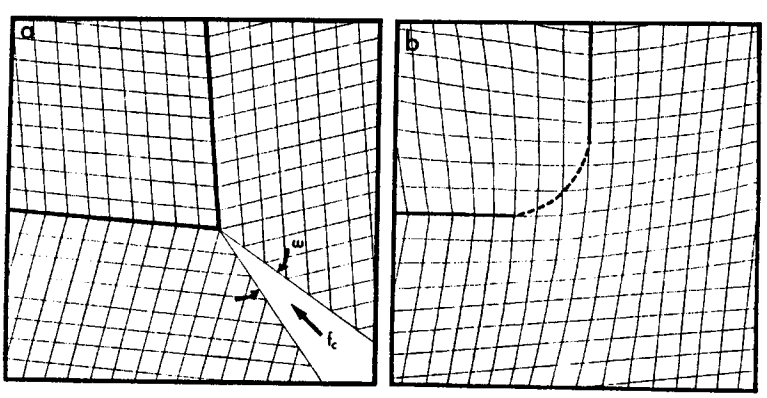

Figure 12. Junction formation between two ferroelastic walls. (a) The angular misfit ω between two parts of unstressed lattice adjacent to the corner of two twin domains causes an effective force, f_c, which (b) closes the open wedge. This closure causes the domain walls to curve, and generates elastic stresses which emanate from the corner.

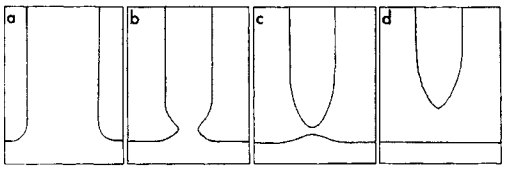

Figure 13. Formation of needle twins. (a) Two right-angled domains attract each other, and (b) bend the domain walls. The area of the grey domains increase with respect to the white domain. (c) When the two junctions join, the grey domains connect whereas the white domain is split into two parts. (d) The new needle domain will not retract under the influence of the interaction between the needle tip and the planar wall, also reducing the wall energy of the needle domain.

This energy, modified by some adjustment of the wall positions, is the characteristic excess energy of the junction. Thermal annealing of ferroelastic microstructures is largely related to the annihilation of such high-energy junctions.

The strong stress fields emitted by such junctions often lead to S-shaped wiggles of neighboring walls with the maximum deformation just above and below the junction.

The most common microstructures contain needle domains as shown in Fig. 5. The most common origin of such needle domains relates to their proximity to another, perpendicular twin wall. Figure 13 shows how a needle forms out of two junctions which attract each other. Once the needle is formed, it may retract and thereby reduce the total surface area of the twin walls. This retraction can be stopped by defects so that annealed samples often show such 'stranded' needle domains (see Fig. 2). The pinning force of defects is sometimes small enough to be overcome by mechanical tapping of the crystal or by local heating with the electron beam in the electron microscope. Once the needle domain is unpinned it will (under open-boundary conditions) continue to retract.

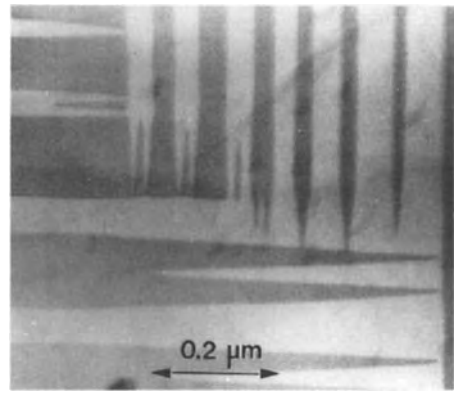

Figure 14. Needle domains with some forked domains in $YBa_2Cu_3O_{7-\delta}$. Forks appear for wide domains whereas simple needles occur for thin domains. (Courtesy of EMAT Laboratories, Antwerp.)

Typical needle domains with pairs of needles forming forks are shown in Fig. 14. The origin of these forks is similar to that of simple needles. The difference stems from the greater width of the forked domains. This larger distance between domain boundaries requires a stronger curvature of the walls in order to form needles, so that it is energetically advantageous to split the needle into two needles (vertical black, pointing downwards in Fig. 14), separated by a third needle between them (white, pointing upwards in Fig. 14). Such patterns do not occur for smaller distances between walls as seen for the horizontal needles at the bottom of the right-hand side in Fig. 14.

5.7 Tweed Microstructures as the Result of Kinetic Processes at $T < T_c$

Rapid quench of ferroelastic material (in particular those involving atomic ordering

processes) may result in a characteristic tweed microstructure (see Fig. 10d–h). Such kinetic microstructures are also observed in materials in which no such structures are seen in thermodynamic equilibrium (e.g., Na-feldspar). Similar tweed structures are sometimes claimed to exist in thermodynamic equilibrium at $T > T_c$, although the experimental evidence appears to be controversial in defect-free materials. It is generally accepted, however, that thermodynamic fluctuations at $T \gtrsim T_c$ are always highly anisotropic, so that each snapshot on a short enough timescale will look tweed-like, and it is conceivable that rapid quench will, indeed, maintain 'equilibrium' tweed at low temperatures.

Such initial tweed may somewhat coarsen kinetically at $T < T_c$ and form a higher contrast tweed with patchy areas separated by wall-like features. Such kinetic tweed is encountered in most ferroelastic materials of the order/disorder type. Extensive computer simulation of tweed patterns has shown that tweed develops into rather dense twin patterns (so-called stripe patterns) via the formation and retraction of needle-shaped domains (Fig. 15).

The term 'tweed' is used here in a generic sense indicating a characteristic microstructure of an interwoven pattern not dissimilar to those seen in woven tissues. Tweed shows usually some preferential orientation of two orthogonal 'weaving' directions.

Although the general appearance of tweed structures is very characteristic, detailed studies show large variations between tweed patterns in different materials and of different physical origins. A tweed pattern with strong contrast on dark field observation is sometimes related to exsolution phenomena and is unrelated to structural phase transitions altogether. Another type of tweed, usually seen as a weak modulation of the strain contrast, exists for all thermodynamic fluctuations which are coupled to structural strain. This structural strain does not usually develop isotropically but depends strongly on the orientation of the fluctuation. Fluctuation waves will often be the largest along two

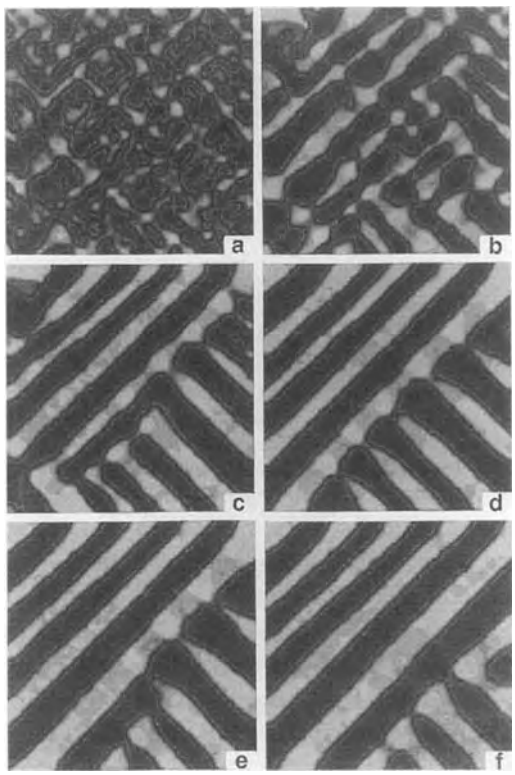

Figure 15. Maps of strain order parameter obtained during annealing at temperature $T_a = 0.43T_c$, after quenching from $4T_c$. (a)–(f) Maps corresponding to annealing times t = 10, 50, 200, 1000, 2000 and 4000 Monte Carlo steps per site. Note the immediate appearance of tweed in (a) due to the pre-existence of embryos even at $2T_c$, the sharpening up of microdomain walls in (b), the coarsening in (b) and (c), and the formation of needle domains in (d)–(f).

elastically 'soft" directions. These soft directions can easily be derived if the elastic properties of the material are known [7].

Fluctuation-induced tweed, in contrast to other forms of tweed, need not display a characteristic length scale of the tweed pattern. Simple fluctuations are described in the Ornstein–Zernicke limit with a Gaussian distribution of the wavevectors ($\bar{k} = (2\pi/l) \cdot \hat{e}$, where l is the length of a fluctuation and $\hat{e}$ is its orientation) centered around $k = 0$. This theoretical result is simply based on the fact that long-wavelength fluctuations are favored because they consume less of the gradient energy in Eq. (10).

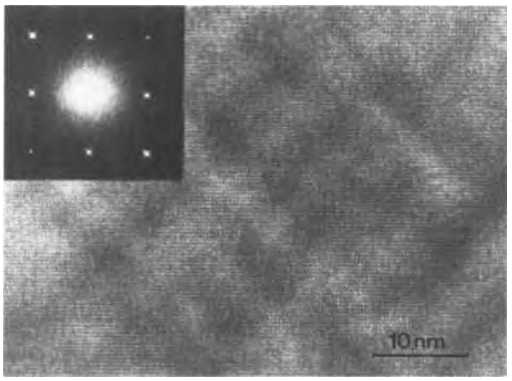

Figure 16. High-resolution image of the tweed pattern in $YBa_2Cu_3O_{7-\delta}$ and the diffraction pattern. The pattern shows preferential elongations in the ⟨110⟩ directions and weakly developed periodicities. (Courtesy of EMAT Laboratories, Antwerp.)

Although fluctuation tweed is elegantly described in such terms, and some experimental evidence from diffraction experiments is compatible with these ideas [8], there is considerable doubt that they describe the physical situation correctly at temperatures other than at $T \gg T_c$. At lower temperatures two additional features appear. Firstly, the amplitude of the fluctuations increases so that energy terms which are anharmonic in the fluctuation amplitude become important. This makes the description of fluctuations in terms of harmonic waves inadequate and requires the consideration of solitary excitations. A simple physical picture is that the areas of positive and negative fluctuations form 'patches' separated by wall-like discontinuities. The same 'patchy' tweed structure also follows from higher-order gradient energies which favor periodic, nonsinusoidal microstructures. Any of these effects will introduce a characteristic length scale for fluctuation tweed, namely either the thickness of wall-like features or a preferential periodicity of the elastic deformation wave. Simple numerical estimates lead for both cases to periodicities of the tweed pattern of 5–15 nm. The challenge for the experimentalist is to determine if such characteristic length scales exist at $T > T_c$. One of the probably most advanced observations in this field is shown in Fig. 16, which shows a patchy tweed pattern with wide range of wavelengths and a characteristic length of $\lambda_m \approx 10$ nm.

Kinetic tweed patterns at $T < T_c$ are better understood than fluctuation tweed at $T > T_c$. The metastable microstructure with the longest lifetime is the twin structure. If a crystal with fluctuation tweed at $T > T_c$ is quenched to $T < T_c$, the tweed structure will rapidly 'square-up', that is, it will form patches where the order parameter inside each patch is close to its equilibrium value. Walls between patches are now very similar to twin walls with a high number of junctions between orthogonal walls. As these junctions generate large strain energies they will be gradually eliminated, and the tweed structure

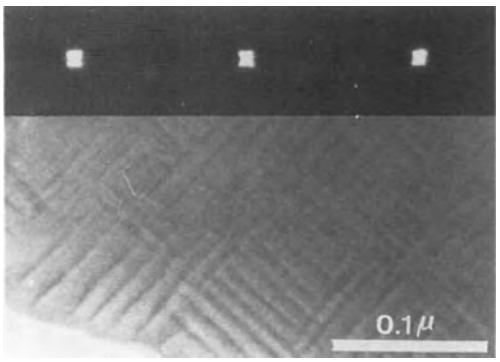

Figure 17. Tartan pattern (coarse tweed) and diffraction pattern of rapidly cooled $YBa_2Cu_3O_{7-\delta}$. (Courtesy of EMAT Laboratories, Antwerp.)

coarsens (Fig. 17). Such coarse tweed structures are sometimes called 'tartan' structures. Further coarsening of tartan to a stripe pattern occurs via the formation and retraction of needle domains (see Fig. 5). A typical sequence of tartan and stripe patterns under beam heating in the electron microscope is shown in Fig. 18.

5.8 Ferroelectric Domains

Electron microscopic work on a ferroelectric wall is hampered by the difficulty of making the reversion of the ferroelectric polarization visible. Since the mid-1960s, Takagi and Suzuki [9] and others have applied electron microscopy decoration techniques to study domain structures in ferroelectric crystals, although the exact physical mechanism of the AgCl–C coating revealing polarization orientation in replicas is still not fully understood. Undeniably, the technique succeeds in showing clear polarization reversal and also seems to allow first attempts to measure the thickness of ferroelectric domain boundaries. Hilczer et al. [10] found that the image of a TGS-cleaved surface shows a domain wall of some 12 nm. Direct observations on ferroelectrics pose unusual problems, since specimens tend to be unstable under the electron beam, and there are difficulties correcting astigmatism. Despite these difficulties, some direct observations in $LiTaO_3$ seem to show very thin domain walls ($\omega \lesssim 0.28$ nm). This observation [11] relates to the observation of the coupled ferroelastic strain, however, and may not directly reflect the domain profile of the spontaneous polarization. Measurements of strain profiles are equally difficult on this length scale, so that the lower limit of reliable information on the value of w in ferroelastics may still be some 0.5 nm. Wider walls, extending over some 5 nm, have also been identified in $KNbO_3$ by Bursill and Lin [11].

6 Microscopy of Structural Ceramics

6.1 Introduction

Ceramics play an ever more important role in science as well as in applications. Ceramics can be divided into different groups, that is, whiteware ceramics, structural ceramics, and electroceramics [1]. Whiteware ceramics deals mainly with the processing of clay and other minerals into objects for everyday life. Electroceramics are oxides, carbides, or nitrides of metal alloys which are used because of their specific magnetic or electrical properties. In contrast, advanced structural ceramics are mainly used in specific components working under extreme conditions such as high temperature, high stress, or high friction. Structural ceramics can be either oxides, carbides, or nitrides of different cations, such as aluminum, silicon, or boron.

At ambient temperatures most ceramics are brittle; they do not show any plastic behavior upon loading. Therefore the mechanical properties of these ceramics are mainly determined by the defects present in them. It is, therefore, essential to characterize the microstructure and defects of these materials. This microstructural characterization includes all the dimensions from the atomic scale to the component (Fig. 1). For example, silicon nitride (Si_3N_4) parts are now used as engine components, e.g., valves, turbo chargers. The Si_3N_4 engine parts have a complex shape and to densify and process the material without flaws is rather complicated. Flaws and defects have to be identified and studied, and the microstructure has to be investigated—often with resolutions from optical microscopy to the atomic level. For example, large defects such as voids or inclusions can easily be identified by optical microscopy. The grain size and grain size distribution of the different materials can be determined by optical microscopy [2] and by scanning electron microscopy (SEM) [3], and specific details of the microstructure can be investigated by scanning tunneling microscopy (STM) or atomic force microscopy (AFM) [4, 5]. Quantitative results on the microstructure can be elaborated using standard quantitative metallography techniques [2, 6]. Structural materials are usually polycrystalline. They consist of many grains in different orientations. The grain boundaries and interfaces of these materials are very important defects, often controlling the properties. Therefore it is essential to investigate the structure and chemical composition of grain boundaries; this requires microscopy at the ultimate resolution of transmission electron microscopy [7, 8].

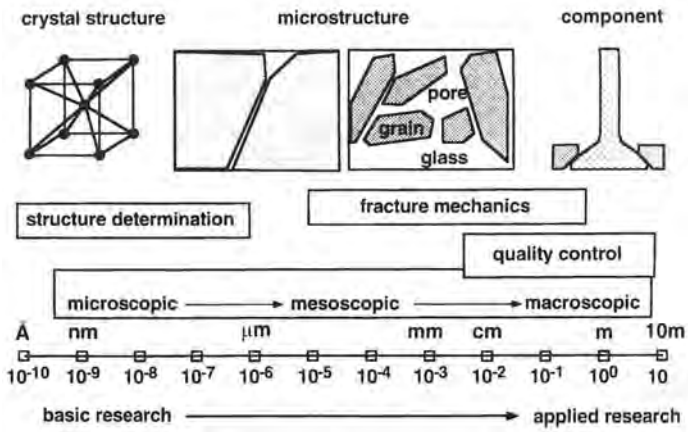

Figure 1. Microstructure ranging from crystal structure to engine components.

Several conferences on the microstructure of ceramic materials have been held over the last few decades. The proceedings of these conferences on ceramic microstructures have been published and reflect the importance of understanding the microstructure of these materials [9–12].

In this chapter, the different techniques for analyzing the microstructure of ceramics will initially be summarized. The important features of the microstructure of three prominent ceramics will be described: alumina, zirconia, and silicon nitride. Finally, some remarks on the microstructure of composites will conclude the chapter.

6.2 Different Imaging Techniques

6.2.1 Remarks on Specimen Preparation

Most ceramics are nontransparent, therefore the optical microscope is used in the reflection mode. To make different grains and inhomogeneity visible, the specimen has to be etched [2, 13]. This involves a sequence of mechanical grinding and polishing. Special materials are required for each ceramic in order to achieve the best possible polishing. Similar to metallographic preparation, the following steps have to be carried out to prepare ceramics for microstructural investigations. Firstly, the proper tool has to be selected for grinding, polishing, cleaning, and etching. However, owing to the brittleness, porosity, and chemical resistance of ceramics, they are quite often difficult to polish compared to metals. Polishing is usually carried out using diamond paste, followed by small silicate particles. If the specimen is polished too much, then the region beneath the polished surface will be damaged leading to artifacts in the microstructure. The specimen has to be etched after polishing. This makes the different grains and components visible. However, the etching of ceramics requires very aggressive chemicals which are often very difficult to handle. Therefore specimens are often etched using plasmas. This etching involves ion etching followed by bombardment with electrons. Thermal

etching is an important technique for revealing the ceramic microstructure. For this technique a polished specimen is annealed in a high-temperature furnace. The temperature and time have to be chosen in such a way that the microstructure is not modified (e.g., by grain growth). Microstructural characteristics can be made visible by thermal grooving [1].

6.2.2 Optical Microscopy

Classic metallographic techniques can also be applied to ceramics. The grain size and different phases can be identified if the grain size is large compared to the resolution of the microscope. The addition of interference layers on top of the specimen improves the phase contrast. This cannot be done as successfully for ceramics as for metals, since ceramics have a much smaller coefficient of reflection compared to metals; also some ceramics are transparent [2, 13]. At the interface between the interference layer and the ceramic the conditions for multiple reflection leading to the desired interference are not fulfilled. Ceramic microstructures can only be studied by optical interference microscopy under the following conditions: (i) If the microstructure consists of different phases and the phases are opaque. The interference layers on the ceramics are mostly ZnSe, ZnTe, and ZnS. (ii) If amplification by multiple reflection is obtained due to the interference layer possessing a reflection index smaller than that of the ceramics. The best material is kryolite (Na_3AlF_6). (iii) If layered specimens and metal/ceramic composites are contrasted by reactive sputtering [2, 13]. The difference in reflectivity between the different components can be increased or reduced depending on the sputtering material.

6.2.3 Microstructural Studies with the Scanning Electron Microscope (SEM)

The resolution of optical microscopy is limited essentially by the wavelength of light. A better resolution can be achieved by using electrons as a 'light source'. Depending on the accelerating voltage, the resolution can be improved [3] by using a scanning electron microscope (SEM). A small probe is scanned over the specimen surface. Ceramics are often electrically insulating materials. Therefore they have to be coated with a conducting layer of carbon or gold [3]. Recently, SEMs have become available that operate at low voltages ($\lesssim 1$ keV) and with a field emission source. The resolution is impressively improved and details such as atomic steps at surfaces can be seen. Operating at low voltages makes coating with a conducting layer redundant.

6.2.4 Microstructural Studies with a Scanning Tunneling Microscope (STM) and an Atomic Force Microscope (AFM)

STM and AFM studies [4, 5] are possible down to the atomic level. Individual surface atoms can be imaged. STM and AFM techniques have had a major impact on the microstructural studies of surfaces with high resolution. STM can only be

performed on conductive materials, such as TiO_2 and doped ceramics. AFM studies can, however, be applied to nonconductive specimens. Recent instrumental developments have made AFM work very easy and convenient. In particular, grain size and grain size distribution can readily be investigated [14]. Different phases can also be identified, as well as specific problems such as surface structures near interfaces.

6.2.5 Microstructural Studies with a Transmission Electron Microscope (TEM)

Transmission electron microscopy is one of the most important tools for the characterization of property dependent quantities of structural ceramics. There are excellent textbooks on TEM [15, 16], high resolution electron microscopy [17, 18], and analytical electron microscopy [19, 20]. The latter technique enables the determination of the chemical composition with high spatial resolution. Special techniques, such as the study of the energy loss near edge structures (ELNES), allow the identification of bonding states and coordination numbers [20–22].

6.3 Essential Microstructural Aspects of Structural Ceramics

Structural ceramics possess a high melting point leading to extremely high strength, often high corrosion resistance, and low thermal conductivity. The advanced structural materials are mainly used in high temperature engines, but may also be used as refractories [1, 12, 23]. However, the toughness of structural ceramics is rather low; most ceramics are brittle. The critical fracture toughness is much lower than for any type of metal, including cast materials. The deformation diagram shows a steep increase in stress as a function of deformation (strain). At a certain, but usually very high, stress the material fractures catastrophically. This behavior makes it very difficult to use ceramics as structural components, since engineers require the failure of a material to be 'announced' by some form of plasticity. The completely elastic behavior of most ceramics shows that these materials do not deform plastically, but that the failure process starts at weak links in the material. These weak links can be flaws or defects in the material, with emphasis on grain boundaries and interfaces. It is essential to characterize the flaws in monolithic ceramics. Ceramics can be toughened by several processes [24], i.e., by including second phases (composites) or particles ready for martensitic transformation [25]. These materials lead to a quasi-plastic behavior; 'ductilization' is the expression used in the literature.

It should be mentioned that increased reliability of these materials can be achieved by flaw control or toughening. The first approach accepts the brittleness of the material and attempts to control the large processing flaws and all other types of weak defect by microstructural control. The second approach attempts to generate microstructures that impart sufficient fracture resistance that the strength becomes insensitive to the size of the flaw. The former has been the subject of considerable research to identify the most

detrimental processing flaws as well as the processing steps responsible for these flaws. The toughening approach has emerged more recently and has the obvious advantage that appreciable processing and post-processing damage can be tolerated without compromising the structural reliability [26].

The resistance of brittle solids to the propagation of cracks can be strongly influenced by the microstructure and by the use of various reinforcements. An understanding of the properties of both the flaw-controlled and the toughened ceramics actually requires determination of the microstructure using different levels of resolution. For the flaw-controlled materials, the largest flaws have to be identified. This can be done by either scanning electron microscopy or transmission electron microscopy. In these studies the microscopy of the undamaged bulk is usually of no interest and is not relevant. Only the microscopy of defects (and regions close to defects) is relevant for the properties. Therefore these microscopical studies essentially only require the study of flaws and defects.

For the toughened material a similar procedure is required. Only the regions of contact between the different phases (heterophase boundaries) have to be studied. This includes an understanding of the bonding and failure mechanisms at the different boundaries. For some toughened materials plasticity occurs in one phase, e.g., in ceramics toughened by metal particles. For these studies the microscopy of deformed materials is also of great interest.

One final area of importance, more on the experimental side, is quite similar to that involved in the microscopy of metals. In precipitation hardened ceramics or plastically deformed ceramics, the microstructure has to be observed at different levels of magnification. For plasticity studies the concentration of dislocations and other defects is required. For polycrystalline ceramics and composites, the structure and composition control of internal interfaces is crucial. This will be elaborated in the following chapters for specific ceramics and for composites.

6.4 Studies on Alumina (Al_2O_3)

6.4.1 Fundamentals of Alumina

Alumina is the most widely utilized oxide ceramic [27]. It is also the only oxide ceramic widely used in single crystal form. Single crystal alumina, often incorrectly referred to as sapphire rather than corundum, is used for both its structural and optical properties. The only other significant uses of bulk single crystal oxides are artificial gemstones and laser hosts (alumina also finds applications in both of these fields). The overwhelming majority of alumina, however, is used in polycrystalline form. The major markets for alumina-based material on a weight basis are refractories, abrasives, whitewares, spark plugs, and engineering ceramics.

6.4.1.1 Crystallography

There is only one thermodynamically stable phase of aluminum oxide, α-Al_2O_3, which has the corundum structure.

The crystal structure is often described as having O^{2-} anions in an approximately hexagonal close-packed arrangement with Al^{3+} cations occupying two-thirds of the octahedral interstices. The properties of single crystal α-Al_2O_3 are listed in the literature [27–30].

However, many processes, such as the oxidation of metallic aluminum and the thermal decomposition of gibbsite, or vapor-deposited amorphous alumina thin films, involve the formation of intermediate metastable alumina phases. These transition phases are denoted as γ, χ, η, ι, ε, δ, ϑ, and κ and are of particular importance because of their use as catalyst substrates, and because the characteristics of α-Al_2O_3 can be affected by the crystal structure(s) of the precursor(s). All the metastable phases have partially disordered crystal structures based on a close-packed oxygen lattice with varying interstitial Al^{3+} configurations. As equilibrium is approached, the structures become more ordered until stable α-alumina is formed.

The sequence of transition aluminas which form is strongly dependent on the starting material and how it is processed. For example, if the starting material is boehmite, AlO(OH), formed from solution or amorphous alumina, then the sequence is $\gamma \rightarrow \delta \rightarrow \vartheta \rightarrow \alpha$. However, if the starting material is gibbsite, α-$Al(OH)_3$, then the sequence may include $\chi \rightarrow \gamma \rightarrow \kappa \rightarrow \vartheta \rightarrow \alpha$, even though boehmite is formed prior to χ. Diaspore, another polymorph of AlO(OH), transforms directly to α-Al_2O_3. Formation of the transition aluminas from hydrated compounds is often accompanied by the development of a highly porous microstructure [31].

The crystal structures of the transition aluminas are characterized by the maintenance of an approximately f.c.c. anion sublattice [31]. While usually treated as cubic, γ-Al_2O_3 has a slightly tetragonally distorted, defect spinel structure (c/a about 0.99, the distortion varying with heat treatment). δ-Al_2O_3 has a tetragonal superstructure, with one unit cell parameter tripled by the cation vacancies, which are thought to be ordered on the octahedral sites of the spinel structure. ϑ-Al_2O_3 is monoclinic with space group $A2/m$, but it is still similar to spinel and often observed to be twinned; η-Al_2O_3 is cubic spinel.

Alumina has a mixed ionic–covalent bond structure, in comparison with the more covalent silicon nitride and silicon carbide, a lower formation free energy, a high melting point of 2050°C, a specific gravity of 3.99, and its single crystals are transparent.

6.4.1.2 Sintering and Application of α-Alumina

Raw powder is generally produced from bauxite (mainly $Al_2O_3.H_2O$, Al_2O_3-$3H_2O$), which is dissolved in an aqueous NaOH solution in an autoclave at 170°C, then $Al(OH)_3$ is calcined at 1100°C to obtain α-Al_2O_3. γ-Al_2O_3 is formed in a firing temperature range of up to 900°C; for temperatures over 1000°C α-Al_2O_3 forms. The alumina powder so obtained can be pulverized to finer grains and refined to higher purity. Recently, new processes have been developed to prepare very high purity and ultrafine-grained alumina from aluminum alkoxide or aluminum organic compounds, which are

useful for higher grade components and films where higher costs can be tolerated.

Since Al_2O_3 is intrinsically a sinterable material because of its higher ionicity [29, 30], full densification can be achieved by pressureless sintering. However, grain growth occurs simultaneously; this can be inhibited by the addition of a very small amount of MgO dopant. Fine-grained nanocrystalline materials can be obtained via a colloidal route, where interaction of the α-Al_2O_3 particles can be controlled by surface charges. The superior characteristics of Al_2O_3 are its thermal resistivity, electrical insulation, hardness, chemical stability, producibility, and economical cost.

Consequently, an extremely wide range of applications have been developed during the last 50 years. In the high temperature engineering applications there are pipes, plates, and jigs for high temperature uses, transparent tubes for sodium lamps, wear-resistant parts like wire guide and nozzles, mechanical seals, and cutting tools. But this material has a number of major limitations, such as low toughness and poor thermal shock resistance and high temperature strength. Therefore recent development work on this material has aimed to improve its toughness by the addition of other compounds, in the form of particles or whiskers. Hot pressed and hot isostatically pressed (hipped) α-Al_2O_3-TiC have been developed for cutting tools [32, 33]. An addition of TiO_2 is used to inhibit grain growth and to improve the thermal conductivity. α-Al_2O_3-SiC whisker composites have been developed for improved strength and toughness [34, 35].

Alumina strengthened and toughened by ZrO_2 particle dispersions has been developed [36]. The increase in toughness is explained as due to the absorption of elastic strain energy by the formation of microcracks through a martensitic phase transformation from a tetragonal (t) to a monoclinic (m) structure of the ZrO_2. The phase transformation itself can also be utilized for toughening [25]. High strength, high toughness materials have been achieved. Current research is growing in the area of nanocomposites.

6.4.2 Microscopy of α-Alumina

Microscopical studies of α-Al_2O_3 can be subdivided into two main sections. One concerns the determination of the grain size and grain size distribution in fine-grained and ultrafine-grained polycrystalline materials. The other concerns the evaluation of defects with emphasis on grain boundaries. Of course it is also of great interest to study the optical properties of single crystal α-Al_2O_3. However, these studies are not included in this chapter. The reader is referred to the literature [29, 30, 37].

6.4.2.1 Determination of Grain Size and Grain Size Distribution

α-Al_2O_3 possesses anisotropic thermal expansion coefficients which result, after grain growth, in internal stresses upon heating the material. Evans and Fu [38] showed that large grains resulted in stresses that lead to microcracking of the material. The microcracks either toughen the material or they can be the main flaws leading to failure of the material. Therefore it is desirable to maintain a small grain

size in the material. Typically, the grain diameter should be less than 1 μm. Control of the grain size and grain size distribution is essential. Abnormal grain growth [20, 30] has to be avoided.

Since for most alumina materials (including ZrO_2-containing Al_2O_3) the mean grain size is often far below 1 μm, optical microscopy does not yield satisfactory results. SEM and atomic force microscopy (AFM) enable the determination of grain size, grain shape, and grain size distribution [14]. For these studies the surface of the polycrystalline material is polished (see Sec. 6.2.1 of this Chapter) and then thermally etched so that the grain boundaries become visible. The resolution of a high resolution field-emission SEM reaches ~1 nm. Almost atomic resolution can also be achieved with an AFM, because the van der Waals forces utilized in this method vary on an atomic scale. The AFM offers high quantitative resolution in the vertical direction. Moreover, the electrostatic charging effects of insulating materials, as occur with SEM using electrons for imaging, do not occur. An easy and quick investigation of the sample surface is possible in ambient atmosphere. Baretzky et al. [14] recently compared the

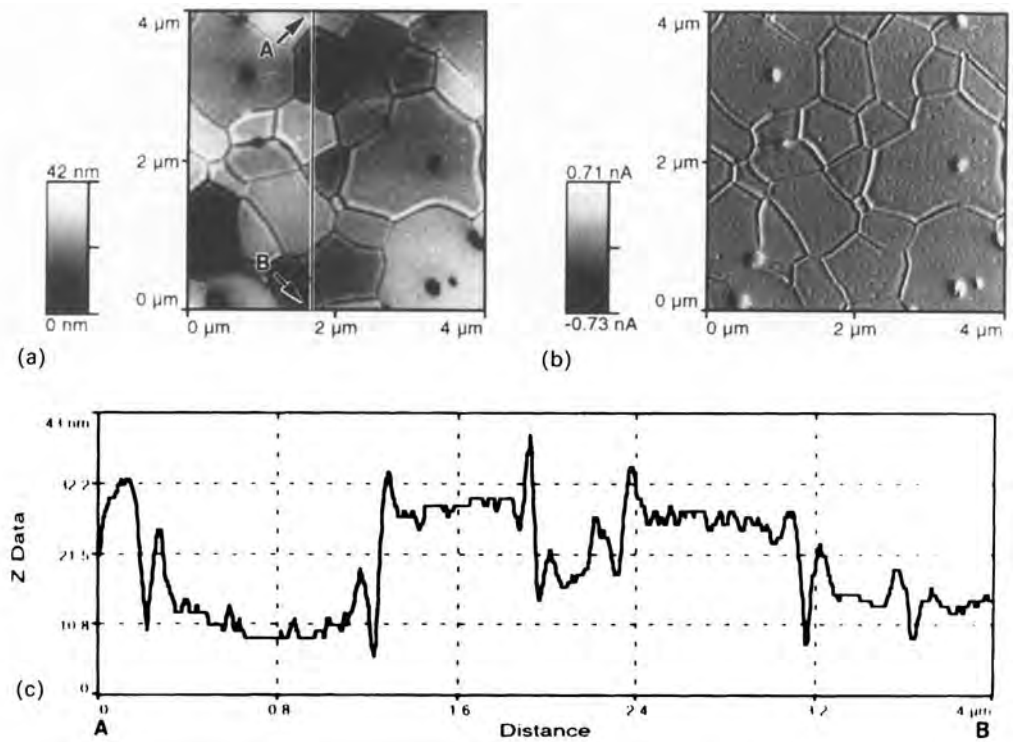

Figure 2. (a–b) AFM micrographs of polycrystalline alumina thermally etched in air at 1200°C for 10 min. (a) Topography image where different heights appear as different brightness values in the color bar. The lowest point was set at 0 nm, the maximum height was determined as 42 nm. (b) Internal sensor image simultaneously recorded, giving the impression of artificial illumination. The measured currents are indicated by different brightness values in the color bar. (c) Quantitative relief profile along line A–B in Fig. 2a. Height data are given as a function of the distance from the origin, defined as point A.

possibility of studying grain size and grain morphology by high resolution SEM (HRSEM) and AFM. The grain size and grain size distribution can easily be determined if the ceramographic preparation is done properly. Figure 2 shows different imaging modes of AFM (topography). With AFM on a very low scale, the atomic microstructure is clearly visible and the size and distribution of grains and pores can be determined. The determination of grain size by optical microscopes is rather difficult.

As an example, in the higher magnification range AFM is compared with high resolution SEM in Fig. 3. The AFM

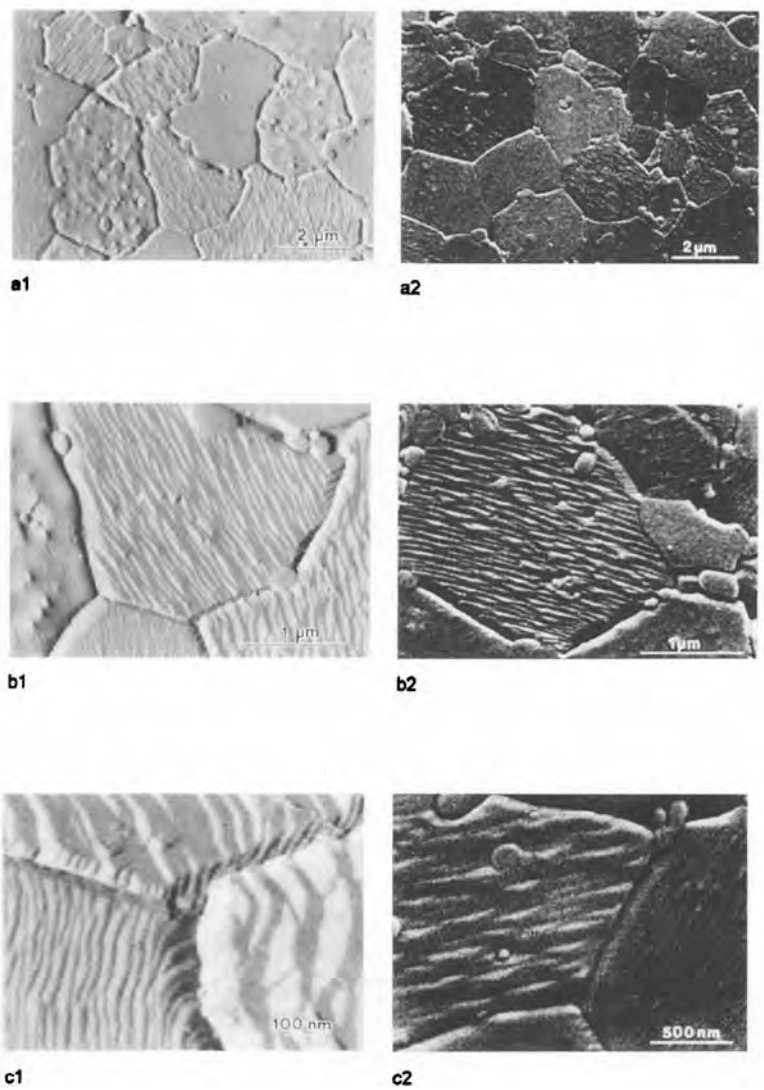

Figure 3. Comparison of AFM (column 1) with HRSEM (column 2) using SiC-doped alumina (sample no. 3) thermally etched under vacuum at 1400°C for 15 min. The magnification is increased from (a) 8000× via (b) 24 000× up to (c) 100 000× for AFM (c1) and 40 000× for HRSEM (c2), respectively.

micrographs are presented in column 1 of Fig. 3 and those of high resolution SEM in column 2. The magnification was increased from ~8000 to 24 000×, up to 100 000× for AFM and 40 000× for HRSEM. The capability of AFM for continuous microscopy, ranging from an overview to the microstructure in one single spot, is demonstrated by the whole series of magnifications, where each micrograph is a magnification of the preceding one. At low magnifications, the microstructural information gained by both AFM and HRSEM is equivalent. Both techniques require ceramographic preparation (thermal etching). Acquisition of the different micrographs usually presents no problem and can be done within a very short period of time. The grain size and grain size distribution can be determined following the standard procedures described, e.g., by Underwood [6].

6.4.2.2 Structure of Undoped Grain Boundaries in α-Alumina

Grain boundaries are often where the failure of a material starts. Therefore it is important to understand the structure and composition of grain boundaries and regions close to the grain boundaries. These studies can only be done on an atomic level by electron microscopy and high resolution electron microscopy (HREM) [39, 40]. Analytical electron microscopy (AEM) yields information on the composition and studies of the near-edge structure in an energy loss (ELNES) result in fingerprints on the bonding and coordination number [21, 22, 41–43].

A bulk of experimental studies of grain boundaries in alumina have been confined to commercial grade polycrystalline alumina, and have been concerned mainly with the crystallographic classification of grain boundaries and the description of grain boundary structures. It is quite interesting that small additions of impurities such as yttrium lead to a change in the distribution of different grain boundary classes [44–46].

Only specific grain boundaries, mainly tilt boundaries, can be studied by HREM [47]. The condition has to be fulfilled that in the direction of the incoming electron beam, strict periodicity occurs within the specimen [48]. (The electron beam has to be parallel to atom columns of the material.) These studies were performed experimentally for different grain boundaries (near $\Sigma 11$ and $1\bar{1}04$ twin) [39, 40]. These grain boundaries were not selected in a technical, polycrystalline, pure material, but from bicrystalline specimens produced by diffusion bonding [49]. The grain boundary misorientation could be adjusted accurately.

The interpretation of HRTEM micrographs requires a comparison between experimental micrographs and simulated images, so that retrieval of the actual structure is possible. This structure can then be compared to results from static lattice calculations. The experimental work by Höche et al. [39, 40] resulted in quite interesting high resolution micrographs (see Fig. 4). A simulated image is included in Fig. 4 as an inset. Reasonably good agreement exists between the experimentally determined structure and the simulated structure. In the interpretation of the micrographs it was possible to differentiate between different metastable structures predicted by theoretical modeling [50]. It was found that the simulated

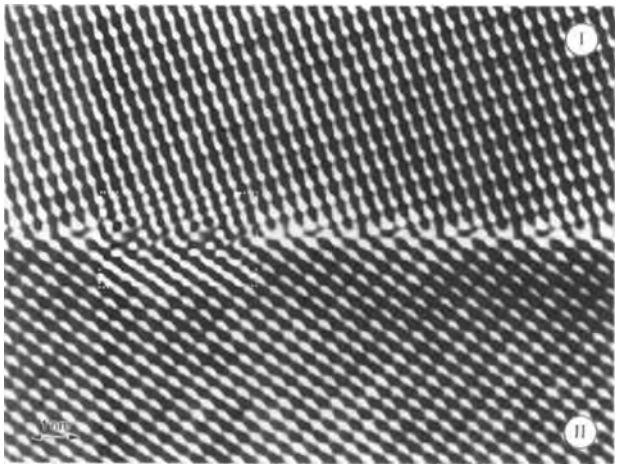

Figure 4. Experimental HRTEM images of the Σ11 grain boundary (Fourier-filtered), [2110] direction; inset: simulated image, thickness ≈ 4 nm, defocus = −5 nm.

images of a specific relaxed structure showed the best agreement with experiments [39]. This agreement was studied quantitatively and it was found that the accuracy of the positions of the columns of ions reached ±0.02 nm. The agreement is not quite satisfactory at the site of the grain boundary. It has not yet been established what causes the difference between the experimental micrograph and the calculated image. This could be caused by deficiencies in the knowledge of the interatomic potentials or by experimental errors (e.g., inhomogeneous TEM specimen, nonequilibrium state of the diffusion bonded grain boundary).

6.4.2.3 Studies of Segregated Grain Boundaries

Alumina has a very low solubility in the bulk for almost all anions and cations [28–30]. Therefore small additions of impurities will easily result in segregation at grain boundaries. Segregated atoms often influence the bonding across the boundaries.

Detailed experimental studies have been carried out on the segregation of calcium doping for a specific grain boundary. These boundaries were produced using ultrahigh-vacuum diffusion bonding of two highly pure single crystals [44]. Two distinct boundary configurations (each having mirror and glide mirror symmetry) were found in the Ca-doped bicrystals. So far only the mirror-related configuration can be identified in the undoped boundary. To estimate the atomistic structure of the grain boundary, simulated images of certain regions of the crystals with different calcium contents were compared to experimental HREM micrographs. The results of these comparisons indicated that the amount of calcium found at this specific twin boundary corresponds to a replacement of ~0.5 monolayers (ML) of aluminum by calcium. These results are comparable to those obtained by analytical techniques.

Recently, great interest has been directed towards studies of the influence of yttrium on the microstructure, segregation behavior, and properties of grain boundaries. It has been established that yttrium

increases the number of special boundaries in bulk α-Al_2O_3 [44, 45]. α-Al_2O_3 scale formed by the oxidation of an aluminum-containing metallic alloy also develops a specific relationship and a columnar grain morphology [51]. Yttrium segregates at grain boundaries and interfaces. Fang et al. [52] showed that yttrium decreases the creep of alumina by about one order of magnitude. The mechanisms of the strong influence of impurities are not yet understood.

The other important impurity for sintering is MgO. MgO reduces the abnormal grain growth of α-Al_2O_3 grain and is therefore essential as a sintering aid. However, different models exist to explain the influence of magnesium. A recently developed model [53, 54] seems to be reasonable for understanding the different mechanisms. However, the atomistic structure of the MgO-containing grain boundaries has not yet been studied by AEM and HRTEM.

6.4.2.4 Grain Boundary Films

Silica-based alumina materials contain an amorphous grain boundary film which wets all boundaries. So far the phenomenon has been studied, along with the wetting of these boundaries [27]. However, detailed consideration of the structure, composition, and behavior of these grain boundary films has not been studied at the same level as in Si_3N_4 (see Sec. 6.6 of this Chapter). These silica-based alumina ceramics are the cheapest materials that can be processed. Their properties are not very good. High temperatures result in a very high creep rate. However, these materials are used as insulators due to their low cost. A detailed analysis of their microstructure reveals that the distribution of the amorphous silica film within the material depends on the exact processing configuration and details of the processing route. Unfortunately, insufficient detailed microscopy studies have been done for this type of material.

Alumina-based ceramics with 95–99% Al_2O_3 have a large proportion of grain boundary glass which must be of carefully controlled composition to confer the required densification behavior and final state properties. The grain boundary glass is usually an aluminosilicate containing additional oxides, such as CaO or MgO. Microstructures of aluminas where the glass is used simply as a densification aid show a uniform distribution of alumina crystals completely separated by glass. In other aluminas, which are fired to higher temperatures, some recrystallization of the alumina may occur to give an interconnected network. In these materials pores are usually located at the interface between the alumina and the glass.

6.5 Studies on Zirconia (ZrO_2)

The traditional applications of ZrO_2 and ZrO_2-containing materials are foundry sands and flours, refractories, ceramic and paint pigments, and abrasives. These applications still account for most of the tonnage used. However, the thermomechanical and electrical properties of zirconia-based ceramics have led to a wide range of advanced and engineering ceramic applications. Early reviews of the then state of knowledge of ZrO_2 are given by Ryshkewitch and Richerson [23] and

Garvie [55]. The recent level of research interest in ZrO_2 can be gauged by examining the series of conference proceedings on the science and technology of zirconia [56–59]. Tough, wear resistant, and refractory, ZrO_2 is being developed for applications such as extrusion dies, machinery wear parts, and piston caps. Composites containing ZrO_2 as a toughening agent are used, e.g., as cutting tools. Ionically-conducting ZrO_2 can be used as a solid electrolyte in oxygen sensors, fuel cells, and furnace elements [27]. TEM played and still plays a major role in revealing the microstructure and the mechanisms responsible for different effects.

6.5.1 Phase Transformations of Zirconia Ceramics

ZrO_2 undergoes several phase transformations upon cooling from the melt [60–62]. At least three crystallographic modifications exist which possess cubic (c), tetragonal (t), and monoclinic (m) symmetry and are stable at high, intermediate, and low temperatures

$$\text{melt} \xrightarrow{2680^\circ\text{C}} \text{cubic} \xrightarrow{2370^\circ\text{C}} \text{tetragonal} \underset{1150^\circ\text{C}}{\overset{950^\circ\text{C}}{\rightleftharpoons}} \text{monoclinic}$$

The high temperature c-phase has the fluorite structure (*Fm3m*), whereas the other polymorphs (t: $P4_2/nmc$, m: $P2_1/c$) are distorted versions of this structure (Fig. 5). The $t \rightarrow m$ transformation is martensitic in nature. The addition of Y_2O_3, CaO, or MgO into the crystal structure maintains the highest temperature configuration (c-ZrO_2) even at low

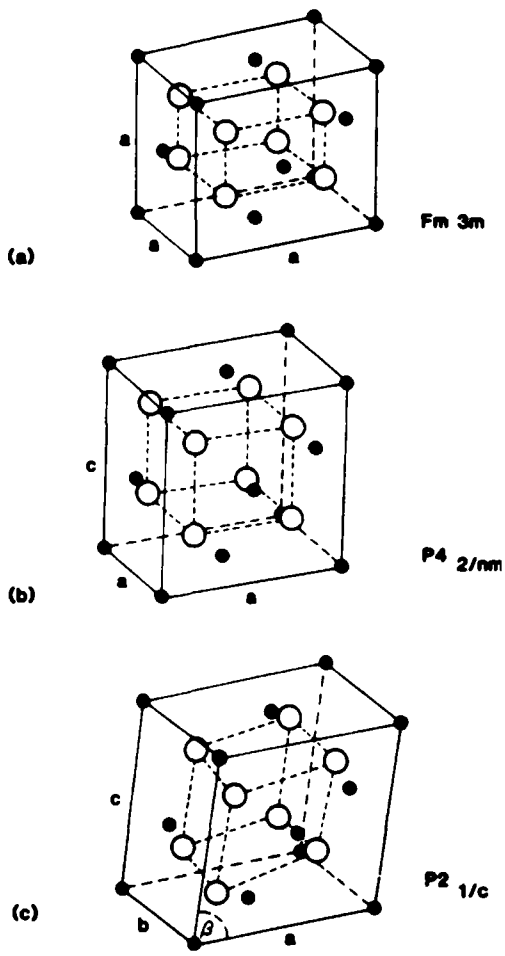

Figure 5. Schematic representation of the three zirconia polymorphs: (a) cubic; (b) tetragonal; (c) monoclinic. Their space groups are indicated.

temperatures. This can be seen from the phase diagram (see, e.g., Fig. 6).

Several types of microstructure can be used as a basis for ZrO_2-toughened ceramics (ZTC). Of particular importance are two different compositions, materials I and II, shown on the phase diagram (Fig. 6). Material I may be densified in the t-ZrO_2 phase field and cooled to room temperature (RT). Then, provided that the grain

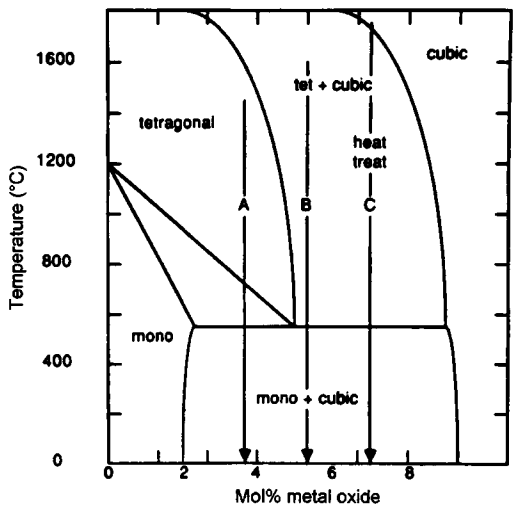

Figure 6. A schematic metal oxide–zirconia phase diagram showing routes for fabricating three different microstructures.

size is less than the critical size required for the transformation, single-phase t-ZrO_2 may be produced (tetragonal zirconia polycrystals: TZP). Composition II (Fig. 6) consists of t-ZrO_2 precipitates in a cubic matrix. Generally, these materials are sintered in the cubic phase field [63–66], but on cooling to the two-phase field, the tetragonal phase forms as precipitates. The size and size distribution of the tetragonal precipitates depends on the thermal treatment in the two-phase field. The t-ZrO_2 precipitates, when small, remain tetragonal upon cooling down to very low temperatures (even liquid helium). This class of materials is referred to as partially stabilized zirconia (PSZ). The shape of the t-ZrO_2 particles depends on the stabilizing agent [56–59]. Conversely, large precipitates transform thermally to m-ZrO_2. Finally, TZP may be used as one of the components in a composite material. Such materials are referred to as ZrO_2-dispersed ceramics (ZDC). The predominant system is Al_2O_3-ZrO_2 (zirconia-toughened alumina, ZTA). The size and distribution of the t-ZrO_2 regions depend on the processing conditions.

The $t \rightarrow m$ phase transformation (Fig. 7) involves a set of transformation strains that increase the volume and change the shape of the particle/grain.

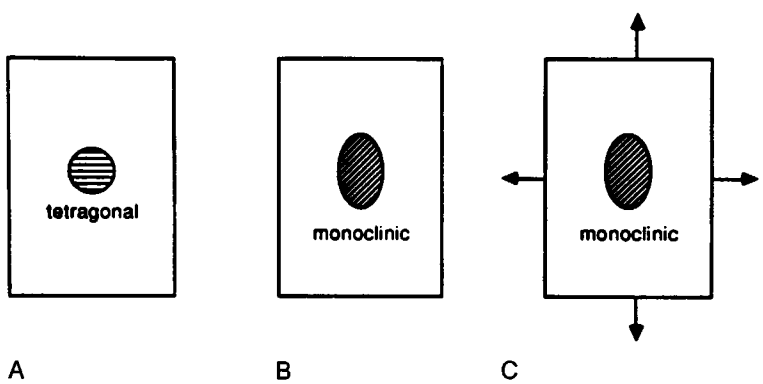

Figure 7. A schematic representation of the zirconia phase transformation. The normal phase transformation to monoclinic is represented by going from A to B; the zirconia particle undergoes a size and shape change as indicated. The material surrounding the particle will oppose the transformation and it is the strain energy that is involved in this constraint that allows the tetragonal phase to be retained. As shown in C, the transformation from A to C can be aided by an applied stress.

Isolated grains invariably transform provided that the nucleation conditions are satisfied. However, for grains embedded in a matrix, strain energy changes tend to oppose the transformation. Then for the transformation to proceed the system has to be 'supercooled' to sufficiently increase the chemical driving force. The retention of t-ZrO_2 to room temperature can be controlled by several microstructural and chemical factors, such as grain size and alloy content.

The microstructure of these materials can be characterized by methods that depend on the level of resolution required for the identification of structures and morphologies. Usually, electron optical instruments are needed. For example, SEM has allowed the determination of the grain sizes and phases in ZrO_2 materials down to the dimensions of about 0.1 μm, whereas TEM has allowed the identification of phases and defects to the atomic level. Some typical TEM micrographs obtained for Mg-PSZ, ZTA (with intercrystalline and intracrystalline t-ZrO_2), and Y-TZP particles are depicted in Figs. 8–10. Major defects in these materials, such as dislocations and precipitates, have also been analyzed by conventional TEM [15], while analytical TEM has enabled the characterization of the chemical composition with a high spatial resolution of ~1 nm [19–21]. Finally, HRTEM has enabled the determination of the atomistic structure, wherein experimentally obtained images have been compared with results of image simulations using specific models [17, 18].

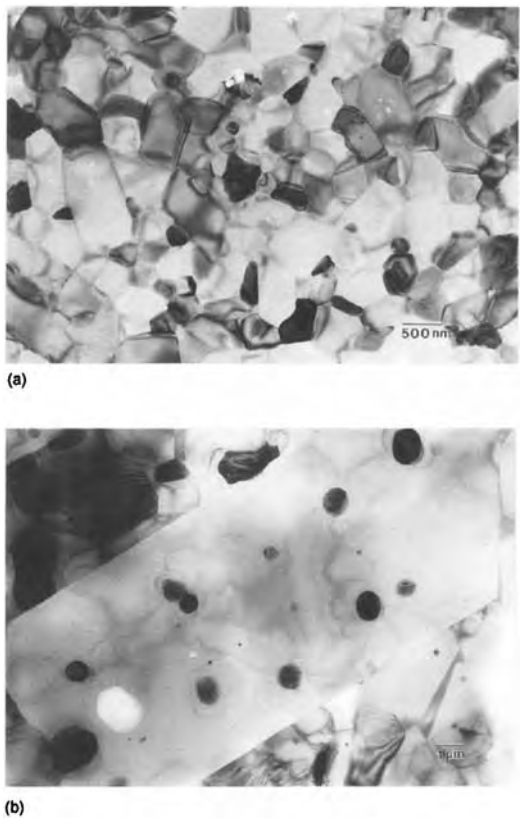

Figure 9. TEM micrograph of an Al_2O_3 ceramic containing dispersed ZrO_2 particles: (a) irregular-shaped, faceted ZrO_2 particles are intercrystalline; (b) Regular-shaped ZrO_2 particles are intracrystalline; the orientation of the particle is random inside the matrix.

6.5.2 Microscopy of the Phase Transformation in Zirconia Ceramics

Many theoretical and experimental studies have been performed with respect to the phase transformations. The nature of the c → t transformation is not yet understood. It is still being debated whether the phase transformation is martensitic or thermally activated.

The details of sections of the phase diagram could be analyzed by AEM. Enhanced precision is illustrated by studies of subsolidus equilibria using AEM to determine the compositions of the coexisting t- and c-ZrO_2 with high spatial resolution and with calibrated standards to determine absolute concentrations [67, 68]. The data (Fig. 11) obtained using crystals containing 6 or 8 wt.% Y_2O_3, grown by skull melting and annealed for long times between 1300°C and 1600°C, have an absolute uncertainty of ±0.2% and represent the best determination to date of subsolidus phase equilibria in a ceramic system in which both coexisting phases show appreciable solid solubility.

The t → m transformation is martensitic in nature [61, 62]. The crystallographic aspects of the transformation are well established. Experimental studies show that the *c*-axis of t-ZrO_2 is parallel to the *c*-axis of m-ZrO_2. The nonvanishing components of the symmetrical unconstrained transformation strain tensor, ϵ_{ij}^T, defined with respect to the tetragonal lattice, for pure ZrO_2 are [69, 70]

$$\epsilon_{11}^T = \frac{a^m}{a^t}\cos\beta - 1 = -0.00149 \quad (1)$$

$$\epsilon_{22}^T = \frac{b^m}{b^t} - 1 = 0.02442 \quad (2)$$

$$\epsilon_{33}^T = \frac{c^m}{c^t} - 1 = 0.02386 \quad (3)$$

$$\epsilon_{13}^T = \epsilon_{31}^T = \tfrac{1}{2}\tan\beta = 0.08188 \quad (4)$$

The shear components have the largest values, while the volume strain for room temperature ZrO_2 is about 4.7%.

Strain fields that occur in association with ZrO_2 particles are important to the transformation, as elaborated below. Consequently, the local strain field in the matrix surrounding a zirconia particle

has been examined by HVEM [70, 71]. Quantitative analysis of the strain field by TEM provided an important contribution to the understanding of the transformation mechanism. The strain analysis was performed at intracrystalline, regular-shaped, spherical, and slightly ellipsoidal t-ZrO_2 particles completely embedded in an Al_2O_3 matrix. Extended contrast fringes are visible around the embedded particles when the matrix is imaged under two-beam dynamical diffraction conditions. By imaging the Al_2O_3 surrounding the particles with different diffraction vectors (Fig. 12) and at different orientations, it was determined that an anisotropic strain field surrounds the t-ZrO_2 inclusions and that the particle is a center of dilatation. The strain anisotropy is attributed to the anisotropic thermal expansion mismatch. The specimens were fabricated in equilibrium at ~1500°C. Preliminary experiments correlating the strain field with the internal orientation of the tetragonal phase are consistent with the hypothesis that maximum misfit with respect to the alumina occurs along c_t [71]. Computer simulated images from contrast calculations based on the above model match well with the observed tetragonal strain field [72, 73]. Additionally, contrast calculations conducted using elastic dipoles yielded misfit parameters which agreed reasonably well with those expected from the misfit strain [70, 73].

Transformed particles are internally twinned, leading to very high displacement fields localized at the particle–matrix interface (Fig. 13). Quantitative analysis indicates that the particle is a center of compression due to volume increase and the fact that the strain field symmetry axis is perpendicular to the internal twin plane.

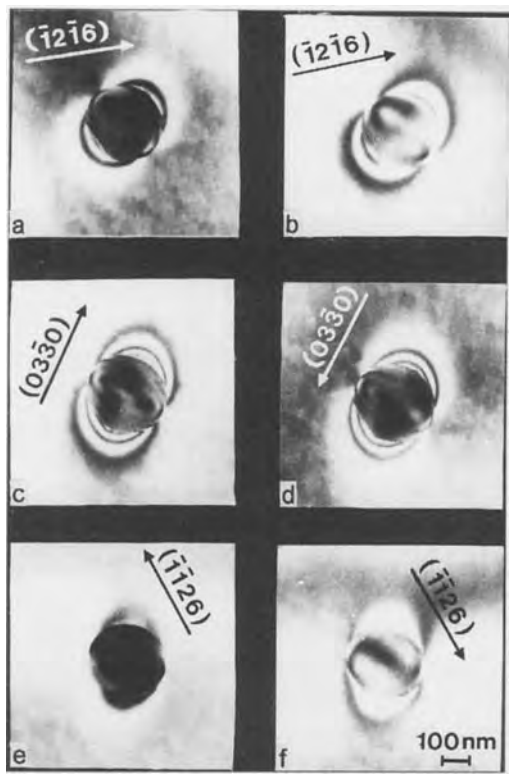

Figure 12. HVEM analysis of the anisotropic strain field in the alumina matrix surrounding an intragranular t-ZrO_2 particle which formed a center of dilatation at room temperature. The particle was imaged in bright dark-field mode under two-beam dynamical conditions with the plane normals (diffraction vectors $\boldsymbol{g}$) indicated.

The transformation and deformation twinning mechanism for a transforming ZrO_2 particle in an alumina, suggested by the observations, is summarized in Fig. 14.

The nucleation of m-ZrO_2 in t-ZrO_2 could also be observed directly by TEM in a fine-grained Y_2O_3-containing t-ZrO_3 polycrystal (Y-TZP). These materials possess a unique microstructure. The t-ZrO_2 grains are $\leqslant 1\,\mu m$ in diameter and constitute $\geqslant 80$ percent of the microstructure; in some samples, c-ZrO_2 grains are present. All grains are surrounded by a thin,

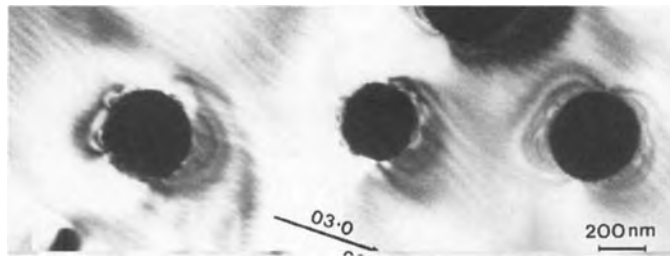

Figure 13. HVEM micrograph of strain fields due to internal monoclinic twins localized at the particle–matrix interface.

continuous amorphous phase [74]. No grain boundary dislocations can therefore be present. Nevertheless, such boundaries are sites of localized residual stresses arising from the thermal expansion anisotropy of t-ZrO_2 [75].

Y_2O_3 is a very effective stabilizing solute and increases the difficulty for martensite nucleation to occur. Among other manifestations of this difficulty, the transformation zone found from in situ crack propagation experiments in the HVEM is discontinuous [76]. The relative stability of t-ZrO_2 in this system facilitates study of the nucleation process. It was shown that t-ZrO_2 can often be made to transform during TEM observations, due to stresses induced by electron beam heating [77]. (ZrO_2 has one of the lowest thermal conductivities among inorganic crystalline solids.) Nucleation is found to occur preferentially at grain boundaries and grain corners, and it is possible to photograph various stages of the transformation. A typical example is shown in Fig. 15. A typical, essentially featureless, high-angle grain boundary is present at the beginning of the experiment. After a short interval of electron irradiation, strain contours develop at a specific site along the grain boundary (the arrowed feature in Fig. 15b). These strain contours oscillate during the experiment and sometimes die away. Occasionally, however, a small lathe of martensite (m-ZrO_2) forms out of these oscillatory contours and begins to grow across the grain (Fig. 15c, d). It is worth noting that the strains close to dislocations, small-angle boundaries, and stacking faults do not act as preferred embryos.

The nucleation in a t-ZrO_2 particle in a precipitation-toughened ceramic is rather complex. The t-ZrO_2 is present as coherent

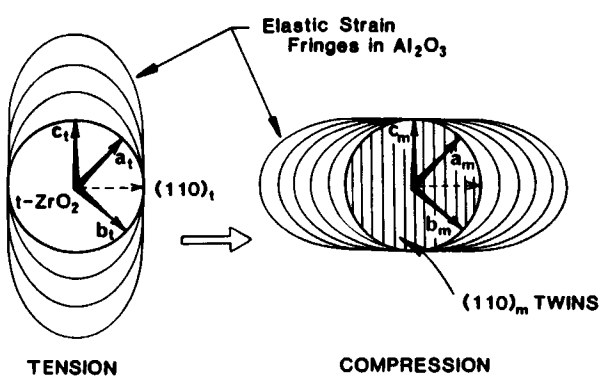

Figure 14. Suggested transformation and deformation twinning mechanism for a transforming ZrO_2 particle in an α-Al_2O_3 matrix.

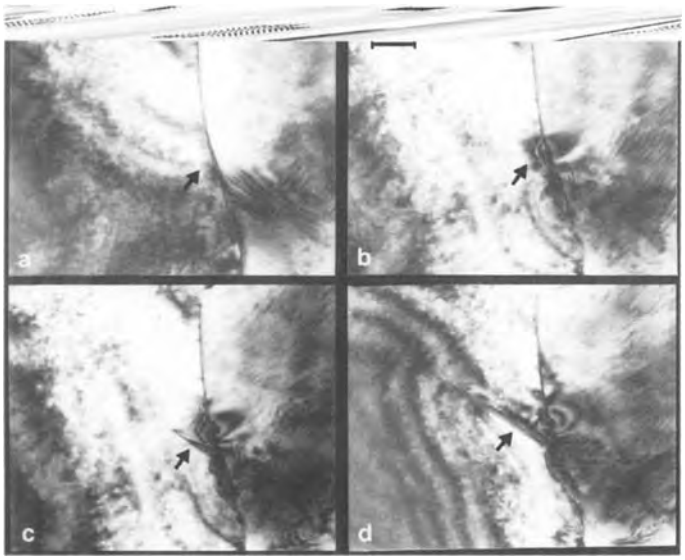

Figure 15. Nucleation in Y-TZP. (a) At the beginning of the experiment, no defects or localized strain contours are visible on the grain boundary; they develop during irradiation, as shown by the arrowed region in (b). On continued irradiation, a martensite lathe (an m-ZrO_2 plate) develops [the arrowed feature in (c)] and grows into the grain (d). Bright field electron micrographs.

precipitates in partially-stabilized ZrO_2 (PSZ), and it has been suggested [78] that the size dependence of M_S is related to the loss of coherency during extended high temperature ageing: the interface dislocations act as sites for heterogeneous nucleation. Indeed, Chen and Chiao [79, 80] concluded that a single screw dislocation with [001] Burgers vector should suffice to nucleate the transformation at room temperature. However, virtually all PSZ ceramics studied to date in the TEM have been essentially dislocation-free; dislocations could not be imaged even at precipitate–matrix interfaces. The role of dislocations as nuclei thus appears ambiguous.

It has been suggested that inhomogeneous internal stresses develop in PSZ ceramics owing to the specific shapes of t-ZrO_2 precipitates [81, 82] in an Mg-PSZ ceramic (Fig. 16): the sharp tips (in comparison to a perfect ellipse) at the end of the particle result in large stresses, which will result in large localized stresses responsible for the nucleation [82, 83].

6.5.3 In Situ Observation of the t → m Transformation in Zirconia

Direct observation of the stress-induced transformation in ZrO_2-containing ceramics was carried out by in situ experiments in a high voltage electron microscope. During deformation, cracks were introduced in a specially prepared TEM

Figure 16. Micrograph of a t-ZrO_2 precipitate in Mg-PSZ with an oblate ellipsoid, having the same principal axes.

Figure 17. Sequence of straining experiments. (a) TEM micrograph taken prior to straining. No m-ZrO_2 inclusions are present. (b) Crack starts to propagate. The crack is marked on all micrographs (c) to (f). Crack propagates on increased loading. t-ZrO_2 inclusion transformed to m symmetry.

specimen where two elongated holes with a transparent ridge between them were formed.

The spatial distribution of zirconia particles in ZTA, which transformed ahead of the crack as it progressed through the material, is summarized in Figs. 17 and 18. The general shape of the transformation zone could be outlined (Fig. 18), although its dimensions were dependent on the microstructure's homogeneity. Clusters of zirconia particles, which were susceptible to transformation even at larger distances from the crack, modified the shape of the zone. The expected transformation ahead of a crack tip within a well-defined transformation zone was thus experimentally verified. Furthermore, the zone height could be evaluated by investigation of the t → m transformation in the 100-μm long wake of the crack [76]. These TEM studies represent direct proof of the stress-induced transformation in t-ZrO_2. The TEM results were used to model the transformation toughening of zirconia-containing composites.

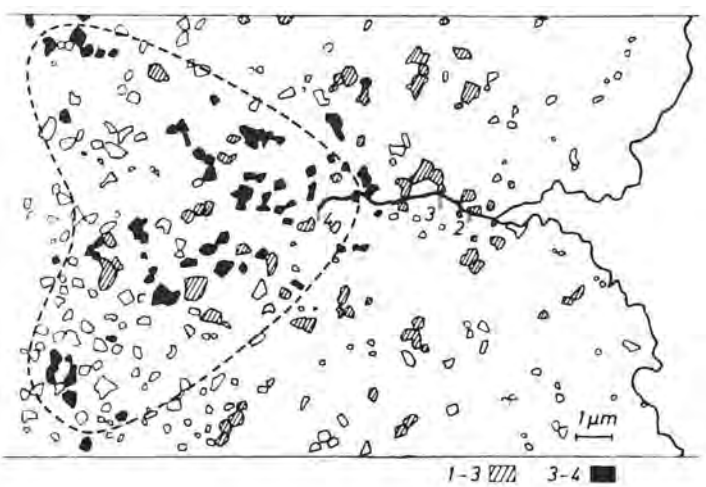

Figure 18. Schematic representation of (partial) evaluation of the straining experiment. The specimen was strained so that the crack propagated to different positions (1, 2, 3, 4). All ZrO_2 inclusions are marked on the schematic drawing. Hatched areas: ZrO_2 grains transformed during propagation of the crack from the hole to position 3. Dark areas: ZrO_2 grains transformed during crack propagation from position 3 to 4. The transformation zone is outlined.

6.5.4 Microscopical Studies of Microcrack Toughening

Buresch [84], Hoagland et al. [85], and Evans [86] postulated the phenomenon of microcrack toughening more than two decades ago and indeed, a range of materials do exhibit trends in toughness in relation to particle size, temperature, etc., qualitatively consistent with this mechanism. However, as yet there is only one fully validated example of this mechanism: Al_2O_3 toughened with monoclinic ZrO_2 [87, 88]. Microcracks occur within regions of local residual tension, caused by thermal expansion mismatch and/or by transformation [89, 90]. The microcracks locally relieve the residual tension and thus cause a dilatation governed by the volume displaced by the microcrack. Furthermore, the microcracks reduce the elastic modulus within the microcrack process zone. Direct evidence of the toughening mechanisms has so far been provided exclusively by detailed TEM studies. Microstructural and microcracking studies were performed on various ZTA materials wherein the proportion of ZrO_2 thermally transformed to the monoclinic phase was varied between 14 and 77%. TEM studies revealed that in these materials all ZrO_2 particles and Al_2O_3 grains are faceted, that the particles are intercrystalline, and that the grain boundaries and interface

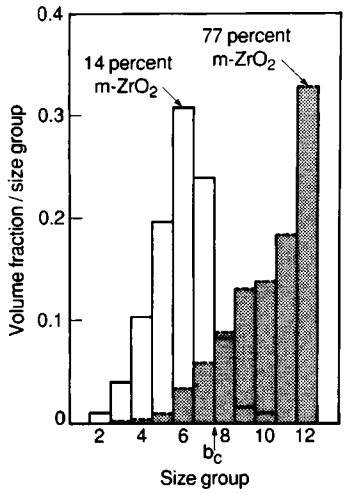

Figure 19. ZrO_2 particle size distribution for materials with 14% and 77% of the ZrO_2 in the monoclinic form. All particles larger than b_c are monoclinic.

boundaries were circumvented by an amorphous layer [91]. The size distributions of the grains and particles have been measured in foils up to 0.8 μm in thickness, with the radii separated into different nonlinear size groups using the volume fraction per size group as the ordinate (Fig. 19). ZrO_2 particles with radii $b_c > 0.3$ μm were found to be monoclinic and contained twin lamellae.

Small interfacial microcracks were usually observed between monoclinic ZrO_2 particles and the matrix grains in those regions where the twin planes of m-ZrO_2 terminated (Fig. 20). Occasional, thermally-induced microcracks were also

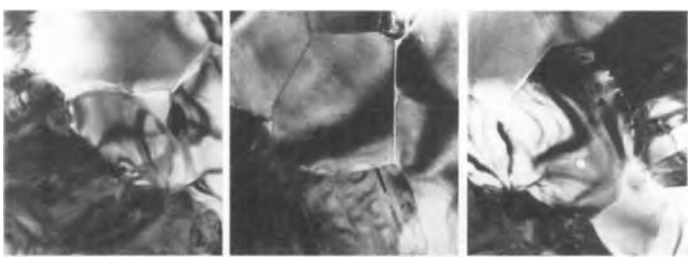

Figure 20. Three examples of microcracks observed at twin terminations in the Al_2O_3/ZrO_2 interface.

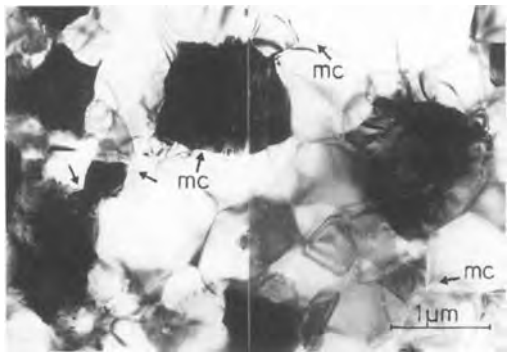

Figure 21. A TEM micrograph revealing typical microcracks (mc) in the process zone.

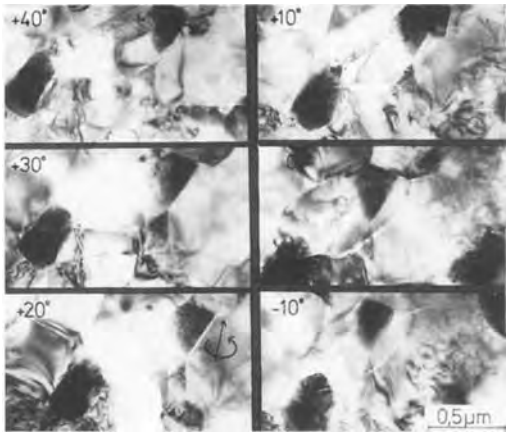

Figure 22. A tilting sequence indicating the technique used to trace microcracks.

detected remote from the macrocrack [87]. These were invariably associated with larger monoclinic particles: the largest having a diameter of ~7 μm. These cracks dominate the strength, resulting in strengths less than those apparent in the predominantly tetragonal material.

Matrix microcracking caused by the growth of macrocracks was studied by preparing thin foils at four distances, y, from a macrocrack (0.5, 1.5, 3, and 6 μm). Radial matrix microcracks were observed, as exemplified in Fig. 21. All such radial microcracks occurred along grain boundaries in the Al_2O_3 matrix. Usually, the interface between the Al_2O_3 and the ZrO_2 was debonded at the origin of the microcrack. The detectability of radial microcracks depended on their inclination with respect to the incoming electron beam. Trends in the visibility of microcracks upon tilting around one axis (Fig. 22) indicated that tilting in all directions would be needed to detect each microcrack present in the foil. However, tilting in the TEM is limited to ±45° in all directions, so that only 0.3 of the solid angle is covered. Therefore the fraction of detectable microcracks is limited to 0.3 ± 0.05.

Subject to this detectability limitation, large regions of TEM foils of known thickness have been investigated. One example is shown in Fig. 23, wherein all

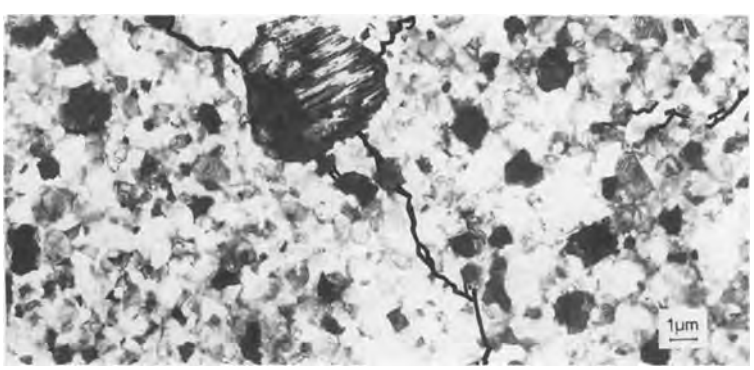

Figure 23. A TEM micrograph with all observable microcracks marked.

microcracks observable under different tilting conditions are marked. The associated projected length, l, of each microcrack has been measured and related to the radius, b, of the originating monoclinic ZrO_2 particle. Additionally, the residual opening of the microcracks, δ, has been determined at the ZrO_2 particle intersection where the opening is usually largest.

The microcrack density could be determined from the micrographs and evaluated using standard techniques of quantitative image analysis [6]. The results of the experiments could be used for an explanation of the toughness increase caused by microcracking [88].

6.5.5 Microscopy of Ferroelastic t′-Zirconia

ZrO_2 reveals, after specific thermal treatment, a ferroelastic behavior [92]. Ferroelastic behavior requires three conditions: (i) A diffusionless phase transition from a high symmetry modification must occur, which generates the ferroelastic material. (ii) The phase transformation must lower the point-group symmetry and must generate a lattice distortion. Usually, the ferroelastic material is composed of at least two different variants (domains) with different orientations. The domains are separated by domain walls. (iii) It must be possible to reorientate the domains by external stresses. The latter property is equivalent to 'switching' the domains by the migration of domain walls.

The t′-ZrO_2 exhibits ferroelastic behavior [93]. The atomistic structure of a domain boundary has been determined [94, 95]. Ferroelastic behavior was produced by compressing quasi single-crystals of t′-ZrO_2 parallel to a [100] direction and the mechanical properties of the material were measured for different deformation temperatures and strain rates [94, 95]. Microstructural evidence of domain reorientation (switching) was observed. Dark-field TEM imaging of the three [112] tetragonal twin variants in a [111] zone was performed before (Fig. 24) and after (Fig. 25) uniaxial deformation parallel to a $[001]_c$ axis. Two sets of twin variants grow at the expense of the third set upon application of uniaxial compression. The diminishing variant was the one with its c-axis parallel to the compression axis. Indentation experiments provided further evidence of domain reorientation near the crack surface. Again, two sets of twin variants grow at the expense of the third set.

6.5.6 Plastic Deformation of Zirconia Ceramics

At elevated temperatures, ZrO_2 ceramics can be deformed plastically [96–98]. The dislocations and dislocation arrangements in the deformed ceramics can be determined by TEM. Fully stabilized c-ZrO_2 usually contains small precipitates and in PSZ ceramics coherent and incoherent precipitates can be identified. TEM observations were performed on plastically deformed specimens. The TEM studies revealed the dislocation arrangements in the materials. Baufeld et al. [99] showed for deformed c-ZrO_2 single crystals containing 11 mol% Y_2O_3 that slip occurs predominantly on the primary slip system,

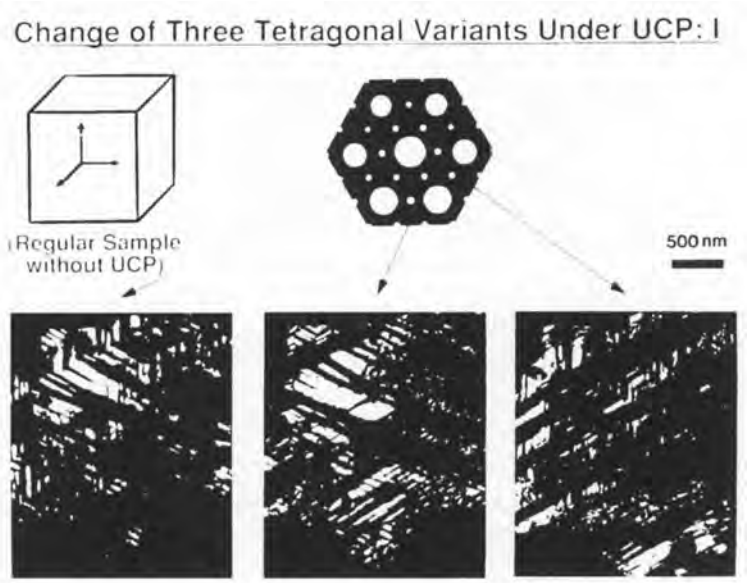

Figure 24. Transmission electron micrographs. Dark-field images of three {112} tetragonal twin variants in a {111} zone axis of an as-heat-treated t'-ZrO_2 material. All three variants are present in the material with about the same probability of 1/3.

and screw dislocations of zig-zag shape within narrow slip bands dominate the microstructure. The strain rate and temperature sensitivities of the flow stress at temperatures ~700°C can be interpreted by the interaction between dislocations and the small (tetragonal) precipitates [99]. Deformation at 1150°C, however, results in serrated flow and the deformation possesses a thermal character [99].

In Y-PSZ ceramics the mechanical properties are determined by the size,

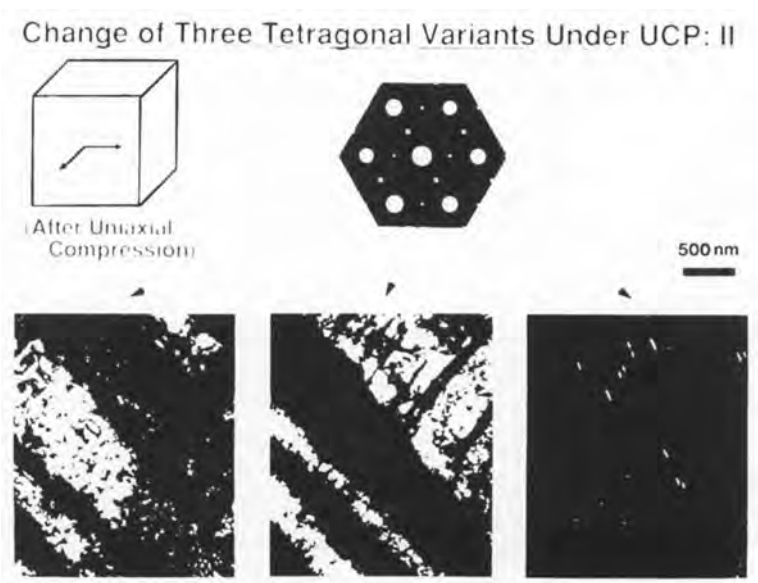

Figure 25. Dark-field TEM images of three {112} tetragonal twin variants in a {111} zone axis of t-'ZrO_2 after the application of uniaxial compression at 600°C. The variant with the *c*-axis parallel to {100} has vanished.

density, and morphology of the precipitates. The morphology of the precipitates can be analyzed by TEM [100]. Cheong et al. [98] pointed out that 'cutting' of the precipitates by a dislocation is anisotropic owing to the lower symmetry and smaller numbers of glide systems. A detailed explanation of the mechanical properties out of a particular microstructure is not yet possible.

6.6 Studies on Silicon Nitride (Si_3N_4)

Silicon nitride is a typical covalent compound with an ionicity of 0.3. It has a higher formation free energy than either alumina or silica, it also has no melting point under ordinary atmospheric pressure, a high vapor pressure, and a very low diffusion coefficient [101, 102]. These intrinsic properties of silicon nitride suggest that this material has poor sinterability to full density. Therefore special sintering technologies such as reaction sintering, hot pressing, gas pressure sintering, and hipping have been developed for this material [103–105]. It is also notable that silicon nitride is easily oxidized in an oxygen-containing atmosphere. As a result, the surface of silicon nitride is always covered by a thin silica layer.

The densification of Si_3N_4 is described as a liquid-phase sintering process. At higher temperatures, SiO_2, which is always present at the surface of the Si_3N_4 particles [106], reacts with the oxide additives to form an oxide melt and, with increasing temperature, an oxynitride melt by dissolving Si_3N_4. While the α-Si_3N_4 particles dissolve and supersaturate the liquid phase, β-Si_3N_4 is reprecipitated [107]. Depending on the composition of the sintering aids, the liquid phase can form an amorphous or a crystalline grain boundary phase during cooling, both of which degrade the mechanical properties of the Si_3N_4 at temperatures >1000°C, because of softening of the grain boundary regions.

For this material, it is essential that its microstructure be controlled by different microscopy techniques. Its microstructural development has to be followed by adequate techniques. These encompass all aspects of microstructural developments, such as nucleation and grain growth.

6.6.1 Nucleation and Growth

Lange [108] investigated hot pressed Si_3N_4 with 5 wt.% MgO and found that the aspect ratio of the grains, and therefore the fracture toughness, was determined by the ratio of α- and β-Si_3N_4 in the starting powder. The strong influence of the α/β ratio on pressureless and gas pressure sintered samples has also been reported by several other research groups [105, 109].

Figure 26 shows the relationship between the number of β-particles in the initial powder (β-nuclei density) and the particle density after complete densification and transformation into the β-phase for five commercial Si_3N_4 powders densified by pressureless sintering with the same amount of Y_2O_3/Al_2O_3 additives [110]. The β-nuclei density was calculated from the β-content determined by X-ray diffraction and the measured particle size distribution of the starting powder under the assumption of the same particle size

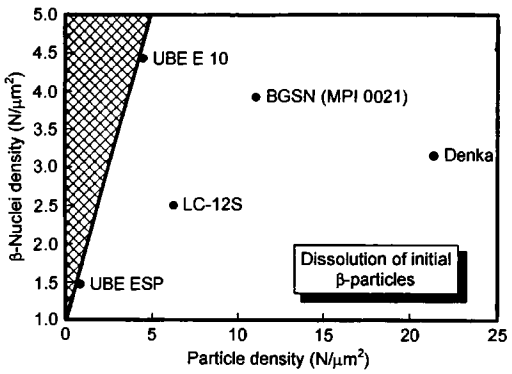

Figure 26. Particle density after pressureless sintering as a function of the calculated β-nuclei density for five Si_3N_4 powders.

distribution for α- and β-particles. The particle density was determined by quantitative microstructural analysis without taking into account the 3-dimensional random distribution of prismatic Si_3N_4 grains. Therefore the measured particle density is somewhat lower than the actual particle density [110].

The hatched area on the left side of the diagram represents powders with a particle density higher than the initial β-nuclei density. This case would imply an additional nucleation either homogeneously or heterogeneously on the α-particles. Powders located on the 1:1 line have the same β-nuclei and particle densities. In other words, all β-particles present in the starting powder grow by dissolution of α-Si_3N_4 particles and reprecipitation as β.

The diagram shows that all investigated powders had an equal or lower particle density in comparison to the initial β-nuclei density. While the UBE powders had approximately the same particle and β-nuclei densities, the particle densities of the BGSN (Bayer AG, Germany) and LC12-S (H.C. Starck, Germany) are smaller than the β-nuclei density, indicating that smaller β-nuclei dissolve during densification. The Denka powder is a β-rich Si_3N_4 powder (97.5%) and complete densification of this powder only occurs by dissolution of the smaller β-particles instead of dissolution of α-grains and reprecipitation on pre-existing β-grains.

A low amount of initial β-nuclei results in a larger interparticle distance of β-grains in the green compact; the grains were able to grow in the first stage of densification without steric hindrance. Therefore the powder with the lowest β-nuclei density (UBE ESP) developed the coarsest microstructure (lowest particle density) with large elongated grains. With increasing initial β-nuclei density, the steric hindrance of grain growth increases, resulting in an increasingly equiaxed microstructure (Denka). The specimens had to be plasma etched prior to the SEM investigation.

By stereology techniques the grain length and aspect ratio distributions were determined for various Si_3N_4 powders. The particles that contain grains with large aspect ratios were intrinsically toughened. Some grains with a large initial diameter can grow in the length direction with minor steric hindrance, more minor than the smaller ones, as pointed out earlier. Their maximum length could reach 100–200 μm. The amount of such large grains depends on the initial β-particle size distribution of the starting powder [110, 111].

6.6.2 The Grain Boundary Film Thickness

TEM investigations are essential for determining the geometrical and chemical

characteristics of the grain boundary film. Clarke [91] was the first to point out that practically all grains were covered with a continuous film consisting primarily of SiO_2 and the sintering additives. The composition of the film is regulated by the thermodynamical phase diagrams [108, 110]. Small angle grain boundaries as well as 'special' grain boundaries are not covered with the film owing to their low intrinsic energy [112]. The typical film thickness ranges from ~0.5 nm to 2.0 nm. There are several imaging techniques however; HREM investigations result in the best measurable film thicknesses [113].

Kleebe et al. [113], Tanaka et al. [114], and recently Pan et al. [115] studied the film thickness with high reliability in different materials. The reliability for the thickness measurements was in the range of ±0.1 nm. The investigations showed that the film thickness was constant for one type of material.

6.6.3 Dependence of the Film Thickness on the Intergranular-Phase Chemistry

The verification of an equilibrium-film thickness implies that each material, with its given secondary phase composition, shows a characteristic film thickness. Previous studies by the authors on Si_3N_4 sintered with different additives in fact revealed a strong dependence of the intergranular-film thickness on the chemistry. For example, the two different materials studied (MgO-doped Si_3N_4 and Yb_2O_3-doped Si_3N_4) were densified with different additives and therefore have a different grain-boundary film chemistry. A consequence of this great difference in the amorphous-film chemistry is the difference in film thickness observed by HREM for these materials [116]. Minor amounts of impurities are expected to have an effect on the intergranular film thickness as well.

The effect of a small amount of impurity on the film thickness was studied by preparing two Yb_2O_3-doped Si_3N_4 materials containing a small amount of CaO (0.25 vol.%) as the controlled impurity [117]. In one material the secondary phase was completely amorphous, while in the other a post-sintering heat treatment resulted in crystallized secondary phases at multiple-grain junctions. Two crystalline secondary phases were observed, $Yb_2Si_2O_7$ and $CaYb_9(SiO_4)_6ON$ (Ca- and N-stabilized apatite). Both materials, sintered and annealed, showed wider grain-boundary films than the undoped material. The annealed material showed a slightly wider film than the as-sintered material (1.4 nm vs. 1.3 nm), which is attributed to a higher calcium concentration at the grain boundaries, as crystallization at triple junctions reduced the overall glass volume in the sintered body, and hence calcium segregates to the boundary. Obviously, the formation of a Ca- and N-stabilized apatite did not completely compensate for the chemical shift in the specimen during annealing. Therefore a slightly higher calcium concentration is expected in the amorphous grain-boundary films in the annealed material than in those in the CaO-doped Si_3N_4 that did not undergo the heat treatment. A similar dependence of film thickness on impurity concentration was also observed in two materials undergoing oxidation [116]. During oxidation the intergranular

phase is essentially purified as additive and impurity cations diffuse to the surface oxide layer [118], resulting in a compositional change that is reflected by a decrease in the grain-boundary film thickness.

6.6.4 A Model System: Low Calcium-Doped Amorphous Silica (SiO_2) Films in Silicon Nitride

Small amounts of CaO additives result in a significant increase in the equilibrium thickness of the intergranular film. This thickness variation may reflect the modification of the atomic structure of the film by the change in chemical composition of the glass. A model system consisting of Si_3N_4 with a pure SiO_2 intergranular phase that was doped with low amounts of calcium was chosen to obtain a better understanding of the influence of impurities of grain-boundary films. Dedicated scanning transmission electron microscopy (STEM) is required for the determination of elemental compositions with a high degree of spatial and energy resolution. The 0.4-nm probe size of the VG HB501 STEM was necessary for elemental analysis of intergranular films of the order of 1 nm in thickness in these materials.

High purity α-Si_3N_4 powder (SN-E10, Ube Corp., Tokyo, Japan) can be sintered

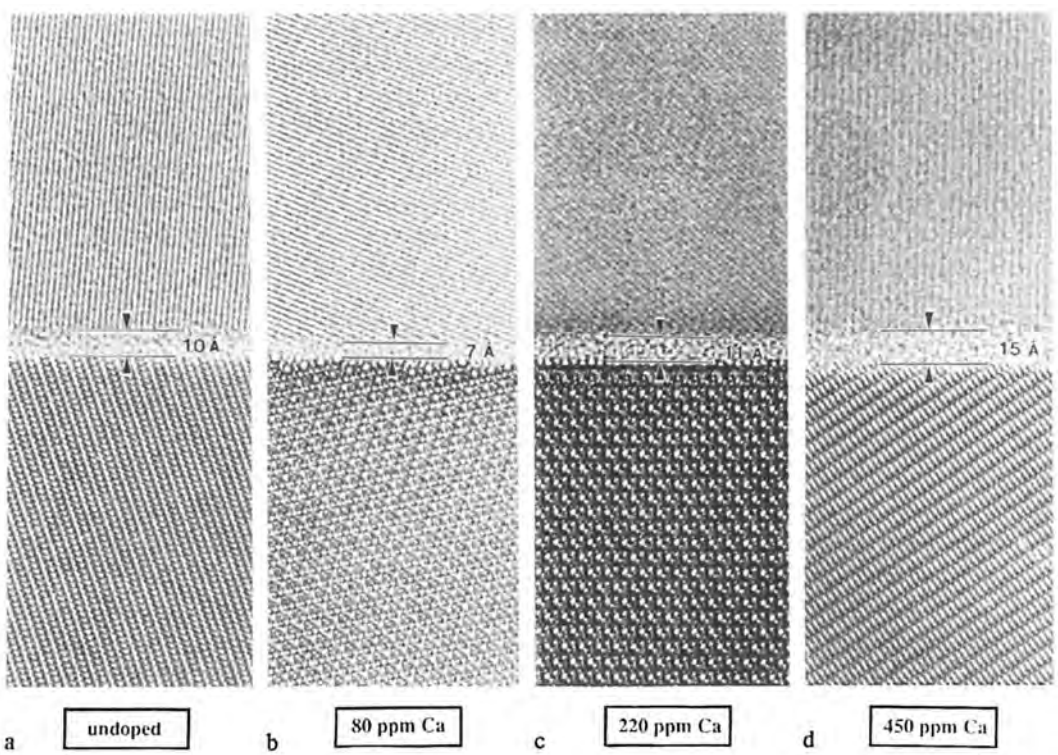

Figure 27. HREM images of grain boundaries in a high purity Si_3N_4 (a) containing an SiO_2 intergranular phase and (b) doped with 80 ppm Ca, (c) 220 ppm Ca, and (d) 450 ppm Ca. Equilibrium film thicknesses were 1 ± 0.1 nm, 0.7 ± 0.1 nm, 1.1 ± 0.1 nm, and 1.5 ± 0.1 nm.

without additives by hot isostatic pressing. The powder contains ~1.3 wt.% oxygen in the surface oxide (SiO_2), but less than 50 ppm of total cation impurities, resulting in a densified Si_3N_4 ceramic with an SiO_2 amorphous grain-boundary phase. Four materials were prepared in this manner, but with controlled amount of calcium (450 ppm, 220 ppm, 80 ppm, and undoped) added to the α-Si_3N_4 powder.

HREM images of these materials with low levels of CaO dopant are shown in Fig. 27. Grain-boundary films in these materials also revealed an equilibrium thickness. The grain-boundary film thickness in Si_3N_4 containing pure SiO_2 amorphous phase was also examined in another undoped Si_3N_4 (prepared from a different Si_3N_4 powder) and in an Si_3N_4-SiO_2 material with a higher SiO_2 content; the film thickness was found to be 1.0 ± 0.1 nm in all of the materials. The presence of calcium was detected in the grain-boundary films of all the materials doped with calcium [119]. Assuming that all the calcium and oxygen are confined in the intergranular phase, the composition of the film can be estimated from the intensity ratio of the calcium and oxygen peaks using electron energy loss spectroscopy. In the 80 ppm Ca-doped material, 1.5 ± 0.3 mol% of CaO was found in the amorphous SiO_2 phase. This value shows good agreement with the simple estimate for the glass containing 1.0 mol% CaO, assuming that all the calcium atoms are localized at the intergranular glass, which is 3.6 vol.% of the material. No impurities were detected in the film in the undoped material, indicating the CaO was present at less than the detection limit of 0.08 mol% CaO. Film thickness as a function of calcium content is plotted in Fig. 28.

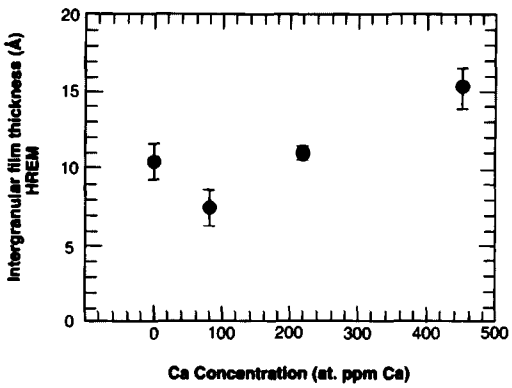

Figure 28. Plot of equilibrium film thickness in high purity Si_3N_4 as a function of the calcium content. The experimentally determined CaO concentration in the intergranular film was determined by high resolution, electron energy loss spectroscopy.

It is interesting to note that a decreasing film thickness in the very dilute region (to a minimum value of 0.7 nm at 80 ppm Ca) is followed by an increase in the thickness as a function of the calcium content.

6.6.5 Interpretation of the Experimental Results

The observed variation in thickness of the intergranular film with the concentration of CaO added can be understood in terms of the forces discussed by Clarke [112] and Clarke et al. [120], namely the attractive van der Waals force and the repulsive steric and electrical double layer forces. In the absence of CaO, we can assume that there is no electrical double layer at the grain boundaries, and so the equilibrium thickness is controlled by a balance between the van der Waals and the steric forces; the resulting grain boundary structure is shown schematically in Fig. 29b to consist of a pure silica glass intergranular

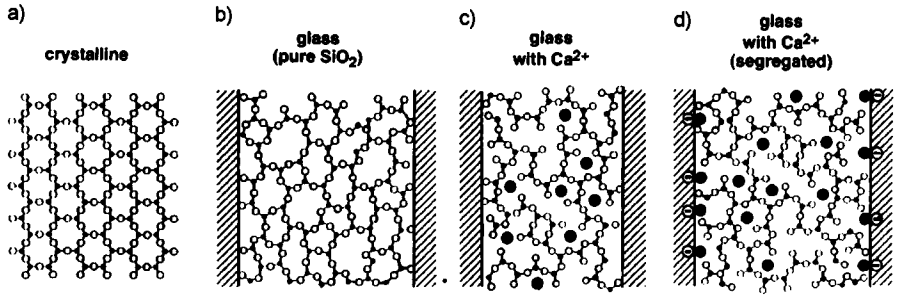

Figure 29. (a–d) Schematic illustration of the changes occurring in the glass structure of the intergranular phase with increasing cation impurity (Ca^{2+}: •) concentration, and its influence on the equilibrium film thickness. A combination of steric and electrical double-layer repulsive forces is proposed to balance the attractive van der Waals dispersion force.

film. The addition of calcia has a dual effect. It is expected to disrupt the network structure of the silica intergranular phase, decreasing the structural correlation length and hence the magnitude of the steric repulsive force, as shown in Fig. 29c. The addition of CaO also provides a charged species to the material which may result in the formation of an electrical double layer, as shown in Fig. 29d. Since CaO is known to be a potent silica network modifier, causing a decrease in the viscosity of several orders of magnitude for additions of less than 1 mol%, it might be expected that the strongest effect of minor calcia additions will be to decrease the steric force and cause a reduction in the film thickness. Further additions of CaO can be expected to increase the repulsive electrical double layer force, leading to further increases in the film thickness. A minimum in the thickness of the intergranular film at a low concentration of a network modifier, as observed at ~80 ppm Ca, is thus consistent with competition between the effects of disrupting the network structure and the development of a force due to an electrical double layer. While more detailed calculations need to be performed to quantify these competing effects, it is nevertheless interesting to note that if all the CaO in the 450 ppm Ca-doped material were adsorbed to the surface of the Si_3N_4 grains, ~40% of the Si_3N_4 surface would be covered by a 0.2-nm thick monolayer, assuming 1-μm diameter grains. If the charge of each Ca^{2+} ion was uncompensated, this would correspond to a rather high surface charge density.

6.6.6 Concluding Remarks

High resolution electron microscopy has an essential and important influence on the development of different Si_3N_4 ceramics. The properties and failure of the materials are not determined by the bulk material but by the composition and structure of defects such as grain boundary phases and triple junctions.

6.7 Studies on Composites

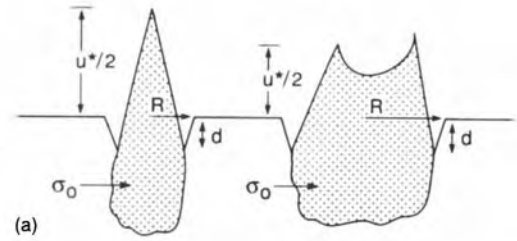
Composites are becoming a more and more important class of materials. They

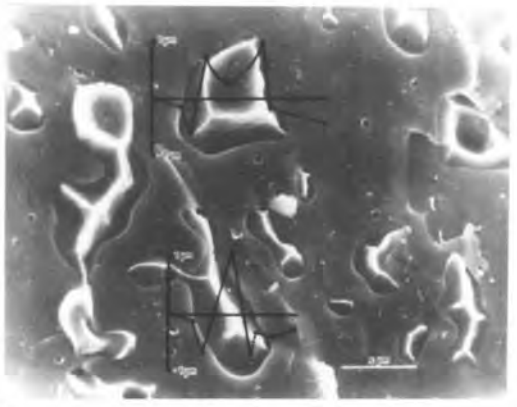
consist of (at least) two components. For a ceramic matrix composite the second (minor) component can be either a metal (metal alloy) or a ceramic.

6.7.1 Al/Al_2O_3 Composites (Lanxide Material)

Of great interest are composites reinforced by metals such as aluminum, copper, or intermetallic alloys. The microstructure depends on the processing route. Those materials processed after the lanxide techniques were investigated by SEM and TEM, and the following salient features were observed. Conventional TEM analyses provide information on two important features: precipitates and dislocations [24, 26]. The size distribution of the precipitates can be determined by TEM; sometimes the precipitates possess a bimodal distribution. The larger precipitates (median diameter ~100 nm) contribute to void nucleation upon ductile fracture of the metallic inclusions. The smaller precipitates (median diameter ~20 nm) are potent dislocation pinning sites. AEM has been used to provide information concerning the character of the precipitates. The larger precipitates contain copper, silicon, and iron in addition to aluminum with trace amounts of chromium. The smaller precipitates consist predominantly of copper and aluminum. In this case no segregation of any impurity is observed at the interface.

SEM investigations of the fracture surface have provided quantitative information about the plastic stretch and the extent of debonding (Fig. 30a). Also various modes of ductile failure have been





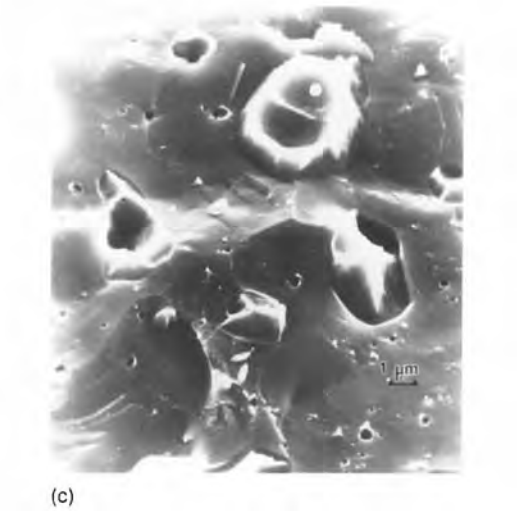


Figure 30. (a) A schematic diagram of the ligament cross section after failure. (b) A scanning electron micrograph of a fracture surface with the topology of the ductile ligaments (as evaluated by stereo microscopy) superposed; this is a typical failure of a ligament having a circular cross section. (c) SEM of a large precipitate at the base of a hole.

identified, as also observed on lead/glass. Specifically, the failure of axisymmetric reinforcement zones often involves the nucleation of a single hole of the center of the neck which rapidly expands to failure (Fig. 30b). In some instances, particles are apparent at the base of the holes (Fig. 30c). These particles are ~100 nm in diameter and probably coincide with the larger Al/Cu/Fe/Si precipitates identified by TEM.

Stereo measurements used to evaluate the plastic stretch to failure, u^*, and the interface debond length, d, revealed that the normalized plastic stretch, u^*/R, varied appreciably between ligaments, ranging from $u^*/R \sim 0.8$ to 2.8. However, there was no systematic dependence on either the ligament dimension R or the aspect ratio. All ligaments have thus been used to provide a cumulative distribution, such that the mean stretch is $\overline{u^*/R} = 1.6$. The debond length also has appreciable variability and ranges between $d/R \sim 0.1$ and ~0.5, but there is no discernible dependence on the aspect ratio. The median value is 0.2. The quantitative experimental data can be used to explain the properties of the material as a result of the microstructure [24].

6.7.2 Al/Al_2O_3 Composites (Processed by Infiltration)

The samples were prepared by slip casting alumina powders [42]. Slurries with 45 vol.% solid were cast into plates, dried, and sintered at 1450°C and 1650°C for 1 h for two different samples. This process resulted in porous preforms with 25 vol.% open porosity. After sintering, the porous plates were infiltrated with pure aluminum (99.999%) at 1050°C with an argon pressure of 15 MPa, maintained for 30 min. For further details of the alumina preparation and melt-infiltration process, see Prielipp et al. [121].

The effects of impurities and dopants on the sintering and microstructure of polycrystalline alumina have been an important issue for some time. Studies have focused on the possible roles of dopants (or impurities) in promoting sintering and limiting grain growth, with specific attention to magnesium [53, 54]. Presumably, it is the segregation of dopants to grain boundaries and surfaces (pores) that influences sintering and grain growth, but the exact mechanism is still not clear. The experimental difficulties in the detection of some segregates further complicates the problem of identifying the roles different dopants play in sintering and grain growth.

Recently, silicon and calcium were confirmed as promoting abnormal grain growth in α-Al_2O_3 [54]. Calcium is a common impurity in alumina, and calcium segregation to general grain boundaries has been experimentally confirmed by both energy-dispersive X-ray spectroscopy (EDS) in a dedicated STEM and Auger analysis. However, recent TEM/EDS studies have shown no evidence of calcium segregation to basal twin boundaries.

Impurity segregation to the free surfaces of alumina is also an important issue, possibly affecting pore mobility, subsequent bonding of surface films to sapphire substrates, or influencing contact angles during liquid-phase wetting. Calcium has been found to segregate to prismatic free surfaces [122, 123]. However, calcium is thought to segregate to

free surfaces anisotropically with no calcium segregation to the basal surface. In the present work, HRTEM and AEM have been used to study (0001) α-Al_2O_3/Al interfaces in melt-infiltrated polycrystalline alumina composites. Liquid aluminum was infiltrated into a porous alumina preform, thus embedding the pores' surfaces and allowing their investigation by TEM. It will be shown that calcium does segregate to the basal surface and to basal twin boundaries, and that it forms a surface phase on external surfaces.

Figure 31 shows a bright-field TEM micrograph of the general specimen morphology. Since all of the neighboring aluminum grains have a similar contrast, Kikuchi electron diffraction was used to check for local texture. All of the aluminum grains located around the 150-μm diameter specimen perforation were found to be in the same orientation. Therefore it can be concluded that after infiltration the aluminum solidifies at a limited number of nucleating sites, resulting in large aluminum grains which extend throughout the open alumina porosity. The alumina shows an elongated morphology with the basal plane parallel to the long axis of the grains. Thus many of the α-Al_2O_3/Al interfaces are parallel to the basal surface and these were studied in closer detail.

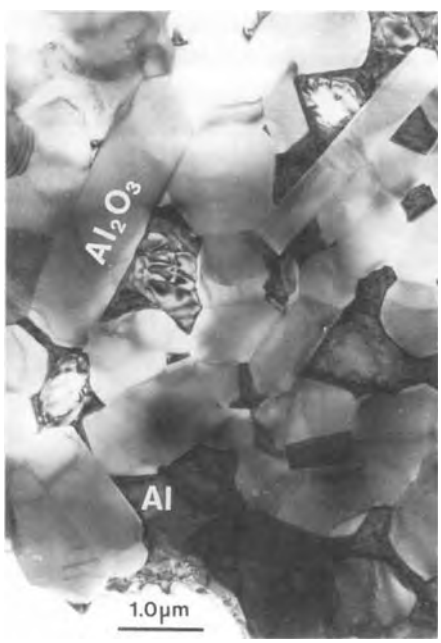

Figure 31. Bright-field micrograph of the microstructure of the melt-infiltrated alumina preform. The aluminum is in the [110] zone axis and appears darker than the randomly aligned alumina matrix grains. Elongated alumina grains are evident.

No wetting defects (open pores) were found between the aluminum and alumina, indicating good wetting of the ceramic by the liquid metal. While this could be explained by the argon pressure used to infiltrate the aluminum into the ceramic matrix, aluminum does not wet the clean (0001) α-Al_2O_3 surface (contact angle greater than 90°), so the lack of wetting defects at the interfaces is surprising.

Figure 32 shows an HRTEM micrograph of a typical basal α-Al_2O_3/Al interface. The alumina grain is in the $[1\bar{2}10]$ zone axis and the interface is parallel to the basal plane, with no steps or facets. The aluminum grain in Fig. 32 is near to a [110] zone axis, but local bending and the presence of dislocations allows only the (002) planes to be visible. The (002) planes are also slightly inclined to the interface plane, and by following them to their termination the transition from bulk aluminum to the interface can be determined. The transition from defect-free α-Al_2O_3 to the interface is more difficult to discern. This can be determined by careful inspection of the (0006), $(\bar{1}012)$, and $(10\bar{1}4)$ lattice fringes and the variation in image contrast from the bulk

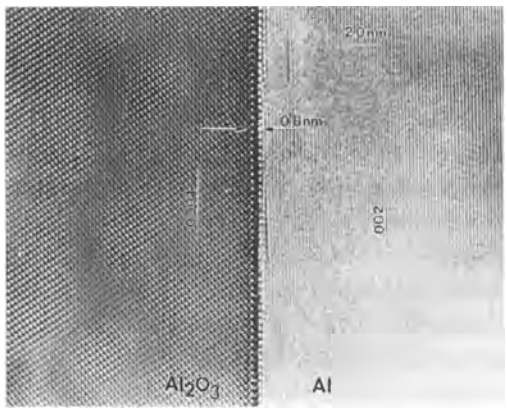

Figure 32. HRTEM image of an (0001) α-Al_2O_3/Al interface. The alumina grain is in the [1210] zone axis, and the aluminum is near to [110]. The width of the interface region is marked by arrows.

regions. Directly at the interface the pattern of the alumina lattice varies significantly from the bulk. This indicates that the symmetry of the relatively wide interface region is different from that of bulk alumina and certainly different from that of aluminum.

The structural width of the interfacial region was determined in two ways. First, visual inspection and measurement of the interface width were conducted from high magnification prints. Secondly, intensity profiles perpendicular to the interface were made from the recorded images. Measurements were taken from more than seven different basal α-Al_2O_3/Al interfaces, and the structural width was found to be 0.8 ± 0.2 nm, where the main source of error is the definition of the last (0006) plane of the alumina, immediately at the interface. The width of (0001) α-Al_2O_3/Al interfaces was measured for both types of sample and no difference was found in the width or periodicity of the interface region.

PEELS and EDS analyses were conducted on the same interfaces as investigated by HREM. This was accomplished by recording images of the region containing the interface at different magnifications (immediately after recording HREM images), which then served as a guide to locate the same interface in the STEM. Kikuchi patterns were used in the STEM to orient the alumina grain in the same zone axis as used for HREM, thus ensuring that the interface was parallel to the STEM electron beam. Figure 33 shows EDS spectra of the interface shown in

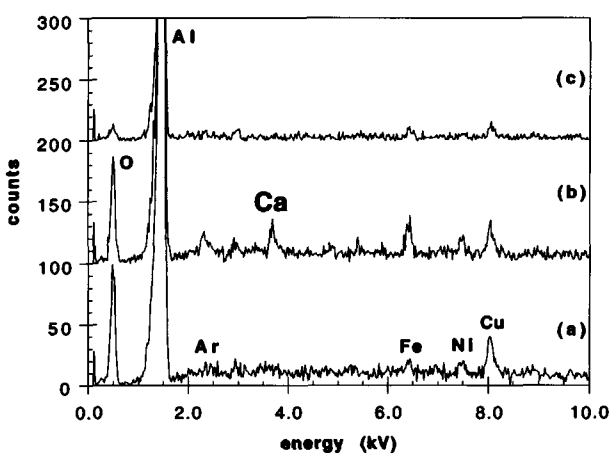

Figure 33. EDS spectra of the interface region shown in Fig. 32, (a) in the alumina, (b) directly at the interface, and (c) in the aluminum. The presence of a small oxygen peak in the aluminum spectrum is due to surface oxide. Argon, iron, nickel, and copper are confirmed artifacts from specimen thinning. Spectra (b) and (c) are shifted vertically for display purposes.

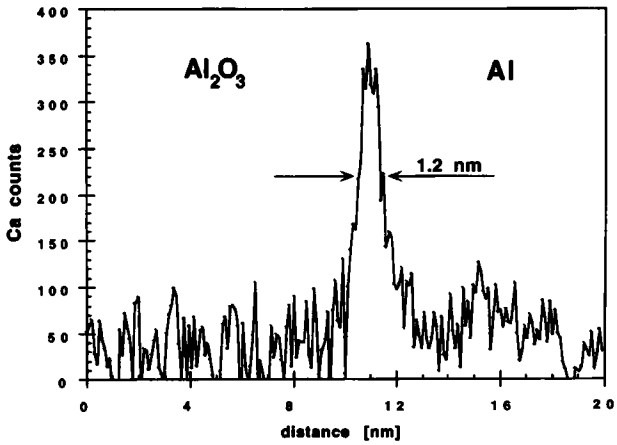

Figure 34. Calcium profile from a PEELS line scan perpendicular to an (0001) α-Al_2O_3/Al interface.

Fig. 32. The spectra were recorded by rastering the beam over a $10 \times 12\,nm^2$ area, (a) in the alumina, (b) directly at the interface, and (c) in the aluminum. The presence of calcium is clearly visible, with a peak significantly above the background level. Quantification of five interfaces by EDS resulted in an average calcium interface excess of $\Gamma = (2.0 \pm 1.0)\,Ca/nm^2$. PEELS line scans perpendicular to the interface were also made for five interfaces, and an example is shown in Fig. 34. Quantification of the calcium excess from PEELS line scans resulted in $\Gamma = (2.5 \pm 0.5)\,Ca/nm^2$. EDS and PEELS were conducted for (0001) α-Al_2O_3/Al interfaces for both types of sample; calcium segregation was found for both types of sample and no significant difference in the excess was detected.

The full-width-half-maximum (FWHM) of the calcium profile from the PEELS line scan provides an upper limit of calcium distribution perpendicular to the interface. This was measured to be $\sim 1.2\,nm$. This value is only an upper limit because it is a convolution of the real calcium distribution with the electron beam intensity profile and therefore agrees with the HREM results.

Figure 35 is a noise-filtered high magnification HREM micrograph of an α-Al_2O_3 basal twin boundary. The twin has been identified as a deformation twin, due to the presence of Moiré-type fringes located

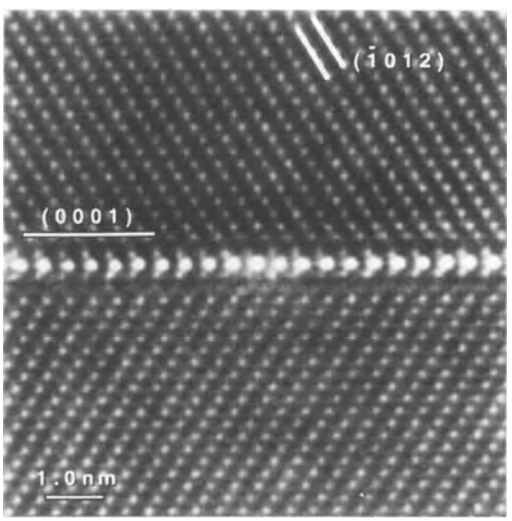

Figure 35. High magnification HRTEM image of a basal twin boundary with a calcium excess of $\Gamma = 1.0 \pm 0.5\,Ca/nm^2$. The zone axis of the upper side of the boundary is [1210]. The objective lens defocus and simulated specimen thickness, as determined from quantitative comparison to image simulations, are $-55\,nm$ and $8.6\,nm$, respectively. The image has not been filtered or processed in any manner.

along its length in the thicker regions of the specimen, which are not found in basal growth twins in α-Al_2O_3 [124]. While the twin boundary shows a pattern and contrast that nominally fit the cation-terminated basal twin structure [124], quantitative HREM image analysis to determine possible atom positions is currently in process. EDS of the twin boundary revealed a calcium excess of $\Gamma = 1.0 \pm 0.5\,Ca/nm^2$.

It should be noted that a detailed search for the presence of glass was conducted using both conventional and HRTEM. No glass phase was found at the interface regions, or at the general alumina grain boundaries or triple junctions. Furthermore, no silica segregation was detected at the interfaces or general grain boundaries, even though the starting powders contained a silica content comparable to that of the calcium. The reasons for this are still not clear.

From the combined results it can be concluded that calcium does segregate to basal surfaces in α-Al_2O_3. Assuming that the calcium cations substitute for the aluminum cations at the (0001) α-Al_2O_3/Al interfaces [125], the measured calcium excess correlates to a coverage (monolayer) of $\theta = 0.25$.

However, from the combined HREM and PEELS line scans, it is evident that the calcium is distributed over 4 ± 1 cation planes, which correspond to a Ca/Al concentration of approximately 8 at.% or a nominal composition correlating to the bulk phase $CaO.6\alpha$-Al_2O_3 [126]. While the detailed atomic structure of the surface phase is still not known, it may correlate to the Ca-driven (2×2) basal surface reconstruction [127]. The presence of the surface phase would be expected to alter the contact angle and wetting of aluminum on alumina and may explain the lack of wetting defects in the composite. Further structural and chemical analysis of the surface phase is currently in progress.

6.7.3 Fiber/Whisker Reinforcement

Practical ceramic matrix composites reinforced with continuous fibers exhibit important failure/damage behaviors in mode I, mode II, and mixed mode I/II as well as in compression. The failure sequence depends on whether the reinforcement is uniaxial or multiaxial and whether woven or laminated patterns are used. However, the underlying failure processes are illustrated by the behavior of uniaxially reinforced systems [24]. The composite's properties are known to be dominated by the interface, and bounds must be placed on the interface debonding and sliding resistance in order to have a composite with attractive mechanical properties. The strong dependence of ceramic matrix composite properties on the mechanical properties of the interface generally demands consideration of fiber coatings and/or reaction product layers. Residual stresses caused by thermal expansion differences are also very important.

The microscopy of interfaces and interphases plays a dominant role in the study of the ceramic composite. TEM is able to determine structure, composition, and chemical reactions at these interfaces. Possible chemical reactions may lead to a change in the interphase properties and therefore also of the composites. The possible chemical reaction may limit the applicability of fiber-reinforced ceramics.

Acknowledgement

The author is grateful to his colleagues Dr. F. Ernst, Dr. H.-J. Kleibe)Bayreuth), and Dr. J. Mayer for many stimulating discussions. The work was financially supported through the Volkswagen foundation under contracts I/70082 and I/70844 (Dr. H. Steinhardt, contract monitor).

Handbook of Microscopy
S. Amelinckx, D. van Dyck,J. van Landuyt , G. van Tendeloo

7 Microscopy of Gemmological Materials

"A material, to be considered a gem, must have beauty, durability and scarcity". This is the definition as listed in the reference textbooks [1, 2]. Gemmology is the study of these materials.

7.1 Optical Microscopy

7.1.1 Introduction

Today the optical microscope is one of the most important instruments of the gemmologist, independent of whether his interest is purely academic or of a more commercial nature. Upon its introduction in the field of gemstones at the beginning of this century, the gemmological microscope hardly differed from the optical microscopes that were commonly used in biology or petrography [3]. It should be borne in mind that these are somewhat special versions of the optical microscope, described in detail in Chap. 1 of Vol. 1 of this Handbook, to which we refer for the physical background on instrument and image interpretation.

Since most of the pioneers of gemmology had a geological or mineralogical background, the petrographical microscope became the standard instrument for the study of gems. The introduction of the microscope in gemmology, and in fact the founding of modern gemmology, came about with the successful introduction, on the gemstone market around the turn of the century, of important quantities of artificial ('synthetic') high quality rubies. These had been produced by means of the patented (1905) 'Verneuil' flame-fusion technique. To avoid the trade of natural, especially Burmese, rubies being disrupted or even coming to a complete stop, accurate and reliable identification techniques became necessary. Soon it was realized that an accurate identification technique consisted of observing the internal features of the gemstone. If synthetic, the latter would reveal bubbles and curved growth lines that could not be mistaken for inclusions in natural stones. This required, of course, the use of a magnifying instrument, the logical choice being a microscope.

In the years that followed, the gemmological microscope gradually evolved into a more specialized instrument. This evolution took two different routes. The rules for grading diamonds—the famous four Cs—are completely different from those determining the value of other precious stones. Two types of microscope were developed accordingly.

7.1.2 Properties and Use of the Gemmological Microscope

In the study of precious stones other than diamonds[1], the microscope is mostly used to identify the gem rather than for grading purposes, as is usually the case with diamonds. The most important questions to be solved by the gemmologist are:

1. What material is it?
2. Is the material natural?
3. Are the properties of this material natural or have they been artificially induced or enhanced?

Commercially, there is also a fourth question worth posing:

4. What is the geographical origin of the gemstone? As, for example, Colombian emeralds fetch better prices than the same quality Brazilian material.

Not all of these questions can be answered by microscopical observations. Other gemmological instruments are needed, such as the polariscope, the refractometer, the dichroscope, and the spectroscope. Not only the optical properties need proper recording: other physical parameters such as the specific gravity and thermal properties can also have a diagnostic value. The main difference between these two groups of properties is, however, the fact that most optical properties can be observed by means of the microscope with proper accessories. The identification of synthetic gems and the detection of treatments is mostly based on microscopical observation.

[1] Commercially speaking, these gems are called 'colorstones'.

The study of inclusions can be particularly rewarding, as pointed out by Gübelin [4]. The identification of the 'paragenesis', i.e., the inclusions that crystallized synchronously with the host, in a particular geological or chemical environment, allows the gemmologist not only to conclude whether the gem is natural or synthetic, but in certain limited cases it is also possible to deduce from which geographical origin or geological deposit it was extracted [5]. Certain treatments, such as heat treatment, also have a marked effect on the gem and its inclusion content, as can be revealed by microscopical observation [6].

7.1.2.1 Stereoscopic Capability

As is the case with 'diamond microscopes', most 'gemmological microscopes' are really stereoscopic microscopes. Stereoscopic microscopes differ from standard or biological microscopes and from polarizing or petrographic microscopes having split optical paths. The positioning of the separate optical paths at angles between 12 and 16° produces a pair of images (Fig. 1) similar to those produced by human eyes when viewing any object at a ± 25 cm distance, which enables 3D vision.

Obviously this type of microscope is ideal for viewing nonflat objects; it was mainly developed for the electronics industry where the manipulation of small components is a key task. Since many electronic components and gems are more or less similar in size, the use of the same optics for both kinds of material is only natural. To benefit from the 3D capability of this type of optics, oblique or reflective illumination in the case of

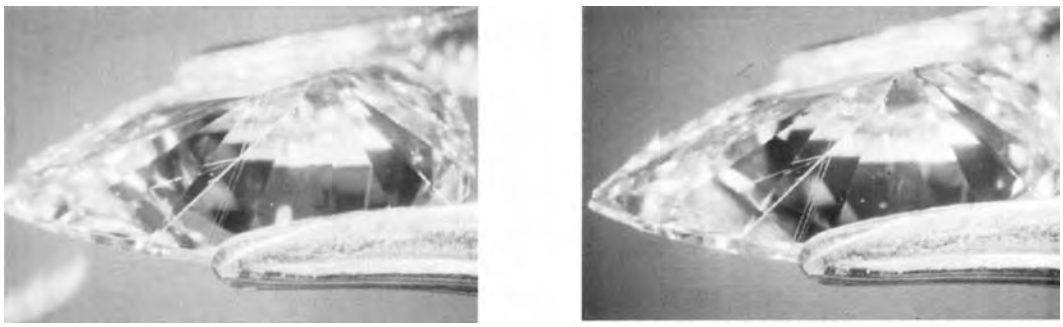

Figure 1. Photomicrographs of a pear-shaped diamond as seen through a stereoscopic microscope. The left and right images [(a) and (b), respectively], showing a pear-shaped diamond with some structural features (surface growth lines) and an associated needle-like inclusion, are clearly different. Together they produce a stereoscopic effect similar to normal binocular viewing. The ability to see in 3D is very important to the gemmologist in order to determine whether the observed features are on the surface (external) or underneath the surface (internal). An important part of the quality evaluation of diamonds is based on this difference.

transparent, translucent, and opaque materials, and dark field illumination for transparent materials, are compulsory. Independent of the quality of the optics, the maximum magnification of stereoscopic microscopes is mostly limited to approximately 100×. Nevertheless, accessory lenses exist that make it possible to increase or decrease the total magnification, e.g. a 0.5× lens can be very useful when examining large gems macroscopically[2].

Two major types of stereoscopic microscopes can be distinguished [7]:

1. The Galilei-type stereoscopic microscope consists of two separate oculars which are served by only one shared objective (Fig. 2a).
2. The Greenough-type stereoscopic microscope consists of two separate oculars which are served by two fully separate objectives (Fig. 2b).

Both types can be equipped with sets of objectives with fixed magnifications on a revolver, or with a zoom lens allowing any magnification within a given range. The advantages of the fixed objectives are accuracy of magnification and better resolution. The main advantage of a zoom is obviously the flexibility to choose the optimal magnification most suitable for the job.

7.1.2.2 Depth of Field

Very important to the gemmologist is the depth of field of the microscope. Proper understanding and careful application of this property can be of considerable help in identifying small features on or in the stone. This is especially important in diamond grading where the presence or absence of inclusions is an important quality characteristic. The depth of view or focus depends on the objective magnification and on the aperture size. It decreases at higher magnifications. For the Bausch & Lomb SZ 7, a stereoscopic microscope[3] which is very popular in

[2] Increasing the magnification is of course limited by the resolving power of the objectives.

[3] Today the Bausch & Lomb SZ 7 is manufactured by Leica.

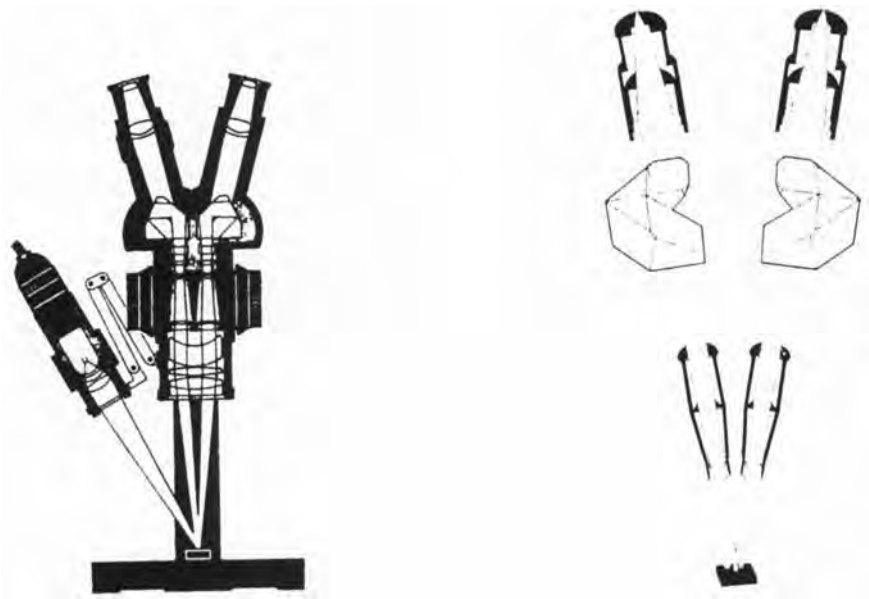

Figure 2. Comparison of two important types of stereoscopic microscope (modified from Van Maaren [7]). (a) Diagram showing the light path in a Galilei-type stereoscopic microscope. Characteristic is the single objective lens shared by the two oculars. (b) Diagram showing the light path in a Greenough-type stereoscopic microscope. Each ocular is served by a different objective lens.

diamond grading, the depth of field ranges from 1 mm at its lowest magnification (1×) to 0.05 mm at the highest magnification (7×).

This means that for this particular type of microscope the position of a small inclusion at an objective magnification of 1× can only be assessed within a 1 mm thick depth range. At the highest objective magnification (7× for this particular microscope), the inclusion can be traced within a layer of only 0.05 mm thickness.

7.1.2.3 Illumination

In diamond grading only two distinct types of (standardized) illumination, i.e. dark field and reflective illumination, are customary. A gemmological microscope must have more illumination possibilities in order to be able to observe all the characteristic features that allow identification of the gem under scrutiny. Transmitted illumination is considered as standard in gem identification. Simple transmitted illumination is perfectly suited for flat (plane-parallel) objects, but is completely inadequate when used with highly refractive, polished gems. This is mainly because total internal reflection on the facets prevents light reaching the eye of the observer, and as a consequence the gem shows dark against a blinding background, thus obscuring the gem for inspection. To arrive at an ideal transmitted illumination, the gem must therefore be placed in an immersion cell in a liquid having approximately the same refractive index as that of the gem (Table 1). This transmitted–immersion lighting is especially effective at bringing about subtle

Table 1. Abbreviated list of immersion liquids and their refractive indices, as used in the transmitted–immersion microscopy of gems (in order of increasing RI)[a]

Liquid	RI	Liquid	RI	Liquid	RI
Water	1.33	Cedar oil	1.51	Cassia oil	1.60
Alcohol	1.36	Monochlorobenzene	1.53	Monoiodobenzene	1.62
Amyl acetate	1.37	Canada balsam	1.53	Monochloronaphthalene	1.63
Petroleum	1.45	Clove oil	1.54	Monobromonaphthalene	1.66
Carbon tetrachloride	1.46	Nitrobenzene	1.55	Monoiodonaphthalene	1.70
Glycerin	1.47	Benzylbenzoate	1.56	Methylene iodide	1.74
Castor oil	1.48	Orthotoluidine	1.57	Methylene iodide + S	1.78
Toluene	1.49	Aniline	1.58	Methylene iodide + S + C_2I_4	1.81
Benzene	1.50	Bromoform	1.59	West's solution	2.05

[a] Adapted after Webster [1].

color zoning and other structural features, such as the characteristic curved growth lines in Verneuil (flame-fusion)-type synthetic rubies.

A side effect of the transmitted–immersion illumination technique is that the stereoscopic viewing is strongly compromised. Obtaining an optimal illumination level simultaneously in both oculars is almost impossible. This effect is even more evident when using polarizing filters. It can therefore be argued that when using only transmitted–immersion illumination, a monotubular microscope would probably be more effective.

Table 1 shows that immersion liquids, which are neither too costly nor too toxic, can be obtained up to a refractive index (RI) of approximately 2. For higher refractive indices, special liquids have to be prepared, which are mostly toxic and rather unstable. To obtain a liquid with an RI of approximately 2.415 (the RI of diamond), a glasslike substance (a complex borate containing lead and bismuth) would have to be used and melted. These practical constraints limit the use of immersion microscopy to liquids having an RI of ±1.75. In transmitted illumination, the observer is looking straight into the parallel light beam, resulting in a low visibility of whitish inclusions. In dark field illumination, on the other hand, the beams of light converge on the gem and are not seen as such, leaving the interior of the gem unlit. Only inclusions, surface features (dust, blemishes, etc.) and facet edges will stand out brightly on a dark background (Fig. 3).

Two important consequences of this kind of illumination are:

1. In order to avoid seeing too much dust and fingerprints on the gem, the stone has to be cleaned prior to the examination.
2. Reflections of light beams on facet edges will be seen, and have to be identified as such. This requires additional skills of the gemmologist.

Another type of illumination, which is restricted to certain applications in gemmology, is so-called coaxial illumination. In coaxial illumination, a narrow, focused, intense beam of light is directed to the object, from a position as close as possible to the objective and parallel to the latter's optical axis. This produces a well-lit area on the object's surface, precisely positioned in the center of the image of the

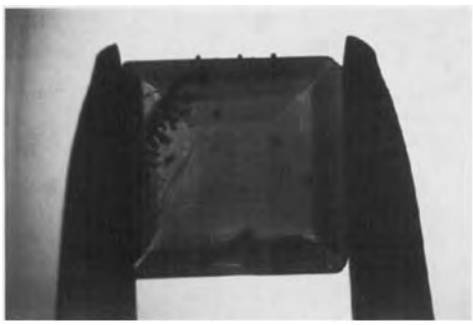

Figure 3. Comparison of transmitted–immersion illumination with dark field illumination. (a) Polished ruby in transmitted–immersion illumination. Only the inclusions are clearly visible; the facet edges are almost completely invisible. Small color zonations are very clearly visible. View perpendicular to the table; 15×. (b) A polished diamond as seen through a typical diamond microscope equipped with dark field illumination. The numerous reflections of the different facets and inclusions necessitate a good understanding by the observer of the behavior of light in a transparent, multi-faceted environment. View perpendicular to the pavilion facets; 15×.

objective, which is almost glare-free, thereby dramatically enhancing the visibility of any surface features which might be present. Typical applications are the study of the surface of pearls and the identification of synthetic opals and heat-treated corundum, to name but a few.

Whereas in research microscopes (certain types of metal microscopes and reverse biological microscopes) coaxial lighting can be obtained using special objectives with beam splitters, in gemmology coaxial illumination is mostly obtained using small microscopy lamps which are attached to the microscope's optics and directed at the object; fiber optic light guides are also used for this purpose. Sometimes it is necessary to combine different types of illumination in order to be able to identify the inclusions or other characteristics under scrutiny. A very useful combination could consist of dark field illumination combined with reflected illumination. The dark field illumination would be used for general illumination and clearly displaying the inclusions, the added reflected illumination could, for instance, separate an opaque inclusion from a highly reflective transparent inclusion, which in transmitted light would produce a similar optical effect. An overview of the different types of illumination and their advantages in observing the different kinds of inclusion[4] is given in Table 2. From this table it can be concluded that for most types of inclusion, dark field illumination with or without reflection illumination is extremely effective. Only structural phenomena such as growth lines and color zonations will be difficult to observe. These types of inclusions are most effectively observed using transmitted–immersion illumination. It is also clear that transmitted–immersion illumination is the most versatile all-round technique available.

7.1.2.4 Polarizing Microscopy

In analogy with polarized microscopy as applied in petrography, the use of

[4] In this context only a descriptive, morphological classification is assumed.

Table 2. Comparison of the visibility of different morphological types of inclusion when illuminated with different types of illumination.

	Transmitted–immersion illumination (TR–IMM)	Dark field illumination (DF)	Reflected illumination (R)	Coaxial illumination (CA)
Crystal inclusions	xxxx[b]	xxxxx[a]	xxx[c]	x[e]
Negative crystals (cavities–voids)	xxxx	xxxxx	xxx	x
Fractures and cleavages	xxxx	xxxxx	xxx	xxx
Healed fractures and fingerprint inclusions	xxxx	xxxxx	xxx	x
Growth lines	xxxxx	xx[d]	x	x
Color zonation	xxxxx	x	x	x

[a] xxxxx: extremely visible; [b] xxxx: very visible; [c] xxx: clearly visible; [d] xx: visible; [e] x: poorly visible.

polarization filters can greatly enhance the identification capability of the gemmological microscope. Just as with the polarizing microscope or the polariscope, the illumination should ideally be parallel transmitted light. In dark field or reflected illumination, polarization is mostly incomplete. On a gemmological microscope, polarization is best obtained using transmitted–immersion illumination. Two different operational modes are possible:

1. *Orthoscopy* (the polarization directions of both polarizer and analyzer are crossed): This technique is especially helpful to discriminate between different types of inclusion based on their optical properties[5]. Otherwise almost invisible birefringent inclusions which are oriented differently to the host become very clearly visible. Strain analysis also becomes possible, and strain centers can readily be identified (Fig. 4). This can be improved further by adding optical compensator plates such as a first order red compensator [8].
2. *Conoscopy* (the polarizer and analyzer are perpendicularly oriented and an auxiliary lens comparable to the Amici–Bertrand lens of a petrographical microscope is inserted): This produces interference figures in birefringent gems and is helpful in discriminating between uniaxial and biaxial materials. This mode can usually only be applied on a monocular microscope. Webster [1] mentions the use of different types of immersion cells which were specifically designed to allow easy identification of the interference pattern of a gem. Among these are the Gübelin hollow glass sphere and the more elaborate Klein and Schlossmacher's immersion sphere fit onto a three-circle Leitz universal stage. Although yielding interesting information, these optical devices, which are not commercially available, have practically no usage today. It is, however, interesting to note that a separate instrument (not a microscope), the Figueras '93 Conoscope [9], is built using a hollow glass bulb much like the Gübelin glass sphere.

[5] Unlike minerals in thin sections, inclusions in gems can have very variable, undetermined dimensions which make identification based on Michel–Lévy charts impossible.

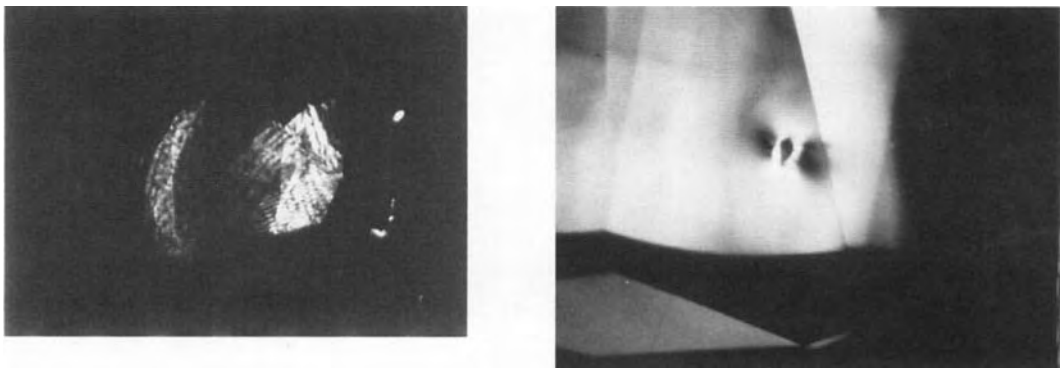

Figure 4. Effect of the application of polarization filters in gemstone microscopy. (a) The inclusion in the middle of this photomicrograph appears to be a strain center in this polished diamond. The contrast of the 'strain wings' around the inclusion is indicative of the amount of strain built up around it. Crossed polarizers; dark field illumination; 35×. (b) The presence of this characteristic interference pattern in an amethyst viewed in the direction of its optic axis is proof of the natural origin of the latter. The distinction between natural and synthetic amethysts is based on the typical Brazil twinning that is present in all natural amethysts and is virtually unknown in synthetic amethysts. Crossed polarizers; transmitted–immersion illumination; 10×. (Crowningshield et al. [23].)

7.1.2.5 Additional Illumination Techniques

Shadowing technique

Koivula [10] has effectively demonstrated that applying different stoppers in the beam of light in between the lamp and the gem produces a marked increase in the visibility of features which are otherwise difficult to discern. This effect could be compared to phase contrast microscopy. Phase contrast microscopy in gemmology was first introduced by Gübelin [11] in collaboration with the German microscope manufacturer Carl Zeiss. The high cost of this equipment and its limited applicability prevented a breakthrough.

Pinpoint illumination technique

A pinpoint illuminator originating from microsurgery has been adapted and modified by Koivula [12] for use in gem photomicrography. It consists of a highly flexible glass fiber light guide with interchangeable light walls of various shapes and sizes, the smallest only measuring approximately 1 mm in diameter. This illumination tool is especially useful for illuminating inclusions located in areas that are difficult to reach. It avoids glare and (sometimes) unwanted internal and external reflections. It is also very effective at showing thin film reflections such as those encountered in healing fractures.

7.1.2.6 Horizontal microscope

One of the constraints of the 'normal' microscope (i.e., a microscope with a vertically oriented light path) is that the stone holder partially obliterates the view of the stone when immersed in an immersion cell. On top of that, working bent over foul-smelling immersion liquids which are being heated by the lamp underneath is not exactly ideal. Not to mention the toxicity

of most of these liquids [13][6]. By 1951 Schlossmacher of Idar-Oberstein (Germany) had solved this problem by designing a new line of gemmological microscopes in which the optical path was horizontally oriented instead of vertically. The gem is now placed in a flat-faced squarish glass cuvette or immersion cell and the stone-holder's axis is vertically oriented at right angles to the optical path. This ensures an almost perfect view of the stone and at the same time a much improved maneuverability.

The committed use of the horizontal immersion microscope became, over the years, the trademark of German gemmology [14]. One of its characteristics is that most of the time the microscopical observation of any gem other than diamond is conducted in transmitted–immersion illumination. Dark field illumination and other types of illumination play only a modest role. This is in sharp contrast to the 'American'-oriented gemmology, or GIA 'gemology', which is based on the use of the famous 'Gemolite' microscope where dark field and reflected illumination are most frequently applied.

7.1.2.7 Further Applications

The Gemmological Microscope as a Refractometer: the Duke of Chaulnes Technique

The refractive index (RI) of any gem can be ascertained by means of the microscope by precisely measuring the displacement of the optical pod on focusing on the top and the bottom of the stone. This optical or apparent depth (OD or D_O) is related to the real depth (RD or D_R) of the stone by its refraction index (Fig. 5).

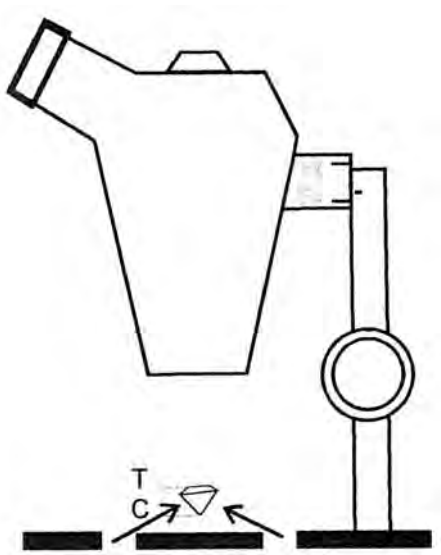

Figure 5. Diagram showing schematically how the 'Duc de Chaulnes' technique is applied to obtain the refractive index or indices of a gem by means of the gemmological microscope. At the highest magnification (i.e., at the smallest depth of focus) the focal point of the culet (F_c) of the gem is recorded by means of a vernier or other mechanical measuring device. Next, the focal point of the table (F_t) is recorded in the same way. The distance between F_c and F_t is the optical or apparent depth (D_O) of the stone. Dividing the real depth (D_R) of the gem by this optical depth (D_O) yields an approximation of the refractive index (RI) of the material.

Using the Duke of Chaulnes method

$$\frac{D_R}{D_O} \approx \text{RI} \qquad (1)$$

This technique is especially interesting when the RI of the stone exceeds the upper limits of the regular Abbé-type refractometer. This latter type needs a contact liquid, which is the limiting factor. Determination of the RI(s) by the Duke of Chaulnes method has no upper limit since no contact exists. In birefringent gems, the accuracy of the measurement

[6] Schneider of Idar-Oberstein has therefore developed a nontoxic vegetal immersion liquid.

can mostly be increased by inserting a polarizer filter.

The Gemmological Microscope as a Dichroscope

Some manufacturers of gemmological microscopes have developed a dichroscopic ocular that has to be inserted just like a regular ocular. Inside this ocular, the field of view is divided into a left and a right field using crossed polarizers. Pleochroic gems viewed through this eyepiece will yield their pleochroic colors.

The Gemmological Microscope as a Spectroscope

Instead of an ocular, a handspectrocope can be inserted into the optical tube of the microscope. The Rayner handspectroscope was specifically built to fit in the eyepieces of most gemmological microscopes. A modern version of this construction consists of a fiber optic light guide placed into the ocular's tube, which is linked to a small PC-based spectrometer. Other more sophisticated applications, such as micro-FTIR spectroanalysis or micro-Raman laser analysis, use a sophisticated scientific research microscope as a base, but are gaining more and more acceptance for the identification of inclusions and/or treatments.

The Gemmological Microscope Used for Crystal Angle Measurements or 'Schmetzer's Microscopic Techniques'

Schmetzer [15] and Kiefert and Schmetzer [16–18] have described two new microscopic techniques for the gemmological horizontal immersion microscope to discriminate between natural and synthetic gems. This is based on the measurement of angles that exist between structural features such as twinning planes and groups of parallel growth planes which run parallel to the crystal faces. Owing to differences in the growth environments, 'habit'-differences also occur (Fig. 6), and are visible as angular differences.

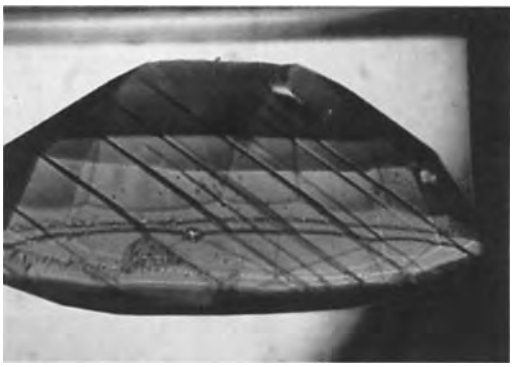

Figure 6. When equipped with polarization filters, crystal angle measurements are possible with the horizontal gemmological microscope in transmitted–immersion illumination. Using the optic axis as the absolute reference, the rotation angle of 90° to the growth planes in this Sri Lankan sapphire identifies them as parallel to *c*(0001). View almost perpendicular to the optic axis, which is oriented diagonally. Crossed polarizers; transmitted–immersion illumination; 20×.

The determination of characteristic structural features such as growth planes or twinning lines comes from the measurement of the angle between the optic axis (OA) (or *c*-axis for uniaxial crystals) and the observed planes. To this effect a special stone holder (Fig. 7) with an angular graduated scale (in degrees) has been developed. The position of the optic axis is first determined in the orthoscopic mode, then the rotation angle to the next crystal plane is read on the graduated scale. A second angular measurement (in-plane angle) can then be taken using an

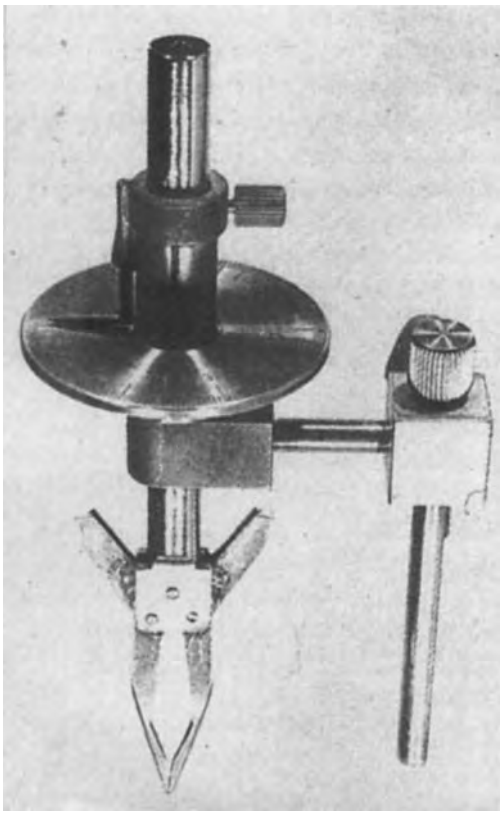

Figure 7. Improved stone holder manufactured by Schneider of Idar-Oberstein with a graduated scale (dial) attached to the vertical axis, allowing easy measurement of the rotation angle between a given plane and the optic axis of the gem.

ocular that has been fitted with a graticule with an angular graduated scale. Measurement of the angles between all visible growth planes allows the identification of these planes and hence the discrimination between different gems from different growth environments.

7.1.2.8 Stone Manipulators

Most manipulators used in gemmological microscopes are of the simple spring-loaded tweezer or stone-holder type. One major disadvantage is that the manipulator only holds the stone. A lot of manipulation is not possible. This can be improved, however, by fitting it onto an $X-Y$ stage which permits precise positioning of the stone during inspection. This manipulation comfort came along in the 1970s with the introduction of the 'Potteratmaster', a sophisticated Swiss manipulator which allowed a round brilliant to spin within three small wheels holding it securely by its girdle. With some accessories, this could also be achieved with fancy shapes. In 1988 the HRD certificates laboratory introduced the 'HRD-gem manipulator', which is, basically, a rotatable vacuum-tweezer. Using silicone-rubber suction pads of different sizes and shapes, almost all sizes and shapes, rough or polished, can be inspected. Using a vacuum, the HRD-gem manipulator can pick up a stone in any required position allowing inspection through the pavilion or the crown-side at will. This results in a very wide field of view. The obvious disadvantage of this manipulator is the necessity to use it linked to a small vacuum pump with an umbilical cord-like vacuum hose.

All previously described stone holders were designed for holding only one stone at a time. For the inspection of whole parcels of small stones these are obviously not very suitable. Van Bockstael [19] mentions the German-made Sortoscope, which solves this problem by using a special sorting tray fitted onto the microscope stand. It includes a sliding white plastic, V-grooved tray which holds the stones and at the same time serves as a diffuse illuminator.

7.1.3 Microscopic Examination of Polished Diamonds

Most of the time, the diamond microscope is used for only one purpose: to grade the quality of polished diamonds. This quality is characterized by the so-called 'four Cs': carat, clarity, color, and cut. The microscope is obviously of no great help when it comes to assessing the carat weight or the color of a diamond. Electronic scales and color reference samples are used for this purpose. The real advantages of the microscope are most obvious when it comes to clarity grading and also, but to a lesser extent, to cut grading.

7.1.3.1 Clarity Grading

The clarity grade of a diamond gives a measure of the number and the importance of the impurities that can be observed in the stone. A basic definition of the different grades was given by the IDC [20] (see Table 3). The internal characteristics are graded as described by the given definitions, which are valid for use by an experienced grader.

At present, four important diamond grading systems are in use (Table 4):

1. The IDC (International Diamond Council) system, which was adopted by the international professional diamond organizations WFDB and IDMA in 1978 and is currently applied by the HRD Certificates Department and three other major grading laboratories.
2. The GIA (Gemmological Institute of America) system applied by the GIA Gem Trade Labs in the U.S.A. and by a number of private gemmological labs throughout the world.
3. The CIBJO (Confédération Internationale de la Bijouterie, Joallerie et Orfèvrerie) system applied by the licensed labs of this international jewelers' organization.
4. The ScanDN (Scandinavian Diamond Nomenclature) system. There are no

Table 3. Clarity grading of polished diamonds[a]

Grade	Definition
Loupe-clean	A diamond is called 'loupe-clean' if, after examination by an experienced grader with a loupe 10× (corrected for spherical and chromatic aberration), under normal light conditions, it has been found free of internal characteristics.
vvs: vvs1, vvs2	Very very small internal characteristic(s), which can be found from 'very hardly' to 'hardly' with a loupe 10×. The size, position, and number of the internal characteristics determine the distinction between vvs1 and vvs2.
vs: vs1, vs2	Very small internal characteristic(s), which can be found from 'fairly hardly' to 'easily' with a loupe 10×. The size, position, and number of the internal characteristics determine the distinction between vs1 and vs2.
si	Small internal characteristic(s), very easy to find with a loupe 10×.[b]
p1	Internal characteristic(s), which can hardly be found with the naked eye through the crown-side of the diamond.
p2	Large and/or frequent internal characteristic(s), easily visible to the naked eye and which reduce(s) the brilliancy of the diamond slightly.
p3	Large and/or frequent internal characteristic(s), very easily seen with the naked eye and which reduce(s) the brilliancy of the diamond.

[a] IDC [20]; [b] since 1991, this IDC grade has been split up into si1 and si2.

Table 4. Comparison of the IDC (e.g., HRD), CIBJO, ScanDN, and GIA clarity grading systems.

IDC (e.g., HRD)	Final decision using loupe 10×									(p = piqué)
								naked eye		
	Loupe-clean	vvs1	vvs2	vs1	vs2	si1	si2	p1	p2	p3
CIBJO	Final decision using loupe 10×									
								naked eye		
	Loupe-clean	vvs1	vvs2	vs1	vs2	si1	si2	p1	p2	p3
ScanDN	Final decision using loupe 10×									
								naked eye		
	Internally flawless (flawless)	vvs1	vvs2	vs1	vs2	si1	si2	p1	p2	p3
GIA	Magnification 10× (loupe-microscope)									(i = imperfect)
								naked eye		
	Internally flawless (flawless)	vvs1	vvs2	vs1	vs2	si1	si2	i1	i2	i3

At present (1996) there seems to be a commercial tendency on the American diamond market to add an si3 grade on the border line between si2 and i1.

actual labs in operation using this system.

Compared with a handheld lens or loupe, the microscope has the advantage of having more than one possible magnification. The most popular types of diamond microscope feature a zoom lens that allows a whole range of magnifications. Furthermore, most diamond microscopes are of the binocular stereomicroscope type. This is not only less strenuous to work with, but it also produces a truly three-dimensional image, which makes the identification of characteristics less cumbersome. Finally, most diamond microscopes feature dark field illumination, which makes even small pinpoints stand out brightly on a dark background. For clarity grading, only 10× magnification is used for the actual assessment. Indeed, the IDC rules clearly specify that the decision on the clarity grade should be made with a 10× loupe. The microscope is only used as an aid to find and identify characteristics. An accessory that allows (semi-)quantification of the effect of the presence of an inclusion on the clarity grade was introduced as early as 1974 by the Diamond Grading Laboratories Inc. in London [21]. This accessory consists of a 'Porton particle size analysis' graticule (Fig. 8) placed in one of the oculars of the microscope. A similar graticule (Fig. 9) was developed later by the HRD Certificates Department. This graticule is used mainly as an internal reference and also as a training device. Since not only the size of an inclusion, but also its contrast to the background, its position in the diamond, and the number of images it produces, defines its grade, a whole set of rules is

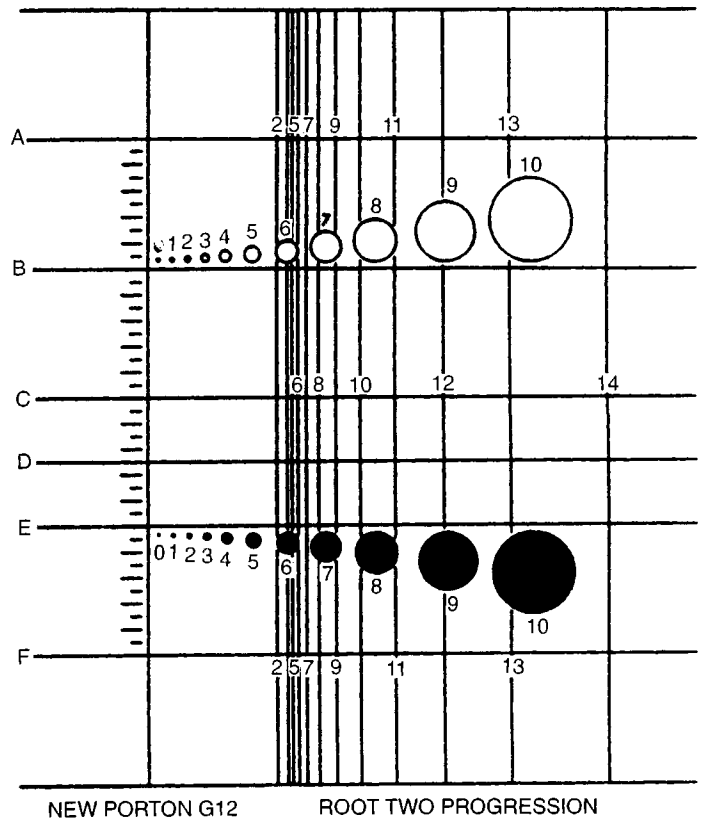

Figure 8. Porton graticule, used to measure the size of inclusions in gemstones.

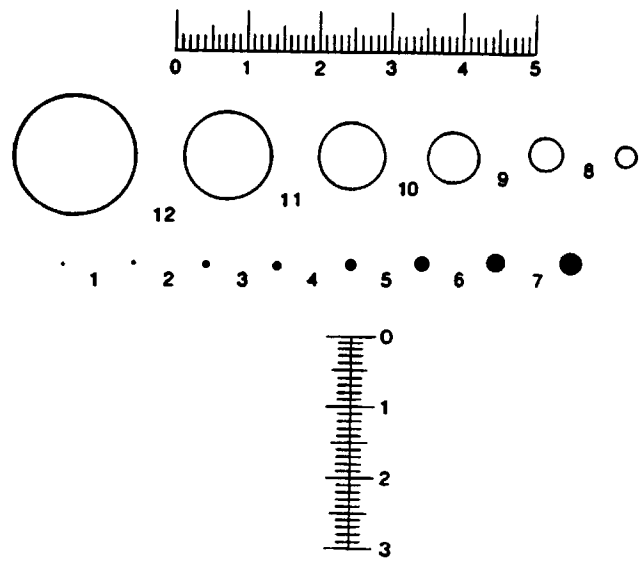

Figure 9. Clarity grading graticule, used by the HRD Certificates Department and by the HRD Institute of Gemmology.

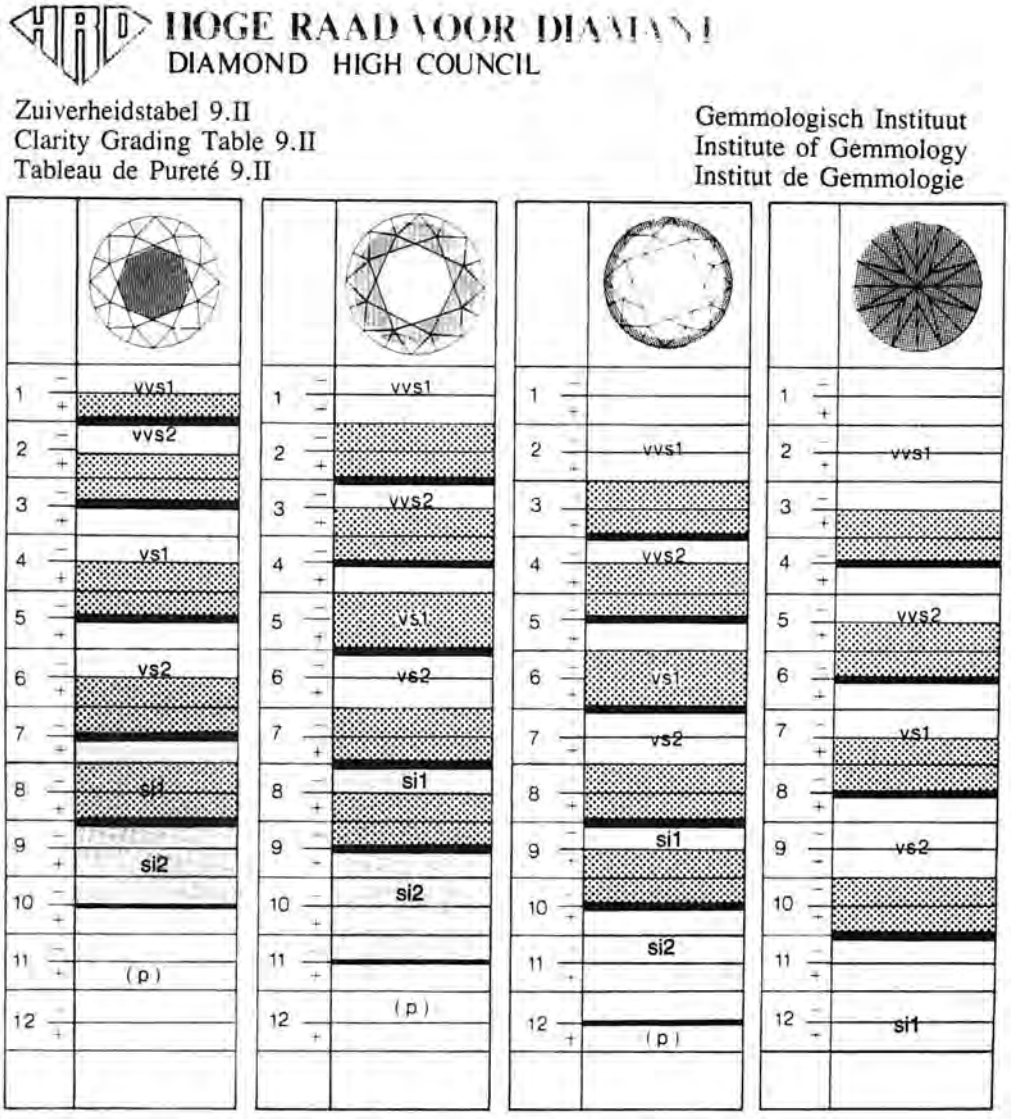
Table 5. HRD clarity grading table.



Contrast	1	2	3	3–4	4	4–5	5
Correction C1	+1	0	−1	−2	−3	−5	−7
Number/code	1	2		3	6		
Correction C2	0	0		+1	+2		

[a] Copyright HRD (1990); [b] this synoptic table translates the four clarity defining parameters (size, contrast to the background, position, and number of reflections) into a clarity grade.

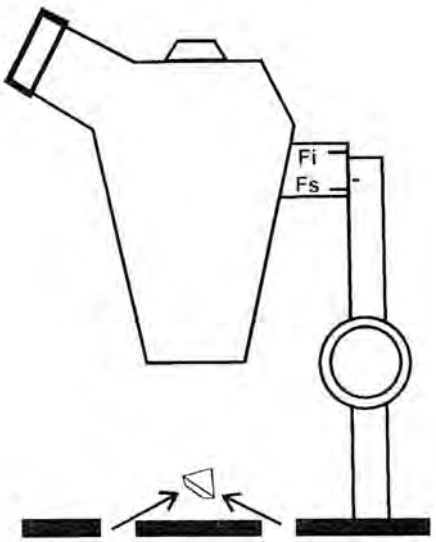


Figure 10. To measure the depth of an inclusion mechanically, the change in the focusing depth ($F_s - F_i$) is recorded with a dial gauge or other mechanical measuring device which is fitted to the microscope (modified from Van Bockstael [22]).

needed to transform these four parameters into a clarity grade. Table 5 relates these parameters to the clarity grade.

7.1.3.2 Measuring the Depth of an Inclusion Using the Diamond Microscope

In order to calculate whether the clarity grade of a diamond can be improved by the removal of an inclusion (repolishing), it is necessary to estimate the distance from the surface of the stone to the inclusion. Most diamond polishers will judge this depth by experience. Depending on the size of the stone and the exact location of the inclusion in the stone, they can balance the expected weight loss and the risk involved in recutting against the expected clarity grade improvement. It is obvious that the observation and estimation of the depth of the inclusion with only a handheld loupe leaves considerable room for error of judgement. For a more accurate observation, the microscope can be used as a superior magnifying instrument. The accuracy of the depth estimation will, however, still depend on the polisher's skill and experience. To overcome this inconvenience, the microscope can be used as a measuring device. This can be done either 'mechanically' or 'optically'. The 'mechanical' depth measurement consists of mechanically measuring the progression of the optical pod between focusing on the surface (focal point F_s) and then on the inclusion (focal point F_i) (see Fig. 10). For this, a dial gauge or other measuring device is fixed onto the microscope stand [22]. The measurement obtained with the dial gauge is only the apparent depth. To obtain the real depth it has to be multiplied by the refractive index ($n = 2.42$ for diamond). The accuracy of the measurement depends largely on the mechanical quality of the focusing thread, and on the optical properties of the microscope lenses. In this respect the depth of focus of the microscope optics at a given magnification is imperative. Since at high magnification the depth of focus is smallest, it is clear that the measurement must be taken at the highest magnification. However, for a given optics the accuracy of the measurement will still be no better than the depth of focus at the highest magnification.

The 'optical' depth measurement avoids both the mechanical error associated with the progression of the optical pod and the optical error produced by the depth of focus of the microscope's optics, which are the limiting factors of the accuracy of the mechanical depth measurement. To arrive at this higher accuracy, the depth of an inclusion is measured in reflection

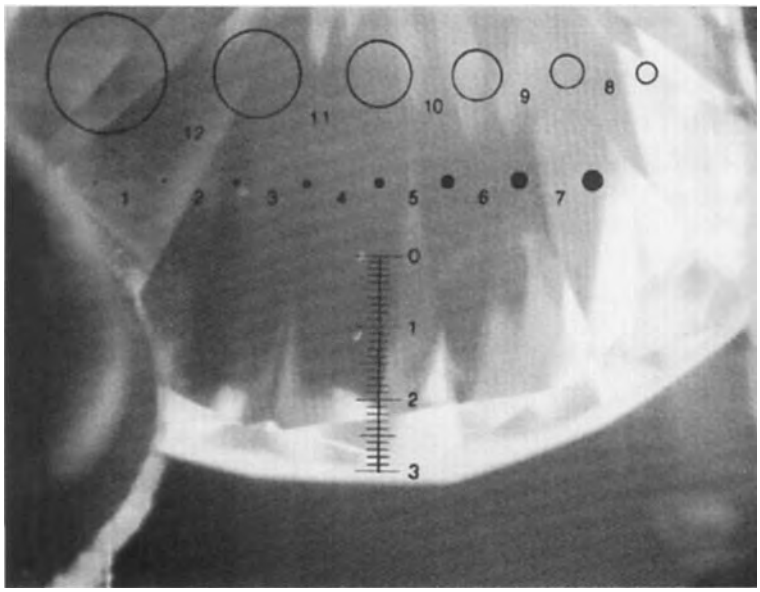

Figure 11. To measure the depth of an inclusion optically, a graticule displaying a linear graduated scale is used to assess the distance between the real image and the reflection of the inclusion. The apparent depth of the inclusion is half this distance.

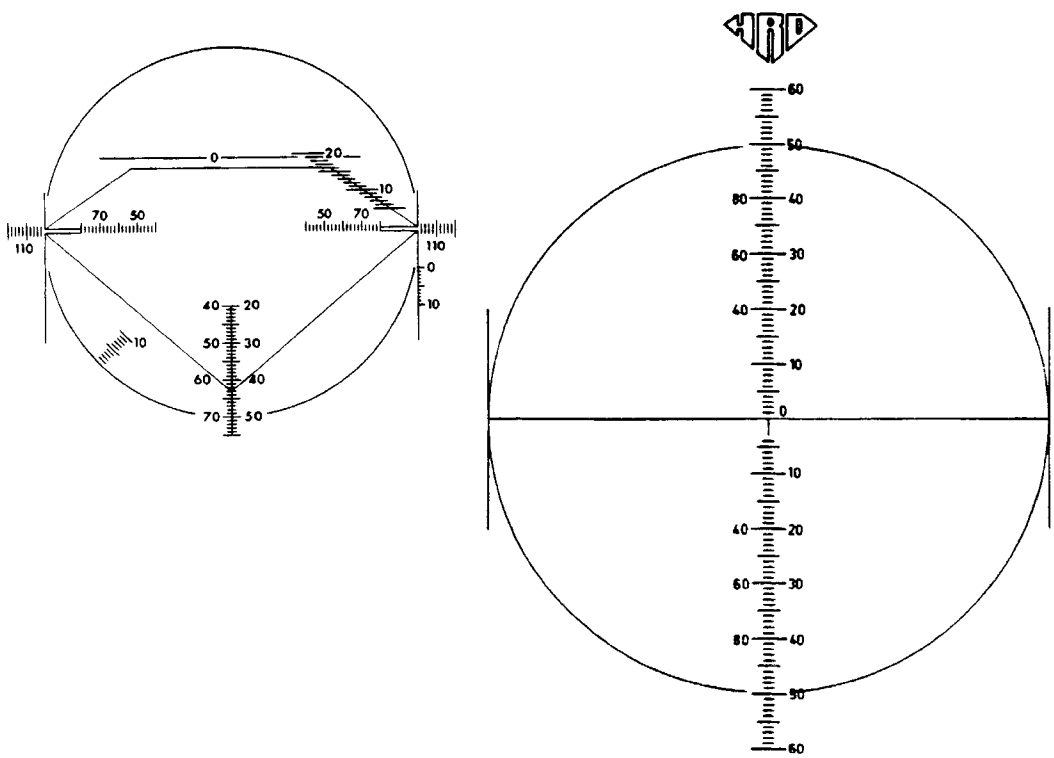

Figure 12. The HRD proportion graticule. The inset (top left) shows the screen used in the standard proportionscope.

with a graticule fitted into the eyepiece of the microscope. The apparent depth of the inclusion is equal to half the distance between the real image of the inclusion and its reflection (see Fig. 11). Multiplication of this figure with a trigonometric constant, a corrective factor for the multiplication used, and, finally, the refractive index of diamond, produces an accurate approximation of the depth of the inclusion.

7.1.3.3 Proportions Grading

For the assessment of the cut, the HRD Certificates Department has developed a 'proportion graticule' (Fig. 12). This allows the grader to measure the crown height, girdle thickness and pavilion depth for a diamond polished in the round brilliant shape. The actual measurement is illustrated in Fig. 13.

The accuracy of the proportions measurement is comparable to, or even better than, that obtained by a regular proportionscope. This is especially so when it is used together with vacuum tweezers, which allow a complete and undisturbed view of the stone. Apart from the proportions, the finish or symmetry deviations can also be quantified using this graticule. The measured results are optimal when the

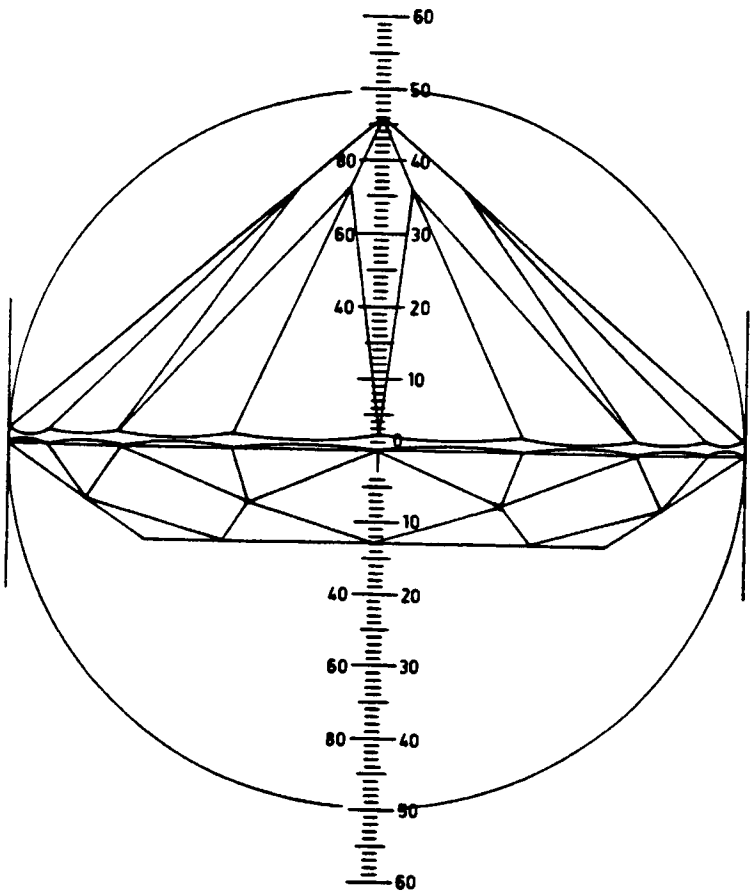

Figure 13. In this example, the crown height of a brilliant is measured using the HRD proportion graticule. At the same time, the girdle thickness can be read from the graduated scale. The crown height is 13% of the total diameter, whereas the girdle thickness indicates 2%.

Figure 14. HRD type IV diamond microscope.

overhead daylight lamp of the microscope is used. Two popular diamond microscopes are illustrated in Figs. 14 and 15. In Figs. 16–19, some of the most typical characteristics in diamond are shown, as seen through the microscope.

7.2 The Use of Electron Microscopic Techniques for the Characterization of Gemstones

It is the purpose of this part of the chapter to illustrate with a few examples the use of electron microscopy techniques for the analysis and characterization of gemstones. In most cases, depending on the technique applied, electron microscopy is a rather destructive technique and is therefore not suited for routine application by nonscientists on polished gemstones. Not the observation techniques themselves, but the required specimen preparation techniques are detrimental.

However, the application of electron beam techniques can teach us a lot about the structural characteristics of the material from which the gemstone is tailored and can thus be used for a thorough and unambiguous identification, e.g., for a set of stones of the same provenance. This section consists of two main parts: in the first, introductory part the experimental techniques of electron microscopy, electron diffraction, scanning electron microscopy, and electron beam based microanalysis techniques are briefly outlined and reference is made to the appropriate detailed chapters of Volume 1 of this Handbook; in the second part a few

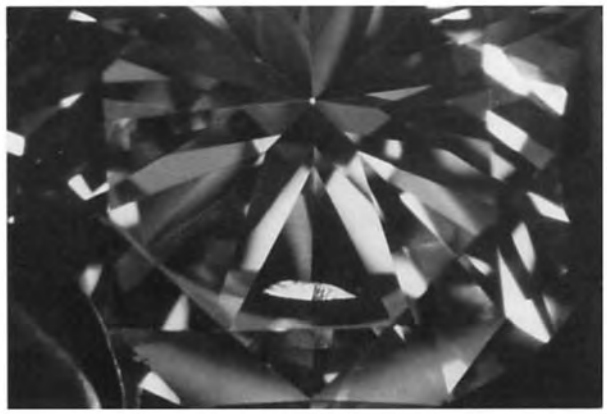

Figure 16. Typical examples of fractures (also called 'gletzes', 'cleavages', or 'feathers') in a diamond.

Figure 17. Typical examples of crystal inclusions in a diamond.

Figure 18. Typical example of a 'cloud' in a diamond. Clouds consist of numerous, very small, pinpoint inclusions.

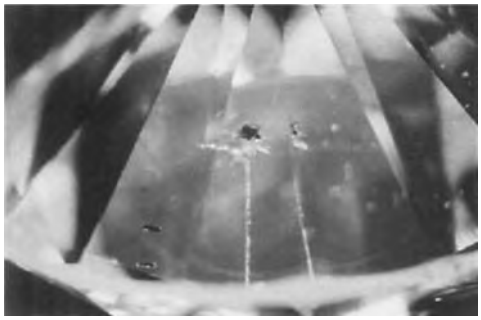

Figure 19. Laser drilling in a diamond. This artificial characteristic was made in order to chemically bleach a very dark inclusion in the stone.

examples are illustrated, mainly from studies performed at the EMAT laboratory in Antwerp (University of Antwerp, RUCA) and from a few other sources from the international scientific literature. Space forbids us to be exhaustive, however.

As pointed out in many of the previous chapters in this Handbook, electron microscopy could be considered chronologically as the successor to optical microscopy, enabling higher magnifications and more detail to be discerned. However, the technique offers more than just a higher magnification, and yields a wealth of structural and chemical information, as we shall see hereafter.

The working principle is easily compared with the optical microscope, one of the main and most sophisticated tools for the nondestructive analysis of gemstones, as was illustrated extensively in Sec. 7.1 of this Chapter. Most important and essentially different is the interaction of the radiation, i.e., light or electrons, with the object. It is this interaction that is responsible for the type of images and contrast that are obtained, and, still more important, the kind of information that can be expected from the image and other recording possibilities. Whereas in light microscopy this interaction is mainly reflection or transmission (for thin samples), the interaction of an electron beam with a specimen can be manifold, especially with a crystalline specimen, which all of our gemstone materials (or nearly all) are.

We will restrict ourselves to the main types of interaction, which are: transmission, elastic scattering (i.e., diffraction at the lattice planes), absorption, secondary electrons or backscattered electrons, characteristic energy losses, and characteristic X-rays emitted from the irradiated area. The first three types of interaction are used in transmission electron microscopy, where a suitable imaging theory is required to interpret the images of the structure, i.e. the defects in the structure, such as stacking faults, twin crystals, grain boundaries, inclusions, etc., as elaborated by Amelinckx in Chap. 4.1.1 of Vol. 1 of this Handbook.

These can nowadays be observed at very high magnifications of up to millions of times and interpreted without ambiguity. By suitable focusing of the lenses, the electron beams diffracted at the specimen can be recorded as a diffraction pattern, which yields information on the structure and the crystallinity of the sample. The characteristic X-rays which are emitted upon irradiating a sample with an electron beam can be analyzed by auxiliary equipment attached to the electron microscope.

Specimens for transmission electron microscopy (TEM) should be very thin: less than 200 nm down to 5 nm, depending on the observation technique or the type of information required. This means that the samples will have to be prepared down to this thickness by specialized techniques

such as sawing, grinding, chemical polishing, ion bombardment, or the like, as have been extensively detailed in Chap. 2.3 of this Volume by Barna et al. These techniques are usually rather destructive and are therefore only or mainly suited for fundamental research on gemstone materials.

A type of electron microscope where the specimen requirements are less drastic, which enables much higher magnification than optical microscopes and a much larger depth of field and range of chemical signals available, is the scanning electron microscope (SEM), the principle of which was treated extensively by Cowley in Chap. 4.2.2 of Vol. 2 of this Handbook. In its simplest mode it utilizes the backscattered and/or secondary electrons from a specimen irradiated with a narrow beam of electrons. The specimen is scanned with this fine beam of electrons and the backscattered or secondary electrons are detected; this signal is recorded on a cathode ray tube (TV screen) synchronously while scanning the specimen. A reliable image of the surface of the specimen is thus obtained. Since no magnifying lenses are required, no lens aberrations spoil the image or the depth of field, which thus becomes very large in comparison with that of the optical microscope. Also, an SEM can be equipped with an X-ray or other microanalysis detector, enabling the determination of the composition at the surface or of particular surface heterogeneities such as, e.g., inclusions or artificially added heterogeneities, on a very small scale.

We shall now illustrate the use of these techniques by means of a few examples of electron microscopy results on gemstone materials.

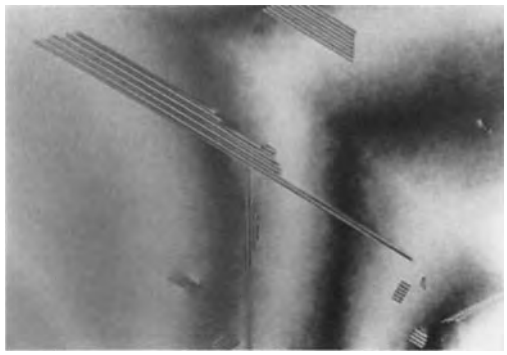

Figure 20. Nitride platelets in diamond observed in diffraction contrast mode (TEM) as a pattern of parallel fringes.

7.2.1 Diamond

An illustration of the use of a scanning electron microscope for a nondestructive study of very small diamonds is shown in Fig. 20, where an approximately 100 μm small, synthetic diamond with an octahedral growth habit is observed at a magnification of 500×. On this figure the very large depth of field of the SEM technique is clearly evident.

Figure 21 shows an example of the combined use of scanning electron microscopy and X-ray microanalytical

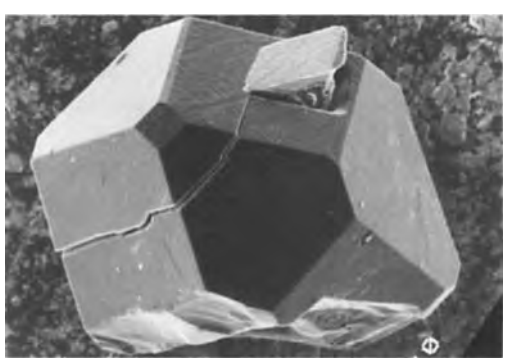

Figure 21. Scanning electron micrograph of a small synthetic diamond (±100 mm). Notice the large depth of field in this SEM image.

techniques, and reveals ion-etched micro-engravings performed on a diamond surface by a procedure developed in Antwerp (Stoneprint). Scanning electron microscopy could also be used to prove the negative relief obtained by ion etching, as shown in Fig. 22a (letter A). The nature of a small accidental particle could be determined by X-ray microanalysis in an SEM to be copper, as evidenced by the spectrum which is illustrated in Fig. 22b.

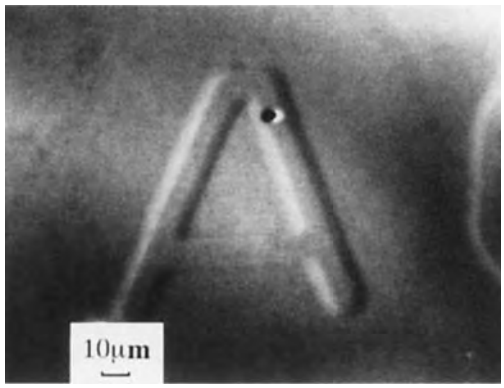
Fundamental studies on the structural defects in natural diamond have revealed the existence of several types of defect often related to the type of diamond: dislocations, dislocation loops, platelets, and voidites [24, 25]. The presence of platelets in diamond can very clearly be observed at high magnification in transmission electron microscopy diffraction contrast (see Chap. 4.1.1 of Vol. 1 of this Handbook by Amelinckx). A thin diamond foil prepared by ion beam thinning intermittent with oxidation down to a thickness of 200 nm clearly reveals these platelets. The fringe patterns are diffraction contrast effects revealing the presence of very fine platelets (Fig. 22). It can be seen that the platelets are lying in strict crystallographic directions.

A detailed electron microscopic study on these platelets was reported by Barry et al. [26]. Figure 23 shows an example of a high resolution image of a platelet. This type of image enabled the authors, by using a number of different techniques such as image matching of perfect diamond images and matching the width and the appearance of the central fringe at the platelet structure image, to conclude that the platelet structure is consistent with a double nitrogen layer in zigzag configuration.

Luyten and co-workers [27, 28] recently reported extensive studies on voidites in type IaB diamonds, their nature, and their presumed relation with transforming platelets and dislocations. It was shown in a thorough analysis using diffraction contrast, electron diffraction, high resolution imaging, and electron energy loss spectroscopy that the voidites are not necessarily related to transforming platelets, but that in both cases the voidite material consists of a nitrogen-containing phase. More details and images of these octahedral-shaped voidites limited by (1 1 1) planes are presented by Bernaerts and Amelinckx in Chap. 1.11 of this Volume. It should also be mentioned that in particular for diamond materials cathodoluminescence originating from the electron beam excitations, as described in Chap. 4, Sec. 1.4.3 of Vol. 1 of this Handbook, by Joy, can yield interesting information on the type of diamond, the defect and (or) impurity center distribution, and their characterization, especially for defects and precipitates that are only present with a low density and therefore sometimes difficult to discern by the above-mentioned contrast techniques.

7.2.2 Quartz

Quartz is the basic material for a number of gemstones (amethyst, citrine, praseolite, etc.). It is well known that this material undergoes a phase transition at 573°C from low (α)-quartz to high (β)-quartz. The existence of a particular type of twins (Dauphiné twins) in quartz is well known but their relation with the nature of the phase transition was only precluded [29].



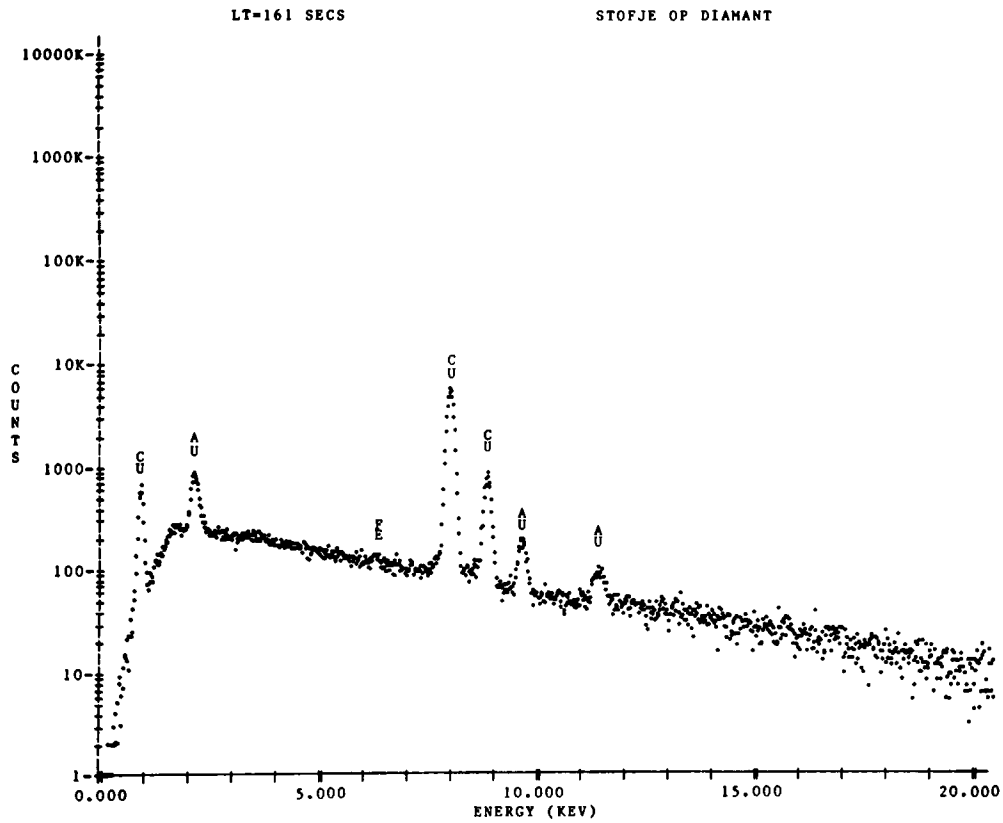


Figure 22. (a) Negative relief lettering on a diamond; the shallow depth relief could be detected by SEM. A small particle of accidental origin was analyzed by X-ray microanalysis and found to be copper from the holder material. (b) The line diagram represents the microanalysis spectrum where, apart from the gold from the intentionally evaporated film, only copper peaks are observed.

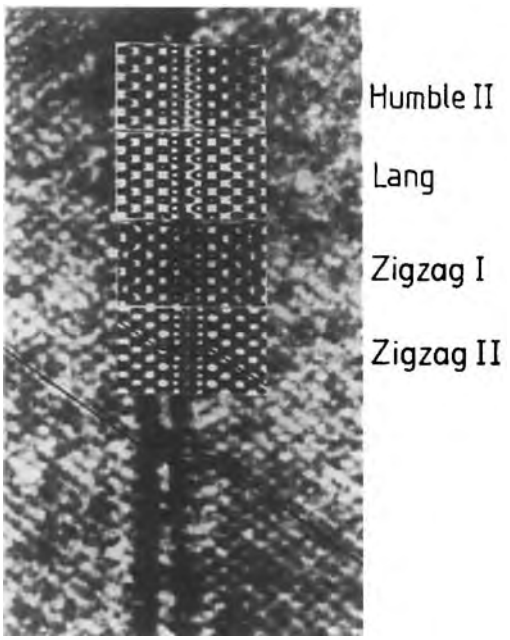

Figure 23. HREM of platelet in diamond; calculated images for various structure models are compared with the experimental image (courtesy of Hutchison).

Figure 24. The phase front between the α- and β-phases in quartz is observed to consist of a regular array of pyramidal Dauphiné twins forming an incommensurate modulated structure, the period of which reduces as the β-phase region is approached. The specimen is close to 573°C; there is a gradient of a few degrees across the area of the photograph.

It has been possible by transmission electron microscopy to characterize the nature of this phase transition as follows [29, 30]. Figure 25 illustrates a time shot of the microstructure taken at the phase transition in quartz. The thinned crystal is heated in a special furnace holder of the electron microscope to a temperature close to the transition temperature of 573°C. Slight electron beam heating is then used to produce a temperature gradient across the observed area shown in Fig. 24.

From the observations and their analysis it could be concluded that at the transition a high density of defects is formed following a regular network with a mesh size that becomes smaller until unresolvable in the β-phase (right part of Fig. 24). These defects could be identified as the well-known Dauphiné twins, which relate two crystallographically equivalent orientations α_1 and α_2 of the α-phase. The observations have led to a novel interpretation of the $\alpha \rightarrow \beta$ transition in quartz, whereby the β-phase can be considered as a time average of the α_1 and α_2 orientations of the α-phase resulting in the existence of an incommensurate phase in between the α and β phases. Theoretical and experimental confirmations and detailed studies have followed this discovery by electron microscopy [31–33].

In amethyst quartz a strong interaction was observed between the Brazilian twins (typical for amethyst) and the Dauphiné

Figure 25. Interaction between Dauphiné twins and Brazilian twins in amethyst quartz observed near the transition temperature.

twins occurring at the phase transition, as shown in the dark field image in Fig. 25 [34].

Various aspects of the nature of the asterism in star quartz are illustrated in Fig. 26. It was shown by Woensdregt et al. [35] that the fine needles causing the asterism are sillimanite and not rutile needles, as generally thought before.

7.2.3 Precious opal

A typical example of the use of scanning electron microscopy is shown in Fig. 27 where a synthetic opal is analyzed. The

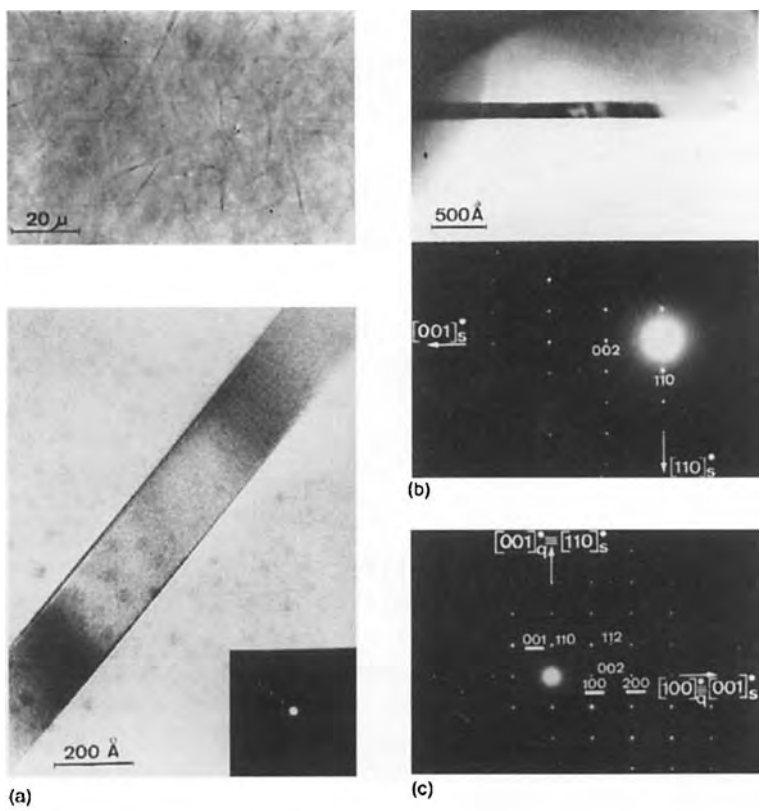

Figure 26. The origin of asterism in star quartz. (a) Transmission electron microscope micrograph of a single sillimanite needle and its electron diffraction pattern. Lattice fringes of $d_{[1\bar{1}0]}$ are visible and the quartz has become amorphous owing to electron beam damage pattern. (b) $[1\bar{1}0]$ electron diffraction pattern of sillimanite. (c) Electron diffraction pattern of the oriented intergrowth of sillimanite (s) and quartz (q). Underlined indices are quartz. [001]* of sillimanite is parallel to [100]* of quartz (courtesy of C. Woensdregt).

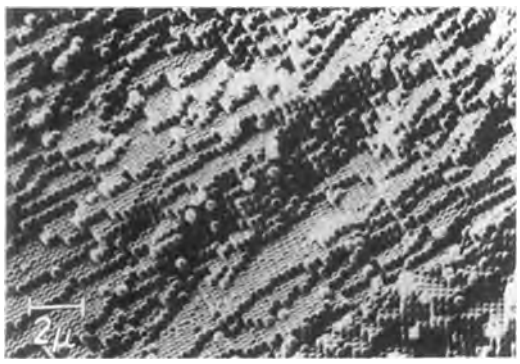

Figure 27. Scanning electron micrograph of a synthetic opal. The regular array of hydrated silica spheres is very evident in this image. The large depth of field results in image sharpness at different heights in the sample.

typical structure of opal as a stacking of small (0.3-mm diameter) spheres in a close-packed arrangement is clearly observed in this SEM image. The advantage of the large depth of field is very evident from this image made by Falter and Liebertz [36]. Object parts several micrometers apart in depth are all in focus. Hexagonal (1 1 1) plane arrays as well as square (1 0 0) plane arrays can be distinguished.

7.2.4 Garnet

As a final example, Fig. 28 shows high resolution images of a garnet crystal thinned by crushing and dispersing crystal fragments on a thin carbon film. A crystal fragment is observed in the high resolution mode, where structural detail of the order of 0.2 nm is observed to confirm the perfect structure.

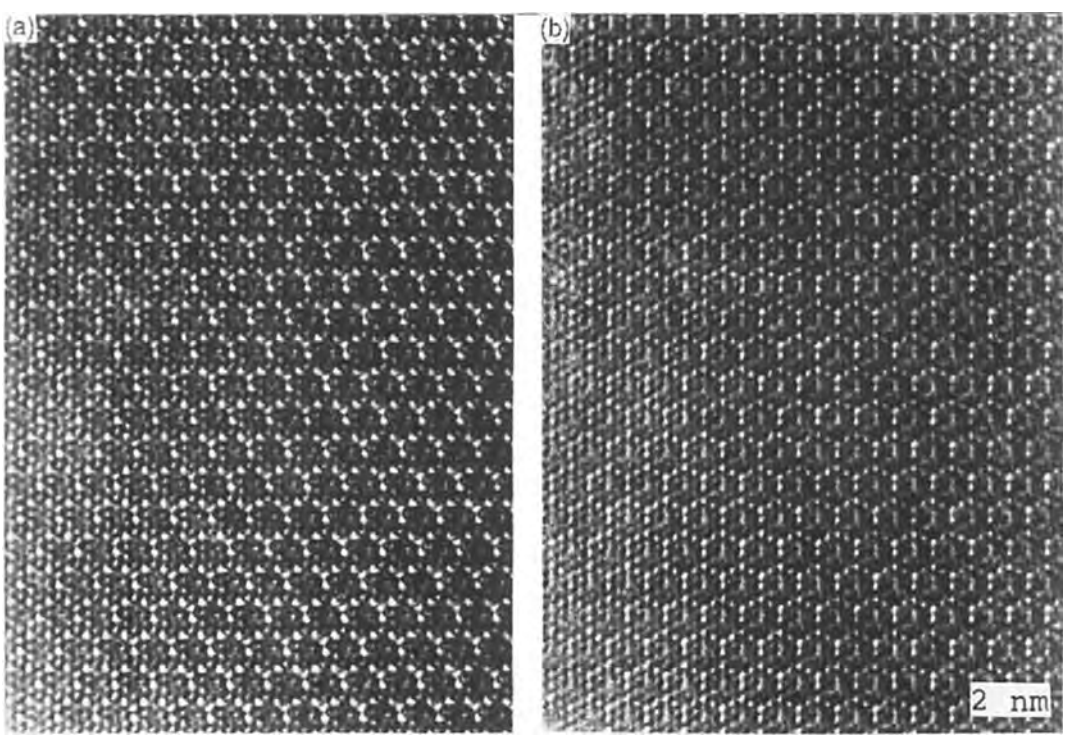

Figure 28. Structural images of a garnet crystal.

7.3 Conclusions

In view of the complexity of this subject, the authors are aware of the fragmentary character of this chapter. They hope, however, that potentialities and disadvantages of the utilized types of microscopy and related techniques can be understood and are well illustrated by the different examples of electron microscopy studies of gemstones that are presented. Semiprecious stones and minerals, being related in that both are naturally grown materials, are often very hard, and contain similar types of growth defects, can mostly be studied by the same methodology. The reader is therefore also referred to the extensive chapter by Barber on this subject (Chap. 1.2 of this Volume).

8 Superconducting Ceramics

8.1 Introduction

Since the discovery by Bednorz and Müller of superconductivity around 30 K in the barium–lanthanum–copper–oxygen system [1], a large number—several hundred—of superconducting compounds with transition temperatures as high as 133 K [2] have been synthesized. Many of these compounds would never have been discovered without the help of various microscopy techniques. In particular, electron microscopy and techniques related to electron microscopy such as energy dispersive X-ray (EDX) spectroscopy or electron loss spectroscopy (EELS) were essential in the evolution of superconductivity research.

Optical microscopy and scanning electron microscopy have strongly contributed to the obtention of single phases of the superconducting compounds and the determination of the morphology as a function of the growth conditions. Polarized light microscopy is one of the few techniques to directly observe the magnetic flux or flux motion in thin superconducting films. Different electron microscopy techniques have played a crucial role in the synthesis and the optimization of the superconducting phases. Sometimes superconducting minority phases—recall the 'green' phase and the 'black' phase in yttrium–barium–copper–oxygen (YBCO) [3]—have been detected and their structure determined with the help of electron microscopy. In many cases, as we will see further, synthesis of new materials and characterization by electron microscopy go hand in hand. Atomic force microscopy (AFM) and scanning tunneling microscopy (STM) are highly important in the elaboration of detail in the surface of bulk superconductors as well as of thin films in different stages of production. Other techniques, such as laser scanning microscopy, positron anihilation, micro-Raman imaging, field electron emission microscopy, and scanning Auger microscopy, are less used techniques, but which certainly provide useful information; their specific use will be highlighted.

In this contribution we will try to illustrate the power of the different imaging and microscopy techniques to solve particular problems in the field of superconductivity. However, it is not the aim to give a survey of all the scientific contributions based on the different imaging techniques. *Physica C*, a journal entirely devoted to superconductivity and superconducting materials, lists over 500 papers which over the past 5 years have been entirely or partially devoted to some

form of microscopy. This shows the impossibility of making a complete survey, but on the other hand also the strength and the importance of direct imaging in superconductivity research.

We will first consider the strength of the different imaging techniques in the field of superconductivity research and then consider a number of problems (physical, chemical and engineering) and see how they can be solved or solutions suggested by the different techniques.

8.2 Imaging Superconducting Ceramics

8.2.1 Morphology Studies by Optical Microscopy

Optical microscopy (OM) is an easy and fast technique to study the morphology of newly synthesized material. Particularly when special requirements have to be met concerning the alignment of grains, or texturing, OM is the technique of choice. The dimensions of most grains is such that the resolution of OM is not the limiting factor. In contrast to other techniques treated in this section, the term 'optical microscopy' seldom appears in the title of a superconductivity paper, indicating that OM is considered a supporting technique in the processing or texturing superconducting materials.

Highly oriented YBCO bulk material can be produced by a melt process or melt texturing ([4–8]); the development and final morphology was followed in all cases by OM. Similarly, single crystals with high critical current values can be grown, OM evaluating the dispersion of foreign grains [9]. The microstructure of different oxides (superconducting or not) in the YBCO phase diagram and the formation conditions of the different phases was monitored by optical inspection of the ceramic samples [10]. The effects of BaSnO additions to melt powder, melt grown (MPMG)-processed YBCO, in an effort to increase the pinning properties of melt textured YBCO, is characterized by a combination of OM, scanning electron microscopy (SEM), X-ray diffraction, and EDX [11]; as usual, a combination of different techniques provides the most complete information.

The crystal growth and decomposition of bismuth-based oxide superconductors $Bi_2Sr_2Ca_nCu_{n+1}O_z$ (BSCCO) has been followed by Komatsu et al. [12] by high-temperature OM. They studied the growth process by slowly cooling a liquid drop on an MgO substrate. The formation of the high-T_c phase by a peritectic reaction between liquid and solid is observed. A sequence of micrographs of the crystals that appear between 865 and 845°C is shown in Fig. 1.

8.2.2 Scanning Electron Microscopy, Scanning Tunnelling Microscopy, and Atomic Force Microscopy Surface Studies

SEM is in a sense the prolongation of OM; it is more a supporting technique than a basic research tool. Only the resolution is better than OM, and the focus depth is infinite (see Vol. I of this Handbook). Like OM, SEM is often used to characterize the surface structure of superconducting

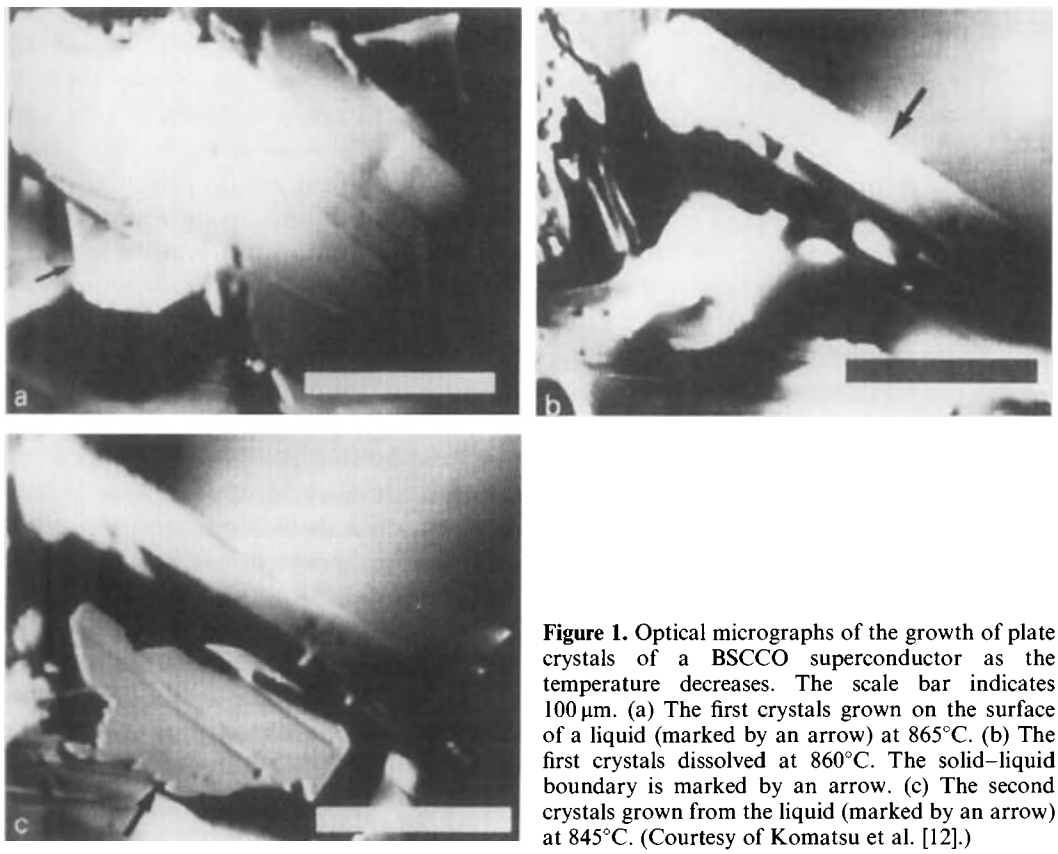

Figure 1. Optical micrographs of the growth of plate crystals of a BSCCO superconductor as the temperature decreases. The scale bar indicates 100 μm. (a) The first crystals grown on the surface of a liquid (marked by an arrow) at 865°C. (b) The first crystals dissolved at 860°C. The solid–liquid boundary is marked by an arrow. (c) The second crystals grown from the liquid (marked by an arrow) at 845°C. (Courtesy of Komatsu et al. [12].)

materials. Unlike OM, however, the samples need not to be polished; because of the enormous depth profile of SEM, it is the preferred technique for the fast inspection of sample composition, grain distribution, crystal size or morphology. The resolution limit—for practical use—is about 10 nm; for most applications this is more than sufficient; when more detailed information is needed there is AFM and STM. The field of applications is therefore more or less the same as in OM, that is, an aid to the synthesis of new superconducting materials and the processing of known superconductors. An advantage of SEM—apart from its depth profile—is the possibility to combine it with energy analysis of X rays, providing compositional information on the area imaged; this has been used, for example, by Su et al. [13] and Lin et al. [14] in studies of single-crystal and sintered wires of YBCO. An interesting study by Lin and Liang [15] investigates the crystallographic defects in YBCO single crystals, revealed by chemical etching with several acids. Different etch pits are observed: some are of the spiral growth type, others have more of a Hopper-like morphology [15]. An example is shown in Fig. 2. For superconducting materials which have synthesis problems, such as $TlSr_2Ca_2Cu_3O_x$ or

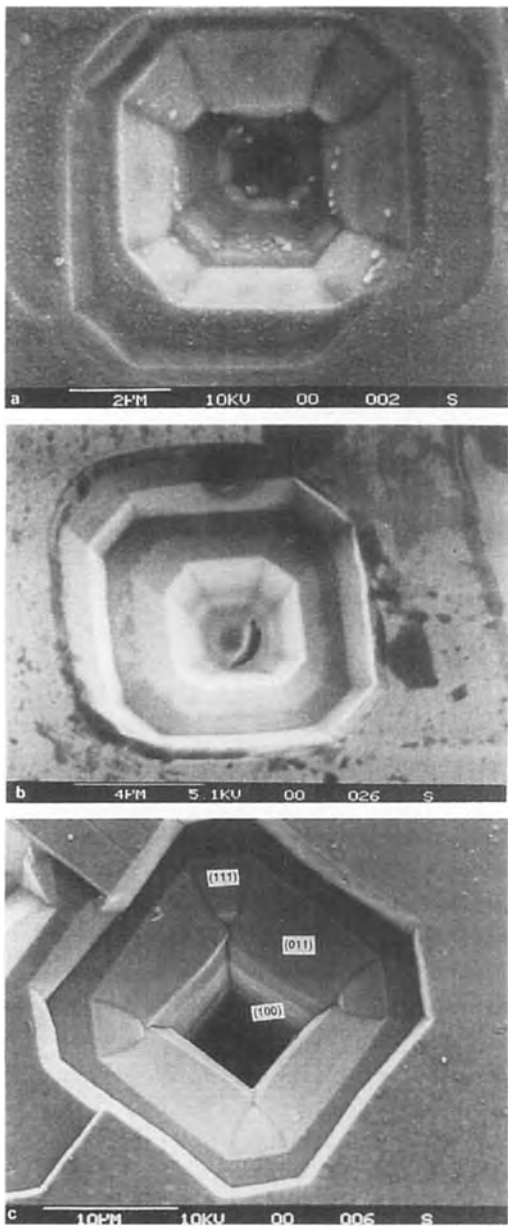

Figure 2. Different morphologies of the typical dislocation etch pits in the (001) plane of $YBa_2CU_3O_{7-x}$ single crystals. (a) By treatment in solution (1 : 4 HNO_3/acetic acid) for 5 min. (b) By treatment in acetic acid for 2 h. (c) By treatment in acetic acid for 4 h. (Courtesy of Lin and Liang [15].)

$Tl_{0.6}V_{0.5}Sr_2Ca_2Cu_3O_x$, SEM helps in establishing the conditions for obtaining single-phase material [16, 17]. As BSCCO is a very anisotropic crystal, it is very promising for thin or thick film deposition. The development of the aligned microstructure during the melt processing of doctor-bladed films can even be followed by SEM [18].

STM or AFM also study the surface, and to some extent overlap with SEM, but they offer a higher resolution; the drawback being that generally a smaller area can be studied. Detailed information on the surface morphology in single crystals of YBCO superconductors has been obtained by, for example, Van de Leemput et al. [19] and by Tanaka et al. [20]. Kroener et al. took advantage of the possibilities of AFM to study the surface and the expansion of YBCO thin films after being patterned by proton irradiation [21]. STM is particularly suited to give information on the growth mechanism of single crystals or thin films. Different reports based on STM have reported on screw dislocation growth [22–24], island growth [25], or layered etching [26]. Apparently there is still some debate on the exact growth mechanism, and some questions remain unsolved: under which conditions do the films develop screw dislocations, and when do they show a layer-by-layer growth behaviour? Zhu et al. [27] have devoted a complete study to this problem for YBCO films as well as for BSCCO films. An image is shown in Fig. 3, where the surface is seen on a unit cell scale and where, under specific conditions, screw dislocations form [27]. Atomic resolution images at room temperature and in an argon atmosphere on BSCCO

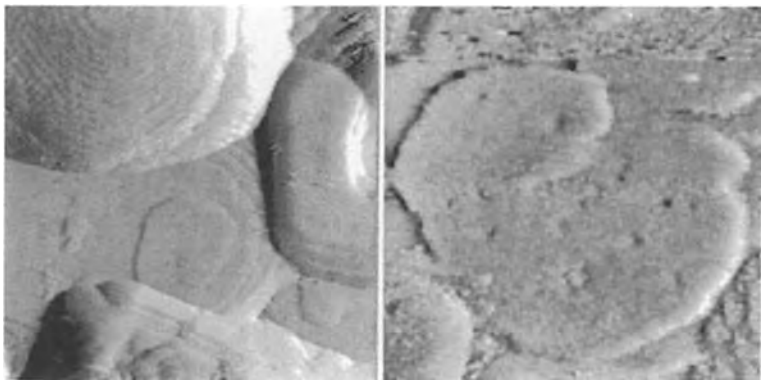

Figure 3. (a) STM image of a $YBa_2Cu_3O_{7-x}$ film grown on a flat substrate; screw dislocations nucleated at the positions of stacking faults or anti-phase domains. The size of the image is 300 × 300 nm. (b) Enlarged image of a single screw dislocation; the size of the image is 120 × 90 nm, the vertical height of the edge is one *c* parameter (1.2 nm). (Courtesy of X. Zhu et al. [27].)

superconductors (2201 as well as 2212) are shown by Boekholt et al. [28] for the [001] cleavage plane. The Bi–Bi (or O–O) distance in the plane is clearly seen. For the 2212 compound, which gives the better resolution because of the better conducting properties, the typical modulation along the *b* axis (see below for the modulated structure) is also revealed in the surface image. Even higher resolution images of the top BiO layer in the cleaved 2212 BSCCO superconductor are reported by Inoue et al. [29], when observed under high-vacuum conditions. The images show the surface modulated structure of the bismuth lattice—already observed by Kirk et al. [30] and Shih et al. [31]—with missing atom rows very clearly (Fig. 4). The modulation at the surface is formed by the ordering of the higher and the lower atoms, and the periodicity is five units, although the bulk modulation is incommensurate (see below). The presence of interstitial oxygen in the BiO layer is observed when 50% of the calcium is replaced by dysprosium [32].

8.2.3 Transmission Electron Microscopy Structural Studies

Since the high discovery of high-T_c superconducting ceramics by Bednorz and Müller [1], and particularly after

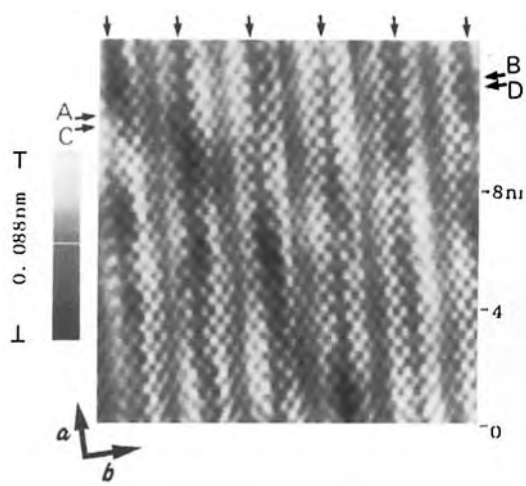

Figure 4. Top STM view (13.2 × 13.2 nm^2) of a cleaved $Bi_2Sr_2CaCu_2O_{8+\delta}$ surface taken at a tip-to-sample bias of −1.02 V and a tunneling current of 0.69 nA. The image was taken in the constant-current mode. The topographic height is shown in grey scale. The image noise is reduced with a low-pass filter. The missing atom rows are indicated by arrows.

superconductivity was found in $YBa_2Cu_3O_7$ [2], electron microscopy has played a major role in the study of superconducting materials—not only in the structural characterization of the materials, but also in the search for the flux pinning mechanism and the development of new superconducting materials. Electron microscopy has several advantages over other structural techniques, the most important being that it combines information from reciprocal space with local information from direct space. In recent years, real space imaging has improved to the level of atomic imaging (see Vol. II of this Handbook), and electron diffraction patterns can be obtained from nanometer scale areas. This makes transmission electron microscopy (TEM) (where we consider direct imaging together with electron diffraction as a unit) extremely powerful for studying small precipitates or defective structures, which for superconducting ceramics in particular are very important.

The literature on TEM studies of superconducting materials over the last 8 years is so extensive—several thousands of papers—that it is an illusion to aim for completeness. We will consider the $YBa_2Cu_3O_7$-type superconductor (1-2-3 YBCO) in somewhat more detail because it is not only the most studied material but it is also the superconductor which is closest to real applications.

8.2.3.1 Structural Defects in the $YBa_2Cu_3O_7$ Superconductor

(110) Twin Interfaces

The structure of 1-2-3 YBCO is based on the perovskite unit cell with the smaller copper ions occupying the corners of the unit cell and the larger barium or yttrium ions occupying the body-centered position; the oxygen ions occupy edge centers. The unit cell consists of three stacked perovskite unit cells along the c direction, with a regular alternation of two barium and one yttrium ions. In the fully oxygenated state ($YBa_2Cu_3O_{7-x}$) with $x = 0$, the unit cell is orthorhombic with $a = 0.382\,\text{nm}$, $b = 0.388\,\text{nm}$, and $c = 1.168\,\text{nm}$. The small orthorhombicity is due to the fact that there are copper–oxygen chains aligned along the b axis with vacant oxygen sites in between at the $(\frac{1}{2}00)$ positions. The structure is schematically shown in Fig. 5a, and a corresponding high-resolution electron microscopy (HREM) image along [100] is shown in Fig. 5b. The fact that the structure of the fully oxidized state is pseudo-tetragonal, introduces twinning on the coherent (110) or $(1\bar{1}0)$ planes; such twinning will minimize the strain introduced by the phase transformation between the tetragonal high-temperature phase and the orthorhombic low-temperature phase. The detailed structure of twin boundaries in $YBa_2CU_3O_{7-x}$ has been the subject of a large amount of speculation, and several models have been proposed. Some of these models assume the twin boundaries to be perfectly sharp up to the interface [33–35] and propose a deformed oxygen coordination around the copper atoms located in the boundary plane [36, 37]. The heavy ion sublattice is assumed to be continuous across the boundary, apart from a small change in orientation due to the twinning shear. Other models assume the boundaries to be diffuse as a result of the presence of several vacancy-containing layers parallel with the interface [38]. It

Figure 5. (a) Schematic representation of the $YBa_2Cu_3O_7$ structure. (b) HREM image along the [100] direction; there is a clear one-to-one relationship between the bright (or black) dot configuration and the heavy ion configuration in (a).

was further suggested that transition metal ions such as iron and cobalt, when substituted for copper, cause fine-scale twinning by introducing an octahedral coordination of oxygen ions around them differing from the linear arrangement in the Cu–O–Cu–O chains [39–44].

In the initial and pioneering work of the EMAT group [45, 46], we have studied 'in situ' their motion during the tetragonal to orthorhombic phase transition. These observations lead to the suggestion that the motion is a combination of a diffusion process and a shear process [47].

An ideally sharp twin boundary would look as shown schematically in Fig. 6a, that is, the orientation of the [100] (or [010]) rows changes abruptly over an angle $F = 90° - 2\tan^{-1} b_0/a_0$. Should the boundary consist of a narrow strip of tetragonal $YBa_2CU_3O_6$ structure, resulting from the presence of a number of oxygen vacancy layers along the boundary, the [100] rows would have the shape represented schematically in Fig. 6b. The orientation now changes in two steps, and a short segment having an intermediate orientation would be formed.

A perfectly sharp boundary is shown in Fig. 7a; such interfaces are observed in well-annealed, nearly stochiometric $YBa_2Cu_3O_7$. Most HREM images published in the literature exhibit a contrast as in Fig. 7b, where the twin interface seems to be spread out over several unit cells, and where the contrast is locally different from the background contrast. There is no evidence for a boundary containing a strip of O_6 structure, such as shown in Fig. 6b; moreover, if such a structure were present we would expect a local change in the interplanar spacing of the (110) lattice planes parallel with the boundary. Applying different digital image-processing methods to high-quality images we have not been able to find evidence for such a twin boundary

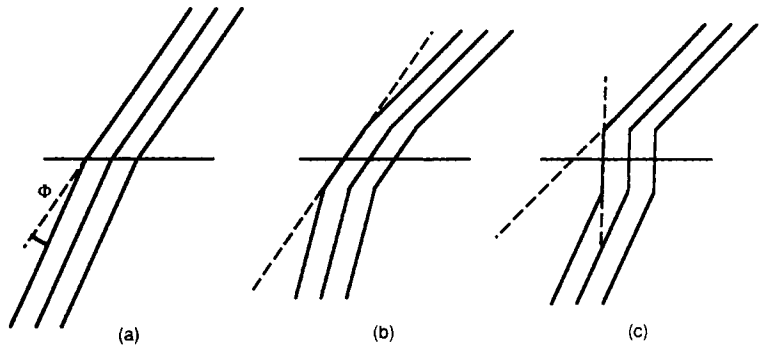

Figure 6. Schematic representation of the orientation change of the [100] lattice rows at a (110) twin boundary of $YBa_2Cu_3O_7$ for two different situations: (a) an ideally sharp boundary and (b) a narrow strip of tetragonal material is assumed to be present along the boundary. (c) A microtwin configuration. The angles are exaggerated to emphasize the characteristic features.

relaxation, putting an upper limit to the spacing change of 2×10^{-3} nm.

In YBCO samples heated 'in situ' inside the electron microscope, the boundary images are in general broadened during the few minutes after the cooling process, especially in samples which have been cycled through the orthorhombic to tetragonal transition and exhibit the short-range ordered ortho II structure due to oxygen loss. These are due, we believe, to intrinsically broad boundaries. Such boundaries sharpen up on further annealing and finally they may become sharp again, provided not too much oxygen is lost. It is reasonable to expect that in such samples the concentration of vacancies is enhanced along the twin boundaries, causing a broadened image.

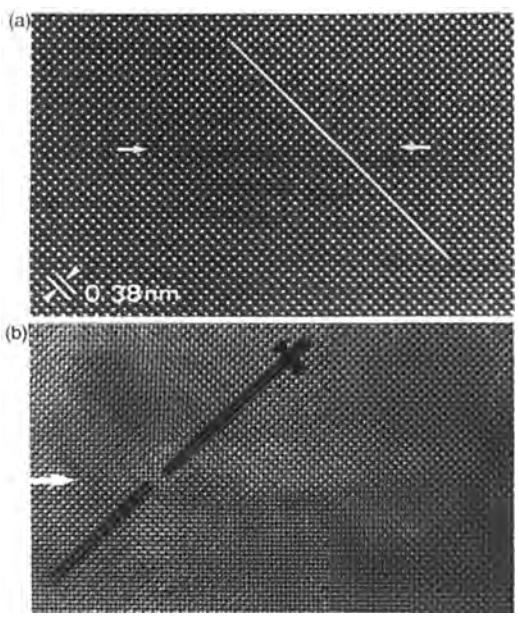

Figure 7. (a) High-resolution image of an 'ideally' sharp (110) twin boundary in $YBa_2Cu_3O_7$. Note the sudden change in orientation of the 100 lattice rows at the line indicated by arrows. (b) HREM image of an oxygen-deficient material, showing a broadened twin boundary in nonstoichiometric $YBa_2Cu_3O_{7-x}$.

The general conclusion is that in well-annealed samples with an oxygen content close to stoichiometric, twin boundaries are sharp on an atomic scale, that is, one or two atomic layers, whereas they are broadened in the oxygen-deficient samples, their width still being a function of the annealing treatment. However, in the interpretation of HREM images of twin boundaries in the literature, one has to be aware of the fact that possible misalignment or the presence of microtwins may broaden the image. The observation of

broadened twin images therefore does not necessarily mean that the boundary is actually broadened. Trivial causes of image broadening have to be eliminated before one can conclude that a boundary is 'intrinsically' broadened.

'In situ' electron microscopy studies of the tetragonal to orthorhombic phase transition has shown that on cooling through the transition, in the initial stage microdomain nuclei in the twin configuration are formed with two families of coherent interfaces, (110) and (1$\bar{1}$0). These give rise to a 'tweed' structure, due to the overlap of narrow microtwins [47], [44]. Such a tweed 'texture' is shown in Fig. 8. The corresponding diffraction pattern then exhibits overall fourfold symmetry; in particular, there is no spot splitting. However, the diffraction spots are not circular but form small crosses extending in the [110] and [1$\bar{1}$0] directions (Fig. 9). It was therefore suggested that the crystal locally still had orthorhombic symmetry whilst macroscopically it shows fourfold symmetry. It was further deduced from video recording that as soon as rather sharp observable twin boundaries are formed, the widening of the twin bands occurs by the lengthwise propagation of ledges along the twin interfaces.

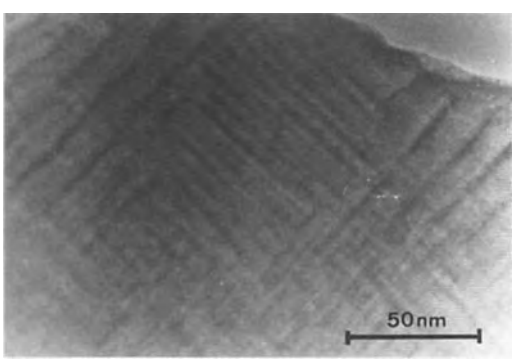

Figure 8. Coarse 'tweed' structure due to interweaved twin boundaries in a beam-heated sample.

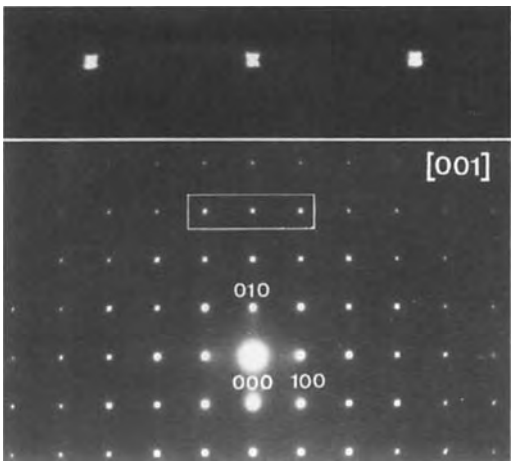

Figure 9. Diffraction pattern produced by a sample exhibiting a 'tweedy' image (see Fig. 8). Note the streaked shape of the diffraction spots in the enlargement.

In the initial stages, that is, during the formation of microdomains, the twin formation proceeds essentially by a rapid diffusion process, aided by the presence of structural vacancies in the CuO_{1-x} layers. In this stage the twin interfaces produce diffuse images, as can be judged from Fig. 8. The widening of the twin bands occurs apparently by a shear mechanism involving the propagation of twinning dislocations, driven by the ordering stresses. Since $b_0 > a_T$ and $a_0 < a_T$ ordering causes an expansion in the b_0 direction and a contraction in the a_0 direction. The cooperative deformation resulting from an ordered domain thus causes a shear stress, as represented schematically in Fig. 10c, which acts on the twinning dislocations and induces their conservative motion along the interfaces. However, in the movement of a twin plane a pure twinning shear cannot produce the desired

configuration since the rows of Cu–O–Cu–O chains have to change by about 90° in orientation, whereas the reset of the crystal structure does not change topologically and is only slightly sheared. Figure 10a represents the CuO_{1-x} layers of a crystal containing a ledged twin interface. A twinning dislocation is present at the position of the ledge. The magnitude of the twinning vector, as deduced from the schematic of Fig. 10b, is given by

$$t = \sqrt{a^2 + b^2 - 2ab\cos q} = b - a$$

since q is small ($\cos q = 1$). In order to restore the ortho I structure, the propagation of the twinning dislocations must be accompanied by 'reshuffling' of the oxygen atoms in the CuO layers along the core of the dislocation in the sense indicated by the curved arrows. The indicated shear stress in Fig. 10a induces the downward motion of the twinning dislocation. This results from the downward shift of the heavy atoms in the top part of the twin with respect to those in the lower part; the oxygen atoms, on the other hand, have to move in the opposite sense

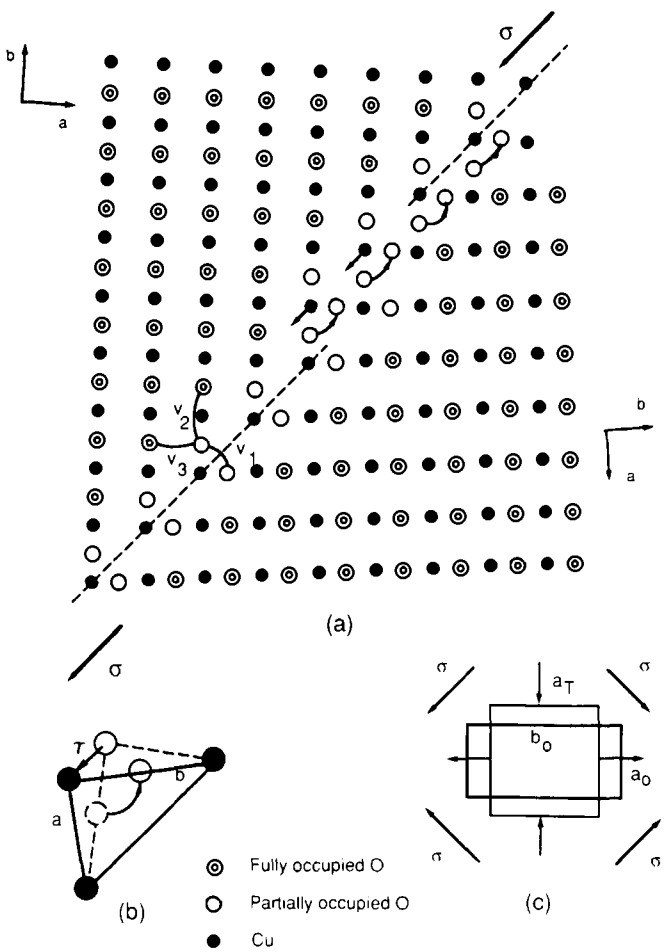

Figure 10. Schematic representation of a twinning-dislocation in $YBa_2Cu_3O_{7-x}$. (a) Atomic configuration in the CuO_{1-x} plane. (b) Atom movements during motion of the dislocation. (c) Stress pattern resulting from the orthorhombic deformation caused by ordering.

over $\frac{1}{2}[1\bar{1}0]$, as indicated by curved arrows. The resulting type of motion has been termed 'synchro-shear' motion [48]. The propagation of one twinning dislocation along the interface changes the width of the twin band by d_{110}. The rapid motion of the ledges is presumably facilitated by the presence of oxygen vacancies along the twin interface. If the boundary was highly oxygen deficient and consisted of a narrow strip of $YBa_2CU_3O_6$ structure, the reshuffling of the oxygen atoms would not even be necessary as long as such a strip is present.

It was found experimentally that twinned crystals can be 'detwinned' by the application of a uniaxial compressive stress along the [100] or the [010] directions of the perovskite lattice at a temperature of 400–450°C under a suitable partial pressure of oxygen so as to maintain the composition [49]. Similar procedures are known to be applicable to many types of crystals such as quartz, $BaTiO_3$, and ferroelastic and ferrobielastic crystals in general. Detwinning under stress can be understood on the basis of the dislocation model presented in Fig. 11. The application of a compressive stress along the *a* (or *b*) direction results in a resolved shear stress on the (110) and $(1\bar{1}0)$ coherent twin planes, which are also the glide planes of the twinning dislocations; the latter can thus move conservatively on such planes. Moreover, the compressive stress causes a bias on the sense of jumping of the oxygen atoms. The a_0 lattice parameter, which measures the Cu–Cu distance, is smaller than the b_0 lattice parameter, which equals the Cu–O–Cu distance. Jumping of an oxygen atom in the sense indicated in Fig. 11 will thus transform a b_0 distance into an a_0 distance. As a result, jumps

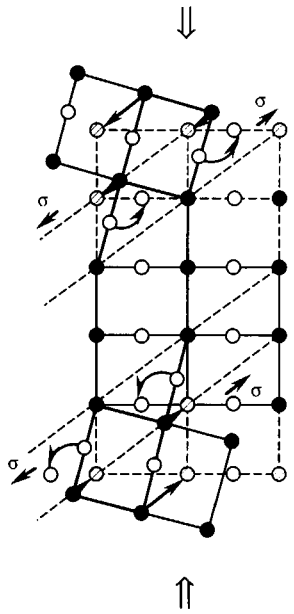

Figure 11. Schematic representation of the atomic movements during 'detwinning' under compressive stress.

which transform a Cu–O–Cu arrangement oriented along the compression axis into a Cu–Cu arrangement are energetically favored since they relieve the applied stress by shortening the specimen. These jumps are precisely those required for the synchro-shear mechanism to operate. Under the uniaxial stress the twin walls limiting a *b* domain (i.e., a domain with the *b* axis along the stress axis) will move towards one another by the combined conservative motion of twinning dislocations and oxygen jumps. Conversely, the twin walls limiting an *a* domain will move apart. The rate-determining step in the process is the short-range diffusion of oxygen along the twin boundary. Increasing the temperature to 400–450°C is therefore necessary to achieve a reasonable oxygen mobility and hence a measurable rate of the twin boundaries.

(001)-Type Defects and the Formation of $YBa_2Cu_4O_8$ and $Y_2Ba_4Cu_7O_{15}$

It is well known that deviations from the ideal composition can be incorporated in a crystal in a variety of ways, either as point defects or as extended defects. In the latter case there are still different possibilities:

(i) nonconservative stacking faults or antiphase boundaries, in chemical terminology called shear planes;
(ii) nonconservative or chemical twinning; and
(iii) precipitates limited by Frank loops.

In $YBa_2Cu_3O_{7-x}$, deviations from the stoichiometric oxygen composition are accommodated mainly as point defects, essentially oxygen vacancies in the CuO layers, which have been shown to form ordered arrangements (see later). Twin boundaries may only play a limited role in accommodating oxygen vacancies.

Excess copper, however, can be accommodated under the form of CuO, as planar defects situated in the *c* plane [50–52]. A high-resolution image of such a planar defect is shown in Fig. 12, viewed along two different directions [100] and [010]. It consists of a double layer of CuO, replacing the single layer of the normal structure (Fig. 13). In the [010] zone this double layer is viewed along the Cu–O–Cu chains; it can also be described as a set of parallel strips of CuO_4 squares in (100) planes, as represented in the [100] projection of Fig. 13. Simulated HREM images for different defocus values and different

crystal thicknesses obtained by means of the direct space algorithm are reproduced in Fig. 14, and confirm the model.

These observations have led to the development of a superconducting mixed layer YBCO family containing regular arrangements of single and double CuO layers. Members of this family are the so called 1-2-4 phase ($YBa_2Cu_4O_8$) [53, 54] and the 2-4-7 phase ($Y_2Ba_4Cu_7O_{15}$) [55]. 1-2-4 and 2-4-7 YBCO can be regarded as members of a series of 'shear structures' derived from the 1-2-3 basic structure by the periodic insertions of supplementary CuO layers. Representing the number of 1-2-3 unit cells separating these supplementary CuO layers by an integer, the 1-2-4 and 2-4-7 structures are represented by the stacking symbols $1\bar{1}$ and $2\bar{2}$ [56, 57]. The minus sign is introduced to indicate that the presence of a double CuO layer causes a lateral offset between successive 1-2-3 blocks over $\frac{1}{2}[010]$. High-resolution images along the [010] direction of the perfect 1-2-4 and 2-4-7 structures are shown in Fig. 15a and b. The double-chain layers are characterized by intense rows of elongated double white dots. Changing the initial composition does not alter the stoichiometry of the resulting material; however, to some extent different phases such as $2\bar{3}$ and $3\bar{3}$ are stabilized over limited areas. Figure 15c shows an example of a complex polytypoid over a limited region. Apart from this series of phases being a mixture of 1-2-3 and 1-2-4 where periodically double $(CuO)_2$ layers are introduced, a different series of copper-rich phases was discovered, in which successive perovskite blocks are separated by triple $(CuO)_3$ layers [58]. An example is reproduced in Fig. 16, together with a schematic inset where the CuO layer

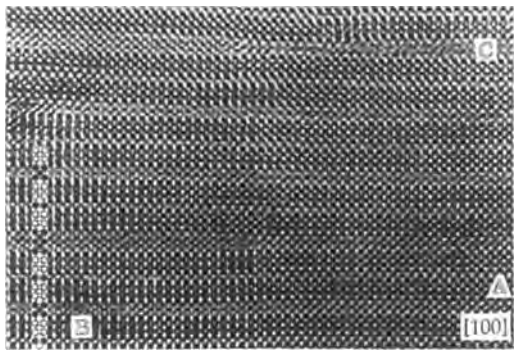

Figure 16. HREM image of YBCO, showing the local presence of triple $(CuO)_3$ and even $(CuO)_5$ layers; in the inset the CuO layers are indicated in black.

configuration is represented by black dots. In some parts of the crystal even isolated CuO multilayers consisting of as many as five CuO layers have been observed in a matrix of essentially 2-4-7 material [56, 57].

Copper Substitution in $YBa_2Cu_3O_7$ Superconductors

Although it seems well established that superconductivity is associated with the CuO_2 layers, doping of the CuO layers seems to play an important role in determining the concentration and the type of carriers. Also, the critical temperature T_c is related to the composition of the CuO layer. It could for instance be shown that the 60 K plateau in the curve relating T_c to the oxygen content in this layer is associated with the presence of the $2a_0$ structure, that is, with the material with ideal composition $YBa_2Cu_3O_{6.5}$ [59–61]. It was attempted to replace copper in the CuO layers, either completely or partly, by other metallic ions such as iron, cobalt, zinc, gallium. Also complex ions such as CO_3^{2-} or SO_4^{2-} were incorporated in the CuO layer, carbon and sulfur occupying copper sites in the CuO chains. Iron substitution is found to induce a 'tweed' texture, the geometry of which could be assessed by assuming that iron occurs in the CuO layers in two types of oxygen coordination: octahedral and tetrahedral. The tetrahedrally coordinated iron ions induce microtwinning by the nucleation of CuO chains along mutually perpendicular directions, which causes the tweed microtexture [62]. Cobalt substitution in small concentrations has a rather similar aspect [63].

Oxygen-Deficient $YBa_2Cu_3O_{7-\delta}$

From a microstructural point of view, $YBa_2Cu_3O_{7-\delta}$ is an interesting compound. It allows a large number of oxygen vacancies ($0 \leqslant \delta \lesssim 1$) in the oxygen sublattice. Depending on their concentration, these vacancies tend to occur in various ordering schemes [33, 46, 64–83]. The $2a_0$ superstructure (ortho II) in nonstoichiometric $YBa_2Cu_3O_{7-\delta}$, due to the alternation along the a_0 direction of filled and empty CuO chains in the CuO layers, was also discovered by electron diffraction and electron microscopy [64, 79, 80]. The oxygen ordering occurs within nanometer-sized domains and is generally highly faulted; therefore, it is difficult to detect by X rays or neutrons. On the other hand, these small dimensions make them eligible for flux pinning centra.

Another important feature of the YBCO compound is its susceptibility to allow elemental substitutions on most of its sublattices, without substantially altering the structure, but inducing quite different physical and chemical properties. We will focus here on those aspects where electron microscopy and electron diffraction have played important roles in

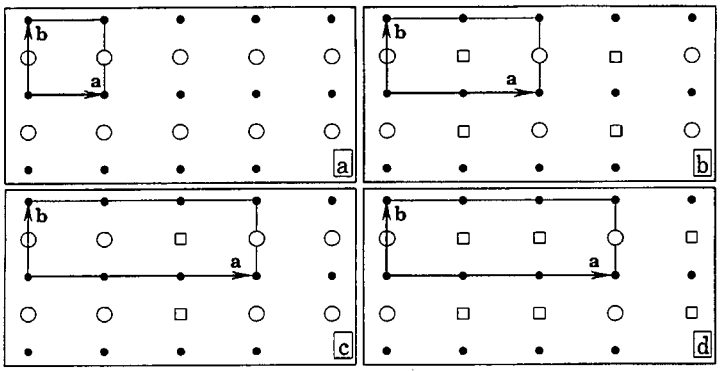

Figure 17. (a) Schematic representation of the CuO plane ortho I ordering. (b) Model of the ortho II ordering. Along a CuO and Cu vacancy, chains alternate. Representations of ordering leading to tripled a-parameters: (c) the ortho III phase with an oxygen content of 6.667; (d) a symmetric phase where roles of vacant and filled chains are reversed, which occurs at oxygen contents of 6.333.

elucidating the structure and bridging the gap between physical properties and structural data.

At room temperature and atmospheric pressure, within the range $0 \leqslant \delta \lesssim \delta_t$, the structure of $YBa_2Cu_3O_{7-\delta}$ is orthorhombic and within the range $\delta_t \lesssim \delta \leqslant 1$, it is tetragonal. Values for δ_t vary around 0.65 [68, 84–88]. In experiments where δ is fixed, the transition temperature T_t increases linearly with δ [89]. Reported values for the orthorhombic to tetragonal transition temperature range between 110°C at $\delta = 0.67$ and 680°C at $\delta = 0.34$.

In the tetragonal phase, the oxygen atoms in the CuO layer are distributed quasi-randomly, with an equal occupation of the O(1)- and O(5) sublattices. The sublattices consist of the oxygen sites between every two copper atoms in the plane, the O(1) sites lying along one direction (defined as ***a***), the O(5) sites along the other (Fig. 17). The formation of short CuO segments along both basic directions of the CuO chain plane is likely to cause local orthorhombic strains that lead to the pretransition tweed texture.

The presence of short-range ordering of oxygen and vacancies is revealed in electron diffraction patterns by the occurrence of diffuse intensities. The diffuse streaks observed in the [001] zone diffraction pattern of Fig. 18 are due to the presence of irregularily spaced, short segments of CuO chains. Short-range order is commonly observed in highly oxygen-deficient samples and can be induced in oxygen-rich materials by a thermal disordering by an in situ heating treatment.

The orthorhombic phase that corresponds to $YBa_2Cu_3O_7$ ($\delta = 0$), is termed 'ortho I'. The CuO plane in the ortho I phase has all O(1) sites filled and all O(5) sites vacant. CuO chains run along ***b*** (Fig. 17a). As a result, for the ortho I phase $a_0 \lesssim b_0$. A second phase, termed ortho II, has every other ***b***-oriented chain evacuated

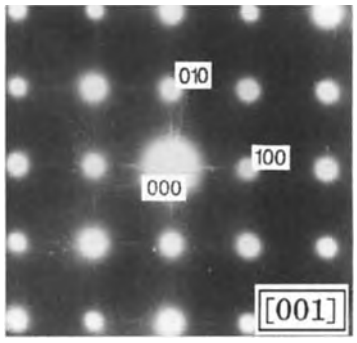

Figure 18. Electron diffraction pattern along the [001] zone, in a tetragonal sample (from the observation of unsplit spots). In situ heating and cooling causes disorder reflected in the presence of diffuse scattering along the basic directions.

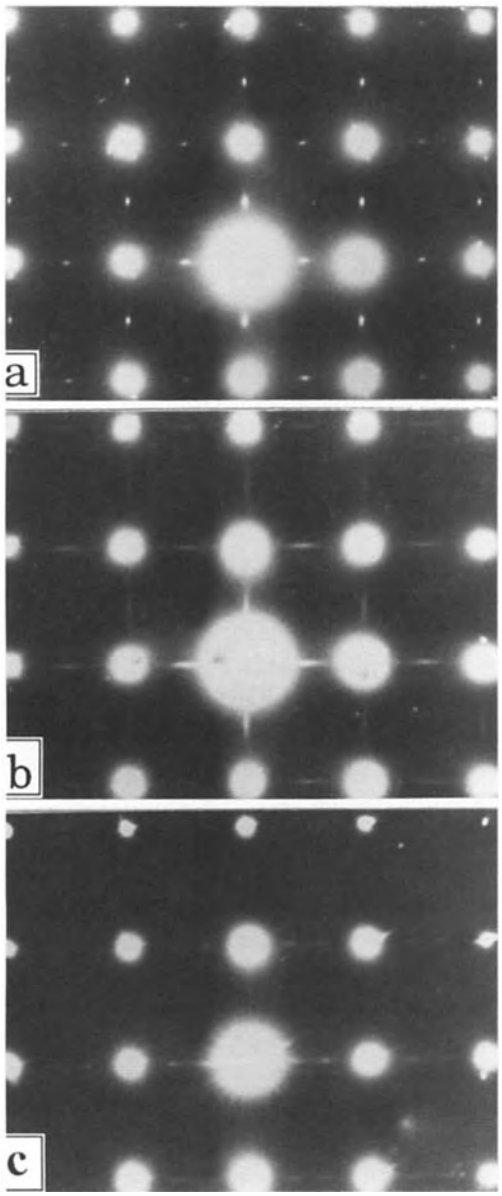

Figure 19. (a) [001] zone diffraction pattern with sharp superstructure reflections at positions $h + \frac{1}{2}k\,l$ appearing in well-ordered ortho II material. Since the material is twinned, spots seem to appear along both basic directions. (b) [001] zone diffraction pattern with streaked superstructure intensity, corresponding to domains that are short-range ordered along ***a***, occurring at oxygen contents at the slopes above and below the ortho II plateau. (c) [001] zone diffraction pattern with spots at positions $h + \frac{1}{3}k\,l$ and $h + \frac{2}{3}k\,l$ due to an ortho III structure occurring in samples with oxygen contents around 6.8.

of oxygen and has an ideal composition $YBa_2Cu_3O_{6.5}$ ($\delta = 0.5$) (see Fig. 2b). The oxygen content range in which the ortho II phase is observed stretches over $0.3 \lesssim \delta \leqslant 0.5$. The new unit mesh that can be defined on the ordered $CuO_{1-\delta}$ plane has dimensions $a_{II} = 7.668\,\text{Å} \approx 2a_p$, $b_{II} = 3.869\,\text{Å} \approx b_p$ (based on Cara et al. [64]). The ortho II phase is easily recognized in [001] electron diffraction patterns (Fig. 19); it produces superstructure spots at positions $h + \frac{1}{2}kl$, characteristic for a doubling of the a parameter. Often, however, in such patterns the b parameter also seems doubled by the appearance of spots at positions $hk + \frac{1}{2}l$ as well. These spots are due to their basic (110) twinning of the orthorhombic matrix, the resulting diffraction pattern (Fig. 19) being the overlap of the two identical patterns, with a rotation difference of about 90°. It was shown by Van Dyck et al. [90] that a disordered array of line defects gives rise to Lorentzian-shaped diffraction spots, with a position associated with the mean spacing of the scattering elements. When chains in the CuO plane are irregularly spaced with a mean spacing of $2a_p$, Lorentzian-shaped diffraction spots at positions $h + \frac{1}{2}kl$ are expected. When the average periodicity increases, the superstructure reflections will become more elongated (Fig. 19b). A second factor influencing the superstructure reflection shape is the ortho II domain shape, small domain dimensions leading to elongated reflections. Intensity and sharpness of the superstructure reflections can thus be considered as indices of the domain size and the ordering quality of the phase. Whereas

an ideal ortho II domain has an oxygen deficiency of $\delta = 0.5$, the strongest and sharpest ortho II electron diffraction intensity occurs at an oxygen deficiency of only $\delta = 0.4$ [91]. The domain size and the ordering quality are thus apparently maximized at $\delta = 0.4$.

Dark field images allow the visualization of the oxygen-ordered domains. The images show that the ortho II domains are elongated or lenticular in shape, with the short axis along the ***a*** direction. The largest ortho II domains (4×20 nm) and a maximal ortho II volume occur at oxygen deficiencies of $\delta = 0.4$. For the $\delta = 0.4$ sample of Zhu et al. [67], from measurements of the ortho II peak surface in a [100] electron densitogram, the ortho II volume fraction was an estimated 50%, in accordance with our results. Samples showing elongated ortho II diffraction spots, correspondingly show ortho II domains in dark field images (Fig. 20b) with reduced dimensions along ***a*** (size: 1×20 nm).

Under high-resolution conditions, imaged along the [100] direction, the ordered domains can be easily visualized. Such images also allow deduction of the stacking of the vacancy rows in successive $CuO_{1-\delta}$ planes along the c axis (Fig. 21). The normal stacking of these rows is vertical, but small domains of a staggered stacking of successive two-dimensional-ordered CuO planes are no exception. The ordered domains also reveal antiphase boundaries with a displacement vector $\boldsymbol{R} = \frac{1}{2}[100]_{OIIa}$. This is best visible under grazing angles along the [001] direction, and indicated by a white line, broken at the defects.

Instead of a doubling of the unit cell due to oxygen vacancy ordering along the

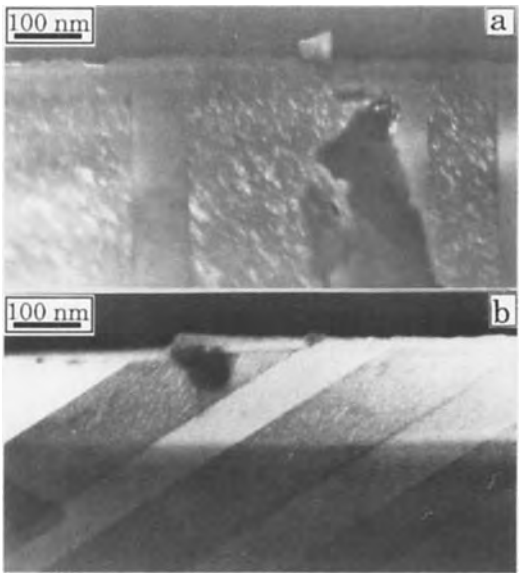

Figure 20. (a) Dark field image showing ortho II ordered domains as bright areas. The corresponding diffraction pattern is shown in Fig. 19a. (b) Dark field image corresponding to Fig. 19b. Domain size is short along ***a*** and large along the CuO chain direction ***b***. The band structure in these images is due to twinning.

b axis, one can imagine different ordering schemes, introducing tripling, quadrupling, and so on of the basic ortho I structure. Electron microscopic observations of the ortho III phase have been reported (Fig. 19c), but much less and more ill-defined than the ortho II phase [72, 92, 93]. Due to the short structural coherence length of this phase, their presence could not be detected neither by X-ray nor by neutron diffraction. The ortho III phase ideally appears at an oxygen deficiency of $\delta = \frac{1}{3}$ (or $\frac{2}{3}$), and compared to the ortho I phase, one out of three Cu_1O_1 chains is depleted of oxygen (see Fig. 17c).

Superstructures with longer periodicities of $4a_p$ and $5a_p$ have also been observed by electron microscopy [94, 95]. These

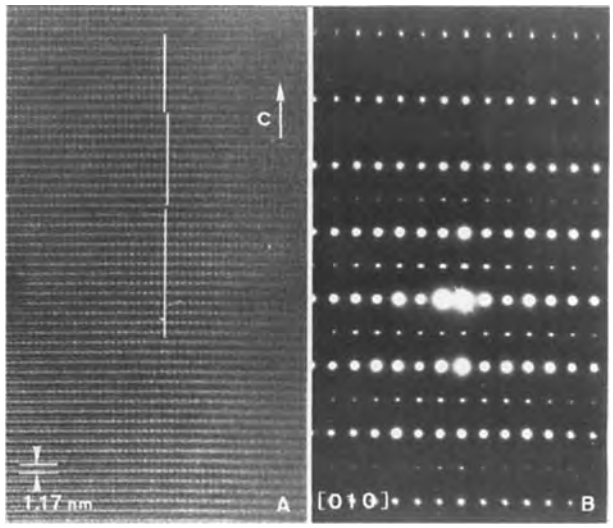

Figure 21. High-resolution images along the [010] axis, of the ortho II phase. The cell doubling can be seen by the white dots that appear every $2a_p$. In this view along the chains, chains are stacked vertically along *c*. Note the presence of antiphase boundaries with displacement vector $\boldsymbol{R} = \frac{1}{2}[100]$.

phases appear on very local scales (a few unit cells wide), and therefore have only been observed by means of HREM. Identifying these phases as (Cu–O) chain ordered phases, they should probably be considered as metastable phases at oxygen contents intermediate to that of the stable ortho I, ortho II, and ortho III phases. Theoretical studies seem to support this conclusion [96, 97].

8.2.3.2 Superconducting Materials and Modulated Structures

Modulated structures, that is, superstructures, commensurate or incommensurate, built on a basic structure, occur frequently in organic chemistry, and this is not different in the family of high-T_c superconducting compounds. We have already discussed the vacancy ordering in YBCO, which introduced doubling, tripling, and so on of the basic unit YBCO unit cell along the *b* axis. We will briefly review here the deformation-modulated structures in the bismuth family (BSCCO) of superconducting compounds and the modulated structures in the thallium- and mercury-based materials by the introduction of carbonate groups. We will also briefly comment on the relationship (or absence of it) between superconductivity and the presence of modulated structures. In less detail we will describe the unusual modulation in the copper-free superconductor $Ba_{1-x}K_xBiO_3$ and the interface-modulated structure in oxygen-deficient La_2CuO_{4-x}.

$Bi_2Sr_2Ca_nCu_{1+n}O_{6+2n}$

It is well established now that the superconducting transition temperature for the $Bi_2Sr_2Ca_nCu_{1+n}O_{6+2n}$ and $Tl_2Ba_2Ca_nCu_{1+n}O_{6+2n}$ compounds depends upon the composition of the material, that is, upon the value of *n*. The critical temperature for the $Bi_2Sr_2Ca_nCu_{1+n}O_{6+2n}$ compounds increases with increasing *n* value from 20 K for $n = 0$ to 80 K for $n = 1$ and to 110 K for $n = 2$ [98–100]. For the thallium

compounds these changes are 80 K for $n = 0$, 110 K for $n = 1$, and 125 K for $n = 2$ [101].

In the bismuth compounds the basic structure is further modulated. This modulation is incommensurate for all compounds but varies with composition, oxygen content, and doping with foreign elements. However, no visible temperature dependence of the modulation has been observed between 20 and 750 K. Since the modulation is a structural aspect, occurring at the atomic level, the most suitable technique to image and investigate it is TEM. Other imaging techniques lack the resolution or they only give information about the surface effects (e.g., AFM or STM). The modulation was first studied by TEM and only later by diffraction techniques such as X-ray or neutron diffraction.

The pure $Bi_2Sr_2Ca_nCu_{1+n}O_{6+2n}$ compounds for different values have been studied by a large number of groups; their HREM results can be found in the literature [102–110]. The effect on the modulation of substituting several elements, such as lead for bismuth, lanthanum for strontium, or yttrium for calcium, is also well documented [111–120].

The most illustrative section in reciprocal space for the description of the modulated structure is $(110)^*$, which is reproduced for the pure BSCCO compound in Fig. 22 for $n = 0$ and 1. Every reflection of the type $00l$ or $11l$ acquires a linear sequence of several satellites. These satellites are situated in the $(110)^*$ plane, but they are not oriented along a simple crystallographic orientation; moreover, the orientation as well as the length of the modulation vector is slightly variable. The wave vector can be modified by partially substituting Sr^{2+} by La^{3+}; details

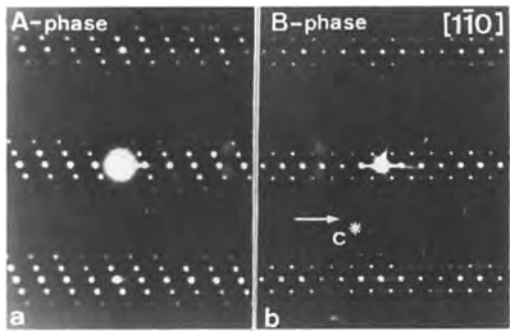

Figure 22. [1$\bar{1}$0] electron diffraction patterns in $Bi_2Sr_2Ca_nCu_{1+n}O_{6+2n}$ showing the incommensurate modulation for (a) the $n = 0$ compound (A phase) and (b) the $n = 1$ compound; the modulation is clearly different.

about these experiments as well as structural models and speculations about the modulation can be found in Zandbergen et al. [120]. In the undoped $n = 0$ material the modulation is roughly along $[115]^*$, but the wavelength is still incommensurate and is of the order of 2.4–2.5 nm. The high-resolution images along the [110] zone clearly reveal the modulation as well as the lattice distortions associated with it (Fig. 23). The (001) planes in the image

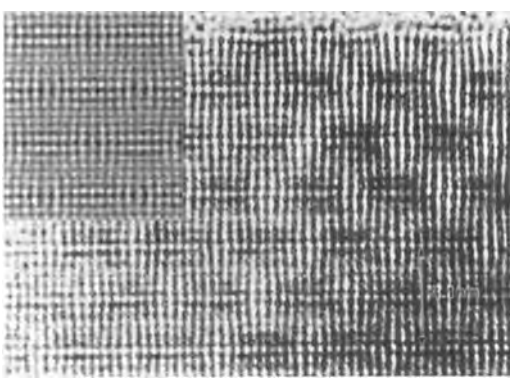

Figure 23. HREM of the $n = 1$ phase of BSCCO, viewed along the [110] direction. Both the (001) and (110) planes exhibit a wavy character. The computed image, for a model exhibiting an excess oxygen shows good correspondence with the experimental micrograph.

are clearly buckled; the lines of more intense white dots can be interpreted as BiO layers, and the variation in spacing along [110] is appreciable. The $n = 1$ phase and $n = 2$ phase produce a similar diffraction pattern (see Fig. 22b); the satellites are also located in the $(110)^*$ plane, and the wavevector $\boldsymbol{q}$ can be chosen along $[110]^*$ and has a wavelength of 2.5–2.6 nm. In the direct image the distortion of the (001) layers is clearly strongest for the $(BiO)_2$ double planes. The observed spacing changes in the BiO–BiO layer distance is of the order of 0.07 nm for the $n = 1$ compound; for $n = 2$ this distortion seems to be less pronounced. The modulation reduces the symmetry of the structure to orthorhombic with point group *mmm*. Such a description of the modulated structure is more elegant in a four-dimensional space; taking the *a* and *b* axis along $[1\bar{1}0]$ and [110], respectively with a length of 0.54 nm and the modulation along the *b* axis one observes systematic extinctions for *hklm* when $h + l + m = 2n + 1$, which suggests the space group to be $L^{Bmmm}_{1\,\underline{1}\,1}$.

Over the years there has been a lot of speculation and a lot of experiments performed to find out the exact reason for the modulation, as well as its relationship with the superconducting properties. Some of the possible reasons for the modulation are: the partial absence of strontium atoms, the partial substitution of bismuth by copper or strontium, the incorporation of extra oxygen, a change in the position of the lone pairs of bismuth, and a lattice mismatch between the BiO double layer and the perovskite layer. These possibilities are discussed in more detail and compared with the experimental evidence by Zandbergen et al. [120].

At this moment the most widely accepted model combines several aspects of the originally proposed model. The main reason for the modulation is the structural misfit between the perovskite slab and the BiO_2 double layer; this misfit introduces strains in the double layer, which because of the asymmetrical arrangement of the electronic configuration (lone pair) of bismuth allows it to be deformed. This deformation then creates the possibility of introducing extra oxygen. This interpretation has also been confirmed by X-ray and neutron experiments [121–126]. Calestani and co-workers [127, 128] have done clear experiments to replace calcium by yttrium and/or bismuth by lead, and following the modulation behavior as well as the superconducting properties. Their conclusion is that superconductivity can occur even in unmodulated material, whereas modulated materials can easily be obtained which are nonsuperconducting. Pham et al. [129] also conclude that superconductivity and structural modulation are not related; also, they find that a modulated structure can exist in pure BSCCO material without any oxygen excess.

$Tl_2Ba_2Ca_nCu_{1+n}O_{6+2n}$

The thallium compounds with compositions $Tl_{2-x}Ba_2Ca_nCu_{1+n}O_{6+2n}$ exhibit the phenomenon of 'mixed layer polytypism', which consists of the occurrence of different stacking sequences of similar lamellae with different thicknesses so as to lead to structures with different ideal chemical compositions. If instead of a double TlO layer only a single (or eventually a triple) TlO layer is present, no offset is observed between successive

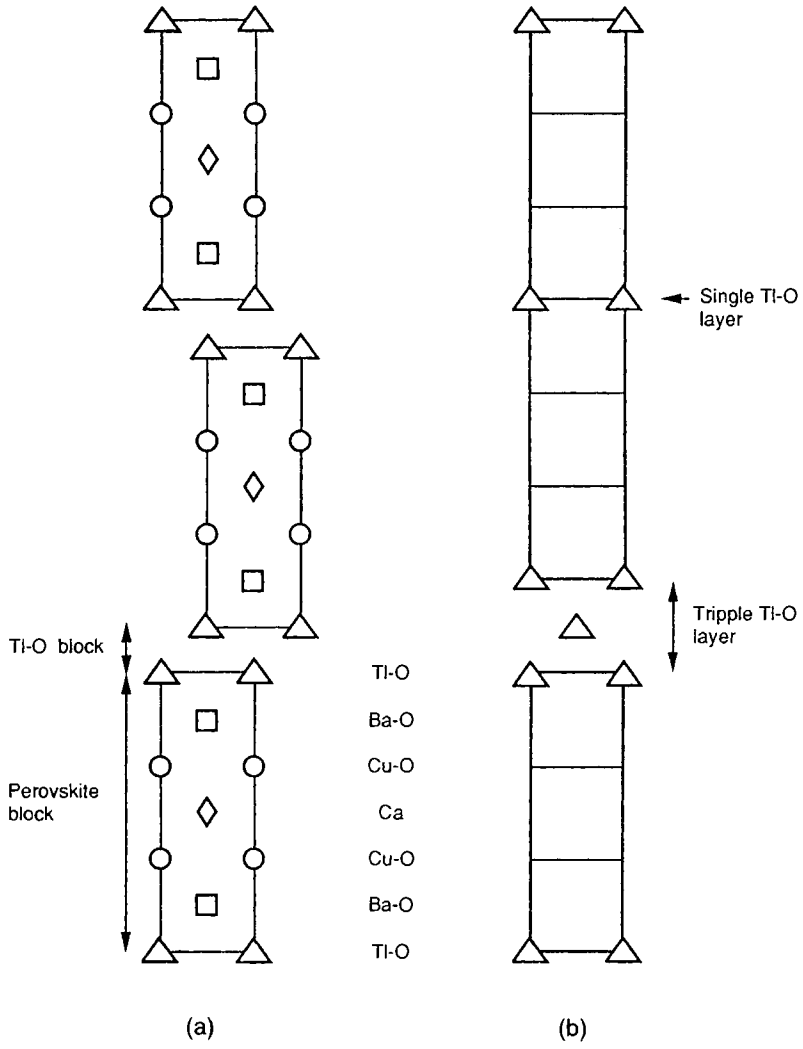

Figure 24. Schematic representation of thallium-based superconducting compounds. (a) The regular 2212 configuration, with double TlO layers. (b) A defect configuration with single or triple TlO layers.

perovskite blocks; this is shown schematically in Fig. 24. Such structures having a monolayer of TlO have been discovered by Parkin et al. [130]. In a specimen with thallium deficiency one can observe stacking sequences with very large periods such as the one reproduced in Fig. 25a. The diffraction pattern of such an area apparently exhibits streaks along the c^* direction, but in reality these streaks can be resolved as sharp spots, suggesting that a regular stacking sequence with a very long period is present (Fig. 25b). To determine the stacking sequence in such a long-period compound, HREM is a unique tool. An example in which all atom columns are clearly resolved is reproduced in Fig. 26. The period is 21 nm and the stacking sequence is indicated. It should further be noted that between a number of successive perovskite blocks an offset is observed whereas this is not the case

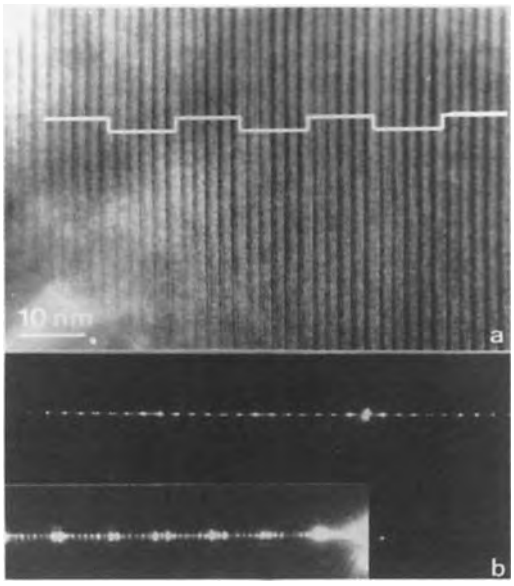

Figure 25. (a) Low magnification of a thallium long-period mixed-layer polytype; the periodicity has been indicated. (b) Electron diffraction pattern of a long-period polytype showing almost continuous streaking. The enlarged inset, however, reveals a dense arrangement of sharp diffraction spots.

between other successive perovskite blocks. This indicates that double as well as single TlO layers occur. This has also been indicated in Fig. 26 where a single and a double bar are used to indicate, respectively, a single and a double TlO layer. A striking feature apparent from this figure is the fact that the sequence of blocks, although complicated, repeats over large areas and that, moreover, also the sequence of single and double layers of TlO repeats with the same regularity. The unit cell of the resulting mixed-layer polytype is body centered. More details, and a convenient way to describe such complex polytypes, can be found in the literature [131, 132].

Long-Period Shear Structure in La_2CuO_{4-x} [133, 134]

The undoped La_2CuO_4 crystallizes in an orthorhombically deformed K_2NiF_4-type structure with lattice parameters $a = 0.5355\,\text{nm}$, $b = 0.5441\,\text{nm}$, and $c = 1.353\,\text{nm}$. The orthorhombic distortion introduced below 530 K is due to a correlated tilting of the CuO_6 octahedra, which are assumed to be rigid and corner linked.

In oxygen-deficient material, however, a shear structure is formed to accommodate the local nonstoichiometry. Evidence is shown in Fig. 27, which is a high-resolution image along the perovskite *a*

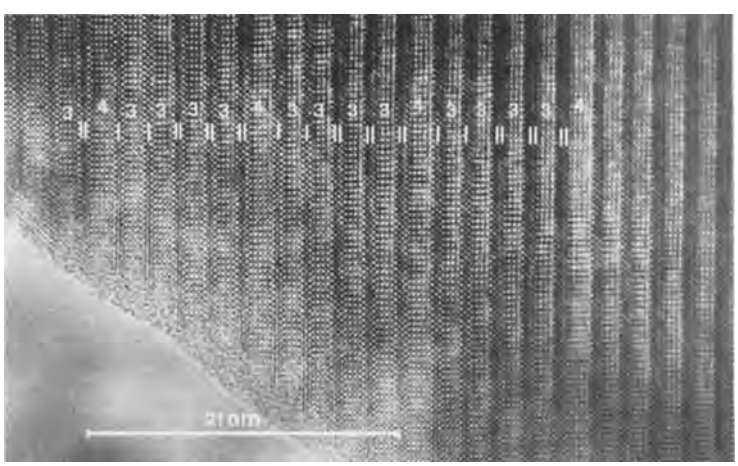

Figure 26. High-resolution image of the long-period polytype of Fig. 25a; the repeat unit of 21 nm is indicated together with the building sequence. The perovskite blocks are indicated by the numbers 3 ($n = 3$) or 4 ($n = 4$), while double and single TlO layers are indicated by double and single lines, respectively.

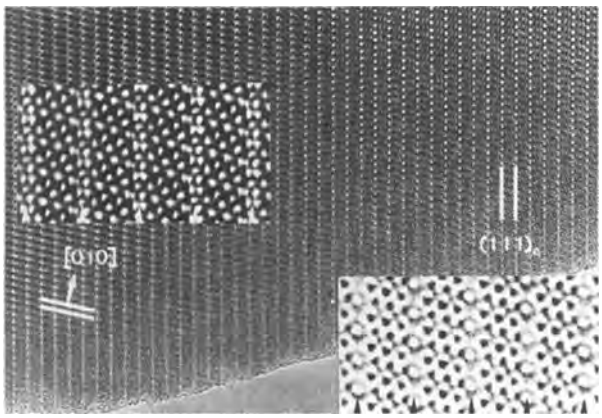

Figure 27. Large area of the La_2CuO_{4-x} shear structure viewed along the $[100]_p = [101]_o$ zone; insets are magnified images at two different thicknesses. The ion columns are imaged as bright dots.

axis, that is, along the orthorhombic [101] axis. Vertical crystallographic shear planes, parallel to the (111) planes of the orthorhombic unit cell, show up prominently in this image. The corresponding diffraction pattern is reproduced in Fig. 28a; the rows of closely spaced reflections are perpendicular to the family of interfaces revealed in Fig. 27, and their spacing is consistent with the observed spacing between successive interfaces. Exploring carefully reciprocal space indicated that all reflections can be indexed in a new monoclinic unit cell related to the basic perovskite lattice parameters by the relation

$$\begin{matrix} \boldsymbol{a}_m \\ \boldsymbol{b}_m \\ \boldsymbol{c}_m \end{matrix} = \begin{matrix} \frac{1}{2} & 0 & \frac{1}{2} \\ 0 & 2 & 0 \\ 7 & 0 & -2\epsilon \end{matrix} \begin{matrix} \boldsymbol{a}_{1,p} \\ \boldsymbol{a}_{2,p} \\ \boldsymbol{c}_p \end{matrix}$$

where ϵ is a small quantity accounting for the offset in the b_0 direction along the shear planes. The approximate lattice parameters of the new interface modulated phase are

$$a_m = 0.66\,\text{nm}$$
$$b_m = 0.76\,\text{nm} \qquad b = 103°$$
$$c_m = 2.66\,\text{nm}$$

From the reflection conditions (l even for $h0l$- or $00l$-type reflections) and taking into account the possibility of double diffraction in electron diffraction, one obtains the space group $P1c1$ or $P12/c1$.

More structural information, however, can be obtained from the high-resolution images, such as that of Fig. 29. This image was obtained from a very thin part of the specimen where the heavy ion columns are imaged as dark dots; the shear planes which are less obvious here are vertical. The correspondence with the crystal structure is indicated in the right bottom

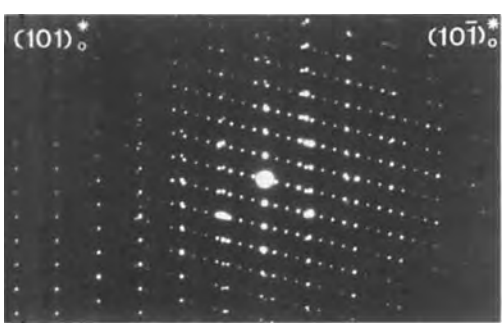

Figure 28. Diffraction pattern of the La_2CuO_{4-x} shear structure across a twin boundary showing the superposition of the $(101)^*$ section, not showing the structure (left part) and the $(\bar{1}01)^*_o$ section exhibiting rows of superstructure spots.

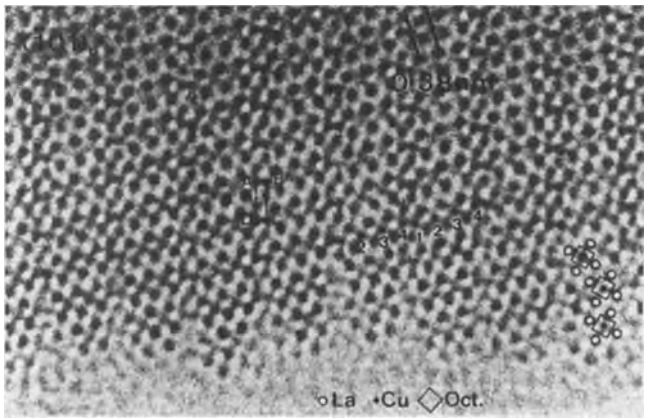

Figure 29. High-resolution image of the long-period shear structure along the a_p zone. The heavy ion columns are imaged as dark dots, the oxygen columns remain invisible. The relation with the basic La_2CuO_4 structure is indicated.

corner. Along the shear planes the projected separation of copper ion columns, such as those numbered 1 and 4, is about $\frac{1}{2}a_p$, which is consistent with the projected separation of the centers of edge-sharing CuO_6 octahedra. This projected structure is represented in Fig. 30.

The proposed model implies that the oxygen loss and the accompanying crystallographic shearing take place above the tetragonal–orthorhombic transition temperature of 530 K, thereby forming a shear structure with the space group $P12/c1$. On cooling, tilting of the

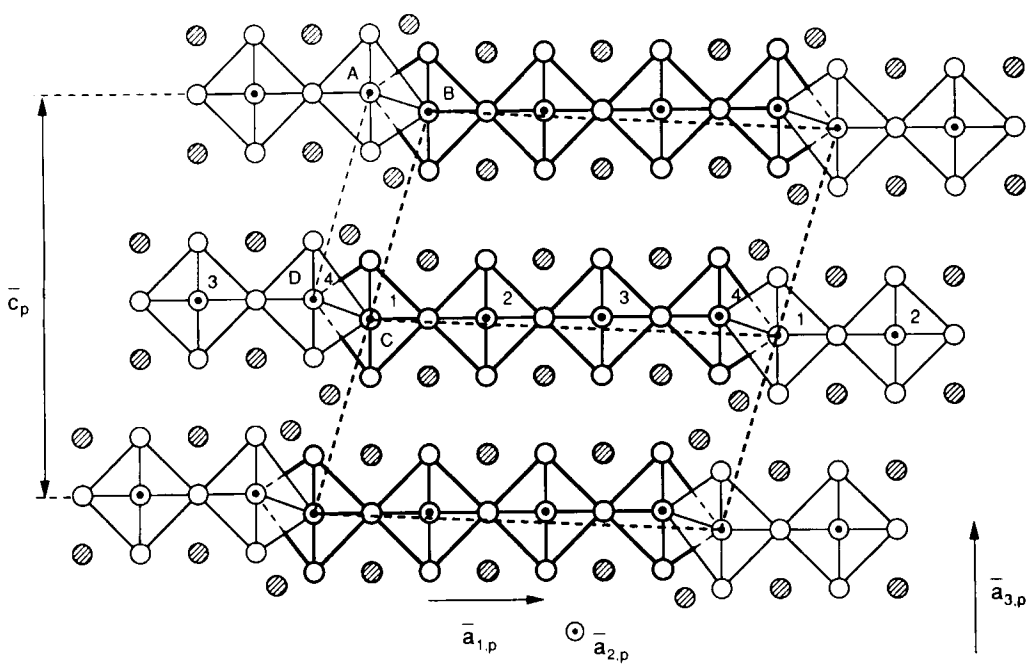

Figure 30. Schematic view of the La_2CuO_{4-x} shear structure along the zone parallel with a_p; the shear planes are formed by edge-shearing CuO_6 octahedra; the tilt of the octahedra has not been represented.

octahedra takes place [133], which is imposed by the edge and corner sharing of the octahedra. The twofold axis is lost and the space group now becomes $P1c1$, which is a subgroup of $P12/c1$, exhibiting the same diffraction conditions.

This is clearly an example of a long-period interface modulated structure where one can determine a new structure exclusively from:

(a) the structure of the unmodulated phase;
(b) electron diffraction of the modulated phase, yielding the space group; and
(c) direct imaging by HREM to determine the displaced atom positions.

Incommensurate Deformation Modulation in $Ba_{1-x}K_xBiO_3$

The overwhelming majority of the new high-T_c superconductors do contain copper; however, $Ba_{1-x}K_xBiO_3$ with $x \approx 0.4$ shows bulk superconductivity below 30 K. Its basic structure is that of the perovskite ABO_3 with A = Ba or K, and B = Bi. It consists of a framework of corner-linked oxygen octahedra. Depending on composition and temperature, rigid tilt of the BO_6 octahedra, combined with a deformation of the octahedra ('breading mode distortion'), give rise to a number of structural phase transitions. More details on these phase transitions and on their relationship to the superconducting properties are given by Verwerft et al. [135].

A structural modulation, incommensurate with the basic lattice, was first reported by Chaillout and Remeika [136] in oxygen-deficient $BaBiO_{3-x}$; Pei et al. [137, 138] observed a similar modulation in $Ba_{1-x}K_xBiO_3$ for all the nonsuperconducting compositions. They showed that the modulation wavelength varies systematically with the potassium content. The interpretation of the modulation has been the subject of several speculations. According to some [38] it is to be attributed to a vacancy ordering, others [137, 138] associate the modulation with the presence of a charge density wave, while Hewat et al. [139] proposed a model involving partial ordering of Bi^{3+} versus Bi^{5+}, accompanied with bismuth or oxygen displacements correlated with the Bi^{3+} lone pair ordering.

Electron irradiation experiments were carried out for accelerating voltages between 40 and 400 kV. Below 100 kV no atom replacements, not even for the light oxygen, are expected. Typical behavior for the investigated $Ba_{1-x}K_xBiO_3$ samples under the electron beam is shown in Fig. 31. After a minimal electron dose, no satellite reflections are observed (Fig. 31a); superstructure reflections appear after

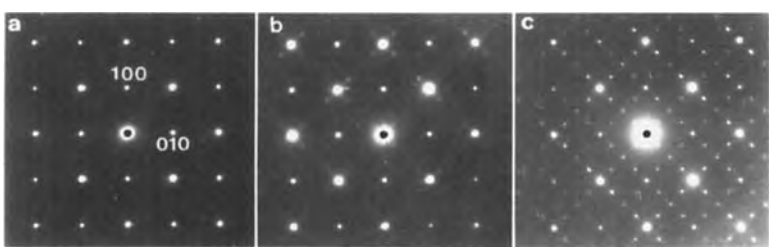

Figure 31. Electron irradiation effect observed in a [001] zone axis orientation of $Ba_{1-x}K_xBiO_3$ (a) after a few seconds of observation. No satellite reflections are observed. (b, c) On irradiating the sample with a defocused electron beam, satellite reflections become visible, and their intensity increases with irradiation.

longer irradiation times (Fig. 31b and c). Care is taken to avoid heating of the sample, so that the modulated structure is to be associated with an electron irradiation effect. Around each basic spot, four satellite reflections are observed in the [001] zone axis diffraction pattern. The wavevectors corresponding to this modulation can be written as $\boldsymbol{q}_1 = (\frac{1}{4} - \epsilon)[110]^*$ and $\boldsymbol{q}_2 = (\frac{1}{4} - \epsilon)[1\bar{1}0]^*$. Actually, in three-dimensional reciprocal space one finds that every basic reflection is surrounded by 12 satellite reflections along all $\langle 110 \rangle$ and $\langle 1\bar{1}0 \rangle$ directions. High-resolution micrographs show that the modulated structure is broken up into microdomains with an average size of 10 nm (Fig. 32). In each of these domains the modulation is described by a single wavevector. The electron diffraction patterns such as Fig. 31c are therefore to be interpreted as a superposition of different microdomains.

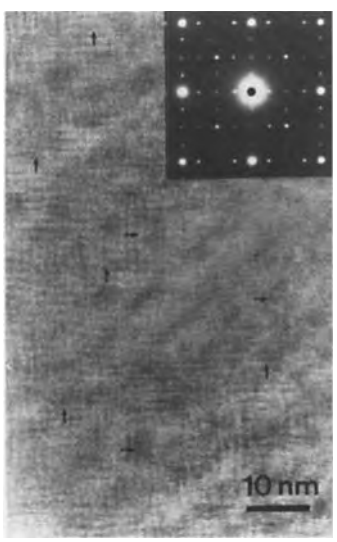

Figure 32. High-resolution micrograph evidencing the existence of microdomains. In each of these domains, the modulation is single wavevector, the modulation wavevector directions are schematized by small arrows.

In each of these microdomains the modulation is described by a single wavevector, which can be written as $\boldsymbol{q}_1 = (\frac{1}{4} - \epsilon)[110]^*$.

The wavelength of the modulation, that is, ϵ, varies with the potassium content. The incommensurability varies from $\epsilon = 0.049$ for $x = 0$, to $\epsilon = 0$ for $x = 0.4$.

In situ heating experiments in $Ba_{1-x}K_xBiO_3$ with the electron beam turned off caused all satellite intensities above 200°C to disappear. When the sample was then cooled down with the beam off, the satellites remained extinct; however, when irradiating the sample again the satellites reappeared at their initial positions. Note that the satellites do not disappear when the electron beam is turned off without heating.

Symmetry analysis of this incommensurate modulation can be worked out in the framework of the superspace formalism; details on the calculations are given by Verwerft et al. [135]. It is concluded that only bismuth atoms are involved in the modulation and moreover they can only be displacively modulated. The final modulation is represented by a $\sqrt{2}a \times \sqrt{2}a \times a$ unit cell; the modulation is a transverse displacive wave with wavevector parallel to the x axis and displacements parallel to the y axis. In the high-resolution image of Fig. 33a, viewed under grazing incidence, one detects a displacement of the brightest dots; the displacement amplitude can be estimated as 0.005 nm. This modulation of the bismuth atoms is represented schematically in Fig. 33b.

From this analysis, all models involving chemical ordering can be excluded; the ordering of Bi^{5+}/Bi^{3+} can also be ruled out since the displacements of the bismuth atoms are too small to result in a complete charge disproportion. In view of the fact

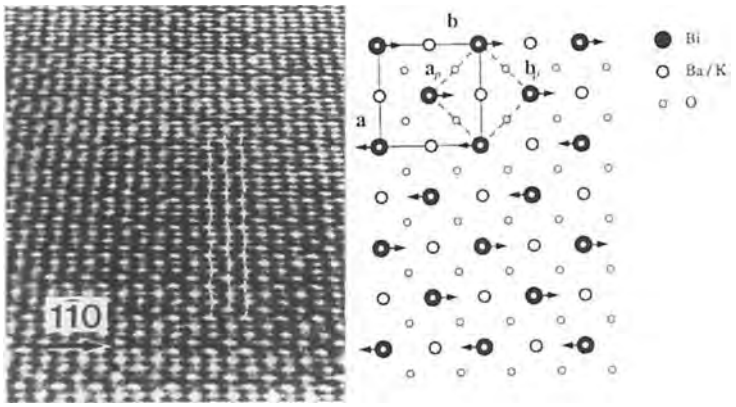

Figure 33. (a) High resolution micrograph viewed at the grazing angle, showing the displacive modulation of the brighter dots. (b) Schematic drawing of the modulation in $Ba_{1-x}K_xBiO_3$ represented in a projection along the [001] direction. Bismuth atoms are represented as black dots, barium or potassium atoms as large open circles, and oxygen atoms as small open circles.

that the modulation only shows up after electron irradiation, it might be argued that it is not a fundamental material property. This, however, is very difficult to accept because of the very low threshold value (<40 kV). Elementary collision theory shows that the maximum energy transmitted to the lightest element, oxygen, is about 5 eV; this is far too low for the creation of oxygen vacancies. We therefore propose a model of time-fluctuating charge disproportion of the bismuth atoms due to displacements from their average positions. Upon electron irradiation it is possible to induce clustering of already existing point defects (e.g., oxygen vacancies), even at very low energy transfers. These clusters can then act as pinning centers for the modulation. Upon heating above 200°C these centers may lose their pinning capability, resulting in a disappearance of the satellite reflections.

8.2.4 Holographic Interference Microscopy and Lorentz Microscopy [140]

Tonamura and co-workers at Hitachi Co. [141] have 'modified' the transmission electron microscope such that it allows direct observation of vortices with the help of electron holography (see Part I of this Handbook). In their method, magnetic lines of force emerging from the superconducting surface can be observed directly in a holographic interference micrograph or by Lorentz microscopy. The basic idea is that vortices are phase objects and consequently cannot be detected on a micrograph where the electron intensity is detected. The phase shift caused by the vortex becomes detectable, for example, by directly measuring the phase distribution in a holographic interference micrograph or by strongly defocusing the objective lens (see Part I).

By interference microscopy the magnetic lines emerging from the surface can be directly observed as contour fringes in a phase-amplified pattern, through holography. In the example of Fig. 34 a magnetic field was applied perpendicular to the lead film, which was cooled to 4.5 K; one fringe corresponds to one vortex. In addition to isolated vortices, a pair of vortices is observed, which are oriented in opposite directions and connected by magnetic force lines.

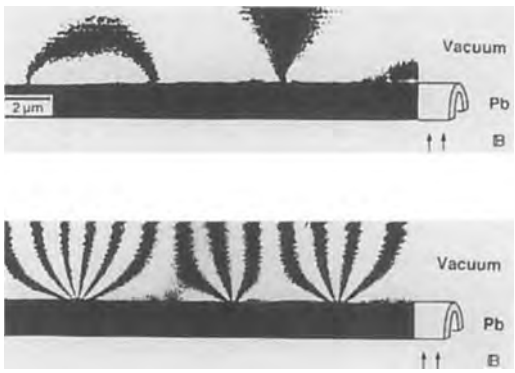

Figure 34. Interference micrographs of magnetic fields emerging from a lead-film (phase amplification: ×2). (a) Thickness 0.2 μm. (b) Thickness 1 μm. (Courtesy of Tonomura [141].)

A two-dimensional distribution of vortices can be dynamically observed by Lorentz microscopy, using a holography electron microscope. A superconducting thin film is tilted 45° to the incident beam, so that the electrons are affected by the vortex magnetic field. An external B field is applied horizontally. A Lorentz micrograph at $B = 100\,\mathrm{G}$ is shown in Fig. 35. Each spot showing a black–white contrast is an image of a single vortex. Using the same methods the vortex lattice in BSCCO ceramic superconductors

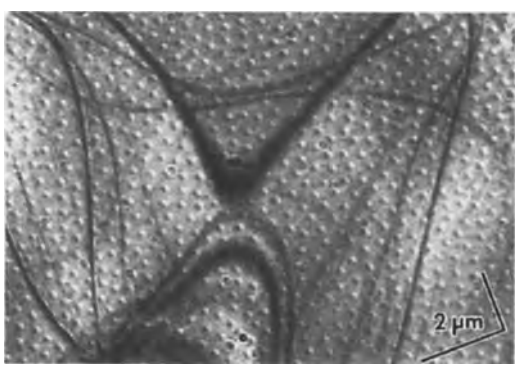

Figure 35. Lorentz micrograph of a two-dimensional array of vortices in a superconducting niobium film at 4.5 K. (Courtesy of Tonomura [141].)

can also be observed and followed as a function of temperature between 4.5 K and T_c. It is found that the image contrast gradually fades with increasing temperature.

8.2.5 Direct Observation of Vortices by Magnetic Force Microscopy

As we have seen before, STM can be applied to conventional type II superconductors to image the hexagonal Abrikosov vortex lattice as well as the electronic fine structure of a single vortex lattice [142]. The imaging of single vortices in high-T_c superconducting materials has taken a lot of effort because of a combination of short coherent length, degraded surfaces, and high mobility of the vortices. Recently, however, Güntherodt's group in Basel obtained remarkable images of single vortices as well as vortex lattices in YBCO thin films by magnetic force microscopy [143, 144].

The magnetic force microscope—very similar to the atomic force microscope—consists of a tiny magnetic tip integrated on a cantilever of about 0.2 mm in length. This tip interacts with the stray magnetic field of the sample. The force on the tip is detected by measuring the deflection of the cantilever. During the experiment shown in Fig. 36 the tip has been scanning over a YBCO thin film at liquid nitrogen temperature (77 K); the individual vortices produce a repulsive force of less than 10^{-12} N. The number of vortices observed increases linearly with the applied external field, and one can easily show that individual vortices carrying one flux quantum ($\Phi_0 = 2.03 \times 10^{-15}\,\mathrm{V\,s}$) are imaged.

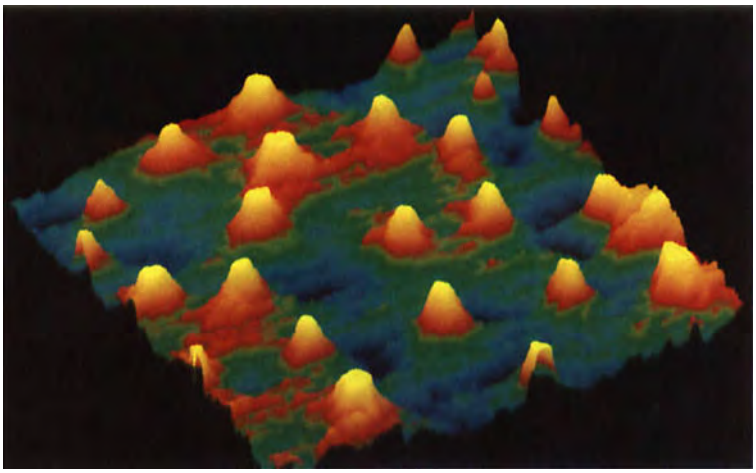

Figure 36. Magnetic force microscopy image of vortices in a YBCO thin film; the image shown is 22 × 22 μm in size. (Courtesy of A. Moser.)

8.2.6 Magneto-Optical Studies

Magnetic flux behavior and critical current density are key phenomena for the current-carrying properties of superconductors. Usually, measurements of magnetic properties give only integral or average data. A direct study of the magnetic flux structure by means of the magneto-optical technique (see Vol. I of this Handbook) provides us with local and much more detailed information. Recently, pushed by the increased interest in ceramic superconductors, this technique was further developed and successfully applied [145–150].

Using the high-resolution Faraday (HRF) effect technique, flux distributions in sintered superconducting samples can be obtained; it can be shown that the flux penetration occurs stepwise, and only the last step of the penetration of the Abrikosov vortices in the individual grains can be observed directly [147]. The high spatial resolution of the HRF technique enables the determination of the flux density profile inside individual grains. From these profiles the intragranular critical current densities and acting local pinning forces can be obtained. Figure 37 shows an SEM image of YBCO grains where BaO spheres (arrowed) can be detected at the grain boundaries. The flux distribution of such a polycrystalline YBCO sample is shown in Fig. 38; measurements were performed at 5 K, and at an external field of $\mu_0 H_{ext} = 273\,\mathrm{mT}$. The flux is found to penetrate the superconducting grains individually. The grain boundaries are clearly visible in the obtained flux distribution. Larger grains show the penetration of

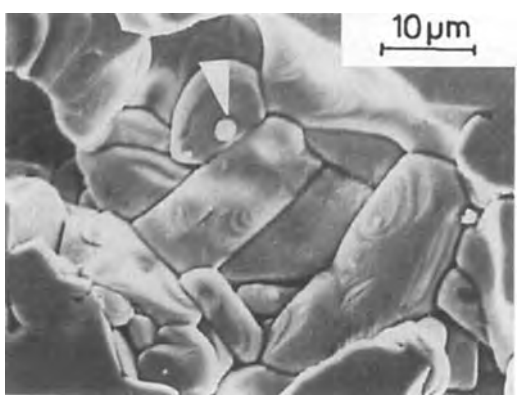

Figure 37. SEM image of $YBa_2Cu_3O_{7-\delta}$ grains. $BaCuO_2$ spheres at the grain boundaries can be detected (marked by a white arrow). Holes due to evaporated CO_2 are found in most of the grains. (Courtesy of Koblischka [144].)

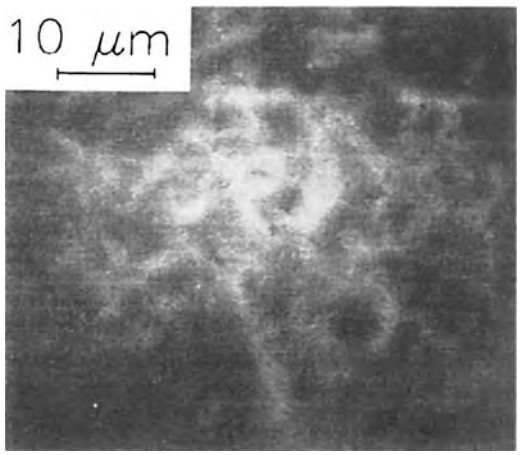

Figure 38. Flux distribution on a polycrystalline $YBa_2Cu_3O_{7-\delta}$ sample such as that of Fig. 36 at a temperature of 5 K and an external magnetic field of $\mu_0 H_{ext} = 273$ mT. The flux is found to penetrate the superconducting grains individually. Characteristic for granular samples, the grain boundaries are clearly visible in the flux distribution obtained. Larger grains also show a penetration of a flux front towards the center of the grain. The flux density gradients pointing towards the center of the grain are also clearly visible. (Courtesy of Koblischka [144].)

a flux front towards the center of the grain, indicating that each grain behaves similarly to a small single crystal in this field regime ($H_{ext} < H_{cl}$).

The magneto-optical technique can also be used to study the altered flux penetration in heavy ion-irradiated superconducting materials. Irradiations with high-energy metallic ions (e.g., 230 MeV nickel ions in [145]) is known to induce columnar tracks of amorphous material along the projectile paths (see later). These columnar tracks are found to be effective pinning centers if an external magnetic field is applied parallel to the tracks. Their radius of a few nanometers coincides approximately with the vortex core radius (for example, see Fig. 50 for lead irradiation in thallium-based material). These structural defects are well characterized by HREM. The HRF technique enables the obtention of direct local (spatial resolution 0.8 μm) information on the pinning behavior in superconductors. Observations in the excellent work of Schuster [145] were done at a temperature of 5 K; the external magnetic field was in all cases perpendicular to the sample surface and therefore parallel to the *c* axis of the material. The Shubnikov phase is imaged as bright domains; the Meisner phase remains dark. The left half of the crystal is the irradiated region, whereas the right half is unirradiated. Figure 39a shows the bright image of the crystal. In Fig. 39b–e the external magnetic field is raised from $\mu_0 H_{ext} = 171$ mT to 512 mT. In Fig. 39f the corresponding remanent state to Fig. 39e is shown; the domain of negative vortices and the annihilation zone separating the domains of different sign are clearly visible (marked by arrows). In this image the coupled behavior of the two kinds of vortice is shown. The negative flux clearly follows the penetration scheme of the positive flux, yielding the same domain pattern [145].

8.2.7 Less Conventional Imaging Techniques

Most of the less conventional methods for imaging high-T_c materials give very precise information, but for various reasons have not become routine techniques for the characterization of superconducting materials.

To investigate the structural properties of single crystals of the type Nd_2CuO_4, $(LaSr)_2CuO_4$, or $YBa_2Cu_3O_7$, investigators such as Bdikin et al. [151] are using

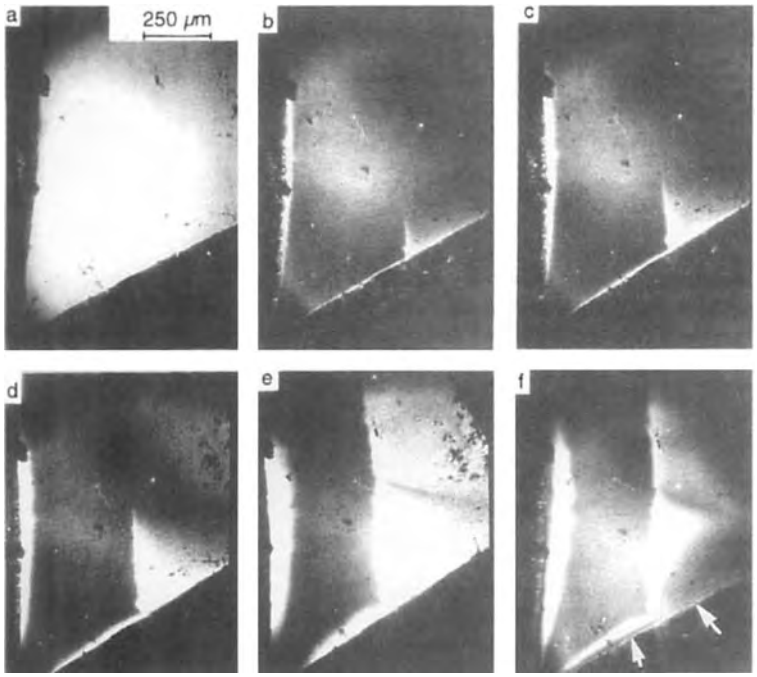

Figure 39. Domain pattern at 5 K of a $DyBa_2Cu_3O_{7-\delta}$ single crystal irradiated with 0.5 GeV ^{127}I ions. Only the left half of the crystal was exposed to the irradiation. (a) Bright field of the region, shown for comparison. (b) $\mu_0 H_{ext} = 171$ mT. (c) $\mu_0 H_{ext} = 256$ mT. (d) $\mu_0 H_{ext} = 341$ mT. (e) $\mu_0 H_{ext} = 512$ mT. (f) Corresponding remanent state $\mu_0 H_r = 512$ mT to (e); clearly visible are the domains of negative vortices as marked by arrows. (Courtesy of Schuster et al. [142].)

X-ray anomalous transmission effects (the Borrmann effect). The angular scanning topograms and Borrmann topograms allow them to deduce information about the presence or absence of an inversion center in the structure. The method clearly only holds for single crystals; for strongly distorted crystals the interpretation of the results is still problematic.

Surface information can be obtained not only by STM or AFM but also by other techniques such as scanning Auger microscopy (SAM) and angle-resolved photoelectron spectroscopy (ARPES). Most superconducting ceramics are highly anisotropic and have pronounced (001) cleavage planes, making them highly suitable for surface studies such as SAM or ARPES. For the bismuth superconductors the cleavage plane is clearly between the two BiO layers, but in YBCO there is a controversy on the terminating plane, being either between the BaO and the CuO_2 plane or between the CuO and the BaO layer. Different techniques (SAM [152], HREM [153, 154], STM [155, 156], ARPES [157, 158], and X-ray spectroscopy (XPS) [159, 160]) give different results, and often one technique provides contradictory answers. We therefore have to conclude that most probably YBCO cleaves on both planes. Schroeder et al. apply a special cleavage technique such that both surfaces from a single cleavage can be studied and correlated by SAM [161].

An important problem in high-T_c ceramics is the exact chemical composition: the deviation of the local composition with respect to the average composition or the nominal composition. Direct imaging techniques such as elemental mapping of the different element by energy dispersive spectroscopy (EDS), EELS, or Auger

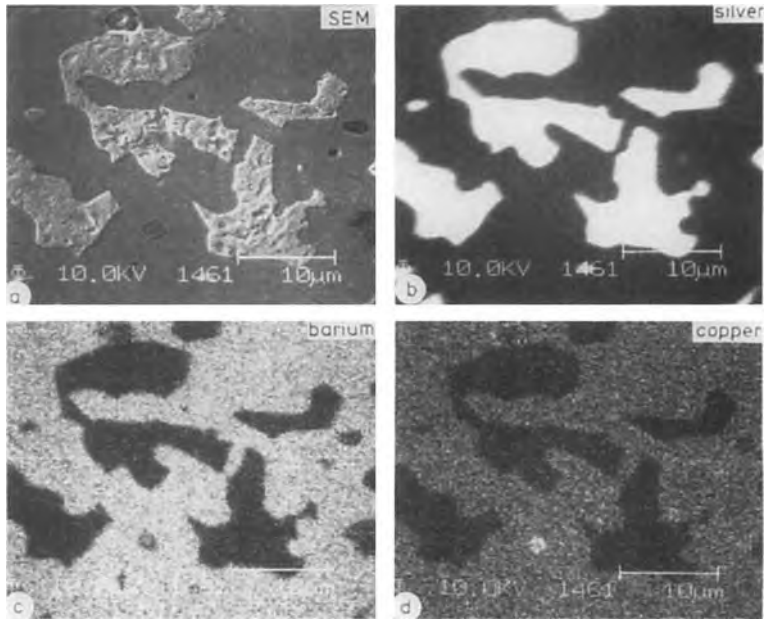

Figure 40. Typical $YBa_2Cu_3O_{7-\delta}$ and silver grains (SEM) of a $YBa_2Cu_3O_{7-\delta}$–30 wt.% silver sample after (a) polishing and various elemental AES maps of (b) silver, (c) barium, and (d) copper. (Courtesy of Udayan De [159].)

electron spectroscopy (AES) provide useful information for the synthesis of new superconducting materials. A good example is shown in Fig. 40 [162], where silver-added YBCO ceramic composites have been investigated by high-resolution scanning Auger electron microscopy. The silver particles within the matrix are clearly revealed, and the eventual effects of silver diffusion can be studied. The study of Udayan De [162] showed no detectable effects of interdiffusion of silver into the YBCO phase. A similar example comes from Mokhtari et al. [163], who studied the influence of iodine insertion on the YBCO superconducting properties by EDS and SEM.

As usual, the combination of different techniques is the most powerful. A beautiful illustration is given by Dravid et al. [164], who analysed the 'well-known' (001) planar defects in $YBa_2Cu_3O_{7-x}$, generated by decomposition of the material in a humid atmosphere. These defects were first detected by Zandbergen et al. [165] and correctly interpreted as double CuO layers forming locally the $YBa_2Cu_4O_8$ structure. Dravid et al. [164] brought direct chemical evidence by combining HREM observation of the defects together with local X-ray microanalysis and EELS of the defect under consideration. Figure 41 shows the HREM image and the X-ray and EELS spectra of the matrix and the planar defect. The EELS Cu-L_{23} edge from the fault region is compared with the Cu-L_{23} edges of the adjacent 1-2-3 matrix and with that of a CuO external standard. Visual inspection shows a remarkable similarity with the edges of the CuO precipitate. For the microanalysis a probe size of a little less than 1 nm was used. Although this is an example where results from the literature were only confirmed, it is clear that the method opens enormous possibilities for the analysis of

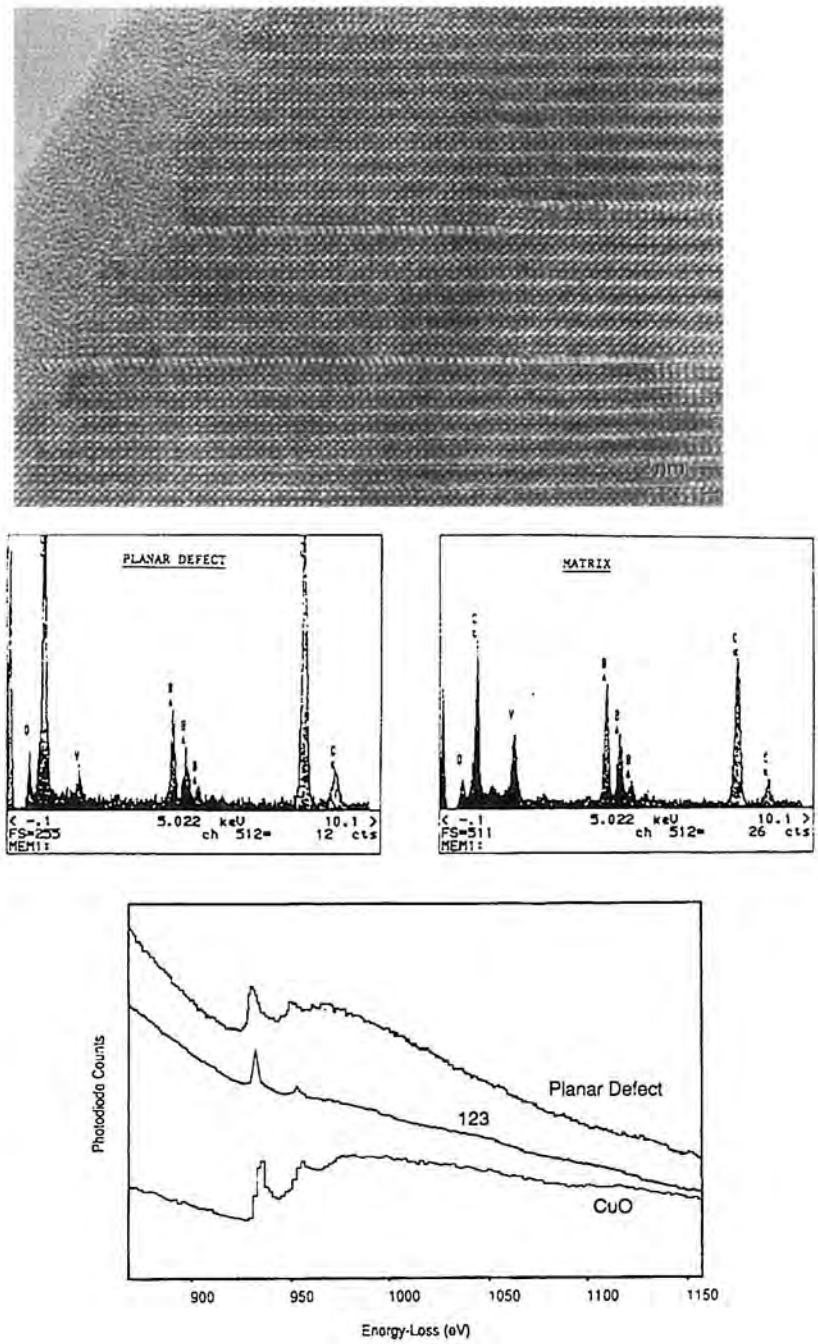

Figure 41. (a) HREM image showing a couple of (001) double layer planar defects in $YBa_2Cu_3O_{7-\delta}$. (b) X-ray spectra from the planar defect (left) with a <1 nm probe and from the matrix (right) with a larger probe. (c) EELS Cu-L_{23} edge from the fault region along with the Cu-L_{23} edges of the adjacent 1-2-3 matrix and a CuO external standard. (Courtesy of Dravid et al. [161].)

nanoprecipitates or nonstoichiometric defects within known superconductors. A similar combination of techniques is described by Faulques et al. [166] in their study of iodine insertion in high-T_c cuprates; they use Raman spectroscopy, XPS, and EELS to locate the iodine in bismuth, thallium, and YBCO superconductors.

Although field emission microscopy or spectroscopy was the first technique to provide atomic resolution (for an excellent overview see [167]) and although it does provide information about the electronic properties of the sample surface, it is not a very popular technique for the study of superconducting materials. It has been used by Shkuratov et al. [168] to study the evolution of the Fermi level at various temperatures between room temperature and about 100 K. The fact that atomic resolution is more easier attained by other techniques, and the stringent conditions on sample preparation, has clearly retarded the applications of field emission microscopy techniques.

Methods to investigate the spatial variation of the critical temperature T_c and the critical current J_c provide relevant information for the development of high-T_c superconducting electronic devices. When the devices contain insulating layers, SEM can no longer be used because of charging effects. Low-temperature scanning laser microscopy (LTSLM), however, can be used for this purpose. Details of the experimental set-up can be found in the literature [169, 170]. The method not only provides the local variations in T_c or the weak links with reduced critical current but is also able to characterize every layer of a multilayer device separately [170].

Also, the imaging of local electrical inhomogeneities in thin films at room temperature is an important feature, since they do not only reduce the reproducibility of the main parameters, but may also result in an excess of the $1/f$ noise in the junctions. By laser irradiating the thin films and monitoring the spatial distribution of the laser beam-induced electrical response in a thin film, one is able to image electrical inhomogeneities such as microbridges or grain boundary junctions [171].

Flux creep measurements are normally performed by SQUID (superconducting quantum interference device) or torque magnetometers, but flux creep effects can also be directly imaged [172]. They use the property of the high-resolution Faraday effect to allow dynamic observations of the Shubnikov phase and directly observed effects of flux creep.

8.3 Specific Problems in Superconductivity Research

8.3.1 Surface Studies by Transmission Electron Microscopy

Although SEM, STM, and AFM or even AES, XPS, or low-energy electron diffraction are more straightforward techniques to provide information on the surface, TEM can provide important information, inaccessible by other techniques. HREM has the advantage of providing at the same time an image of the surface as well as of the underlying structure. For the $YBa_2CU_3O_7$ structure—as for all superconducting ceramics based on the perovskite structure—the cleavage plane is the (001) plane, but the terminating plane is found to be the BaO plane or the

CuO plane, never the superconducting CuO_2 plane [173, 174, 175]. On the other hand, a very detailed and careful study has been made by Xin et al. [176]; they found the terminating layer to be the CuO_2 plane, corresponding to a sequence of bulk–Y–CuO_2. The results are confirmed by different image simulations where the different possible models are compared with experiments. The same authors also suggest partial oxygen loss at the terminating plane; the evidence for this, however, is less convincing. For the very anisotropic bismuth-based superconductors the preferential cleavage plane is clearly between the two BiO layers [177]. For the more exotic compound

$$Pb_2Sr_2Ca_{0.5}Y_{0.5}Cu_3O_{8+\delta}$$

—abbreviated to PSCYCO—which has a stacking

$$-CuO_2-(Ca, Y)-CuO_2-SrO-PbO-$$
$$(Ca,Y)-PbO-SrO-$$

the surface plane is the SrO layer, indicating that the coupling between the SrO layer and the PbO layer is the weakest; this can be deduced from the high-resolution image of Fig. 42 [178] by comparing the experimental image with the calculated images.

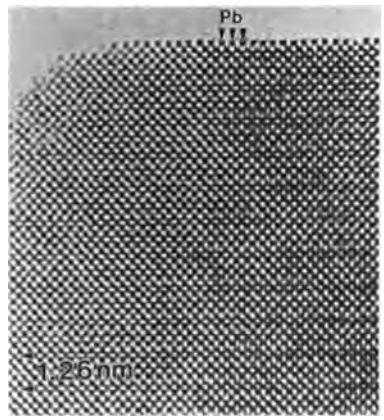

Figure 42. [110] HREM image of PSYCO, showing a (001) surface. In the top layer the terminating black dots can be identified as lead atoms.

8.3.2 Characterization of Superconducting Thin Films

Most of the recently discovered superconducting compounds can be grown in thin film form. This growth proceeds mostly by sputtering, laser ablation, chemical vapour deposition, or molecular beam epitaxy on substrates of different types and different quality. Most attention by far has been devoted to the growth of $YBa_2Cu_3O_7$ on different substrates. Most superconducting thin films have been grown on MgO or $SrTiO_3$; however, more exotic substrates such as $LaAlO_3$, $NdGaO_3$, or Mg_2TiO_4 are also used [179–199]. More recently, films have been successfully grown on technologically relevant single-crystal substrates such as silicon, GaAs, Al_2O_3, or SiO_2. Silicon and GaAs have a large misfit with respect to YBCO, and tend to react at the growth temperature, inducing a strong chemical interaction and a rough surface with microcracks [183]. These problems can be overcome by the introduction of buffer layers, intended to act as diffusion barriers and to enable the relaxation of thermal stresses. Buffer layers reported in the literature include yttria-stabilized zirconia (YSZ), Y_2O_3, CaF_2, SrF_2, BaF_2, or the semiconducting $PrBa_2Cu_3O_7$ [184]. Recently, complex barrier layers have been used in order to optimize the epitaxy and the physical parameters. YBCO films on silicon now have critical temperatures around 90 K and critical currents over

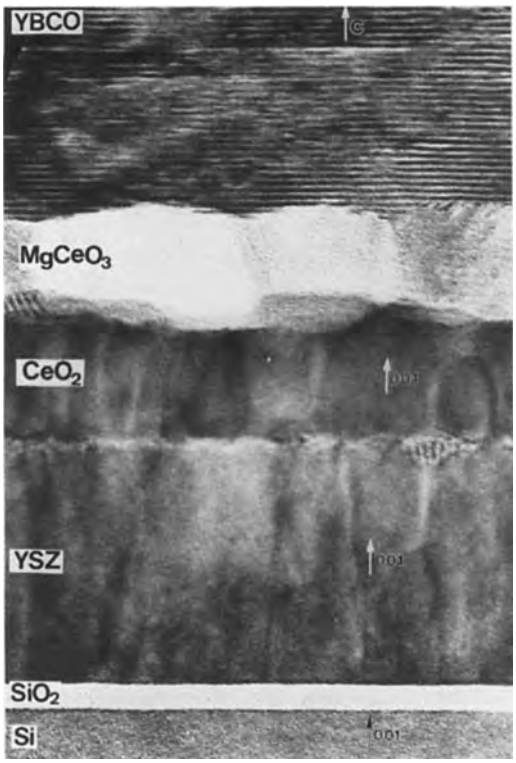

Figure 43. HREM image of a YBCO film on an MgO–CeO_2–YSZ buffer.

10^6 A cm^{-2} at liquid N_2 temperature [185]. An example of such a film with an extremely complex buffer sequence is shown in Fig. 43. The direct growth of Y_2O_3 or CeO_2 on silicon leads to polycrystalline film formation where grain boundaries are assumed to be diffusion paths and the surface of these films is found to be corrugated. However, a single-crystal oriented YSZ buffer can be formed on silicon in spite of the presence of a 3–5 nm thick amorphous layer on the YSZ–Si interface. For microstructural applications, including Josephson-based and high-frequency devices, a specific YBCO film orientation is required. For *c* axis-oriented YBCO films, different in-plane rotations can be achieved by sandwiching additional MgO seed layers. It is seen, however (Fig. 43), that there is a strong interdiffusion between the CeO_2 layer and the MgO layer, forming the $MgCeO_3$ compound [185].

A lot of attention is being devoted to the optimization of such sequences of thin films. As well as after the deposition, imaging techniques play a major role in the characterization of the films and the film quality during deposition. The most useful techniques for this purpose are SEM, AFM, STM, and TEM. Very often the combination of different techniques provides the most complete information; examples of these are given in the literature [186–191].

The surface morphology and roughness, extremely important in thin film technology, is best studied by STM or AFM. A beautiful illustration is given by Lang et al. [191] in their study of the different growth stages of *c* axis-oriented $YBa_2Cu_3O_7$ thin films on $LaAlO_3$. For a reliable study it is desirable to have films with different thicknesses prepared under similar deposition conditions using identical targets and substrate materials. To obtain this, Lang et al. use the 'half shadow technique' [191] whereby thin films with a thickness gradient are obtained. This allows them to study by STM the nucleation and growth of two-dimensional islands (Fig. 44), their coalescence, and the formation of well-developed growth hills (Fig. 44) and a continuous film. The growth mechanism is clearly a layer growth with respect to the height of the YBCO unit cell. In addition to the normal island growth, spiral growth has also been observed by STM (Fig. 45). Gao et al. [188] observed in this way a 'brick wall' microstructure during the growth of a YBCO film on an MgO

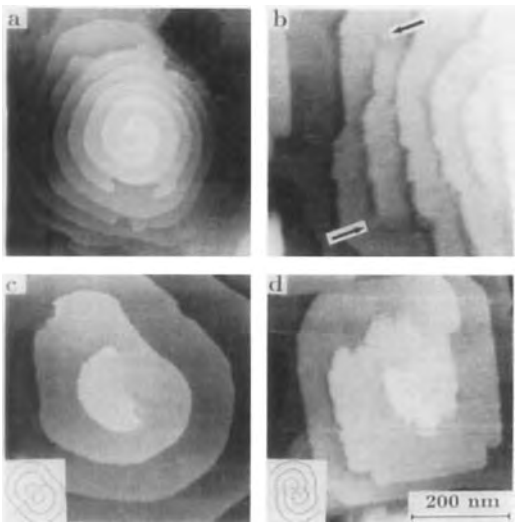

Figure 44. Different kinds of growth hills with screw dislocations: (a) single right-handed screw dislocation with about 8 turns of growth steps; (b) annihilated pair of dislocations (marked by arrows) of opposite sign; (c) a pair of screw dislocations of opposite sign further apart from each other than 2rc, sending out loops of steps; and (d) pair of screw dislocations of like sign with a step activity indistinguishable from that of a single spiral. The scale bar is valid for all figures. (Courtesy of Lang et al. [188].)

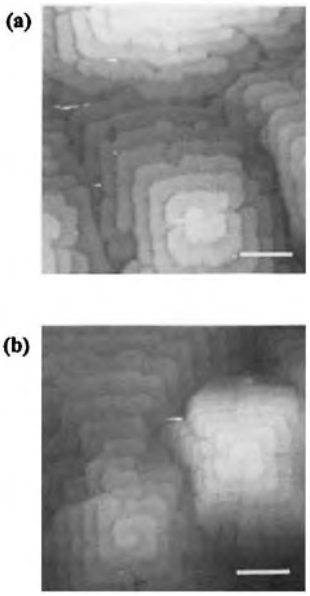

Figure 45. STM images (the white markers correspond to a length of 100 nm) reveal the surface topography of a 100 nm thick $YBa_2CU_3O_7$ film obtained by 90° off-axis magnetron sputtering. The presence of terraces directly results from the epitaxial, layer by layer growth process. The *c* axis of the film is perpendicular to the (001)-oriented MgO substrate. The film is composed of islands growing along screw dislocations. The screw dislocations are anticlockwise in (a) and clockwise in (b). (Courtesy of C. Van Haesendonck.)

substrate. This apparently results from the overlap between terraces belonging to adjacent spiral-shaped islands.

8.3.2.1 Thin Film Sample Preparation for Transmission Electron Microscopy

It is clear from the foregoing discussion that in the study of thin films (not only superconducting thin films) HREM plays an extremely important role. Preparing reliable and reproducible samples for electron microscopy, without altering or destroying the film or the substrate–film interface is therefore crucial. A lot of attention has to be devoted to produce so called 'cross-section' samples, where both the film and the substrate can be revealed over distances as large as possible. The initial sample is generally of the order of 10 mm × 10 mm × 500 μm, the last being the thickness of the support. Such a sample is sliced (a few hundred micrometre widths) by a diamond saw or wire saw perpendicular to the film. Then the different slices are glued together, generally with the superconducting thin films facing each other; sometimes it is advisable to glue them all in the same direction [193] (Fig. 46). To reduce the ion milling time, the glued stack is mounted on a tripod holder [194] and thinned down to 10 μm; details are given by Traeholt et al. [193, 196]. During ion milling, the incident angle is kept as small as possible, and one

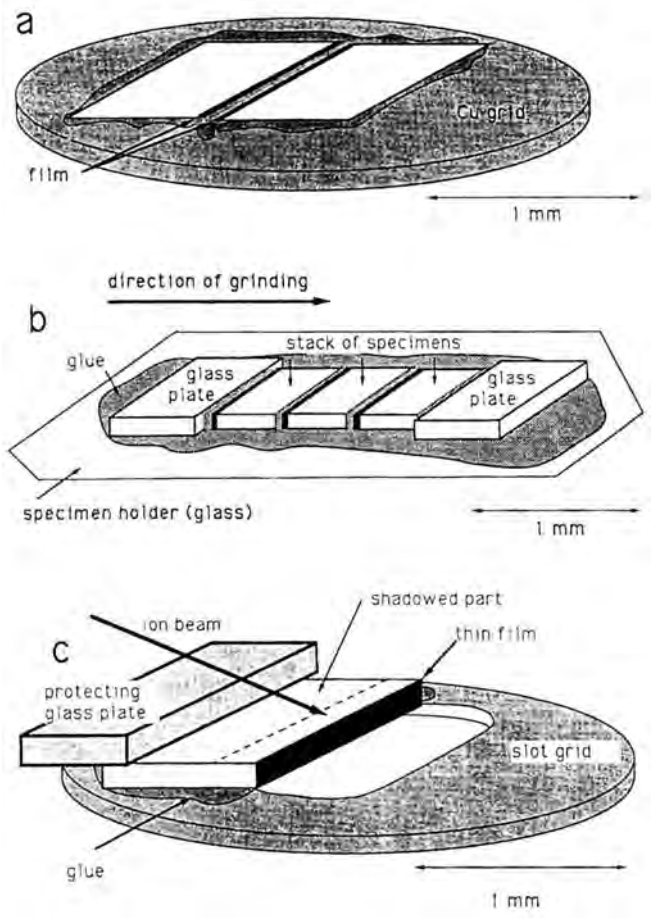

Figure 46. (a) The most common way to make TEM cross-sections. The cross-section is mounted on a support grid with the film sides facing each other. Ion milling of the cross-section is done with two guns while the cross-section is rotating. (b) All film sides are facing the same direction. The grinding direction is opposite to the normal of the film as indicated. The glass pieces function as protection. (c) The set-up for ion milling. A major part of the cross-section is shadowed by the glass piece to keep a thick supporting region. The ion milling is done with one gun without rotation of the specimen. (Courtesy of Traehold et al. [190].)

has to verify regularly by OM the thickness of the sample. Traeholt describes a special shadowing method using a glass piece, a nonrotating sample set-up, and ion milling from one side only [196]. With the recent ion milling machines, using a retarding field, incident angles down to 1° can be obtained, producing large electron-transparent areas.

8.3.2.2 Precipitate Identification

Another important feature in the thin film production is the presence—or the absence—of foreign precipitates. Some of these precipitates (e.g., CuO, BaCuO, $YCuO_2$, Y_2BaCuO_{5-x}, or $Y_2Cu_2O_5$, originating from unreacted material) are to be avoided; others such as nanoprecipitates of Y_2O_3 could have a favorable effect on the flux pinning properties of the material. Virtually the only technique to study these precipitates and to determine their structural relationship with the YBCO is the combination of HREM, ECX, and nanodiffraction. Innovative work in this field has been done by Eibl and co-workers [179]. The small size of these precipitates has provoked some ambiguity about the

composition and the orientation relationship with the underlying substrate. In a recent paper by Verbist et al. [192] the different proposals are tested with respect to each other; two different epitaxial relationships are found. The YBCO *c* axis can be parallel to the [001] or the [110] axis of Y_2O_3. The [110] precipitates are only situated near the foil surface. The information from HREM, together with the Fourier transform and the simulated images, allow identification of the precipitate unambiguously as Y_2O_3. The epitaxial relationship can be deduced from the HREM or from a nanodiffraction experiment.

8.3.2.3 Substrate–Superconducting Film Interface

In order to grow epitaxial films and to have a better understanding of the interface problems it is important to have a detailed image of the substrate–film interface or the interface between subsequent buffer layers. Cross-section electron microscopy is virtually the only technique providing reliable and detailed information. Innovative work in this field has been done by Eibl and co-workers [179, 195] and by the group around Zandbergen [180, 193, 196, 199]. The latter have studied convincingly the YBCO–MgO interface of a thin film produced by laser ablation. Concerning the first atomic layer on the MgO substrate, a number of ideas were put forward. Tietz et al. [197] suggested that the first YBCO layer is the—superconducting—CuO_2 layer; this would indeed provide the best continuation of the oxygen sublattice. Pennycook et al. [198] reported that the thermodynamically lowest energy is obtained for the interface with the CuO chain plane as the first layer. They performed *Z*-contrast on laser-ablated thin films and found that the first layer is indeed the CuO layer or the CuO_2 layer next to the BaO layer. Traeholt et al. [196] showed by HREM that the first layer is indeed the CuO layer but that two types of interface configurations occur:

(1) The YBCO lattice and the MgO lattice continue up to the interface; this often creates a periodic strain in the substrate.
(2) The YBCO lattice and the MgO lattice are separated by an amorphous layer with a thickness of the order of the two atomic layers; in this case most strain is released.

A more complex example of growth of YBCO on a YSZ substrate is illustrated in Fig. 47 (from the work of Wen et al. [199]). In all samples they observed the formation of an intermediate layer of $BaZrO_3$, located between the YSZ substrate and the superconducting film. HREM allowed the determination of the stacking sequence of the $BaZrO_3$–YBCO interface as $(BaZrO_3)$–ZrO_2–BaO/CuO–BaO–(YBCO) with the CuO layer as the initial YBCO layer. Occasionally the BaO layer was also found to be the initial layer.

8.3.2.4 Towards Applications

High-T_c $YBa_2Cu_3O_{7-x}$ films can be used in hybrid circuits integrating active superconducting elements and interconnections with semiconductor devices. The chemical interaction between YBCO and silicon, the relatively large mismatch in thermal expansion coefficients, and the lattice parameters hamper the use of silicon in

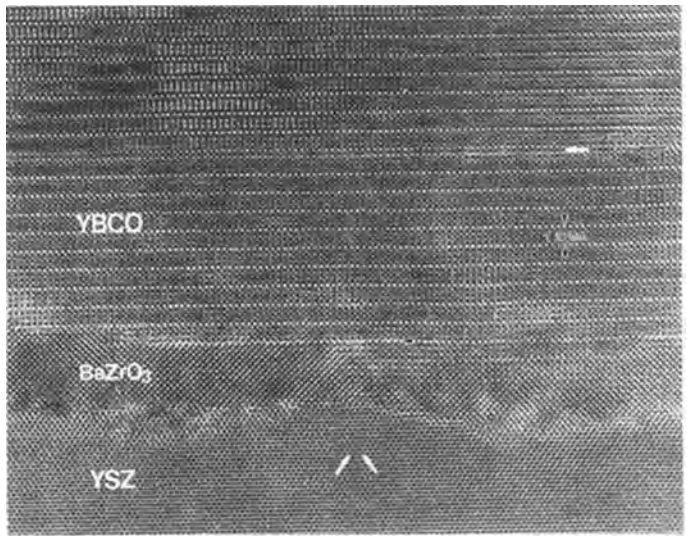

Figure 47. HREM image of a YBCO film on a YSZ substrate taken along [110] of YSZ. A reaction layer of $BaZrO_3$ between YSZ and YBCO is observed. Steps at the $BaZrO_3$–YBCO interface correspond to a whole unit cell of YBCO. The black arrowhead indicates that the CuO layer as the initial layer of the YBCO film. The white arrow indicates a stacking fault. The interfacial dislocations are indicated by two white arrows. (Courtesy of Wen et al. [196].)

direct combination with YBCO. Different buffer layers are used to eliminate the chemical interaction [200–204]. High-quality YBCO films can be grown on double CeO_2–YSZ buffer layers. An additional MgO seed layer on top of the CeO_2–YSZ buffer allows the introduction of in-plane rotations of the YBCO film. This effect can be used in bi-epitaxial technology for the fabrication of Josephson junctions (JJs) where differently oriented parts of the YBCO film form controllable, isolated grain boundaries which are suitable as weak links [205, 206].

An optical micrograph of three microbridges is presented in the Fig. 48a, and an enlarged image of the central microbridge is seen in Fig. 48b. In the center of the bridge the line which separates two parts of the substrate with and without seed layer is visible.

High- and low-angle tilt grain boundaries in the YBCO film on an MgO–CeO_2–YSZ buffer can be analysed by electron microscopy. At low magnification the high-angle grain boundaries appear to be wavy; however, careful inspection by HREM reveals that the high-angle grain boundaries are mostly faceted. An area of distorted contrast at the grain boundary is confined within one or two YBCO unit cells from each side. The grain boundary shown in Fig. 49a also shows a darker band near the interface; in that area the lattice image shows more pronounced {110} fringes. This is more clearly illustrated in the enlargement of Fig. 49b. Simulated images under different conditions show a correlation between this lattice distortion and the local oxygen

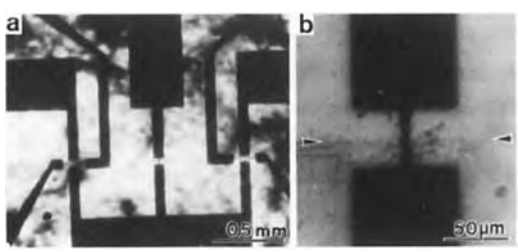

Figure 48. Optical microscope image of patterned YBCO film on a buffered silicon substrate. (a) Three microbridges in parallel. (b) Enlarged part of the central microbridge; the arrows show the boundary between parts with and without MgO seed layer.

content. In a very similar way, extended defects occurring at the grain boundary can be analysed [207].

8.3.3 Ion Irradiation of Superconductors

In order to investigate the interaction of crystal defects with flux lines, several groups have introduced defects of a known size and number into well-characterized material. High-energy heavy ions produce latent tracks of several nanometers in diameter along their path through crystalline matter. These defect lines are known to act as pinning centers. Gerhäuser and co-workers studied the effect of 0.5 GeV ^{127}I irradiation in the bismuth 2212 superconductor [208, 209]. Zhou et al. [210] studied the microstructure of the same material after 12 MeV iron ion bombardment. Watanabe et al. [211] used 173 MeV xenon irradiation in YBCO films. Irradiation of thallium 2223 superconducting materials with Xe ions were performed by Hardy et al. [212]. The results for the different heavy ions and different materials are very similar: when observing along the ion irradiation direction, discs with a diameter around 5–10 nm are visible (Fig. 50a) with a density corresponding to the applied dose. Tilting experiments or stereo microscopy reveal the three-dimensional cylindrical shape of the heavy ion tracks. The structure of the damaged regions is revealed by HREM

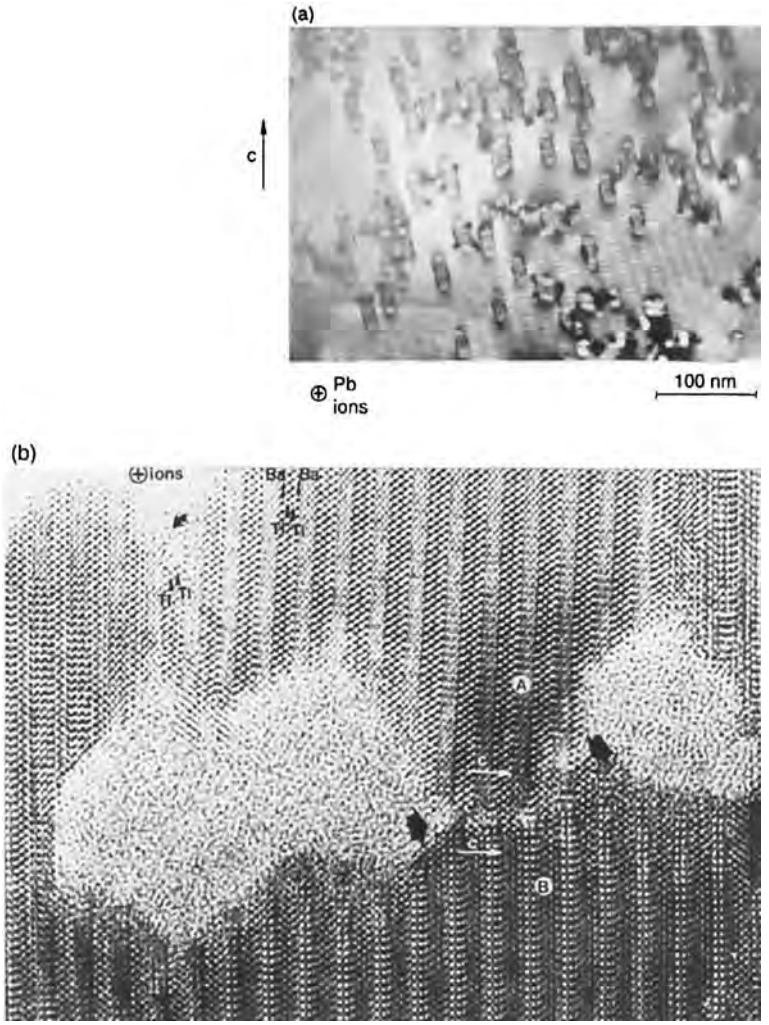

Figure 50. (a) Thallium 2223, lead-irradiated material, recorded with the beam almost parallel to the ion path. (b) [010] HREM image of lead-irradiated thallium 2223; the nature of the ions is reproduced in the top part of the image. The curved arrows indicate a microcrack at the level of the TlO layers.

(Fig. 50b); the inner part of the track is amorphous, and in the outer part some reconstruction has often occurred (Fig. 50) [213]. In a recent experiment we have irradiated different thallium superconductors (2212, 1223, and 2223). Ceramic plates of 150 μm thickness were irradiated at 300 K with lead or uranium ions of 6 GeV; total fluences varied between 5×10^{10} and 2×10^{11} ions cm^{-2}. The average diameter of the ion tracks is 9–10 nm, irrespective of the ion used and the fluence. A strain field is clearly visible around the tracks. The nature of the tracks can be determined by HREM: the core of the tube is clearly amorphous. Some of the projected traces are not circular (Fig. 50); this is attributed to a slow recrystallization which is sometimes observed 'in situ' under the electron microscope. As a result of the high strain, specific defects are formed, as shown in Fig. 50b, which is a [010] HREM image where the positions of the atoms are imaged as bright dots. Three

tracks are evident; the recombination of the structure at the interface between the amorphous and the crystalline areas can be observed. In between two neighbouring tracks, microcracks are formed in the crystal, and parts A and B are rotated over an angle of about 2° with respect to each other. The crystal apparently cracks at the position of the TlO layers (see curved arrow in the left part of the image). The formation of such defects is of primary importance to understand the physical behavior of irradiated materials.

Proton irradiation (e.g., see Kramer et al. [214]) at energies of 200 MeV gives completely different results. Immediately after irradiation, no defects were observed, but after ageing for over 90 days, the same samples showed defects with an anisotropic strain contrast. TEM shows that two types of defects are formed, small clusters (0.5 nm) with no special orientation and extended defects between 2 and 7 nm in length and 0.2 nm in thickness which concentrate along {100}⟨010⟩. The explanation given by Kramer et al. [214] is that protons predominantly produce point defects of copper and oxygen, which cluster over time. The effect of neutron irradiation on high-T_c materials has been well summarized and reviewed by Kirk and Weber [215]. Upon irradiating YBCO one observes a dark, strain-induced contrast of circular defects with a mean size of 4.5 nm at a fluence of $3 \times 10^{23}\,m^{-2}$ ($E > 0.1$ MeV) [216]. The defects, which are shown to be responsible for the increased pinning, can be studied by TEM. The defects, with a size of about 2–3 nm, are most probably amorphous or heavily disordered structures [217]. Zandbergen et al. [218] reported on the limitations on the monitoring of neutron-induced defects by TEM. Their samples were either ion milled or crushed and deposited on holey carbon film. Zandbergen et al. claim that the samples deteriorate inside the electron microscope due to an intercalation, leading to the appearance of planar defects; Frischherz et al. [217], however, show that by taking enough care during the experiment, the electron microscopy results are perfectly reliable.

Using TEM one can also follow the irradiation in situ [219]. Room temperature irradiation of YBCO-type single crystals with 200 keV neon ions or 300 keV xenon ions have been performed inside the electron microscope. The defects produced are (i) mobile extended defects which recover rapidly under normal observation conditions and (ii) amorphous areas which are stable and can be observed by HREM (Fig. 51).

8.3.4 Grain Boundary Structures

Establishing the structure–property relationship for grain boundaries has been the

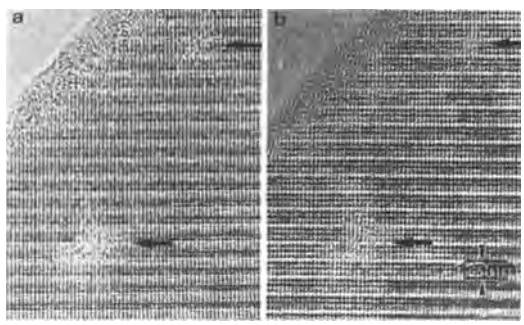

Figure 51. [100] HREM images of $YBa_2CU_3O_7$ irradiated with 300 keV xenon ions inside the electron microscope; amorphous radiated areas of about 1 nm in size are clearly visible.

goal for materials scientists and physicists for many decades. Although a clear relationship exists, the details of this relationship remain elusive. Critical current transport across grain boundaries of oxide superconductors is such an example [220]. Grain boundaries can be imaged by HREM [221–227], often by imaging along an axis common to both grains (e.g., see Fig. 49). This technique allows the deduction of the atomic configuration in the vicinity of the interface, but provides little or no information on the chemical composition in the immediate vicinity (first few nanometers) around the grain boundary. Detailed comparison with computer-simulated images partially overcomes this problem, but one has to be extremely careful with the obtained information, because slight thickness, focus, or orientation changes will considerably alter the experimental image [185].

Better compositional results can be obtained by combining HREM (structural information) with other techniques, such as EDX or EELS, better suited to obtain the local composition. Dravid et al. [220] probed in this way the hole concentration along the grain boundary in the 1-2-3 YBCO structure; they note significant changes in the O_K pre-edge peak by EELS. The changes are correlated to the hole concentration changes in the p-type cuprate superconductor. Similar work has been done by Alexander et al. [228], where grain boundaries in YBCO are imaged and structurally analysed by TEM, but where complementary compositional information is obtained from analytical electron microscopy and Auger electron spectroscopy. These authors systematically observe an excess of copper and a deficiency of oxygen at the boundaries.

A special and very promising technique to characterize materials in general and grain boundaries in particular is the so called *Z*-contrast technique (see Vol. 1, Chap. 4, Sec. 11.11). Using a combination of high-resolution *Z*-contrast imaging and EELS in a scanning transmission electron microscope, the local hole depletion and the local atomic structure can be studied simultaneously. The atomic resolution *Z*-contrast can be used to position the probe for energy loss spectroscopy, which by the analysis of the pre-edge feature of the oxygen K-absorption can be correlated with the hole depletion to an accuracy of 5% [229]. They conclude that no significant hole depletion has taken place in the symmetric boundaries, whereas in the asymmetric boundaries they measure a significant depletion in a zone extending over a far greater area than the disordered structure in the image. An example of the *Z*-type contrast is shown in Fig. 52.

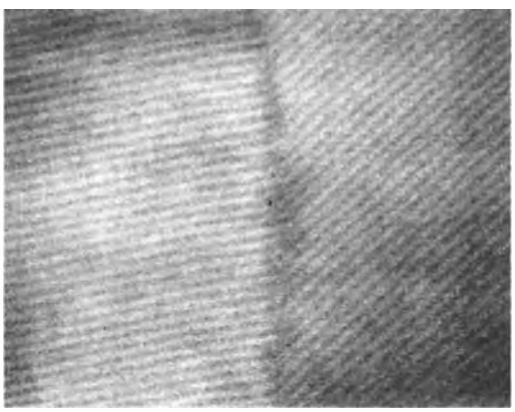

Figure 52. *Z*-contrast image of the asymmetric 29° (near Σ17 (001) 28.7°) grain boundary. The image shows a clear disordered/amorphous region at the grain boundary. (Courtesy of Browning et al. [226].)

8.3.5 Synthesis and Development of New Superconducting Phases

Numerous investigations have been performed in copper oxides since the discovery of superconductivity. The structure of layered cuprates show great flexibility to accommodate various cations in the normal layers which ensure the connection between the superconducting copper layers. The role of these noncopper cations in superconductivity is much more important than was expected at the beginning of the search for high-T_c superconductors.

Electron microscopy has played an extremely important role in the development of new superconducting materials. In some samples only traces of superconductivity are found, but when the phase responsible for the superconducting behavior can be identified and its composition determined, a new superconducting material is born. In other cases the presence of planar defects in existing superconducting materials provides the clue for the development of new superconducting materials. An extremely good example of this is the discovery of double (CuO) layers in normal 1-2-3 YBCO material [50], which has led to the development of the 1-2-3.5 [53] and 1-2-4 [54] superconductors. Further experiments have led to structures such as the 1-2-5 [230–232] or even the 1-2-6 [233] phase; however, these phases are only present in very local areas or are formed under the electron beam of the microscope.

Electron microscopy has also played an important role [234–238] in the development of the infinite-layer superconductors such as $Ca_{1-x}Sr_xCuO_2$ [231] and related structures. A large number of bismuth-, thallium- and mercury-based superconducting compounds of the type '1 2*n* *n* + 1' and/or '2 2*n* *n* + 1' [239–246], and very often TEM imaging was the key for their development. However, particularly with the recent development of superconducting oxycarbonates and mercury-based superconductors, TEM has played an extremely important role. I will illustrate this with some of our recent work, a collaboration between the University of Caen, the CNRS Grenoble, and the University of Antwerp.

Development of Superconducting Oxycarbonates

The '1-2-3' derivatives

$$(Y,Ca)_n(Ba,Sr)_{2n}Cu_{3n-1}CO_3O_{7n-3}$$

whose structure consists of an ordered replacement of rows of CuO_4 groups by CO_3 groups in $YBa_2Cu_3O_7$, are the first example of superconducting oxycarbonates. Two oxides of this series have been shown to exhibit superconducting properties — $(Y_{1-x}Ca_x)_{0.95}Sr_{2.05}Cu_{2.4}(CO_3)_{0.6}O_y$ [247] and $YCaBa_4Cu_5(NO_3)_{0.3}(CO_3)_{0.7}O_{11}$ [248]; both correspond to the members $n = 2$ of the above series. These compounds have a T_c (onset) of 66 and 82 K, respectively, with superconducting volume fractions of 5 and 15%, respectively, at 5 K.

The second type of oxycarbonates to exhibit superconducting properties is represented by the phase

$$(Ba_{1-x}Sr_x)_2Cu_{1-y}O_{2y+x}(CO_3)_{1-y}$$

[249, 250] with a T_c (onset) of 40 K and a Meissner volume fraction of 20%. Its structure belongs to the $Sr_2CuO_2CO_3$ type, that is, it consists of octahedral

copper layers connected through rows of carbonate groups. The close relationship between the $Sr_2CuO_2CO_3$-type structure and the perovskite structure suggests that the CO_3 groups should also be able to accommodate all the layered cuprates, that is, layered structures involving rock salt and perovskite layers. This is the case for the recently discovered superconductors $Tl_{0.5}Pb_{0.5}Sr_4Cu_2CO_3O_7$ [251], $Tl_{1-x}Bi_xSr_4Cu_2CO_3O_7$ [252], $Bi_2Sr_4Cu_2CO_3O_8$ [253], and $Bi_2Sr_{6-x}Cu_3O_{10}(CO_3)O_{10}$ [254].

The oxycarbonate

$$Tl_{0.5}Pb_{0.5}Sr_4Cu_2CO_3O_7$$

exhibits a critical temperature up to 70 K with a Meissner volume fraction of 70% at 5 K. The structure of this tetragonal phase consists of the intergrowth of double rock salt layers $[(Tl_{0.5}Pb_{0.5}O)(SrO)]_x$ and single perovskite layers, linked through layers of CO_3 groups. The oxycarbonate $Tl_{1-x}Bi_xSr_4Cu_2CO_3O_7$, which exhibits a similar structure, is characterized by a lower critical temperature ($T_c = 54$ K) but also a large Meissner volume fraction of about 60%. In fact, the structure of these two superconductors can be described as an intergrowth of the two structures $Sr_2CuO_2CO_3$ and '1201', that is, $Tl_{0.5}A_{0.5}Sr_2CuO_5$ (A = Pb or Bi). As a consequence, these oxides can be considered as the first members ($n = n' = 1$) of the intergrowth with the general formula $(Tl_{1-x}A_xSr_2CuO_5)_n(Sr_2CuO_2CO_3)_n$. The remarkable feature of these two phases deals with the fact that the two structures which form their framework either do not superconduct or exhibit a lower critical temperature. $Sr_2CuO_2CO_3$ has indeed never been observed to superconduct, whereas only traces of superconductivity (less than 1%) up to 60 K were detected in the 1201 phase $Tl_{0.5}Pb_{0.5}Sr_2CuO_5$ [252], which might be due to the presence of traces of this oxycarbonate. In a similar way, the 1201 phase $Tl_{1-x}Bi_xSr_2CuO_5$ was found to exhibit a significantly lower T_c of 45 K (onset) with a broad transition [255, 256]. Thus, it clearly appears that the intergrowth of the two nonsuperconducting structures, the oxycarbonate $Sr_2CuO_2CO_3$ and the 1201 phase, significantly improves the superconducting properties.

In the same way, the two superconductors $Bi_2Sr_4Cu_2CO_3O_8$ [253] and $Bi_2Sr_{6-x}Cu_3(CO_3)_2O_{10}$ [254] correspond to the members $n = n' = 1$ and $n = 1$, $n' = 2$ of the intergrowth

$$(Bi_2Sr_2CuO_6)_n(Sr_2CuO_2CO_3)_{n'}.$$

Figure 53 shows, as an example, the schematic structure of $Bi_2Sr_4Cu_2CO_3O_8$,

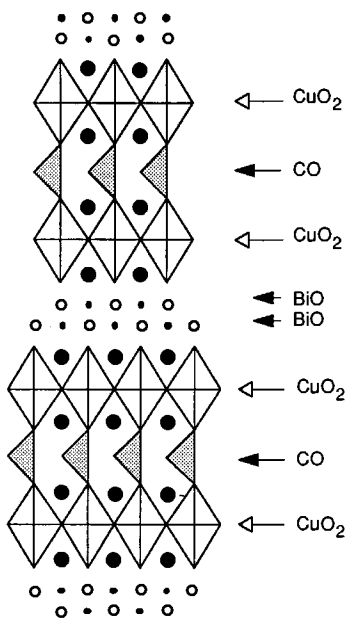

Figure 53. Schematic structure of the 30 K superconductor $Bi_2Sr_4Cu_2CO_3O_8$, the $n = n' = 1$ member of the intergrowth series $(Bi_2Sr_2CuO_6)_n(Sr_2CuO_2CO_3)_{n'}$.

which consists of an intergrowth of single 2201 layers with single $Sr_2CuO_2CO_3$-type layers. The second member, $Bi_2Sr_{6-x}Cu_3(CO_3)_2O_{10}$ is deduced from the latter by replacing the single $Sr_2CuO_2CO_3$-type layers by double oxycarbonate layers.

The most striking feature is the value of the critical temperature: 30 K for $Bi_2Sr_4Cu_2CO_3O_8$ and 40 K for $Bi_2Sr_{6-x}Cu_3(CO_3)_2O_{10}$; both T_c values are higher than those of the mother structures. $Bi_2Sr_2CuO_6$ exhibits a maximum T_c of 22 K [257], whereas $Sr_2CuO_2CO_3$ does not superconduct. Also spectacular is the increase of the T_c from 30 to 40 K as the thickness of the nonsuperconducting layer $(Sr_2CuO_2CO_3)_{n'}$ increases.

The recent discovery of the 62 K superconductor $TlSr_{4-x}Ba_xCu_2CO_3O_7$ [258] demonstrates the great ability of CO_3 groups to occupy cationic sites different from the copper sites. This phase indeed exhibits a very original structure (Fig. 54) closely related to that of $Tl_{0.5}Pb_{0.5}Sr_4Cu_2CO_3O_7$; and was determined and analysed by HREM. The structure of $TlSr_2Ba_2Cu_2CO_3O_7$ can be obtained by a shearing mechanism along $\bar{c}$, that is, by a translation over $\bar{c}/2$ of the latter structure every four CuO_6 octahedra. From this shearing mechanism, it appears that the $[CuO_2]_x$ layers of each block remain unchanged and form infinite layers parallel to (001). This is not the case for the $[TlO]_x$ ribbons which are limited to four thallium atoms along $\bar{b}$ and are connected to ribbons of four CO_3 groups. Thus, the $[TlO]_x$ layers of the structure $Tl_{0.5}Pb_{0.5}Sr_4Cu_2CO_3O_7$ are replaced by

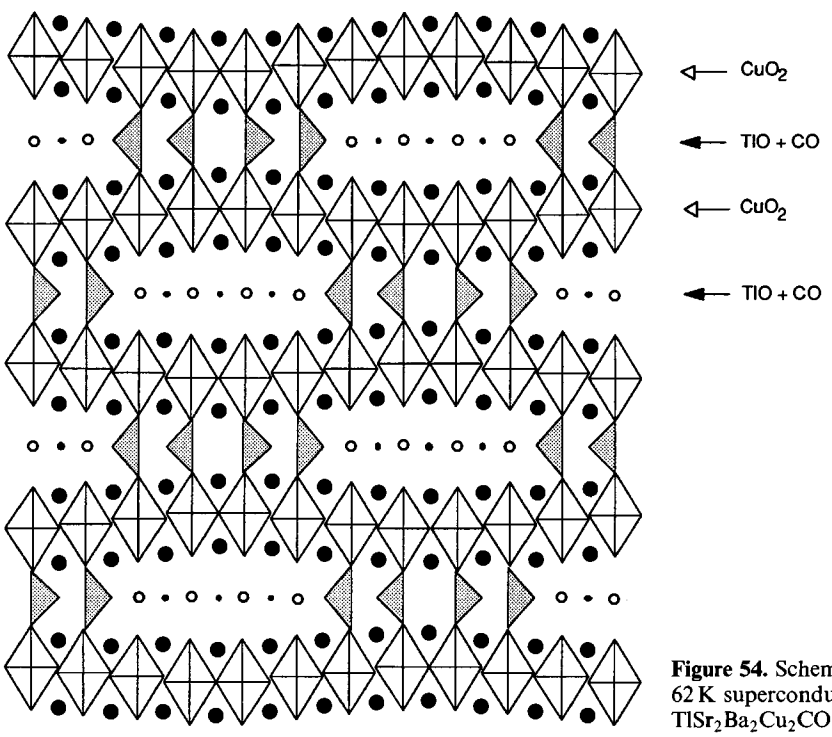

Figure 54. Schematic structure of the 62 K superconductor $TlSr_2Ba_2Cu_2CO_3O_7$.

mixed layers $[(TlO)_4(CO)_4]_x$ characterized by a sequence of four thallium atoms and four carbonate groups along $\bar{b}$. Such a replacement of thallium by carbon implies a strong waving of the octahedral copper layers (Fig. 54) in order to accommodate the differences between the apical Tl–O distances (~2.00 Å) and C–O distances (1.30 Å). Consequently, two successive perovskite layers wave in antiphase so that the larger space between such layers is occupied by thallium, whereas the CO_3 groups are located in the narrower spaces. This waving behavior is clearly observed in the HREM images of Fig. 55; without these convincing observations one would never be able to imagine such a complex and unusual structure. A similar modulation behavior is observed in a number of other related structures such as $HgBa_2Sr_2Cu_2CO_3O_7$ [259] and $Hg_{0.5}Pb_{0.5}Sr_{4-x}Ba_xCu_2(CO_3)O_{7-\delta}$ [260, 261]. In fact, this new structure is also closely related to that of the 1201 thallium cuprates, which consists of single perovskite layers intergrown with rock salt layers. It can be described as a 1201-type structure in which the $[TlO]_x$ layers are replaced by ordered mixed $[(TlO)_4(CO)_4]_4$ layers. One observes again that the critical temperature of this phase is significantly higher than the 1201 mother structures: $TlSr_2CuO_5$ ($T_c = 0$ K) and $TlBa_2CuO_5$ ($T_c = 10$ K), and $TlBaSrCuO_5$ ($T_c = 43$ K). So, it is remarkable that the introduction of CO_3 groups in the 1201 cuprates enhances T_c to 62 K.

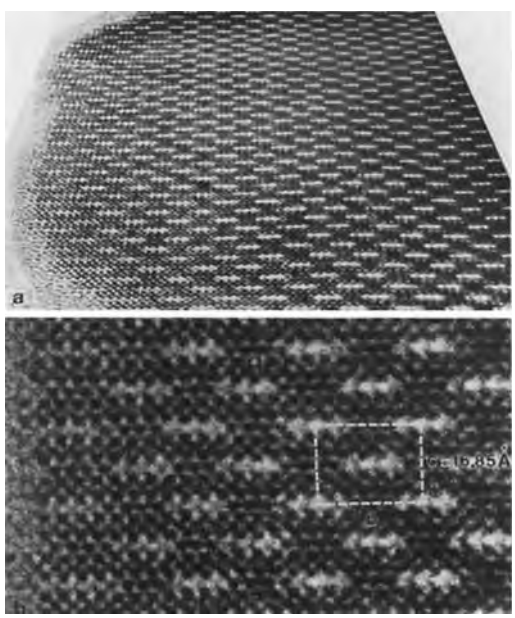

Figure 55. HREM images of modulation in superconducting $Hg_{0.3}Tl_{0.7}Sr_{1.5}Ba_{2.5}Cu_2CO_3O_{7-\delta}$. (a) At lower magnification, under grazing incidence. (b) At high magnification.

Mercury-Based Cuprates

Owing to its preference for twofold coordination, mercury will ensure a junction between either octahedral perovskite layers or pyramidal copper layers, forming linear $Hg^{II}O_2$ groups. The latter layers contain a large number of vacancies, so that they can accommodate the oxygen necessary to create the mixed valence Cu(II)–Cu(III). The great flexibility of the structure of layered cuprates makes it possible to introduce other cations, besides mercury, in the intermediate layers and simultaneously allows incorporation of additional oxygen. After the discovery of the 94 K superconductor $HgBa_2CuO_{4-\delta}$ [262], five series of mercury-based superconducting cuprates have been isolated; four of them belong to the 1201, 1212, 1223, and 1234 structures, respectively, whereas the fifth one is an intergrowth of the 1201 and 2201 structures.

The '1201' Mercury-Based Cuprates: The first oxide of this series that was discovered

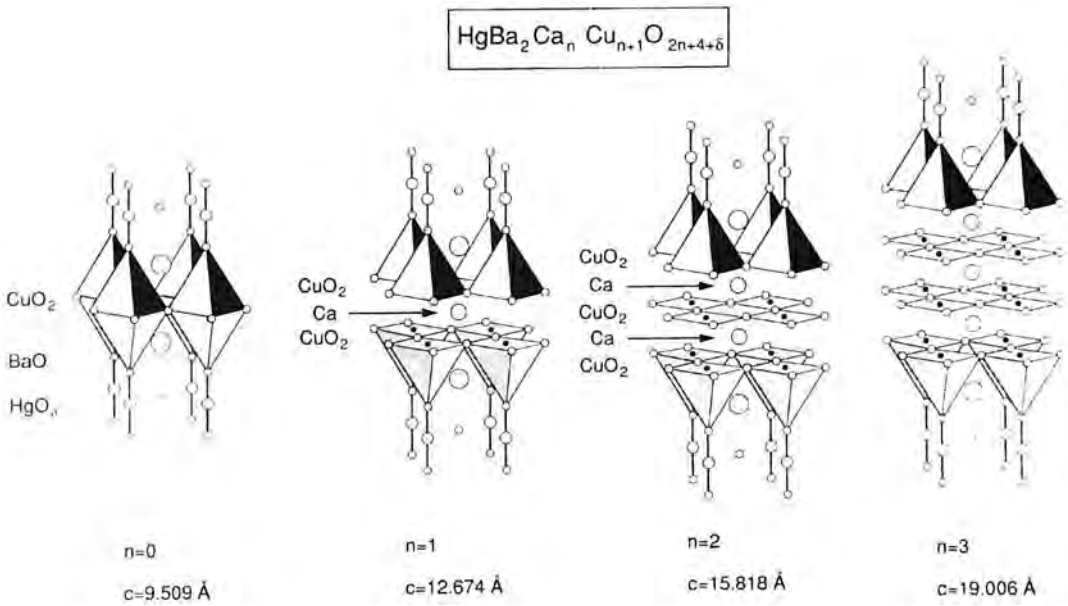

Figure 56. Schematic representation of several members of the structural family $HgBa_2Ca_{n-1}Cu_nO_{2n+2+\delta}$. (a) $n = 1$ or '1201' $HgBa_2CuO_{4+\delta}$. (b) $n = 2$ or '1223' $HgBa_2CaCu_2O_{6+\delta}$. (c) $n = 3$ or '1223' $HgBa_2Ca_2Cu_3O_{8+\delta}$. (d) $n = 4$ or '1223' $HgBa_2Ca_3Cu_4O_{10+\delta}$.

by Putilin et al. [261] can be described as single perovskite octahedral copper layers connected through linear HgO_2 groups (Fig. 56), leading to the ideal formula $HgBa_2CuO_4$. Additional oxygen is then intercalated at the level of the mercury atoms, according to the formula $HgBa_2CuO_{4-\delta}$, which allows an adequate number of holes to be introduced to satisfy the mixed valence Cu(II)–Cu(III). Nevertheless, the mean value of copper of 2.12 ($\delta = 0.06$) is still much smaller than that observed for $YBa_2Cu_3O_7$. This suggests that in this phase the mercury layers have the same role of hole reservoirs as in the bismuth cuprates or the thallium cuprates.

The substitution of bismuth for mercury is possible; it occurs for the particular molar ratio of Hg/Bi = 1. A new superconducting phase with composition $Hg_{0.5}Bi_{0.5}Sr_{2-x}La_xCuO_{5-\delta}$ has indeed been isolated recently [263] for $0 \leqslant x \leqslant 0.75$. As shown from the [100] and [110] HREM images of this phase (Fig. 57), its structure belongs to the 1201 family, that is, it consists of single

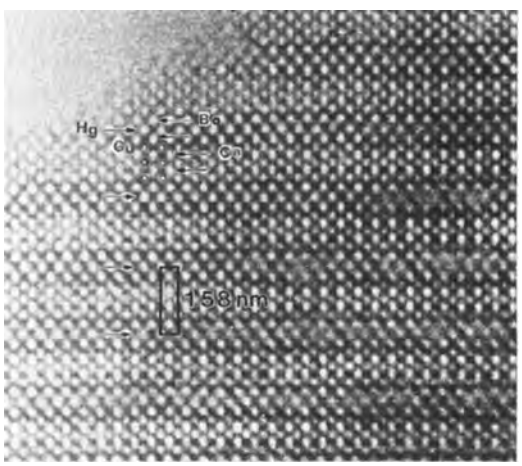

Figure 57. High-resolution image along [100] of $HgBa_2Ca_2Cu_3O_{8+\delta}$. Under this contrast the heavy ions are imaged as bright dots; the imaging code as well as the unit cell are indicated.

perovskite slices $[Sr_{1-x/2}La_{x/2}CuO_3]_x$ intergrown with double rock salt layers $[(Bi_{0.5}Hg_{0.5})(Sr_{1-x/2}La_{x/2})O_{2-\delta}]_x$ (see Fig. 56). Its critical temperature, T_c (onset) $\approx$27 K, is much lower than that of the 1201 barium-based cuprate. Nevertheless, it is interesting to compare its properties to the other 1201 structure cuprates $TlSr_2CuO_{5-\delta}$ and $Tl_{0.5}Pb_{0.5}Sr_2CuO_{5-\delta}$ which do not superconduct. The weaker superconducting properties of this cuprate compared to the pure mercury cuprate $HgBa_2CuO_{4-\delta}$, especially the lower T_c and the broad character of the transition, may be due to the cationic disorder that appears between bismuth and mercury in the rock salt layers. The latter may indeed hinder a perfect coupling between the $[CuO_2]_x$ layers.

The synthesis of the two series of cuprates

$$Hg_{0.3}Pb_{0.7}Sr_{2-\delta}La_xCuO_{4+\delta},\ 0 \leqslant x \leqslant 0.65$$

and

$$Hg_{0.4}Pr_{0.6}Sr_{2-x}Pr_xCu_{4+\delta},\ 0 \leqslant x \leqslant 0.1$$

[261], confirms the ability of strontium to form the 1201 structure. The tetragonal lead cuprate resembles closely the bismuth cuprate, that is, it consists of the stacking of $[(Sr,La)CuO_3]_x$ perovskite layers and $[(Pb,Hg)O_\delta]_x$ rock salt layers with a statistical distribution of lead and mercury. The situation is different for the praseodymium cuprate. The latter exhibits an orthorhombic symmetry, due to a doubling of one '*a*' parameter; this doubling of the unit cell and the ordering between mercury and praseodymium in the $(Hg–Pr)O_\delta$ plane can be detected from HREM images (Fig. 58). The diagnostic volume fraction of the as-synthesized materials is generally weak.

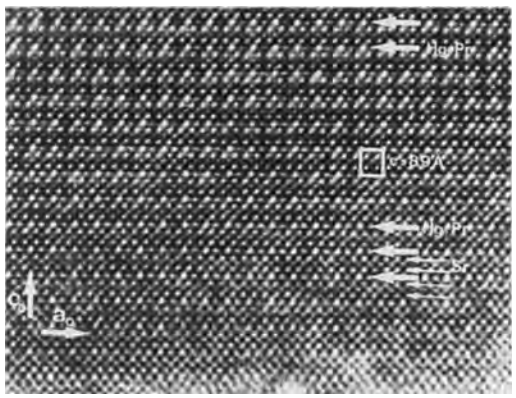

Figure 58. HREM image of $(Hg_{0.4}Pr_{0.6})$-$Sr_{2-x}Pr_xCuO_{4+\delta}$ along [010]. In the thicker areas (upper part of the figure) the Pr–Hg ordering along the *a* axis is clearly observed.

To improve these properties, different treatments are performed. Annealing at 300°C under an oxygen pressure of 20 bar does not modify T_c, nor the diamagnetic volume fraction. The preparation of a deficient lead–mercury phase

$$(Hg_{0.5}Pb_{0.5})_{1-y}Sr_{1.35}La_{0.65}CuO_{4-\delta}$$

leads to the formation of an almost single phase whose parameters are not significantly different from those of the stoichiometric oxide.

The "1212" Mercury-Based Cuprates: After the discovery of superconductivity at 134 K in the system mercury–barium–calcium–copper–oxygen [264], TEM observations allowed the identification of the (poor fraction) of the 134 K superconducting phase, and four mercury-based superconductors with the 1212-type structure have been synthesized almost simultaneously. The first one, $HgBa_2CaCu_2O_{6+\delta}$ [265], exhibits a T_c of 120 K; it can be considered as being derived from the '1-2-3'-type structure. Indeed, the structure of $HgBa_2CaCu_2O_6$

corresponds exactly to the replacement of univalent copper Cu(1) by mercury in the insulating phase $YBa_2Cu_3O_6$. In fact, additional oxygen must be introduced at the level of mercury ($\delta \approx 0.2$) in order to induce superconductivity; the oxygen atoms are distributed over the anionic sites of the rock salt layers in the 1212 structure, so that $HgBa_2CaCu_2O_{6+\delta}$ can also be described as an intergrowth of double pyramidal copper layers and oxygen-deficient rock salt layers. Unfortunately the present structure could only be synthesized under a high pressure of about 50 kbar, so that other routes or other mercury-based cuprates were investigated to reach this critical temperature.

Starting from the idea that the rock salt layer of the 1212 structure may be oxygen-deficient if one introduces mercury, two superconducting 1212-type cuprates were synthesized. The first one, $Y_{0.6}Ca_{0.4}Ba_2Cu_2[Hg_{1-x}M_x]O_{6+\delta}$, with $M = Ca + Cu$ [266], is single phase for $0.4 \leqslant x \leqslant 0.50$, whereas the second one, $Nd_{1-x}Ca_xHg_{1-x'}Cu_{2-x'}O_{6+\delta}$ [267], is almost single phase for $0.4 \leqslant x' \leqslant 0.60$ with $x' = 0$ and 0.2. The X-ray diffraction and HREM study of these oxides show that they both belong to the 1212 series, in agreement with their tetragonal symmetry ($a \approx 3.8$ Å and $c \approx 12.5$ Å). An HREM image along [100] is shown in Fig. 59 for

$$Y_{0.6}Ca_{0.4}Ba_2Cu_2[Hg_{0.6}Cu_{0.2}Ca_{0.2}]O_{6+\delta}$$

These images were extremely useful for the location of the heavy ions. From symmetry considerations as well as from image simulations, one can easily identify the double BaO layers sandwiching the HgO layer. It is clear that the distance between the two BaO layers is larger than the distance between the CuO_2 layers. Most

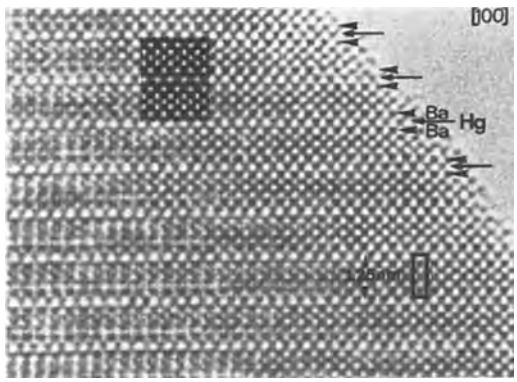

Figure 59. HREM image of $(Y_{0.6}Ca_{0.6})Ba_2Cu_2O_{6+\delta}$ along [100]; the heavy ion configuration is clearly imaged as dark dots in the thinner parts. The 0.387×1.25 nm projected unit cell is indicated. The computer simulated image for a thickness of 3 nm and a defocus value of 60 nm is shown as an inset.

grains are very perfect and almost no (001) planar defects are present. The structure of this phase belongs to the 1212 family, that is, it consists of double pyramidal copper layers intergrown with distorted rock salt layers containing several kinds of cations (mercury, calcium, and copper), according to the general formula

$$[Y_{0.6}Ca_{0.4}]_{FC}Ba_2[Hg_{1-x}M_x]_{RS}Cu_2O_{6+\delta}$$

with $\delta \approx 0.6$ and M = Ca, Cu. The HREM image contrasts observed for the neodymium phase are very similar to those obtained for the yttrium phase, showing that the intermediate rock salt layers are built up from $[HgO_\delta]_x$ or $[Hg_{1-x}Cu_xO_\delta]_x$ slices. The susceptibility curves show that both series of cuprates are superconductors with T_c (onset) values of 90 and 110 K for $Y_{0.6}Ca_{0.4}Ba_2Cu_{2.25}Hg_{0.5}Ca_{0.25}O_{6+\delta}$ and $Nd_{0.6}Ca_{0.4}Ba_2Cu_2HgO_{6+\delta}$, respectively. For both cuprates, the diamagnetic volume fraction of about 25% is characteristic of bulk superconductivity, but in all cases the transition is very broad. This is easily explained by an inhomogeneous

distribution of the cationic species in the rock salt layers; the latter point has been illustrated by EDS analysis, which shows dramatic variations of the cationic distribution from one crystal to another in the 'Nd–Hg'-based cuprates.

The 1212 structure of the mercury-based cuprates can also be stabilized by the introduction, besides mercury, of lead or bismuth. The presence of these cations allows the strontium phase to be synthesized. This is the case for the cuprates $(Pb,Hg)Sr_2(Ca,Y)Cu_2O_{6+\delta}$ [268] and $Hg_{0.5}Bi_{0.5}Sr_2Ca_{1-x}R_xCu_2O_{6+\delta}$ with R = Nd, Y, Pr [269] which exhibit superconductivity up to 90 and 94 K, respectively. The structure of these phases is very similar to that of the barium 1212 cuprates, strontium replacing barium and $[Pb,HgO_\delta]_x$ or $[Bi,HgO_\delta]_x$ layers replacing the $[HgO_\delta]_x$ or $[Hg,CuO_\delta]_x$ layers. They are all characterized by a disordered distribution of mercury and lead or bismuth in the rock salt-type layers. This disordering may be the origin of the broad transition observed for these compounds.

The behavior of the 1212 phase $Bi_{0.5}Hg_{0.5}Sr_2Ca_{1-x}Y_xCu_2O_{6+\delta}$ is very different from that of the 1201 oxide $Bi_{0.5}Hg_{0.5}Sr_2CuO_{4+\delta}$ [263], which does not superconduct. Such a difference between the 1212 and 1201 oxides was previously observed between

$Tl_{0.5}Pb_{0.5}Sr_2(Ca_{1-x}R_x)Cu_2O_7$

and

$Tl_{0.5}Pb_{0.5}Sr_2CuO_5$

[270]. In the same way, the insensitivity to different annealing treatments seems to be a common character of several mercury-based oxides [263, 266, 267, 271].

It is worth pointing out that all the mercury-substituted 1212 cuprates exhibit a smaller critical temperature than the pure mercury cuprate $HgBa_2CaCu_2O_{6+\delta}$. This may be due to the cationic disordering introduced at the level of the mercury layer. Nevertheless, one important feature deals with the fact that all these cuprates, in contrast to $HgBa_2CaCu_2O_{6+\delta}$, can be synthesized at normal pressures

The '2201–1201' Intergrowth $HgTl_2Ba_4Cu_2O_{10+\delta}$: The great similarity between Tl(III) and Hg(II), which are both characterized by a $5d^{10}$ external electronic configuration, suggests that mixed 'Tl–Hg' superconducting cuprates should exist. The superconducting cuprate $HgTl_2Ba_4Cu_2O_{10+\delta}$, [272, 273] confirms this idea. This new phase, which exhibits a tetragonal symmetry ($a = 3.85$ Å and $c = 42.2$ Å), has been detected and studied by HREM. From the [100] image (Fig. 60) one can easily identify the double rows of bright dots with the double thallium

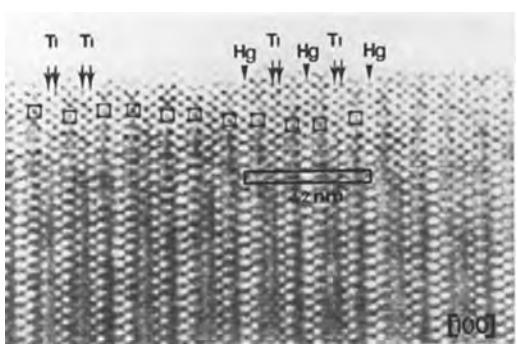

Figure 60. [100] HREM image showing the 4.2 nm unit cell as well as the configuration of the heavy ions. The barium configuration has been indicated by squares, the mercury ions by arrowheads, and the thallium double layers by double arrows. In the left part we observe an occasional defect where the Tl_2–Hg–Tl_2–Hg chain is interrupted by a double Tl_2–Tl_2 sequence.

layers, as previously observed in the 2201 cuprate $Tl_2Ba_2CuO_6$ [272], whereas the single row of bright dots can be identified with the thallium or mercury monolayers observed for the 1201 cuprates, $TlSr_2CUO_5$, or $HgBa_2CuO_4$. They are indicated in Fig. 60 with double arrows and single arrowheads, respectively. The square barium configuration, imaged as dark dots in the thinnest part of the sample, is identified in Fig. 60. From this study, it clearly appears that the ideal structure of the new phase $HgTl_2Ba_4Cu_2O_{10+\delta}$, represented in Fig. 61, consists of an intergrowth of the 2201

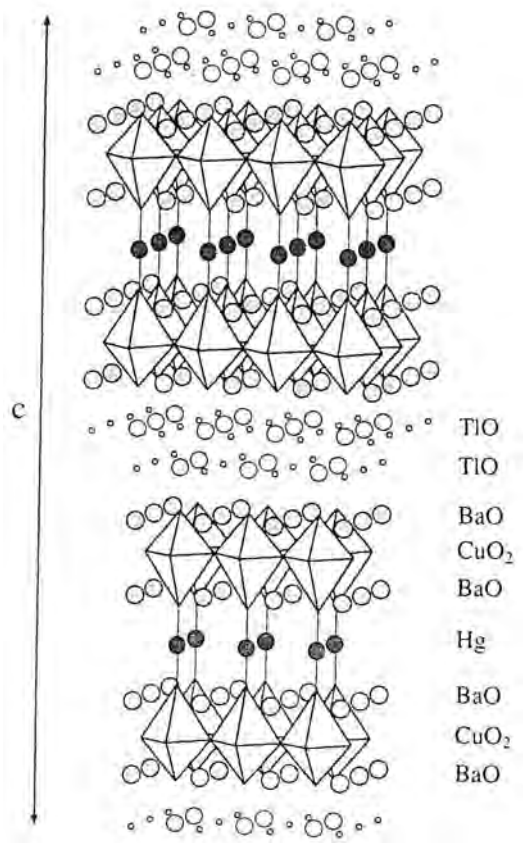

Figure 61. Schematic representation of the idealized structure of $Tl_2HgBa_4Cu_2O_{10}$.

and the 1201 structures, that is, it is built up from single octahedral perovskite layers intergrown with distorted triple and double rock salt-type layers alternately. Taking into consideration the observed molar ratio Tl/Hg = 2, the higher stability of the 2201 phase $Tl_2Ba_2CuO_6$ with respect to the 1201 phase $TlBa_2CuO_5$, and the ability of mercury to form the 1201 phase, it appears most likely that the 2201 slices are mainly built up from thallium bilayers, whereas the 1201 slices contain mainly mercury. Nevertheless, partial mixed occupation of these two kinds of cation sites cannot be ruled out. As a consequence, the structure of this phase can be represented by the formula

$$[Tl_{2-\delta}Hg_\delta Ba_2CuO_6]^{2201}[Hg_{1-\delta}Tl_\delta Ba_2CuO_{4+\delta}]^{1201}$$

The '1223', '1234' and '12nn+1' Cuprates: Recently, several higher-order members of the mercury-based superconducting homologous family $HgBa_2Ca_{n-1}Cu_nO_{2n+2+\delta}$ have been synthesized in more or less pure form [274]. The critical temperature (onset of the Meissner signal) of these materials is known to increase from 94 K (for the $n = 1$ compound) to 126 K for the $n = 2$ compound, and even to a maximum of $T_c = 133.5$ K for the $n = 3$ member. For larger n values, T_c seems to decrease [275], similar to the behavior of the related thallium compounds [276].

The structure of all members is similar; they contain rock salt-like slabs [(BaO)(HgO_δ)(BaO)] alternating with perovskite slabs of the type $[(CuO_2)(Ca)]_{n-1}(CuO_2)$. The existence and the structure of the $n = 1$ member of this family was first reported by Putilin

et al. [262]. Samples containing sequences of the higher-order members were later found by Schilling et al. [264]. HREM not only allows study of the perfect structure of higher-order members of the mercury family but also investigation of possible defects in such compounds. High-quality high-resolution images for the lower members of the $12(n-1)n$ family have been published [277, 278].

Electron diffraction images along several reciprocal zone axes show that some materials include crystallites corresponding to n values ranging from 2 to 7. The higher members of this series cannot be obtained in a pure form so that X-ray studies are extremely difficult, if not impossible. A compilation of [100] diffraction patterns corresponding to these n values is shown in Fig. 62.

Real space observations allow the investigation of the perfection of the cyrstals. For the $n = 1$, $n = 2$, and $n = 3$ compounds, hardly any deviation from perfection is found, and virtually no secondary phases are met. An example of a [100] high-resolution image for the 1223 compound is shown in Fig. 57; the cation configuration can be readily identified from symmetry considerations. There is a one-to-one correspondence between the white dot configuration of the HREM image and the cation configuration. Such semi-intuitive interpretations have of course to be confirmed by computer simulations based on the structure model as determined by neutron diffraction and knowledge of the electron microscope parameters [278]. Such calculated HREM images for different thicknesses and different defocus values allow us to analyze in detail the atomic structure of planar defects in the present compounds.

The most common defect encountered, particularly for higher-order members of the family, is the intergrowth of different n

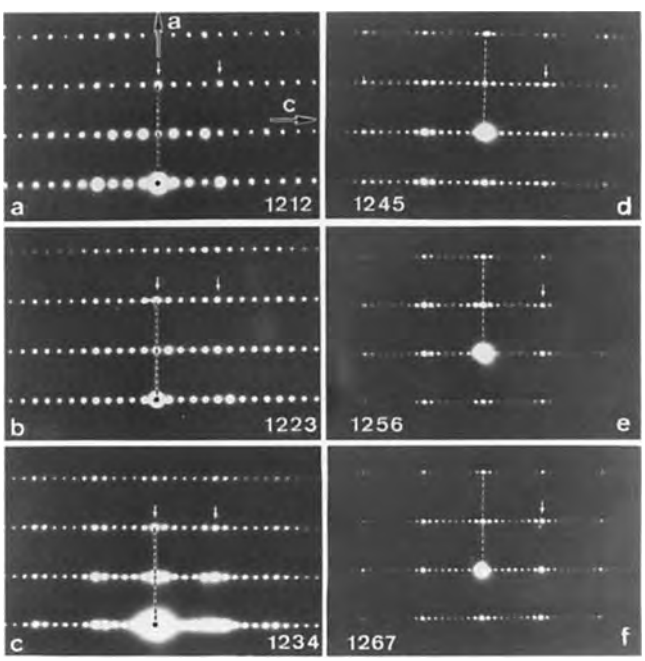

Figure 62. [100] electron diffraction patterns for different members of the series with n ranging from (a) $n = 2$ to (f) $n = 7$.

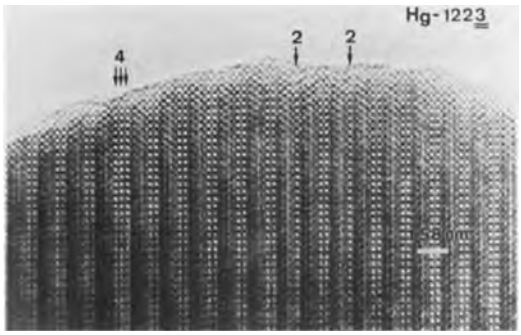

Figure 63. Occasional stacking errors in a mercury 1223 crystal; locally, mercury 1212 (indicated by the numeral 2) and mercury 1234 (indicated by the numeral 4) are found. The calcium configuration shows up here as very pronounced dots, compatible with a focus value of around −200 Å.

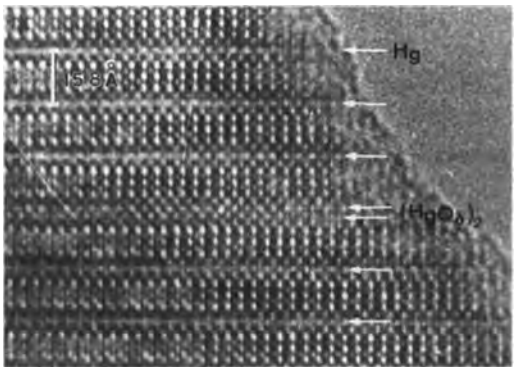

Figure 64. HREM image of an isolated defect in a mercury 1223 crystal, where a double layer of HgO_δ is present, creating locally the 2223 structure.

members. Generally, such defects are isolated, occurring in an otherwise perfect crystal. Examples are shown in Fig. 63 where in a 1223 crystal locally two slabs of 1212 (indicated by the numeral 2, referring to the number of copper layers in the structure) and one slab of 1234 (indicated by the numeral 4) are found. With the help of the image simulations, which allow us to identify the extra bright dot configuration in Fig. 63 as the calcium layers, such defects can readily be analyzed. For materials corresponding to n values exceeding 4, these defects are a common feature.

A most remarkable defect, however, is shown in Fig. 64. The image contrast is such that the copper ions are imaged as bright dots, while the mercury plane is imaged as a more or less diffuse line with maxima at the projected atom positions. It is evident from the imaging code that locally we have four rock salt layers rather than the usual sequence of three layers [(BaO)(HgO_δ)(BaO)]. A single mercury layer is replaced by a double mercury layer of bright dots. Simulated images of a trial structure with a double (HgO_δ) layer in the structure confirm the present interpretation.

The occurrence of such defects with a double (HgO_δ) layer suggests the feasibility of producing '$22n-1n$'-type materials. Compounds such as Hg–22 $n-1$ n can only be stabilized if the oxygen sites of the mercury layers are occupied by more than 50%. The neutron diffraction refinements of the different mercury members show that the largest occupation factors for those oxygen atoms is at most 40%. However, by replacing some of the mercury by other elements, such as praseodymium or copper, the '2212' structure with a double (HgO_δ) layer can be stabilized [279].

In some of the preparations (for details, see Kopnin et al. [280]), the critical temperature T_c was much lower than the above-reported values. With the help of microanalysis and HREM one can find that some of the mercury positions are occupied by carbonate groups but in a very disordered way. Electron diffraction, which is very sensitive to local ordering or short-range ordering, does not show any

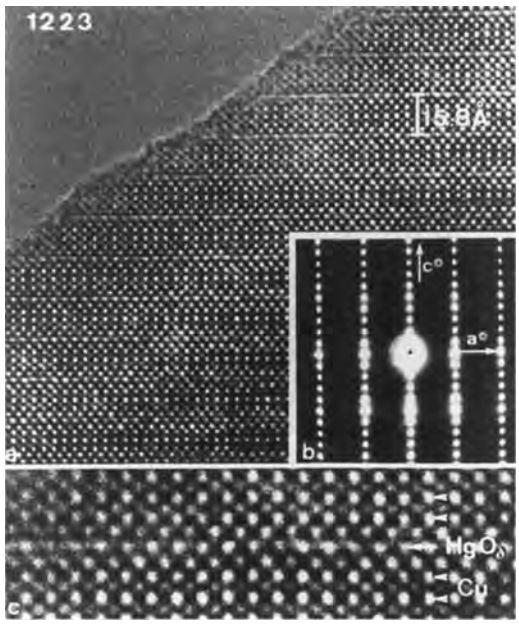

Figure 65. (a) HREM image along [010] of a mercury 1223 compound, showing the individual cation columns as bright dots. (b) The corresponding electron diffraction pattern. (c) Higher magnification of part (a); note that in the HgO_δ layer the intensity of the individual dots is not homogeneous.

diffuse scattering (Fig. 65b). Also, the corresponding HREM image of Fig. 65a does not show any superstructure formation. The HgO_δ layer can be easily identified as the more diffuse layer; along this layer, however, we do see variations in the intensities of the different bright dots (see Fig. 65c, which is an enlargement of Fig. 65a). One can quantify these variations by making densitometer traces along the HgO_δ layer as well as along one of the neighboring CuO_2 layers. The results are shown in Fig. 66, where we have plotted the intensity for different bright dots along a single HgO_δ row; there is clearly a pseudo-periodic variation in the intensity; such variation is not observed in the corresponding measurements for the BaO or the CuO_2 layer (Fig. 66b). These intensity variations are correlated with the occupation of the mercury sublattice, which from detailed EDX measurements is only $Hg_{0.7-0.8}$. The presence of carbonate groups cannot be verified by EDX, because carbon is at the limit of detection and contamination will always introduce carbon.

9 Non-Periodic Structures

9.1 High-Resolution Imaging of Amorphous Materials

9.1.1 Introduction

It is tempting to consider the atomic structure of an amorphous solid as a random collection of atoms, but for most glasses and amorphous thin films this is far from accurate. Both positional and compositional order are relatively well-defined over short distances—nearest and next nearest atomic neighbors—what is often called the 'local structure'. It is possible to define local structural units such as $SiSi_4$ or SiO_4 tetrahedra in amorphous Si or glassy SiO_2. These have symmetry and geometry equivalent to corresponding crystalline phases and the way in which the units are connected is often recognizably the same as that of the crystal, although deviations from regularity are much more pronounced. Beyond about 2 nm the long-range structure of all amorphous solids can be represented by truly averaged properties (except for compositional inhomogeneities in materials which exhibit immiscibility).

In contrast, the 'medium-range structure'—from about 0.6 to 2 nm—is difficult to determine and to specify [1]. Diffraction techniques, which have provided most of the structural information on amorphous solids, become decreasingly useful beyond third neighbors, for obvious reasons. X-ray and neutron diffraction involve massive averaging, over at least 10^{20} atoms, over all types of pair correlations $P_{\alpha\beta}(r)$ in polyatomic solids, and over all directions in space. The distribution functions are one-dimensional (1-D) and the various functions $P_{\alpha\beta}(r)$ overlap—usually in antiphase due to charge ordering—thus submerging information about the spatial (or temporal) variability of the structure. Any structural ordering revealed by diffraction thus represents a lower bound—the actual structure may be much more organized (and more exciting).

The paucity of structural information beyond about 0.6 nm obtainable by diffraction techniques can be complemented by high resolution electron microscopy (HREM). Ideally, the amplitude and phase of the scattered electron wave is retained in the imaging process so that structural information from a microscopic region of a specimen is retained in a real space HREM image, albeit in a scrambled form. Averaging is thus reduced by many orders of magnitude. The effective specimen volume is now typically a 4 nm cube containing, say, 10^4 atoms, and the image is a two-dimensional (2-D) rather than a 1-D

representation of the three-dimensional (3-D) structure.

Studies of the structure of amorphous solids by electron microscopy have, however, produced very variable results, often depending on the type of material and on the questions asked. Glasses are metastable with respect to the crystalline state and the detection of nucleation and incipient crystallization represents one of the simplest problems. Both bright-field and dark-field medium-resolution electron microscopy give unambiguous identification of crystallites that are (typically) larger than 2 nm in diameter. Similarly, the presence of voids or columnar structure on a scale of a few nanometers can be tackled with considerable confidence. A single-phase polyatomic glass may also be metastable with respect to phase separation into two or more immiscible supercooled liquid phases of different compositions, on a scale of a few nanometers upwards. Examination of the detailed morphology, denoting spinodal or 'nucleation and growth mechanisms' represents one of the major triumphs of electron microscopy applied to this field [2].

However, this chapter concentrates on the more open (and demanding) questions surrounding the medium-range structure of amorphous solids studied by high resolution microscopy.

HREM bright-field images of glasses and amorphous semiconductors usually display a grainy structure on a scale of 0.2–0.4 nm. This is sometimes described as a 'pepper and salt' structure, although it is usually possible to recognize 'fringes' that may be parallel and sometimes straight over areas of 2–5 nm^2. The appearance is similar to (distorted) lattice fringes of crystalline solids and, as there may be some regularity and symmetry, and the fringe spacings are often characteristic of similar crystalline phases, the possibility arises of treating these as coherently scattering domains. Similar effects may be seen in tilted illumination dark-field images, where the coherently diffracting regions appear as bright patches in an otherwise random speckle pattern. Here we concentrate on bright-field HREM images.

Axial bright-field images of several amorphous alloys show pronounced fringe-like detail on a scale of 1–2 nm: results that can be linked to the close-packed structures of these glasses. For the more open structures typical of elemental amorphous semiconductors and oxide glasses, the situation is less clear. Apart from a few cases (e.g. near an interface with a crystal or in very thin specimens), the amount of structural information is very limited. To date, HREM has provided few really essential clues to the nature of the amorphous state. But the situation is changing rapidly, and it is perhaps not overoptimistic to claim that within 10 years the last statement will be redundant.

Optimism is based on two recent advances. Firstly, improvements in resolution limits now allow state-of-the-art microscopes to image, routinely, atomic density fluctuations in the region of 0.2 nm (typical of the detail seen in amorphous metals), and even more adequately to record features of the structure of oxide glasses and amorphous elemental semiconductors. Secondly, it is now possible to compare experimental HREM images with simulated images of atomic models that are sufficiently large to give realistic results. The process is aided, of course, by the marketing of user-friendly software

packages for computing images and to modify atomic models.

9.1.2 Obstacles to Progress

9.1.2.1 Resolution Limit

A fundamental problem that has colored the history of HREM investigations of amorphous solids stems from the fact that the structural information is delocalized in reciprocal space. Instead of the narrow diffraction rings typical of a polycrystalline solid, scattering from amorphous solids gives a series of diffuse halos with rapidly decreasing intensity as the scattering angle increases. Neglecting scattering from the surfaces, inelastic scattering etc., the orientationally averaged scattered intensity from a specimen containing N atoms can be represented by the static structure factor:

$$S(Q) = \frac{\left|\sum_{i=1}^{N} \exp(i\boldsymbol{Q}\cdot\boldsymbol{R}_i)\right|^2}{N} \qquad (1)$$

where $\boldsymbol{R}_i$ is the position vector of the ith atom, $\boldsymbol{Q}$ is the scattering vector, and $Q = |\boldsymbol{Q}| = 4\pi \sin\theta/\lambda$; 2θ and λ are the scattering angle and electron wavelength. For previous generations of microscopes the information limit extended to (at best) only the first peak of $S(Q)$ at $Q_1 = 20$ to $30\,\mathrm{nm}^{-1}$, including one oscillation of the contrast transfer function. Attempts were made to extend the range of Q-space sampled by using tilted illumination, but the benefits this offers are outweighed by the image artifacts introduced.

In terms of the Abbe theory, the electron wave scattered by the specimen is

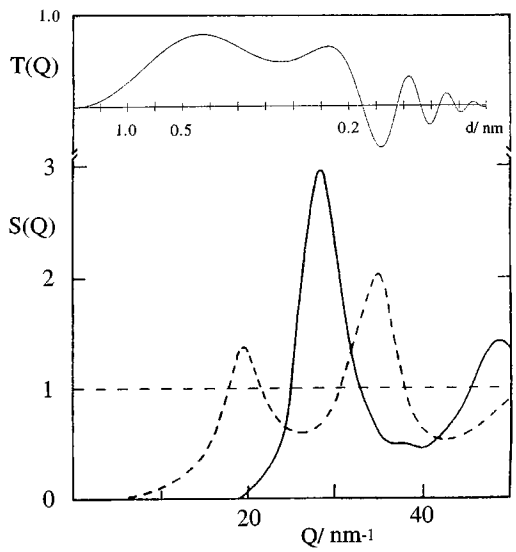

Figure 1. The contrast transfer function $T(Q)$ for a JEM200CX with a high-resolution polepiece [3] at a defocus of 45 nm, together with the structure factor $S(Q)$ for amorphous Ge and amorphous Pd_4Si. Interplanar spacings ($d = 2\pi/Q$) are marked in the upper diagram.

modified in the diffraction plane (the back focal plane of the objective lens) by a scattering angle-dependent instrument response function: the contrast transfer function (CTF), denoted here by $T(Q)$. Typical $S(Q)$ data and $T(Q)$ for a JEM200CX with a specially designed high resolution polepiece which allows a point-to-point resolution limit of slightly less than 0.2 nm [3] is shown in Fig. 1. Structural information is contained in the oscillations of $S(Q)$ and the information transferred to the real-space image corresponds to regions of Q-space where the scattered amplitude,

$$\sum_{i=1}^{N} \exp(i\boldsymbol{Q}\cdot\boldsymbol{R}_i)$$

and, therefore, $S(Q)$, departs from unity and $T(Q)$ is nonzero. Negative and

positive values of $T(Q)$ imply contrast reversal—bright features in the image would become dark if $T(Q)$ changed sign, and information is suppressed near zeros of $T(Q)$. For faithful image reproduction, all the oscillations of $S(Q)$ should lie within the first lobe of $T(Q)$, which is clearly impossible (see Fig. 1). Even for current high-voltage microscopes, only the first peak of $S(Q)$ for most amorphous alloys lies within the first lobe. The problem is less severe for crystals—diffraction space information is localized at a few discrete peaks, and it is often possible to arrange suitable values of $T(Q)$ at these points to give adequate imaging.

9.1.2.2 The Projection Problem

A second major problem is overlap of the images along a column normal parallel to the beam direction z. For a thick aperiodic specimen, the projected potential of a column of atoms parallel to z corresponds to dense, randomly positioned cluster of points in the x,y plane [4, 5]. As the medium-range structure under examination is unlikely to exceed 2 nm in any direction, the image of a 10 nm thick film consists of overlapping contributions from about 4–5 such regions. Atomic detail is thus undecipherable in specimens thicker than about 0.5–1 nm, and foils thicker than about 10 nm can be treated as white (or strictly grey) noise objects. Calculations by Bursill et al. [6] show this to be the case: reliable atomic positions are obtainable only for films thinner than about 0.6 nm. Most HREM work has assumed this result and has been directed to the simpler task of assessing the extent of positionally ordered regions, with characteristics similar to microcrystallites or aperiodic 'amorphous clusters'.

This appears to be a most useful area for detailed study, with the likelihood that HREM measurements can provide significant, experimental structural evidence to complement X-ray and neutron scattering data on the local structure. There is evidence that even in 'random' atomic models for glasses, and particularly metallic glasses, 'pseudo-Bragg' features are detectable in projections of the atomic coordinates of the model. Early work on this topic by Alben et al. [7] has been extended by Wallis [8], Gaskell and Wallis [9], and by Mountjoy [10]. These latter authors have also related the quasi-Bragg planes to the position of the first (sharp) diffraction peak seen in silicates and many other amorphous solids for which no generally agreed explanation exists.

Recognizable (Bragg-orientated) structure in an HREM image occupies only a fraction of the volume and the remainder (randomly positioned atoms or Bragg 'misorientated' regions) generate noise. Krivanek [11] has given a useful rule of thumb to estimate the minimum size of an orientated region visible in an otherwise disordered foil—planes of Ge in a microcrystallite will be visible if the diameter is greater than about one-third of the foil thickness. Calculations were for the specific case of {111} planes of the diamond-cubic structure which are not densely populated, so that the estimate should provide a reasonable lower bound for many materials. This estimate has been confirmed by image simulation of an approximately 0.5 nm crystallite of γ-Pd_3Si in a matrix of dense random-packed alloys of the same composition [12] and

similar work [13] on amorphized regions in γ-$ZrSiO_4$. Crystalline lattice fringes are almost impossible to detect for crystal/total foil thicknesses less than about 0.23. Interestingly, the corresponding diffraction spots are identifiable in the optical diffractogram at a foil thickness of about twice this value.

9.1.2.3 Electron Beam Damage and Similar Specimen-Dependent Problems

Those used to the art of recording high-quality HREM images of amorphous solids will recognize the need for careful alignment of the optics. Clearly, correction of astigmatism, current and voltage centering [14] are essential at the time of taking a through-focal series of images. Examination of the images after the experiment is also vital, to check for absence of instrumental aberrations, specimen drift etc., and to select the most appropriate defocus conditions. In this regard the two-dimensional Fourier transform of the image—that is, the power spectrum, obtained by optical diffraction or computer processing—can be an essential diagnostic tool. The power spectrum should consist of continuous, circular bright rings with dark rings corresponding to zeros of the CTF [14]. During the experimental phase, such careful alignment takes time. There may also be the need for high current density, simply to see image defects, so that electron-beam damage may irrevocably alter the specimen. Even adopting the stratagem of aligning the optics on one part of the specimen, then recording images on another—perhaps even 'shooting blind' and relying on post-experiment inspection to select appropriate areas, defocus conditions etc.—may prove fruitless, to the extent that many materials become totally inaccessible to HREM studies. Oxide glasses containing mobile cations such as Na^+ or Li^+, low-melting chalcogenide glasses, and even some relatively refractory amorphous metals can be difficult or impossible to study. Crystallization under the beam is, of course, an additional problem and diffraction patterns recorded at the beginning and end of a through-focal series are needed to examine this possibility.

The general rule of thumb is that glasses should be refractory and have a low ionic conductivity—like silica, say. Amorphous alloys may have the advantage of being metals and having a reasonable electronic conductivity, thereby reducing beam-induced damage. But they also need to be resistant to oxidation or sublimation. For materials that are prone to oxidation (e.g. Fe- or Ti-containing alloys) 1 nm of the oxide coating each surface of a 4 nm specimen can ruin image interpretation as well as adding to the noise, so that the use of in situ techniques (e.g. Sinclair et al. [15]) or specially built devices to transfer the specimen from the preparation chamber may be inevitable.

9.1.3 Information Content of Axial Bright-Field Images

Interwoven with attempts to obtain convincing electron micrographs of amorphous solids have been the theoretical and computational studies of the information content of HREM images of amorphous solids. The subject has been reviewed in depth by

Howie [4, 5]; the more recent work will be emphasized here.

Problems arise partly because the image approximates to a projection of the atomic density through the thickness of the foil. While information is localized in the x, y plane of the specimen, correlations observed in a micrograph can arise from the chance correspondence of atoms separated by large distances in the z direction. It is thus necessary to judge whether the appearance of a micrograph represents more order than that associated with random arrangements of atoms or local structural groups. Problems are compounded by aberrations of the microscope. Even if the power spectrum of the specimen is featureless, corresponding to a white-noise object, oscillations in the contrast transfer function can produce an image which in previous generations of electron microscopes, can appear remarkably similar to an experimental image [16]. It is thus critical to compare the observed image with that expected for the material without the structural features being sought but, preferably, with those – such as local structural features – that can be assumed or are known from diffraction studies.

The least satisfactory approach – apart from computational convenience – is to use a completely random object as the model. The problem is that when an experimental micrograph is shown to contain features that are nonrandom, as in the analysis of images of α-Si recorded with a 400 kV instrument [17], where the question arises of the extent to which this reflects the known local ordering in α-Si, extending to (at least) second and third neighbors. As indicated above, perhaps the most satisfactory method is to simulate the image from atomic coordinates for a realistic atomic model that gives a good representation of the diffraction data. Alben et al. [7] discussed the order found in models for monoatomic amorphous metals and tetrahedral semiconductors. More convincingly, Schmidt et al. [18] have simulated bright-field images, including instrumental aberrations, of models for α-SiO_2, and have compared them with their experimental data.

An alternative method is to randomize the phases of the Fourier components which comprise the image, while preserving the amplitude (and thus the power spectrum). As mentioned above, the advantage offered by HREM over scattering techniques is preservation of the amplitude and phase of the scattered waves. The nonrandom character of the phase thus represents a key diagnostic. If the phase were a random function of the x, y coordinates, then positional order must be nonexistent. By randomizing the phase, by optical filtering [19] or computer simulation [17, 20, 21], a 'zero information' image can be created with the same power spectrum as the original. If the original, experimental micrograph contains structure additional to that seen in the zero information image, then that structure can be considered to be real—and otherwise, not. An approximate (but very convenient) method involves comparison of images from thin (<5 nm) and thick (10–15 nm) regions of the same specimen. Both have approximately the same power spectrum and are observed under almost identical microscope conditions, but only the thin specimens can be expected to show structurally significant features. The thicker regions thus provide their own internal standard.

Another technique for detecting ordered regions submerged by 'noise'

involves two-dimensional (2-D) correlation techniques [21–23]. The principle is to form the 2-D correlation function (in one dimension, the Patterson function, equivalent to the pair correlation function), which for an arbitrary function $f(\boldsymbol{r})$ is given by:

$$P(\boldsymbol{r}) = \int_{\boldsymbol{R}} f(\boldsymbol{R}) f(\boldsymbol{r}+\boldsymbol{R})\,\mathrm{d}\boldsymbol{R} \qquad (2)$$

$P(\boldsymbol{r})$ is proportional to the probability of finding an atom at $\boldsymbol{r}$ relative to any given atom site. This is applied to the 2-D intensity distribution in the image. The method, as described by Timsit et al. [22, 23] considers a microcrystallite of Si in a matrix of (simulated) α-Si. The central region of the image of the crystal was used as a 'template' to define the pixels representing the vectors $\boldsymbol{r}$. Specifically, the correlation function is (apart from normalization terms):

$$P(m,n) = \sum_{j=1}^{J} \sum_{k=1}^{K} I(j,k) I(j+m, k+n) \qquad (3)$$

where $P(m,n)$ is the value of the cross-correlation function at pixel (m,n), $I(p,q)$ is the image intensity at pixel (p,q) within the $P \times Q$ image area, and (j,k) are indices within the $J \times K$ template area. The image region occupied by the crystal which corresponds to the intensity pattern of the crystal template is highlighted in $P(m,n)$ and Timsit et al. showed that a template of one-third to half the crystal dimension is needed to give convincing results. The effectiveness of this process depends, of course, on a good choice of the symmetry of the template, which for an unknown specimen would involve extensive trial and error.

Attempts have been made by Fan and Cowley [17] to introduce another quantitative and objective measure of order. They show that departures from randomness can be expressed in terms of a relative entropy, defined in terms of the deviation of the intensity distribution in a micrograph from the most probable (gaussian) distribution. Specifically, the relative entropy Q_e is defined by:

$$Q_e = -N \sum f_j \ln\left(\frac{p_j}{f_j}\right) \qquad (4)$$

where f_j is the probability that an image pixel has intensity I_j (where j is one of n grey-scale values), p_j is the probability given by the entropy-maximizing Gaussian distribution, and N is the number of image pixels. Fan and Cowley show that $Q_e/n = 0.5$ for a simulated random image of a-Si, but for an experimental image (which shows very few signs of order by visual inspection) Q_e/n is 1.9, a significant departure from 0.5. The relative entropy method has also been used to gauge the information content of different members of a through-focal series and to assess the value of phase randomization techniques.

In the following sections, an attempt is made to survey the information that has been obtained, despite the problems mentioned, in a range of amorphous solids.

9.1.4 Amorphous Metals

A number of studies of amorphous metals by HREM have now been published and the general conclusion is that, providing the microscope has adequate point-to-point resolution to image the close-packed planes (~0.23 nm) and the foils are sufficiently thin (2–6 nm), then a surprising degree of positional ordering is observed.

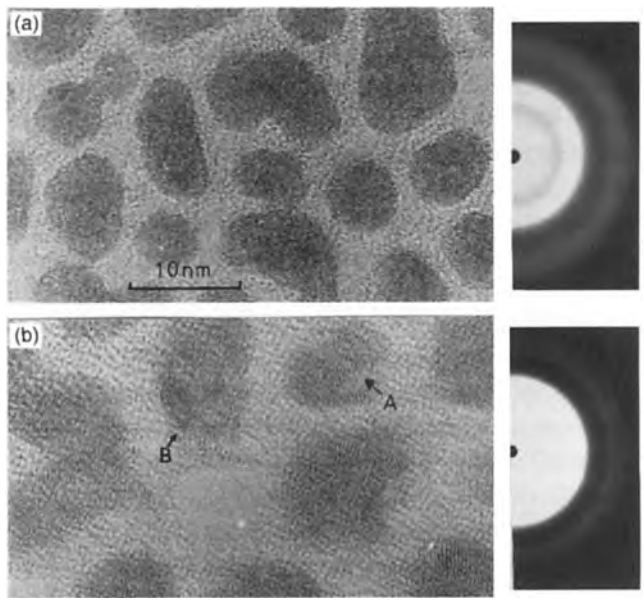

Figure 2. (a) High-resolution image of a particulate Pd–Si alloy recorded with axial illumination at 500 kV. The diffraction pattern is shown on the left. (b) Image of an α-Pd–Si alloy showing increased signs of order (as indicated by a splitting of the second diffraction peak). Note the resemblance to twins in the particles marked A and B. (Adapted from Gaskell and Smith [25].)

The early work of Gaskell, Smith and coworkers [24, 25] showed that thin discontinuous clusters of α-Pd–Si alloys prepared by flash evaporation onto a cooled rocksalt substrate exhibited 'lattice fringes' covering areas as large as 4–6 nm^2 in thin regions of the specimen (Fig. 2a). The general appearance of small distorted domains, similar to those seen in (larger) multiply twinned particles, is enhanced if the evaporation rate is reduced—twin boundaries can now be seen clearly (Fig. 2b). The diffraction pattern also shows some increased order.

More recent work by Hirotsu and coworkers [26, 27] shows that an even more stable alloy, α-Pd–Cu–Si, exhibits pronounced positional ordering, with parallel, often straight, lattice fringes over areas of about 4 nm^2. Again, the degree of order is a function of preparation conditions or of annealing. A typically careful reinvestigation of Pd–Si alloys by Anazawa et al. [28] serves as an example of this type of investigation. Amorphous thin films of $Pd_{82}Si_{18}$ were prepared by sputtering and the composition subsequently analyzed. Images were recorded in a 200-kV, high-resolution microscope with an interpretable resolution limit of less than 0.2 nm. Part of a focal series of the as-prepared film (Fig. 3) shows the presence of ordered regions, with well-defined fringes of spacing 0.19 and 0.22 nm with some geometrical symmetry. These resemble images simulated by a multislice method from a model of the same composition but with an embedded face-centered cubic (f.c.c.) cluster (Fig. 4). The electron diffraction data show classically diffuse halos typical of amorphous alloys, but the HREM images color this interpretation and give clear hints of the nature and extent of the medium-range ordering. Films of the same composition annealed at temperatures up to 673 K show the development of crystallites, with associated changes in the diffraction pattern.

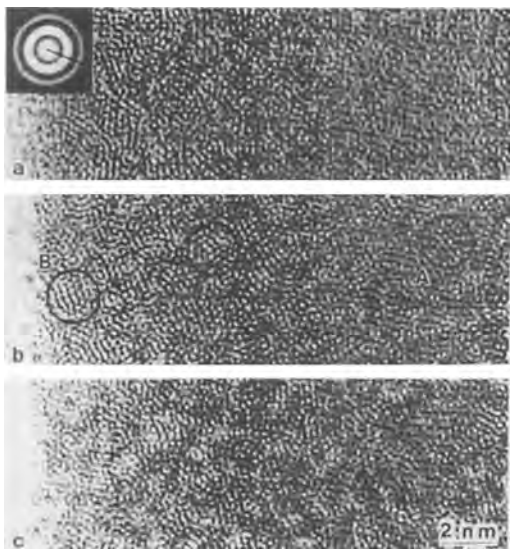

Figure 3. HREM images of α-$Pd_{82}Si_{18}$ as a function of defocus: (a) 40 nm; (b) 80 nm; (c) 120 nm. The electron diffraction pattern (upper left) displays classical diffuse halos. (Courtesy of Anazawa et al. [28].)

The images shown in Figs. 2 and 3 pose the question of how order in amorphous solids should be characterized. Except where stated, the diffraction patterns indicate no serious departures from the characteristic diffuse 'amorphous' rings, but both bright- and dark-field images suggest a degree of microcrystallinity. Dubois et al. [29] have shown that correlated, positionally ordered domains are not inconsistent with the diffraction data for α-Ni–B alloys, and there is no reason to suppose that this is a special case. Moreover, simulation of images of atomic models built with no impressed (or inserted) elements of translational order do, nevertheless, display features similar to the experimental images of the as-prepared glasses. Illustrations of this point are provided by simulated images for several models of

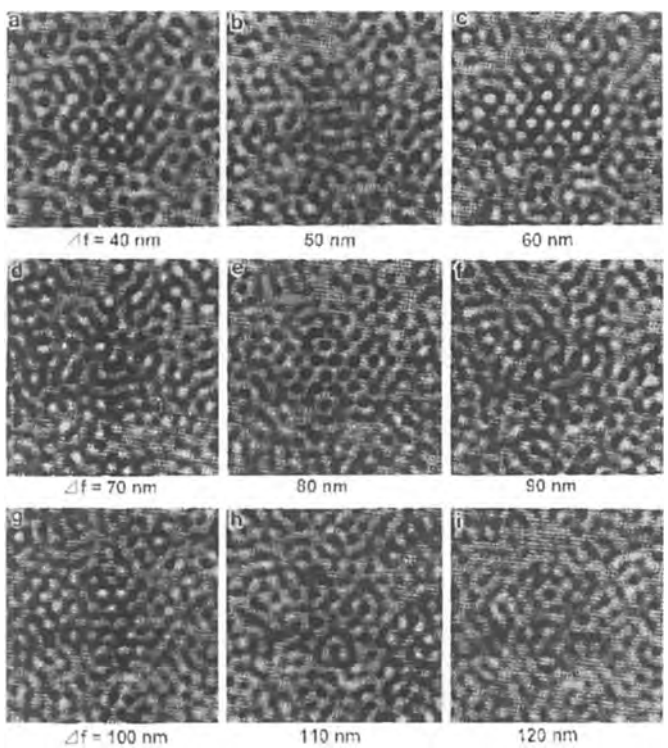

Figure 4. Simulated HREM images of an atomic model of $Pd_{82}Si_{18}$ at different defocus values Δf. The model consists of a random matrix of the alloy with an f.c.c. crystallite of the same composition embedded in the center. (Courtesy of Anazawa et al. [28].)

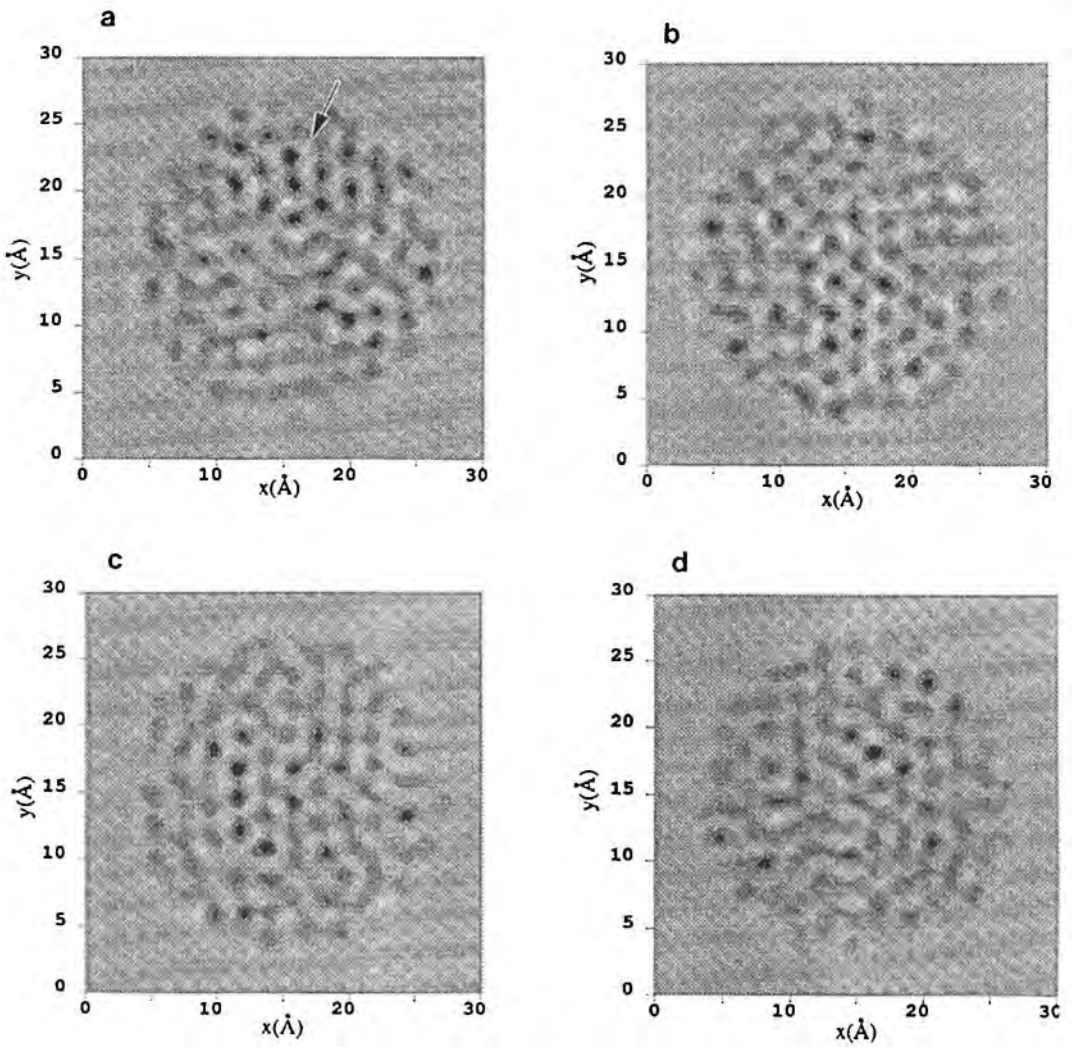

Figure 5. Simulated HREM images of several atomic models for amorphous monoatomic metals (or alloys). In each case, the models are orientated so that the scattering vectors corresponding to the two highest values of the anisotropic scattered intensity are in the plane of the diagram and (i) horizontal and (ii) at about 1 o'clock. Planar fluctuations in atomic density are thus viewed end-on and either vertically or at 10 o'clock. (a) A 500-atom spherical core cut from the center of Finney's 7994-atom model [30]; (b) a similar segment nearer the edge of the same model; (c) 1659-atom model consisting of the Ni coordinates from Beyer and Hoheisel's [31] model for α-$Ni_{81}B_{19}$; (d) 1456-atom model with the metal atom positions from Dubois et al.'s model [29] for binary metallic alloys of composition Pd_4Si, etc.

amorphous monatomic metals or alloys (Fig. 5) [10].

There is little reason, therefore, other than prejudice, to regard materials like a-$Pd_{82}Si_{18}$ as being somewhat less than ideal glasses and the detail of the medium-range structure offered by this type of investigation is challenging and exciting. It should be possible to establish whether the order, revealed by neutron scattering principally,

extending to about 1 nm in several typical amorphous alloys, is essentially microcrystalline, multiply twinned, or simply relates to the atomic density oscillations (as in Fig. 4), as expected in essentially random, densely packed solids subject to volume constraints. The existing HREM images provide some support for each of these possibilities, without definitely eliminating any.

9.1.5 Oxides

Amorphous solids can be formed from open structures typified by a-SiO_2 to close-packed oxides such as MoO_3 or WO_3. Oxides possess the distinct advantage for HREM work that the characteristic lattice spacings are larger than in metals, so that even 100 kV instruments can produce acceptable results, but most open-packed structures display less prominent image features. Images of the close-packed amorphous solids show more tendency toward medium-range ordering; for example, both MoO_3 and WO_3 show relatively well-defined, small ordered domains. WO_3 is a particularly interesting case because as-prepared specimens, heat-treated at relatively low temperatures, transform progressively and continuously to a microcrystalline state [31–33].

In SiO_2, however, correlated regions of lattice fringes are seen only rarely, in selected cases. For example, small clusters (about 10 nm in diameter) precipitated from aqueous solution were shown, by examination of the bright-field image and optical microdiffraction patterns, to be more ordered than similar material condensed from a high temperature, gas-phase reaction [34]. Bursill and Thomas [35] conclude that a commercial silica gel shows no evidence of nonrandom features.

9.1.6 Amorphous Tetrahedral Semiconductors

More effort has been devoted to imaging amorphous semiconductors and to attempts to interpret them, than has been spent on all other amorphous solids combined. In some ways this is a pity. Despite their commercial potential, amorphous elemental and compound semiconductors are not typical of amorphous solids. They are not glasses (the glass transition is hidden by crystallization), as they cannot be obtained from the melt except by ultra-rapid quenching. Moreover, thin films are prone to oxidation, and the first peak of the structure factor is weak. Comprehensive reviews of the subject have been given by Howie [4, 5].

Interesting images of α-Si and Ge were presented by Smith et al. [36] who observed little nonrandom structural detail in films around 10 nm thick, as expected [11]. Thinner films of α-Ge, notionally 1 nm thick, are relatively rich in nonrandom features and this finding is also supported by phase-randomization studies.

Some controversial images of α-Si deposited on a cleaved γ-Si wafer in UHV were reported by Phillips et al. [37] and Ourmazd et al. [38]. A cross-section near the interface between the crystalline Si and the amorphous film was examined using a 400-keV instrument, revealing ordered regions that were claimed to be 3 nm 'submicrocrystallites' on the evidence

of lattice fringes and optical microdiffraction patterns. The diffraction spots were small and orientationally related to the planes of the substrate. The extent of ordering, both positional and orientational, decreased with distance from the interface up to about 80 nm. The term 'orientational proximity effect' (OPE) was coined to describe the phenomenon. However, the generality of the OPE has yet to be confirmed, and there has been some difficulty in reproducing the effect under different conditions. The presence of ordered regions in amorphous solids near an interface with a compositionally similar crystal has been looked for on other occasions and not seen. Gaskell and Saeed [39] have attempted to observe the effect in Ge by sequentially depositing thin films of α-Ge over small islands of γ-Ge, and have examined the interfacial regions. While there is some evidence of order in the very thin regions—the images obtained were similar to those found by Smith et al. [36]—the fringes are not preferentially located near the interface and have no orientational relationship to the planes of the crystal. The effect may be limited – to certain types of interface, or to specific elements – or it might be destroyed by a thin oxide film that forms in vacuum (not UHV) between sequential depositions of γ- and α-Ge. However, there are instances where cross-sections of interfaces show some orientational effect, even when the two materials joined at the interface are different (e.g. the Si–SiO_2 interface [40]), although other studies [13] have shown that it is not always obvious just where the interface lies between a crystal and an amorphous overlayer, making it difficult to assess the spatial extent of the OPE.

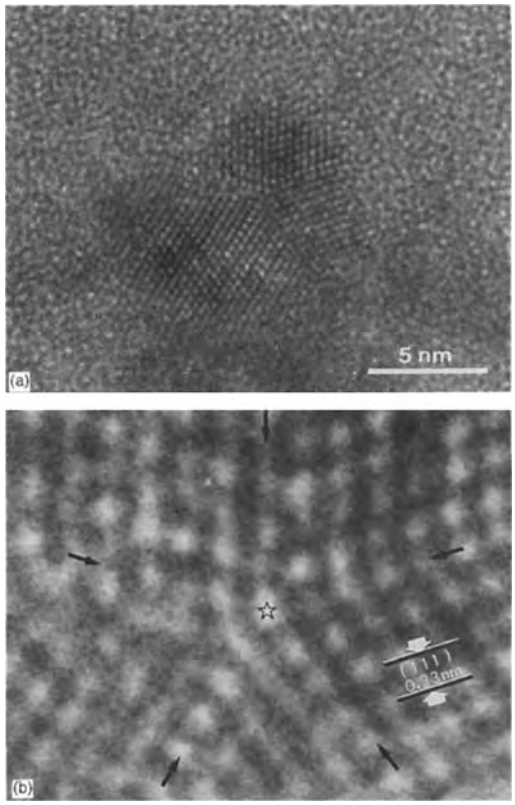

Figure 6. (a) An isolated, multiply twinned, nucleus of γ-Ge in a matrix of α-Ge; (b) the center of the nucleus showing the 0.33 nm {111} planes and the pentagonal symmetry of the {111} twin boundaries (arrows). (Courtesy of Okabe et al. [41].)

Some indication of the possibility of pentagonal, or polytetrahedral, structures in α-Ge is given by the HREM images reported by Okabe et al. [41]. What appears to be a pentagonal nucleus can be seen, from which diamond-cubic crystallites radiate (Fig. 6). Since pentagonal symmetry is inconsistent with translational periodicity, the possibility of such 'non-crystallographic' 'amorphons' has a long history [1]. However, there is relatively little experimental evidence for such structures, even though they represent a

bridge between glasses, crystals, and quasi-crystals.

Amorphous carbon is a relatively new addition to the portfolio of elemental amorphous tetrahedral semiconductors. Although 'ordinary' amorphous carbon has a structure reminiscent of crystalline graphite, it is also possible to prepare a solid with atomic characteristics similar to crystalline diamond. HREM images [42] of this amorphous tetrahedral carbon have shown distinct differences from the more graphitic solid. The fringe spacings are characteristically different and the structure is reminiscent of α-Si and Ge. (See also Chap. 1.11 of this Volume.)

A further question surrounds the lack of evidence for medium-range ordering in bright-field images of amorphous semiconductors (and oxide glasses) compared with the relative ease of observation in amorphous metals. One obvious conclusion is that amorphous metals simply are more ordered – an essential property of densely packed atoms perhaps. Another possibility is that the signal-to-noise level of HREM imaging is particularly low for low-atomic-number solids like Si and SiO_2, and that, except in special cases, the signal is almost submerged below the noise and HREM images simply reflect this.

More attention might be focused on inelastic scattering and small angle elastic scattering due to microvoids and the (rough) surfaces of a thin foil. The effect of each contribution is to add a strongly Q-dependent, small angle contribution to the noise. Graczyk and Chaudhari [43] and Patterson et al. [44] have shown that the first diffraction peaks of (relatively thick) films of α-Ge and α-Si are partly hidden by a continuous background, to which the inelastic scattering intensity I_i is the dominant contributor. Images formed from inelastically scattered electrons can be considered as an incoherent sum of beams scattered through angles determined by the energy loss [45] and are degraded compared to images formed by purely elastic scattering processes. Secondly, the low-Q incoherent inelastic scattering (involving only 'self' terms in the pair distribution function) simply contributes 'colored noise'.

The 'signal' – represented by the first peak of $S(Q)$ – is weak for α-Si and Ge compared with the amorphous metals, for which the first peak is the most prominent feature of $S(Q)$ (Fig. 1). Moreover, the 'noise' due to inelastic scattering will be weaker in α-Pd–Si alloys than in Ge or Si. Since the first peak in $S(Q)$ lies at $30\,nm^{-1}$ ($20\,nm^{-1}$ for α-Ge), and as I_i/I_c decreases rapidly with Q, inelastic scattering is relatively insignificant for amorphous metals. I_i is further reduced by the higher average atomic number of the metals: the ratio I_i/I_c decreases as Z^{-n}, where $n \simeq 1$. Taking all these effects together, Gaskell [46] has estimated that the total signal-to-noise ratio for α-Pd_4Si is likely to be larger than for α-Ge and Si by factors of at least 10 and 15, respectively.

9.1.7 Concluding Remarks

The extent of new structural information directly attributable to HREM studies is distinctly variable. There is a strong dependence on the nature of the material, on the thickness of the specimen, and, possibly, on the presence of special features, such as

a 'template' provided by the interface with a crystal that induces morphological order throughout significant thicknesses of the amorphous material. The structured images of amorphous alloys arouse the natural suspicion of surface artifacts—an inevitable consequence of the thinness of the foil. Even though α-Pd_4Si is relatively stable against crystallization and oxidation and only minor beam-induced crystallization is observed, the possibility of these effects cannot be discounted. Although it is likely that artifacts do not alter the import of the investigations cited, the possibility of oxide formation, surface metallization, or surface reconstruction has reduced the credibility of several otherwise promising measurements. Studies including perhaps in situ preparation, with careful control of the electron dose, are urgently required.

Having cited all these caveats, it is also right to stress the almost unique potential of the technique. HREM, applied to the right materials, can help to break the deadlock that still exists with regard to our interpretation of the structure of amorphous solids. There is no doubt that scattering techniques are reaching (or have reached) their limiting range (about 1 nm). There is also a growing realization that progress in the next phase will depend absolutely on an adequate understanding of the details of the medium-range structure, leading to an assessment of the relative virtues of models predicated on randomness on the one hand, and disturbed order (crystallographic or noncrystallographic) on the other. At the moment, the latter seems to be nearer the truth for most important types of glass and the former for the amorphous tetrahedral semiconductors. A truly fascinating puzzle.

9.2 Quasicrystalline Structures

9.2.1 Icosahedral Quasicrystals

In the search for ultrahigh-strength Al alloys, Shechtman et al. [1] tried to force more Mn into solid solution by very rapid solidification. In 1984, to their surprise they found, using selected-area electron diffraction (SAED), in an Al–14 at.% Mn alloy a metallic phase displaying icosahedral $m\bar{3}\bar{5}$ symmetry (an icosahedron is a polyhedron enclosed by 20 equilateral triangles, Fig. 1d) and no periodic translation order. The term 'quasicrystal' (QC) was coined by Levine and Steinhardt [2] for such a quasiperiodic crystal, although the term 'quasilattice' was used earlier by Mackay [3] for the two-dimensional (2-D) Penrose pattern [4] consisting of an aperiodic distribution of fat (72°) and thin (36°) rhombi and displaying five-fold symmetry (see Fig. 4b). In fact, Mackay obtained an optical transform of this pattern quite similar to the one shown in Fig. 1a and also proposed a three-dimensional (3-D) quasilattice consisting of acute ($\alpha = 63.43°$, namely, arctan2) and obtuse ($\alpha = 116.57°$) rhombohedra showing icosahedral symmetry. Icosahedral quasicrystals (IQCs) were immediately also identified by SAED in rapidly solidified Ti–Ni [5], Pd–U–Si [6], Mg–Al–Zn [7], and Al–Li–Cu [8] alloys. The era of QCs thus began. Readers interested in the fundamental characteristics of QCs are referred to *Quasicrystals: A Primer* by Janot [9] and the three volumes on *Aperiodic Crystals* edited by Jaric et al. [10].

IQC is a 3-D QC. Its characteristics, quasiperiodicity and unconventional or forbidden five-fold symmetry, are quite

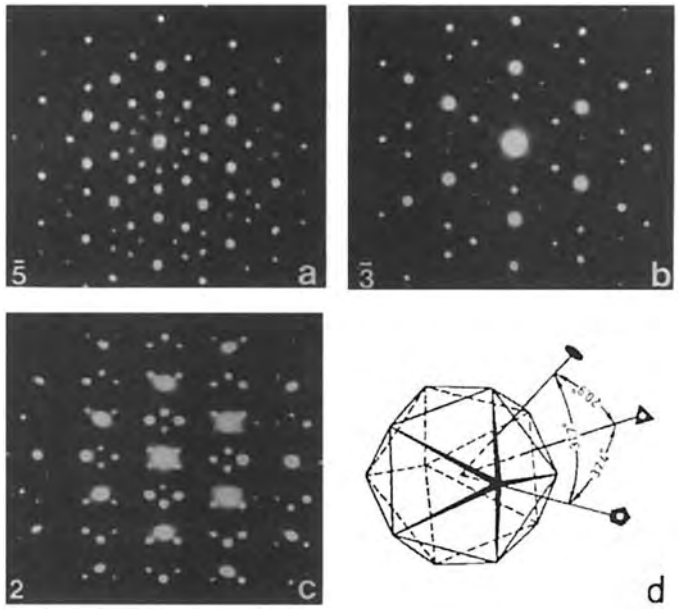

Figure 1. Electron diffraction patterns of the Ti–V–Ni icosahedral quasicrystal displaying (a) $\bar{5}$, (b) $\bar{3}$, and (c) 2-fold symmetries. (d) The $m\bar{3}\bar{5}$ point group of an icosahedron. (Reproduced from *Philos. Mag.* [5] by permission of Taylor & Francis Ltd.)

obvious in the electron diffraction patterns (EDPs) (Fig. 1). The tilted angles among the $\bar{5}$-, $\bar{3}$-, 2-fold EDPs in Fig. 1a–c agree with the angular relations of an icosahedron shown in Fig. 1d. The collinear diffraction spots within them are not equally spaced as in a crystalline substance, but show a τ distribution, such as $1{:}\tau{:}\tau^2$, where $\tau = (1+\sqrt{5})/2 = 1.61803\ldots$ is the irrational golden number associated with five-fold symmetry ($\cos(36°) = \tau/2$, $\cos(72) = (\tau-1)/2$). Moreover, the QCs formed by very rapid solidification are fine grained (of the order of μm in size) and sometimes in small amounts mixed with other phases. These factors make SAED an advantageous technique for discovering new QCs. In fact, IQCs were encountered earlier both in Al–Fe–Cu (the ψ phase) and Al–Li–Cu (the T2 phase) alloys, but their X-ray powder diffractograms, owing to the forbidden five-fold symmetry, could not be indexed then. Since the discovery of the Al–Mn IQC by SAED, a large number of IQCs have been found in binary and ternary Al alloys by means of X-ray powder diffraction methods [11].

If an IQC can be isolated from the matrix, either chemically or electrolytically, it can be examined by scanning electron microscopy (SEM). Figure 2 shows such

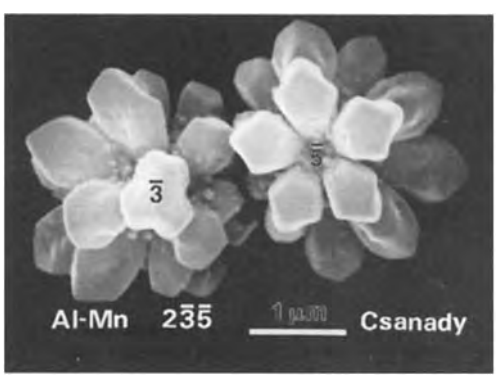

Figure 2. Scanning electron micrograph of icosahedral flowers chemically extracted from an Al–Mn alloy. (Courtesy of Dr Agnes Csanady.)

Figure 3. Scanning electron micrograph of an Al–Cu–Fe quasicrystal displaying the pentagonal dodecahedron morphology with the $m\bar{3}\bar{5}$ symmetry. (Courtesy of Dr A. P. Tsai [12] and reproduced from *Jpn J. Appl. Phys.* by permission.)

an image of the icosahedral flowers obtained by Dr Agnes Csanady from an Al–5.5 at.% Mn alloy by extraction in a solution of 2% KI in methyl alcohol. Figure 3 shows an SEM image of the pentagonal dodecahedron morphology (another regular polyhedron, enclosed by 12 regular pentagons, displaying icosahedral symmetry) of a single grain of Al–Cu–Fe IQC [12]. The $\bar{5}$- and $\bar{3}$-fold rotational symmetries, and consequently the icosahedral symmetry, are obvious in both cases. The slowly solidified Al–Li–Cu IQC shows a triacontahedron (enclosed by 30 rhombi) morphology and also exhibits icosahedral symmetry [13]. It is of interest to note that a triacontahedron contains 10 acute and 10 obtuse rhombohedra and constitutes the 3-D quasilattice [3]. Al–Cu–Fe, Al–Li–Cu, and Al–Pd–Mn IQCs are stable at high temperatures, and therefore large single crystals of millimeter or even centimeter size can be grown by slow solidification.

The five-fold symmetry of IQCs can also be shown by using high-resolution electron microscopy (HREM) imaging at the atomic scale. Figure 4a shows an HREM image of a Ti–V–Ni IQC taken along the five-fold axis [5]. Some of the

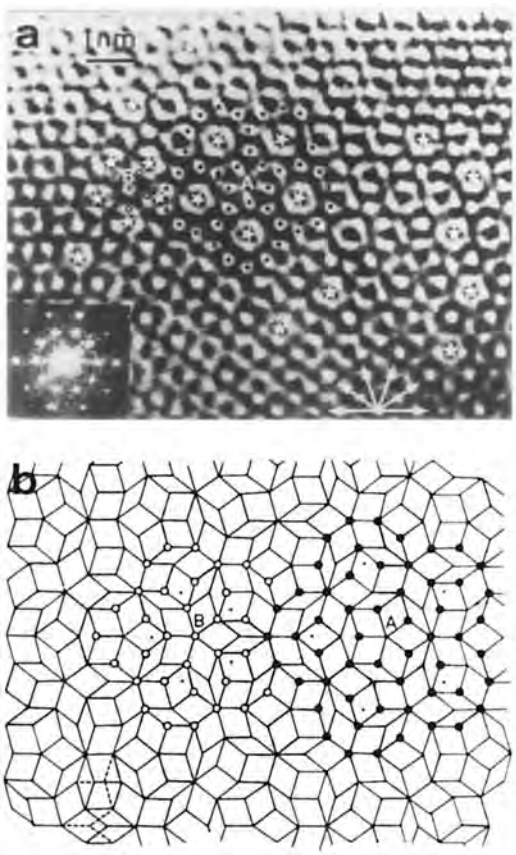

Figure 4. (a) High-resolution electron microscope image of the Ti–V–Ni icosahedral quasicrystal showing the frequent occurrence of a bull's-eye contrast surrounded by 10 bright dots (some are marked). The inset (bottom left) is the optical transform. The local five-fold configurations surrounding A and B are almost the same as those at A and B in the Penrose pattern (b). In the upper left-hand corner, an aperiodic row associated with the irrational τ is outlined; in the bottom left-hand corner the rearrangement of fat and thin rhombi in two flattened hexagons is shown by dotted lines. (Reproduced from *Philos. Mag.* [5] by permission of Taylor & Francis Ltd. (b) is adapted from A. L. Mackay, *Physica* [3].)

image points with a bull's-eye contrast are marked by stars, and the 10 bright image points surrounding some of these stars are marked by black dots. The different five-fold configurations centered on A and B agree well with the Penrose pattern given by Mackay [3] (compare A and B in Fig. 4a with the corresponding A and B in Fig. 4b). The optical transform of this HREM image shown as an inset in Fig. 4a, like the five-fold EDP given in Fig. 1a, consists of concentric decagons of spots.

9.2.2 Decagonal and Other 2-D Quasicrystals

Soon after the discovery of the Al–Mn 3-D IQC, a 2-D QC with the quasiperiodic plane perpendicular to the periodic 10-fold axis, the decagonal quasicrystal (DQC), was found coexisting with this IQC [14, 15]. If a five-fold axis of an IQC is changed to a 10-fold one, the other five-fold axes and the three-fold axes disappear, and a DQC with a periodic stacking of 2-D quasiperiodic planes results. It was shown that a block of about 0.41 nm consisting of two aperiodic layers is the basic unit, and the periodicity of DQCs can be 0.41, 0.82, 1.23, or 1.64 nm [16]. In the Al–Pd–Mn system both IQC and DQC exist, with the latter having a higher Mn and lower Pd content than the former [17]. Wollgarten et al. [18] found such a DQC lamella with a periodicity of 1.2 nm along the 10-fold axis parallel to one of the five-fold axes of the IQC matrix in an Al–Pd–Mn alloy. In order to obtain the information concerning the composition of the lamellae of a few nanometers thickness, Z-contrast imaging and the electron-energy-loss spectroscopy (EELS) techniques were used. In the Z-contrast technique the image is formed by electrons scattered by large angles, and the local brightness is proportional to the square of the mean nuclear charge Z. Such a picture of a lamella which was oriented edge on is shown in Fig. 5a. The lamella appears darker than the matrix, indicating a lower mean Z value. The EELS was recorded using a probe diameter of

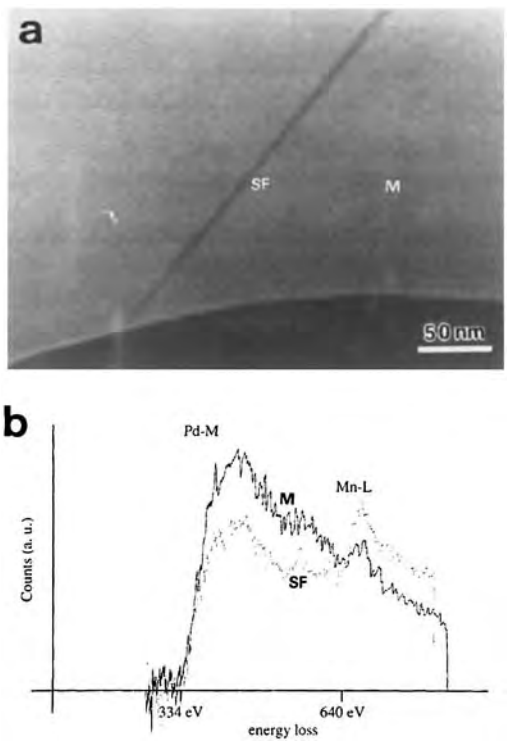

Figure 5. Z-contrast image of a lamella of a decagonal quasicrystal in a matrix of an icosahedral quasicrystal in an Al–Pd–Mn alloy. The darker contrast indicates a lower mean atomic number (a lower Pd and a higher Mn content) which is confirmed by the EELS (b). The peaks can be identified as Pd $M_{4,5}$ and the Mn $L_{2,3}$ edge. (Courtesy of Dr M. Wollgarten and reproduced from *Philos. Mag.* [18] by permission of Taylor & Francis Ltd.)

0.3 nm in a scanning transmission electron microscope (STEM). The solid and broken curves in Fig. 5b show the EELS spectra recorded from the matrix and the lamella, respectively. Evaluating the peaks of the Pd $M_{4,5}$ and the Mn $L_{2,3}$ edge by standard methods yields the result that the palladium content was about 67% (±13%) and the Mn content about 200% (±50%) of that of the icosahedral matrix. The stoichiometry of the matrix was determined by energy-dispersive X-ray microscopy (EDX) measurements to be $Al_{74}Pd_{16}Mn_{10}$. The EELS results therefore indicate an approximate composition of the lamella of $Al_{69}Pd_{11}Mn_{20}$. This is close to the composition of the Al–Pd–Mn alloy in which DQC has been found [17].

A stable DQC [19] with a decaprism morphology growing along the 10-fold axis [20, 21] (see the SEM image in Fig. 6) has been found in slowly solidified Al–Cu–Co alloys. Its 10-fold ED pattern shows a 10-fold aperiodic distribution of diffraction spots. The bright image points in the HREM image show a periodic arrangement along the 10-fold axis and an aperiodic arrangement with a τ relationship along the two-fold axis (both marked on the HREM image shown in Fig. 6).

Owing to the two-fold symmetry inherited in an SAED pattern, the five-fold EDP of a DQC with the point group $\bar{1}0m2$, where $\bar{1}0$ is equivalent to 5/m, shows a 10-fold distribution of electron diffraction spots. However, this is not the case with the convergent-beam electron diffraction (CBED) pattern which shows the real symmetry of a substance in the direction of the electron beam. In the CBED pattern of the Al–Cu–Co DQC shown in Fig. 7,

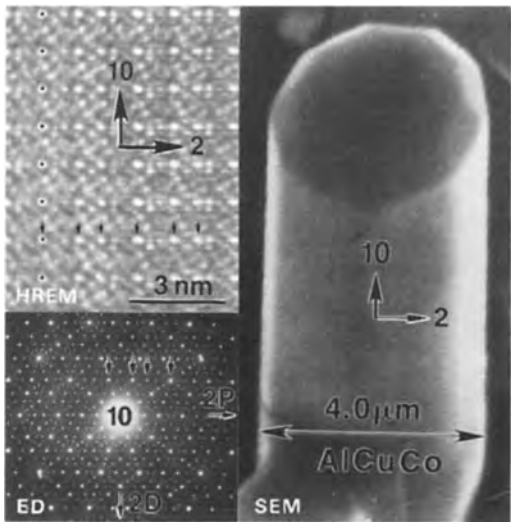

Figure 6. SEM image showing the decaprism growth morphology along the 10-fold axis of the Al–Cu–Co decagonal quasicrystal. The 10-fold electron diffraction (ED) pattern and the HREM image taken along a two-fold axis showing the periodic and aperiodic arrangements along the 10-fold 10 and two-fold 2P directions, respectively, are also shown. (Courtesy of Dr L. X. He.)

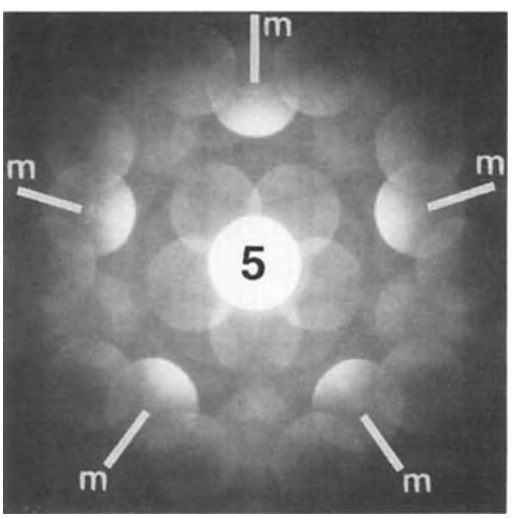

Figure 7. Convergent-beam electron diffraction pattern of an Al–Cu–Co decagonal quasicrystal showing its 5m symmetry. (Courtesy of Dr M. Tanaka and reproduced from *Mater. Sci. Eng.* [22] by permission of Elsevier.)

the discs clearly show 5m symmetry with mirror planes parallel to the 5 axis (space group $\bar{1}0m2 = 5/mm2$) in the Al DQC [22]. However, DQCs with the point group 10mm (space group $P10_5/mmc$) have also been found by CBED in several alloy systems, such as $Al_{70}Ni_{20}Fe_{10}$ [23]. Moreover, CBED is also very effective for showing any departure from the true five-fold or ten-fold symmetry when there are a large amount of defects in a QC [24].

The Fourier-filtered scanning tunneling microscopy (STM) image of the Al–Cu–Co DQC decaprism with a cross-section of a few millimeters is shown in Fig. 8 [25]. It looks exactly the same as the HREM image taken along the 10-fold axis of this DQC [26]. Both images show an aperiodic arrangement of 'decagon wheels' consisting of 10 bright image points surrounding a bull's-eye contrast at the center. The STM image shows the true surface structure, whereas the HREM image results from the projection of a 3-D structure along the electron beam. Some objections have been raised to the use of the projected HREM image to explain the 3-D structure. The bright image points in the STM image were shown to represent Cu/Co atoms at the center of pentagons in the Penrose pattern [25]. This proves the quasiperiodic nature of QCs and thus rules out the possibility of five-, ten-, or icosa-fold twins advocated by Pauling [27]. Moreover, this result also shows that one may use the HREM image to interpret the bulk quasicrystalline structure, especially if the HREM images compare well with simulated ones. Figure 8 also shows several quasiperiodic layers with an atomic step of about 0.21 nm between any two of them.

Figure 8. Scanning tunneling microscope image of the surface structure of an Al–Cu–Co decagonal crystal. Ten-fold and quasiperiodic arrangements on several atomic layers are obvious. (Courtesy of Drs A. R. Kortan and H. S. Chen and reproduced from *Phys. Rev. Lett.* [25].)

In addition to the DQCs with a 10-fold rotational axis, other types of 2-D QCs, such as the octagonal QCs with an eight-fold rotational axis [28] and dodecagonal QCs with a 12-fold rotational axis [29], have also been found using SAED and HREM. The octagonal quasilattice was shown by HREM to consist of squares and 45° rhombi associated with the irrational $\sqrt{2}$, whereas the dodecagonal quasilattice of squares 60° and 30° rhombi was associated with $\sqrt{3}$. Furthermore, one-dimensional (1-D) QCs with periodic layers stacked aperiodically have also been found [30].

9.2.3 Quasicrystalline Structures

From the above discussion it is clear that quasiperiodicity is a fundamental property of a QC. For instance, if the length of the side of the fat or thin rhombi is considered to be unity, then the spacings between two lattice points along the oblique direction at the upper-left-hand corner in Fig. 4b are $\tau:1:1:\tau:\tau^{-1}:1:\tau:1$. This is an aperiodic series of 1 and the irrational τ, and one needs two lengths to describe the positions of the 1-D lattice points. In a 3-D QC, there will be three such series, and one needs six basic vectors to describe the position of a quasilattice point [31–33]. Hence, IQCs can be considered as periodic in the six-dimensional space and the formula used to calculate the structure factors, diffraction intensity, image contrast, HREM simulation etc., for crystals can principally be applied to a QC if the position vector $\boldsymbol{r}$ in the real space and the reciprocal vector $\boldsymbol{g}$ in the reciprocal space are raised from the 3-D to the 6D space. Of course, the calculated results in the 6D space have to be projected back to the 3-D physical space. As in incommensurate crystals, this mathematical treatment will materially simplify the study of quasicrystalline structures. In fact, QCs are a special kind of incommensurate structure, with unconventional rotational symmetries and no average lattice.

Five-fold symmetry and any other rotational symmetry above six-fold are forbidden in a periodic lattice, but not in a quasiperiodic lattice, such as the 2-D Penrose lattice. In order to ensure an aperiodic tiling, there are strict local rules governing the tiling of the fat and thin rhombi in Fig. 4b or the 3-D acute and obtuse rhombohedra. In other words, there is strict position order in a quasilattice, although it is aperiodic. Therefore, high-quality QCs can give as sharp X-ray reflections or electron diffraction spots as can crystals.

If the 6D superspace is divided into two orthogonal 3-D spaces, one parallel or physical space $E^{\parallel}$ and one perpendicular or pseudo space $E^{\perp}$. For simplicity, this can be illustrated in the 2-D–1-D case. Figure 9a shows the irrational projection of a 2-D square lattice E onto the 1-D parallel space $E^{\parallel}$ [34]. If the lattice points within the stripe with an irrational slope of $\tan\alpha = \tau$ and a width of the projected diagonal of the square on $E^{\perp}$ are chosen, the projected line segments will follow the $LSLLSLSL\ldots$, where $L = \sin\alpha$, $S = \cos\alpha$, and $L/S = \tan\alpha = \tau$. This is the famous Fibonacci series associated with the golden number τ. This irrational number can be successively approximated by a ratio of F_{n+1}/F_n, where $F_{n+1} = F_n + F_{n-1}$, $F_0 = 0$, $F_1 = 1$, such as 1/0, 2/1, 3/2, 5/3, 8/5, 13/8,.... If the stripe in Fig. 9a is

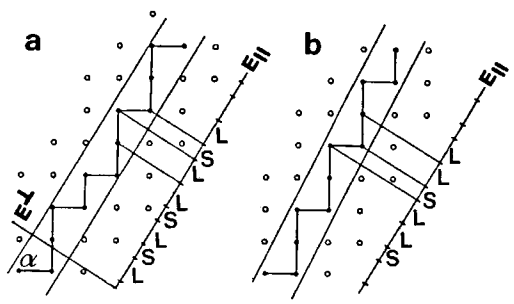

Figure 9. Projecting a stripe of a 2-D square lattice (a) irrationally ($\tan\alpha = \tau$, the golden number) onto a 1-D $E^{\parallel}$ space to yield an aperiodic Fibonacci series, or (b) rationally ($\tan\alpha = 2$) to yield a periodic lattice with a repeat unit of *LLS*. The latter results from a 2/1 approximation of the irrational τ. (Adapted from Elser and Henley in *Phys. Rev. Lett.* [34].)

rotated slightly and the slope becomes rational, say 2/1, then the projected line segments will be a 1-D periodic lattice, namely, *LLSLLS*... (Fig. 9b). Obviously, both 1-D periodic and aperiodic lattices can be embedded in a 2-D periodic lattice, depending on whether the slope of the projection stripe is rational or irrational. From this point of view, a QC can be considered as a crystal with an infinitely large unit cell, since the ratio of F_{n+1}/F_n approaches τ when n approaches infinity. Or, in other words, a QC is the end member of a series of crystalline phases with τ inflations. Recently, a series of monoclinic $Al_{13}Co_4$ phases with their lattice parameters a and c inflated to about τ, τ^2, τ^3, and τ^4 have been found [35]. These inflated phases have similar pentagonal layers, as in $Al_{13}Co_4$ and the Al–Co DQC. Such crystalline phases are called 'crystalline approximants' or simply 'approximants' [34]. The local structure and composition in a QC and its approximant are alike. However, the subunits are arranged periodically in an approximant and aperiodically in a QC.

Thus, the five-fold EDP and the simulated HREM image of the Al–Mn IQC can be calculated using a 6-D approach which is then compared with the experimental results. When indexing of the diffraction spots or reflections, we need consider only the 3-D quasilattice or the 6-D periodic lattice. There are several 6-D indexing systems [33, 36, 37]. However, in order to calculate the diffraction intensities and the image contrast, the 6-D periodic unit cell has to be decorated with 6-D superatoms. The 6-D structural model of a QC can be constructed from the structure of its 3-D approximant, such as body-centered cubic (b.c.c.) α-(AlMnSi) [34] and b.c.c. $Mg_{32}(Al,Zn)_{49}$ [38]. The simulated HREM images of the Al–Mn IQC have been calculated both from the bare quasilattice and from the quasiperiodic structural model using the Mackay double icosahedra found in cubic α-(AlMnSi) [39].

Simulated HREM images have also been calculated using the 3-D multislice method, either from a huge quasicrystalline structural model consisting of 59 567 atoms [40], or from a large unit cell (3.88 nm × 3.30 nm) by using a periodic extension method [41].

9.2.4 Defects in Quasicrystals

As there are two or three kinds of unit cell in a QC, one has to consider the tiling mistakes which do not exist in crystals. For instance, the fat and thin rhombi in the two flattened hexagons at the bottom-left-hand corner in Fig. 4b can also be tiled differently, as shown by the dotted lines. This does not change the shape of the hexagons and thus causes no distortion [42]. However, the position of some lattice points in this 2-D quasilattice is changed, and consequently the phase in the density-wave description of the QC will change accordingly. Following the terminology used for incommensurate crystals, this kind of defect is called a 'phason strain' or simply a 'phason' [43, 44]; the displacement strain is called a 'phonon'.

Both whole and partial dislocations have been observed in QCs, and diffraction contrast experiments using the criterion $\boldsymbol{g}^{\parallel} \cdot \boldsymbol{b}^{\parallel} = 0$ have been carried out in order to determine their Burgers vector $\boldsymbol{b}$ in the

physical space. However, complications arise because $\boldsymbol{g}^{\parallel} \cdot \boldsymbol{b}^{\parallel} = 0$ does not mean $\boldsymbol{g} \cdot \boldsymbol{b} = 0$. Both $\boldsymbol{g}$ and $\boldsymbol{b}$ are now in the 6-D space and the extinction criterion $\boldsymbol{g} \cdot \boldsymbol{b} = 0$ contains two terms

$$\boldsymbol{g} \cdot \boldsymbol{b} = \boldsymbol{g}^{\parallel} \cdot \boldsymbol{b}^{\parallel} + \boldsymbol{g}^{\perp} \cdot \boldsymbol{b}^{\perp} = 0$$

Woolgarten et al. [45] differentiated two cases:

Strong extinction condition:

$$\boldsymbol{g}^{\parallel} \cdot \boldsymbol{b}^{\parallel} = \boldsymbol{g}^{\perp} \cdot \boldsymbol{b}^{\perp} = 0$$

Weak extinction condition:

$$\boldsymbol{g}^{\parallel} \cdot \boldsymbol{b}^{\parallel} = -\boldsymbol{g}^{\perp} \cdot \boldsymbol{b}^{\perp} \neq 0$$

The disappearance of the diffraction contrast of a dislocation under both extinction conditions has been verified experimentally [18, 46]. This shows that a dislocation in a QC causes both phonon and phason strains. However, the extinction criterion in the diffraction-contrast technique gives only the direction of the Burgers vector of a dislocation and provides no information concerning its magnitude. Moreover, sometimes it is not easy to find suitable reflections to satisfying the above extinction conditions.

Wang and coworkers [47–49] extended the defocus CBED technique of Cherns and Preston [50] to determine both the direction and magnitude of the Burgers vector $\boldsymbol{b}$ of a dislocation in a QC if $\boldsymbol{g} \cdot \boldsymbol{b} = n$ is treated in 6-D space. In the defocus CBED pattern, a high-order reflection fringe in the $\boldsymbol{g}$ diffracted disc and its corresponding deficient line in the transmitted disc, when crossing a dislocation with a Burgers vector $\boldsymbol{b}$, will split into $n + 1$ sublines with n nodes. The sense of $\boldsymbol{g} \cdot \boldsymbol{b}$ will be positive (or negative), if on the $\boldsymbol{u} \times \boldsymbol{c}$ side of the dislocation line of the reflection fringe twists along (or opposite to) the $\boldsymbol{g}^{\parallel}$ direction, where $\boldsymbol{u}$ is the line direction of the dislocation and $\boldsymbol{c}$ is a vector pointing to the incident beam cross-over from the dislocation line. When the splitting behavior of six reflection fringes with linearly independent indices (in the simplest case they may be chosen from three linearly independent reflection rows) is observed using the defocus CBED technique, six independent equations $\boldsymbol{g}_i \cdot \boldsymbol{b} = n_i$ $(i = 1, 2, \ldots, 6)$ will result, and from these the 6-D Burgers vector $\boldsymbol{b}$ can be obtained.

Figure 10 shows a defocus CBED pattern taken from a dislocation line (denoted by $\boldsymbol{u}$) in an Al–Cu–Fe IQC [49]. Six high-order Laue zone (HOLZ) lines (marked 1–6) crossed by the dislocation line are split into 3, 2, 3, 2, 3, and 2 sublines, respectively. The corresponding values of $\boldsymbol{g} \cdot \boldsymbol{b}$ are determined to be -2, -1, 2, -1, -2, and 1, respectively. After indexing these six $\boldsymbol{g}$ values, let $\boldsymbol{b} = [b_1, b_2, b_3, b_4, b_5, b_6]$. A set of six linear

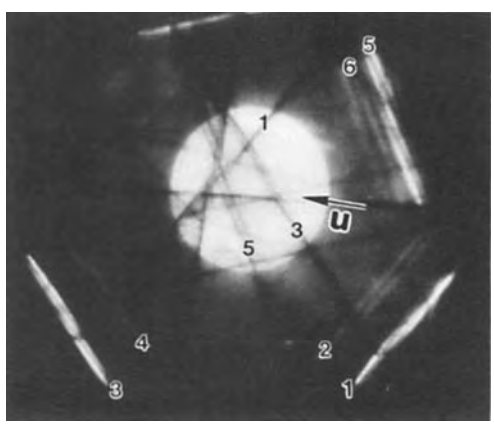

Figure 10. Defocus CBED pattern showing the split of the bright diffracted and the dark transmitted fringes into sublines caused by a dislocation line (direction $\boldsymbol{u}$) in an Al–Cu–Fe icosahedral quasicrystal. (Courtesy of Dr R. Wang and reproduced from *Phil. Mag.* [49] by permission of Taylor & Francis Ltd.)

equations with six parameters is obtained:

$$\begin{bmatrix} -4 & -6 & -8 & -2 & 4 & 2 \\ -3 & -3 & -5 & -1 & 3 & 1 \\ -2 & -4 & 4 & 6 & -2 & -8 \\ -1 & -3 & 3 & 3 & -1 & -5 \\ 0 & 2 & -4 & -4 & 2 & 6 \\ 1 & 1 & -3 & -3 & 1 & 3 \end{bmatrix} \begin{bmatrix} b_1 \\ b_2 \\ b_3 \\ b_4 \\ b_5 \\ b_6 \end{bmatrix} = \begin{bmatrix} -2 \\ -1 \\ 2 \\ -1 \\ -2 \\ 1 \end{bmatrix}$$

The Burgers vector $\boldsymbol{b}$ is found to be $\boldsymbol{b}^5 = [1, 1, -2, 1, -1, -1]$ in the direction of a five-fold axis of the IQC along an edge of the acute rhombohedron. The Burgers vector components in the physical and pseudo spaces are irrational: $\boldsymbol{b}^{5\parallel} = (3 - 2\tau, 2 - \tau, 0)$ and $\boldsymbol{b}^{5\perp} = (-2 - 3\tau, 0, -1 - 2\tau)$. Similarly, dislocations of the three-fold type with Burgers vectors $\boldsymbol{b}^3$ in the direction of a three-fold axis along the body diagonal of the acute rhombohedron [49] and of the two-fold type with $\boldsymbol{b}^2$ in the direction of a two-fold axis along the face diagonal of the acute rhombohedron [47, 48] have been found.

Phason strains will modify or change the phase term of the wave-density expression of a QC. In real space this corresponds to tiling mistakes or a rearrangement of the tiles [42], such as the transformation of *LSLLSLS*... into *LLSLLSLL*... in Fig. 9. This is in fact the transformation of a Fibonacci aperiodic association with τ into a 2/1 approximant series. In reciprocal space, phason strains will cause a movement of the diffraction spots of a QC towards the positions corresponding to the approximant [34]. Phasons and the corresponding transformation of a QC to an approximant has been studied using either electron diffraction or HREM in octagonal QCs [51–53], DQCs [26, 54–58] and IQCs [59–62]. Moreover, domains and discommensurations have also been observed in octagonal QCs [63, 64] and in DQCs [22, 23].

Readers interested in the electron diffraction and microscopy of QCs are referred to some recent reviews [65, 66] and edited volumes [67–70].

10 Medical and Dental Materials

10.1 Introduction

Generally, the term of biomaterials means materials that are used for restoration of functions which were destroyed by a disease or by an accident in the human body. For instance, it is well known that gold is one of the oldest biomaterials used in dentistry. Figure 1 exhibits the early Phoenician dental restoration which was to maintain teeth in a fixed position in the mouth known as the Gaillardot specimen, dating from about 600–400 BC. Ambrose Paré, who has often been called 'the father of surgery', described a palatal obturator which was a device to fill a perforation of the hard palate in his *Ten Books of Surgery* (1563). This device consisted of a curved sheet of gold large enough in size to cover the hole and shaped to conform to the configuration of the mouth.

In the 1770s, surgeons were in dispute over the manner by which to fix a fractured bone. Iron wire was used although it was very difficult to evaluate whether the use of metal increased the incidence of infection. The first study of biocompatibility of metals to tissue was performed using platinum, gold, silver, lead, etc. in a series of experiments with dogs in 1829 undertaken by Levert [1]. Various metals and alloys were tested in the nineteenth century and the reaction of metals to tissue was recognized in the early 1900s. To provide a successful application of an implant, it was clear that the implant must be put into the body without bacterial contamination but also that an adequate combination of metal components should be selected to avoid the disintegration due to electrolytic reaction. Apart from this basic understanding, the knowledge of biomaterials developed on a basis of trial and error over many decades. Today, biomaterials science is a recognized interdisciplinary field bringing together medical, dental and materials science.

Table 1 lists conventional biomaterials, used currently, which are classified by their functions and applications. Such biomaterials are roughly divided into two categories: structural and functional materials. Structural biomaterials, on the one hand, are used for withstanding cyclic loading, such as mastication or walking motions. Functional biomaterials, on the other hand, are applied to realize a specific biofunctional purpose, because of their peculiar characteristics, such as a drug delivery system with the degradation or bioerodability, a hemidialysis membrane with permeability. Furthermore, these biomaterials may be implanted either

Figure 1. Retentive prosthesis supposedly of Phoenician origin dating from 600–400 BC. (Photo by K. Yasuda with permission from the Louvre Museum, Paris.)

entirely within the soft and/or hard tissues (e.g., a bone plate, a hip joint) or partially in the tissue but with penetration of an epithelial surface (e.g., intraoral mucosae, such as dental implants, because a part of the device is exposed to the exterior of the body). They may also be placed on an epithelial surface (e.g., a denture).

Essentially, the requirements of biomaterials are that there should be a lack of significant interaction between the material and the surrounding biological system of the human body. That is, they should be nontoxic, nonirritant, noncarcinogenic, and nonallergenic as well as providing suitable mechanical properties such as strength, rigidity, elasticity, and high chemical stability in an aggressive environment inside of the human body. These requirements are considered to be divided into two parts at an interface between the material and surrounding biological system (e.g., tissue, blood, extracellular fluids, etc.) because a clinical application of the materials involves the creation of the interface. Figure 2 shows a schematic illustration of structural aspects depending on the size of biomaterial and biological system at the interface [2]. For example, surface roughness of an implant device may affect cell behavior at the 10 μm scale, since adsorptive and migratory behavior of cells play an important role in forming a functional seal with percutaneous devices which must penetrate through a stratified epithelium, such as dental implants, auditory prostheses, catheters for dialysis, etc. An oxide layer of passivating metals and alloys also plays an important role in resisting corrosion in physiological environments.

Because of the preference for energetically favorable reaction sites, which are the emergence sites of dislocations on a surface or the various interfaces intersected at a surface and along grain boundaries, corrosion is induced preferentially at these surface structures. When a metallic implant meets with tissue, an interaction takes place at the interface between the surface atoms of the oxide layer and the molecular components of the biological system. Consequently, cations are released from the oxide layer into the body fluids, and are able to bind to proteins in the biological system which will induce an effect on tissue. Thus, the study of biomaterials science is carried out by considering the interface from two quite different aspects. First, biomaterials science itself deals with matters such as the specific suitability of mechanical properties, corrosion resistance and other characteristics necessary to realize functional performance within the body. Second, the effects of the chosen biomaterials on the biological system in the body forms the study of biocompatibility.

Table 1. Classification of medical and dental materials according to category, application and function.

Biomaterials	Principal applications	Function applied
Metals and alloys		
316 stainless steel	Joint replacement	Strength and wear resistance
	Spinal instrumentation	Toughness
	Fracture fixation	Rigidity
Titanium,	Joint replacement; tibial components	Strength and wear resistance
Ti–6Al–4V,	Fracture fixation;	Rigidity
Ti–6Al–7N	Pacemaker encapsulation	Strength and biocompatibility
Co–Cr alloys	Joint replacement;	Strength and wear resistance
	Dental implants,	Toughness
	Dental prostheses	Strength
	Orthodontics	Resilience
	Heart valves	Toughness
Gold alloys	Dental restorations; fillings	Ductility
	Dental restorations; prostheses	Strength
	Dental restoration; bridges	Resilience
Platinum and PGM	Electrodes	Conductivity and corrosion resistance
Hg–Ag–Sn amalgam	Dental restorations	Plasticity and hardness
Ceramics and glasses		
Alumina	Joint replacement; femoral stems	Strength and inertness
	Acetabular cups	Wear resistance
	Dental implants	Strength and rigidity
Calcium phosphates	Ceramic femoral stems	Strength and inertness
	Scaffold material bone repair	Biological affinity
	Surface coating on metals	Biological affinity
Bioactive glasses	Bone replacement	Biological affinity
Porcelain	Dental restorations	Hardness and inertness
Polymers		
Polyethylene (UHMWPE)	Joint replacement	Wear resistance
Polytetrafluoroethylene (PTFE)	Soft-tissue augmentation	Biocompatibility
	Membrane for blood-gas exchangers	Permeability and biocompatibility
	Vascular prostheses	Antithrombotic
Polypropylene	Membrane oxygenator	Permeability and biocompatibility
Polyesters	Vascular prostheses	Antithrombotic
	Drug delivery systems	Bioerodibility
	Absorbable sutures	Bioerodability
Polyurethanes	Blood-contacting devices	Antithrombotic
Polyvinylchloride (PVC)	Tubing	Antithrombotic
Polymethylmethacrylate (PMMA)	Dentures	Strength and biocompatibility
	Intraocular lenses	Flexibility and gas permeability
	Joint replacement	Strength
Silicones	Soft-tissue replacement	
Hydrogels	Ophthalmology	Optical characteristics
	Blood-contacting devices	Hemo-compatibility
Composites		
Dimethylacrylate-quartz	Dental restorations	Compressive strength
Carbon fiber – thermosetting resins	Bone repair	Toughness and biocompatibility
Carbon fiber – thermoplastics	Bone repair	Toughness and biocompatibility
Carbon–carbon	Bone and joint replacement	Strength and toughness

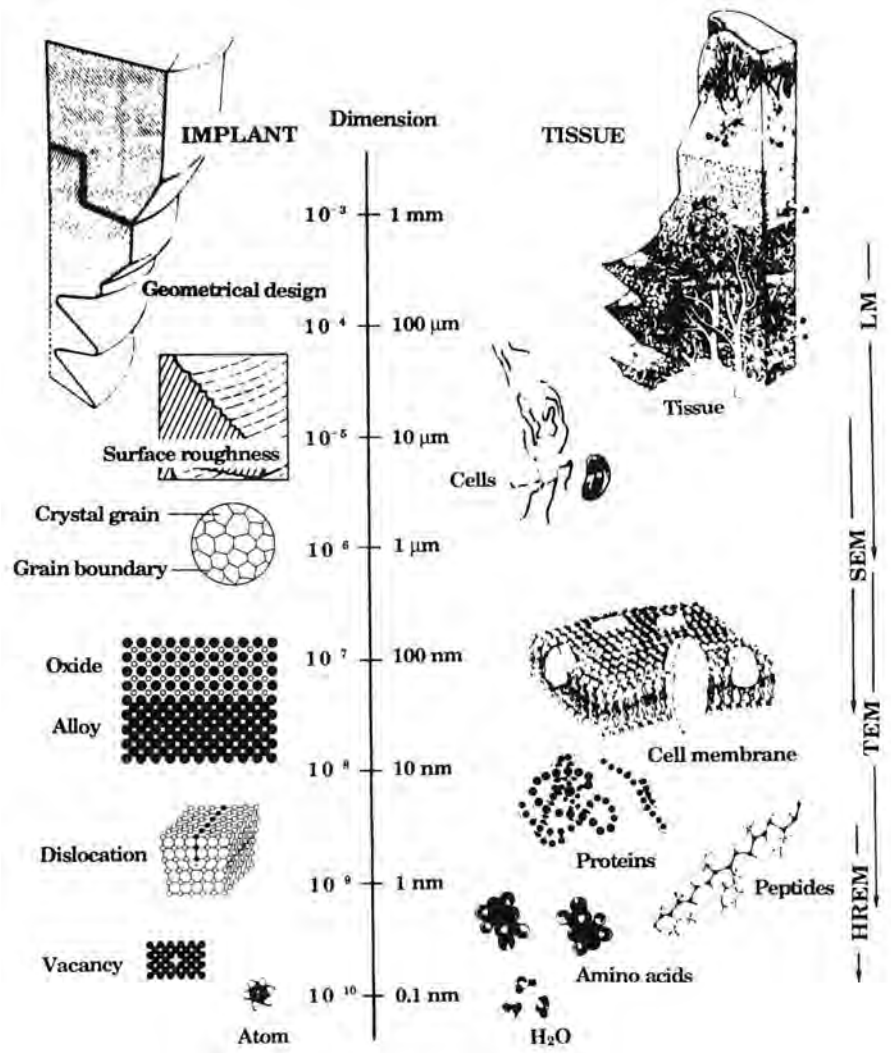

Figure 2. Schematic illustration of the approximate dimensions of some geometrical structures and elements that occur at the interface between a biomaterial and biological system. (After Kasemo and Lausmann, 1988 [2], with permission.)

10.2 Biocompatibility

The term of biocompatibility is defined by Williams [3] as the ability of a material to perform a specific function in the human body with an appropriate host response in the tissues. When a biomaterial is applied to a patient and is in contact with the tissues, the following series of events will be induced from the biomaterial to tissue: (i) an initial physicochemical interaction between constituents of the biomaterial and molecular components of the tissues at the interface; (ii) the generation of the local host response due to the constituents

of the biomaterial immediately adjacent to the interface or to the vicinity of it, and (iii) the systemic distribution and responses following the transporting of physicochemical interaction products away from the reaction sites to remote sites in the body [4].

The initial physicochemical interactions will occur at a solid–liquid interface established between the biomaterial and the body fluids such as blood, serum and extracellular fluid immediately after the implantation. Then, proteins contained in the body fluids will be adsorbed onto the surface of the biomaterial. Adsorbed proteins are affected strongly on cellular response to the biomaterial, for example, adsorbed insoluble globulin enhances the adhesion of fibroblasts, the foreign particles originated from the biomaterial were ingested by macrophages, and thrombus formation on a tube which is fabricated by polyvinyl chloride gave rise on the surface exposed to blood [5]. But also, deterioration of the biomaterial is induced during the interaction at the interface by the mechanisms of depolymerization, cross-linking, oxidative degradation, hydrolysis, crazing and stress cracking in polymers, oxidation, crevice, pitting and galvanic corrosion, stress corrosion cracking and fatigue in metals and alloys, and dissolution in ceramics.

According to a hypothetical model proposed by Williams [4], a sequence of normal wound healing is described chronologically in relation to the tissue responses as follows: (i) an area of wound is filled with blood clot after injury of soft tissue; (ii) blood vessels are dilated, and acute inflammatory response takes place with cells; (iii) the repair process is brought about by capillaries growing into the wound area, by collagen storage in fibroblast to form the connective tissue; and (iv) the healing of the wound is completed by resolution of the fibrous scar tissue. The duration of each stage in the sequence, however, may depend on a balance between the injury and repair, even though no infection occurs. Furthermore, if the damage of the tissue is mild, the inflammatory response may develop into the chronic inflammation. Consequently, the tissue response may never be resolved and may always be accompanied with inflammatory cells as well as new collagen and blood vessels.

By contrast, a sequence of wound healing in the presence of an implant which is not totally inert is described as an interaction between degradation of the biomaterial and host tissue responses as follows: (i) a fibrous capsule is formed surrounding the implant, if the material is not decomposed in the environment; (ii) an extensive response is induced in the tissue, if a release of constituents occurs from the reaction products on the surface of the material; (iii) a chronic inflammatory response takes place in the tissue, if the material leads to persistent stimulus to inflammation by more severe degradation in the tissue; and (iv) an extensive chronic response is provided by aggressive tissue environment, if the degradation is intensified by a cellular activity on the surface of the material.

The remote or systemic effects are explained that if an interfacial reaction leads to the formation of reaction products, and to release of constituents from the products, these constituents are soluble and are taken up rapidly in the extracellular fluids. Therefore, these constituents are able to transport away in either lymphatic or vascular systems to various organs and tissues throughout

the body. Consequently, the solubilized constituents of material are metabolized and excreted, or stored in some tissue depots. As to the fate of these products in the tissue, if these constituents show an irritation to tissues, effects will arise systemically or at remote sites in the body.

Degradation of a biomaterial is an important factor in relation to biofunctionality. If a polymer is degraded relatively rapidly in the body, it can be used as adhesive for sutures, drug-delivering devices and reabsorbable implants serving as temporary scaffolding. Metals and ceramics are applied in orthopedics, because of their relative stability in the body. The degradation of these materials, however, has often led to malfunctioning of prosthetic devices due to the biological medium as well as cellular activity.

Thus, the biocompatibility of candidate materials has been evaluated mainly on the basis of morphological features of the 'fibrous capsule' enveloping the implant which is affected by each stage of the events using light microscopy (LM), scanning electron microscopy (SEM), and transmission electron microscopy (TEM), depending on required dimensional scale.

10.3 Applications of Microscopy to Evaluate Biocompatibility

10.3.1 Biological Responses Between Cultured Cells and Biomaterial

Generally, experiments in vivo do not allow the examination of the specific cellular reaction to the biomaterial, because numerous populations and chemical factors are involved in the implantation. To distinguish and to analyze the sequence of events which have been described in the previous section, and parameters affecting the interaction process, comprehensive studies have been carried out on cell culture in the presence of biomaterials. For example, the biomaterial–bone interface is studied in the relatively well-defined environment of tissue culture such as organ cultures with calvaria and cell culture with bone marrow cells [6].

To assess the influence of synthetic calcium phosphate powders on osteoblast activities, the ability of osteoblasts to migrate from bone explant to other substrata was examined by means of LM, SEM and TEM on isolated human bone cells in culture [7]. Pure β-tricalcium phosphate (β-TCP) and hydroxyapatite (HAP) which have been used as prosthetic and restorative materials for the skeletal system, were powdered in a mortar and passed through a sieve of less than 50 μm. These powder specimens were seeded in the medium after cells in culture reached confluence. After 600 ks (7 days) maintaining the co-culture of cell and material, the internalization of particles of β-TCP or HAP by the two osteoblast cell populations was examined to assess the biocompatibility using SEM and TEM observations. The isolated human bone cells showed capable of ingesting synthetic calcium phosphate granules. It was suggested that the bone cells were able to participate in the degradation of calcium phosphates by the acidic environment of the phagolysosomes which were confirmed by TEM observations.

This technique also enables us to assess cytotoxicity, due to release of cytotoxic products from cell–material interaction (i.e., enzymatic actions). To evaluate cytotoxicity of collagen which is used as an artificial skin, van Luyn et al. [8] developed a sensitive in vitro test system using methylcellulose as the culture medium. This system can be examined by interactions between cross-linked sheep dermal collagen or its extracts and human skin fibroblasts with the methylcellulose culture for a test period of 500 or 600 ks (6 or 7 days) without refreshing the culture medium. Possible cytotoxic effects are measured by counting cell numbers and evaluated cell morphology by phase-contrast light microscopy [9]. Figs. 3a and b exhibit the phase-contrast light microscopic images of a multilayer of completely spread human skin fibroblasts in control culture and of human skin fibroblasts cultured with a disc specimen after 600 ks (7 days), respectively. A significant decrease of cell number and morphological changes of cell are observed in the micrographs. They [10] reported a discrimination of primary cytotoxicity due to extractive constituents from the material, and secondary cytotoxicity induced by a release of cytotoxic products resulting from enzymatic cell–biomaterial interactions, because a pendant molecule can be released by enzymatic attack.

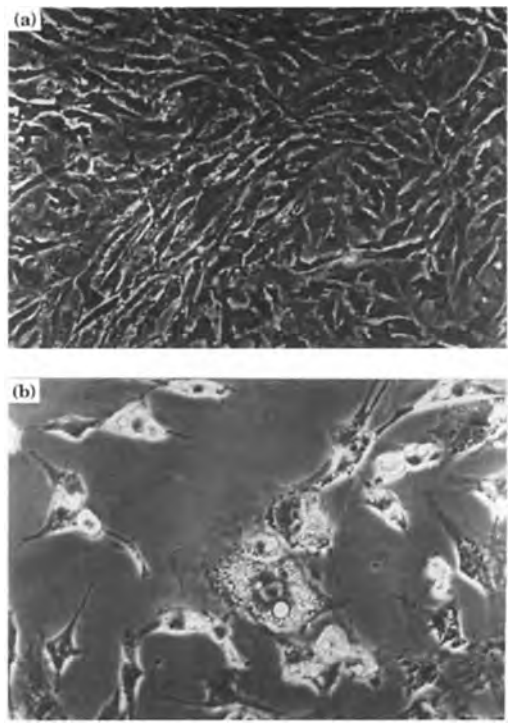

Figure 3. Light micrographs of cell cultures, (a) a multilayer of completely spread human skin fibroblasts in control culture for 0.6 Ms. Some cells contain very small biorefringent particles. (b) Human skin fibroblasts culture with disk-shaped specimen of hexamethylenediisocyanate for 0.6 Ms. Original magnification ×720. (After van Luyn et al., 1992 [9], with permission.)

To elucidate the interaction between tissues and alloy particles which were derived from wear or corrosion of a prosthesis at the cellular level, Rae [11] performed a cell cultural study. His method was as follows. First, foetal rat knee joints were grown in organ culture for 1.2 Ms (2 weeks). At the beginning of the culture period, particulated cobalt, chromium, molybdenum, cobalt–chromium alloy, nickel, or titanium was injected into the joint cavity of limbs. Then the cultures were removed at various time intervals, examined histologically and compared with control cultures. His observation showed that the particulated cobalt, nickel and cobalt–chromium alloy were more toxic than chromium, molybdenum, and titanium. Furthermore, it was found that the synovium was partially destroyed and the metallic particles were enclosed by aggregation of necrotic tissue. The test using monolayer cultures of mouse

peritoneal macrophages showed that particulate titanium, molybdenum and chromium were tolerated by cartilage and synovial cells, and did not impede phagocytosis by macrophages. By contrast, cobalt, nickel and a cobalt–chromium alloy induced localized areas of necrosis in the cartilage and synovium of the knee joint, and damage in the cell membrane of macrophages in the culture.

These methods for assessment by tissue cultures of suitable cells have been developed as a more sensitive technique to evaluate cytotoxicity of candidate materials. The evaluation is made of cell growth rate or cell lysis in comparison to positive and negative controls. Although the assessment by cell culture methods is highly sensitive, this may not accurately reflect the course of events realized at tissue sites in the human body, especially concerning long term effects. There are differences of opinion as to the correlation among the cell culture test, the implantation test into an animal and clinical usage test [12]. Discussion of the biological tests on dental materials has been undertaken by a joint working group for the FDI (Fédération Dentaire Internationale), ADA (American Dental Association) and ISO (International Standards Organization) in 1977. Thus, methods and criteria for the biological tests of candidate materials have been established precisely on dental materials [13].

10.3.2 Biological Responses Between Tissue and Biomaterial

To examine biocompatibility of material by tissue response, experimental works have usually been performed on healthy animals of the same strain in carefully controlled environments. Such an animal model is advantageous to distinguish the complex clinical situation from different well defined elements which can be controlled, so allowing the study of isolated problems. Various species of animal have been employed in such experiments according to the requirements of each study. For example, dogs are often used for studies on orthopedic implant fixation because their bone structure is close to that of humans.

In the preparation of specimens for LM and TEM observation, there is a well-defined series of steps in the fixation, dehydration and embedding of biological materials and, in general, it is only necessary to adopt a very standard routine which is now followed in many laboratories. Furthermore, it is necessary to prepare ultrathin sections of specimens by cutting because of the limited penetration of the incident electron beam in the electron microscope operating at a conventional accelerating voltage up to 100 kV. For adequate penetration and resolution the specimen should not be thicker than 100 nm, since biological specimens already possess a great wealth of structural detail in the 2–100 nm range. The artifacts associated with the cutting are common, because distortions in a fine network structure of the specimens cannot be relaxed after the cutting. An important requirement is the staining of a thin section to provide a sufficient contrast for a differentiation of each part in a microtexture of a biological specimen which is quite different from a crystalline specimen.

Bakker et al. [14] studied phagocyte/polymer interface interactions which will

induce degradation of biomaterials, with dense implants made of polysiloxane and porous implants made of polyether urethane, polypropylene oxide and a polyethylene oxide hydantoin/polytetramethylene terephthalate segmented polyether polyester copolymer for tympanic membrane as a total alloplastic middle ear prosthesis. The implants, which were 100–125 μm thick, were placed at three different sites in the middle ears, in submucosa of tympanic membrane tissue, and between bulla bone and surrounding muscle tissue. The middle ears were dissected from the sacrificed rats after prescribed implantation periods. Sections cut 7 μm in thickness were stained with hematotoxylin-eosin for LM after finishing the standard routine procedure in biological specimens, whereas ultrathin sections were sliced by a microtome, stained with uranyl acetate and lead citrate for TEM. The phagocyte/polymer interactions were evaluated by a composition of the tissue surrounding an implant by measuring of the area in cross section occupied by phagocytes, fibrous tissue and bone using LM as a function of implantation period. They found that the volume of the phagocyte exuded into tissue surrounding the implants, the degradation and fragmentation of the implant. The thickness of fibrous capsules was in relation to the implantation site which was an important factor to assess the performance of implant.

Therefore Bakker et al. [15] also studied the biocompatibility of these elastomers during a *Staphylococcus aureus*-induced middle ear infection which is the most common microorganism causing wound infection in hospitals, because the infection will interfere with the tissue/implant interface and with implant fixation by fibrous tissue and bone, as well as implant degradation. A total number of 983 LM sections were prepared by the standard routine procedure. To assess the biocompatibility, a composition of the tissue surrounding the implant was quantified by measuring the area in cross sections occupied by phagocytes, fibrous tissues and bone as a function of implantation period. The most significant changes attributable to infection were an increase in the fraction of tissue occupied by phagocytes and a decrease in the amount of fibrous tissue with the presence of an implant. The TEM observations of phagocyte/polysiloxane interface showed none of the features associated with implant degradation. This suggested that the polysiloxane elastomer was not subjected to degradation within a one-year implantation period. In addition to the above, significant bacterial degradation or enhanced polymer degradation associated with the inflammatory process was not found in their study.

Collagen-based biomaterials are thought to be the most advantageous biomaterials because the collagen is the main protein component of body tissues such as bones, tendon, skin, ligaments and cartilage, therefore they have been used clinically in bioprosthetic heart valves, vascular prostheses, wound and burn dressings, etc. Thus, application of the collagen as a biomaterial enables 'same with same' replacement implants. The variety of collagens is determined by the structure and number of repeat units in the molecule which will affect the physical properties of collagens, and is classified as types I–IX. Type I collagen is the most plentiful in connective tissue, tendon

and skin. Types II and III exist abundantly in cartilage and blood vessels, respectively [16]. Although commercial products of collagen-based biomaterials are available, modified treatment is necessary to obtain a suitable application in each case as a biomaterial. For instance, cross-linking is able to obtain a strong and stable network of the membrane. A cross-linking agent, however, may influence greatly the immunogenicity of the product. The most widely used cross-linking technique, which is glutaraldehyde treatment, induces a reduction of antigenicity and degradation of the implant.

Vardaxis et al. [17] applied a confocal laser scanning microscopy (CLSM) to study proliferation and differentiation of mesenchymal cells, which are important in the healing process, using an immunostaining technique. They prepared collagen membranes by conventional cross-linking using glutaraldehyde and by a new method involving microwaving and glutaraldehyde. Disk-shaped collagen membranes were implanted in subcutaneous pockets of the ether-anesthetized rats. These membranes were removed from the sacrificed rats after prescribed periods of implantation. The removed membranes and their surrounding tissue were prepared into specimens according to the standard procedure in biological science. Then, the sections were stained by several different procedures to differentiate specified microstructures; for example, a two-step immunostaining procedure was employed with monoclonal antibodies against alpha smooth muscle actin and vimentin labeled with rabbit-antimouse fluorescein isothiocyanate for quantification and three-dimensional imaging by CLSM. They indicated that significant proliferation of

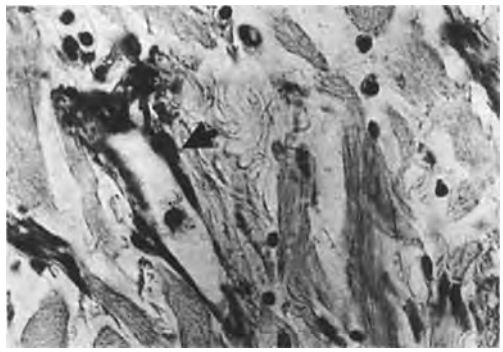

Figure 4. Light microscope of a noncross-linked collagen membrane implanted in animal for 2.8 Ms. An arrow indicates blood vessels formed newly at the rough side of the membrane (400×). (After Vardaxis et al., 1994 [17], with permission.)

small vessels was observed in the interstitium of the fat surrounding the implant, and the endothelial and muscle cells were the proliferating cell nuclear positive after implantation for 350 ks (4 days). The appearance of the cross-linked membrane showed the formation of a new collagen. A prominent vascularization of the implant with vessel ingrowth at the position indicated by an arrow in Fig. 4. Examination by CLSM showed that the tissue reaction around the membrane was one of acute inflammation and early granular tissue formation which is a step in the healing process. The formation of new vessels was also confirmed by CLSM as seen at the position indicated by an arrow in Fig. 5. The geometry of the vessels was followed in the optical serial sections and in the three-dimensional images formed by CLSM.

Scanning tunneling microscopy (STM) has the unique capability of probing the surface structure up to atomic resolution in vacuo, air or liquid. To characterize some aspects of the interface between metallic implants and living tissue, STM

Figure 5. Confocal microscopy image of the connective tissue surrounding a collagen membrane treated with microwave method implanted in an animal for 0.3 Ms. White area shows the membrane. A new blood vessel bud is growing toward the membrane as is indicated by an arrow. (Extended focus image, autofluorescence. Scalebar: 50 μm.) (After Vardaxis et al., 1994 [17], with permission.)

was employed by Emch et al. [18]. They studied biological assays on fibronectin adsorbed on titanium and vanadium coverslips which have been chosen because vanadium is toxic while titanium is inert. Fibronectin is a multifunctional glycoprotein found in both connective tissue and blood, and plays an important role in promoting adherence of staphylococci which cause infection of metallic implants in orthopedic surgery. To examine biological objects with an STM, it was important that a high resolution image was needed immediately during acquisition of data so that real and interesting features were recognized. According to them, this was attained using a video converter which digitized the signal coming from the feedback and the scanning units, and this was transformed into a video signal displayed on a conventional video monitor. They reported that the fibronectin was well adsorbed on the surface of Ti and V substrates, even though these were covered with a natural oxide layer of approximately 10 nm on Ti and 5 nm on V, but it was not bioactive on V substrate.

Ceramics used for implants in medicine and dentistry are of three types: (i) oxide ceramics, such as alumina (Al_2O_3) and zirconia (ZrO_2); (ii) calcium-phosphate ceramics, such as hydroxyapatite (HAP) and tricalcium phosphate (TCP); and (iii) calcium-phosphate containing glass and glasses. Application of ceramics as biomaterials is initially based upon their relative inertness in a biological environment compared to that of metals.

Tissue response between hydroxyapatite granules and human periodontium [19], between single crystal sapphire endosteal dental implant and junctional epithelia of dog [20], between β-TCP granules and bone tissue of monkeys [21] were studied morphologically using LM, SEM and TEM. Certain calcium-phosphate ceramics have a chemical composition similar to the mineral phase in bone tissue. The HAP, TCP and bioglass provide a chemical bond with the bone tissue at their interface after implantation. Orly et al. [22] showed chemical changes in HAP implant under a biological environment realized in human tissue and by cell culture method using TEM and IR spectroscopy. They reported that nucleation and growth of tiny crystals of HAP were

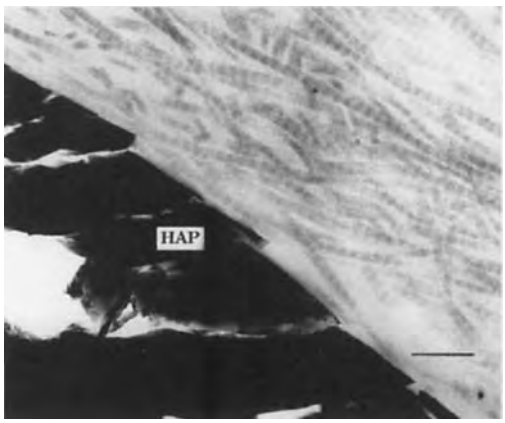

Figure 6. Transmission electron microscope image of collagen fibers running parallel predominantly to the surface of hydroxyapatite. Scalebar: 0.33 μm. (After de Bruijn et al., 1992 [23], with permission.)

found on the surface of the HAP particles which were implanted in human tissue for two months. Initiation of such a mineralization process can be seen in Fig. 6 where collagen fibers are formed predominantly parallel to the HAP surface soaked in cultured bone marrow cells [23]. These collagen fibers integrated and increased in size at the mineralization sites. To perform a stereological examination of osteogenesis at a dental implant, Steflik et al. [24] employed a high voltage electron microscope (HVEM) and conventional TEM under accelerating voltage of 1000 and 100 kV, respectively, because a support by the mandibular or maxillary bone is an important factor for the endosteal implant to succeed. Although densely mineralized collagen fiber matrices were observed in HVEM, they did not give any evidence of mineralization by selected area electron diffraction (SAED) patterns, since the specimens employed were prepared by the routine biological procedure involved in staining. Analysis of the crystalline phase in biologically mineralized tissues is described in Sec. 10.4 of this Chapter.

10.3.3 Interactions Between Blood and Biomaterial

Materials used in the circulatory system (e.g., in artificial heart valves, a totally artificial heart, circulatory-assist devices, oxygenators, liver support systems, renal dialyzers, blood vessel substitutes, and catheters) come into contact with blood flow during service. When blood is contacted with a surface of the artificial organs, various events will be induced at the interface depending upon exposure period. That is, adsorption and/or degradation of blood components, consumption of coagulation factors, and adhesion and aggregation of platelet induce the generation of microthrombi and occasionally life-threatening thromboembolism. The causative mechanisms and prevention of thrombosis and embolization at the interface between blood and biomaterial have been studied by numerous researchers.

Grabowski et al. [25] established a method of evaluating platelet adhesion on various membranes for cardiovascular prostheses exposed to heparinized flowing blood on different species of animal, including human, using SEM. In their study, specimens of membrane were exposed to nonrecirculated blood or to circulated blood of each species for prescribed periods at a constant surface shear rate. The membrane specimens were examined by either phase contrast microscopy or LM after fixation, staining and mounting between a slide glass and cover slip.

SEM observation was also performed. They intended to develop the in situ continuous monitoring of the blood/biomaterial interface reactions by means of video microscopy. Haycox et al. [26] also employed epifluorescent video microscopy to obtain real-time, dynamic information on platelets adhering to candidate biomaterials. Subsequently, Haycox et al. [27], however, stated questions of equivalent reactivity between humans and other animal species. They emphasized the necessity of establishment with respect to a meaningful in vitro blood test compatibility for predicting the performance of candidate material in vivo. To examine platelet interactions with biomaterials, they measured β-thromboglobulin release from platelets into bulk using fresh human blood and a modified Chandler loop system which consisted of a peristaltic pump and a circular tube. The candidate polymers were polyethylene, polyurethane copolymer which consisted of alternating blocks of 'hard' and 'soft' segments, polyvinyl alcohol and a polyurethane prepared with octadecyl pendant groups. The polymer solutions were then solvent cast on the luminal surface of the oxidized polyethylene tube. Adherent platelets were observed using SEM and a colorimetric stain specific for human platelet GPIIIa. They observed four blood reactions: (i) platelets continually adhered, activated and released; (ii) platelets initially adhered and released, but then spread over the surface and passivated it; (iii) platelets did not adhere to the surface but continued to react with unpassivated material; and (iv) platelets were neither adhered nor activated. These reactions were, according to the authors, essential clues to establishing blood compatibility.

10.4 Imaging and Characterization of Tissue Components in the Body

Collagen molecules, which are approximately 300 nm in length, form collagen fibrils by spontaneously aggregating into an ordered arrangement. This ordered arrangement results in a characteristic 60–70 nm transverse D periodicity in the structure. Baselt et al. [28] observed the D periodicity in microfibrils of type I collagen in rat tail tendon and of reconstituted bovine dermal type I collagen by atomic force microscopy (AFM). They showed the D periodicity consisting of alternating grooves and ridges in microfibrils on large-diameter fibrils of the reconstituted bovine dermal collagen as seen in Fig. 7. The authors mentioned that AFM images only reveal a microfibril structure on large-diameter fibrils, while minor band structures appear in TEM images as the most prominent structure on small-diameter fibrils. This is due to

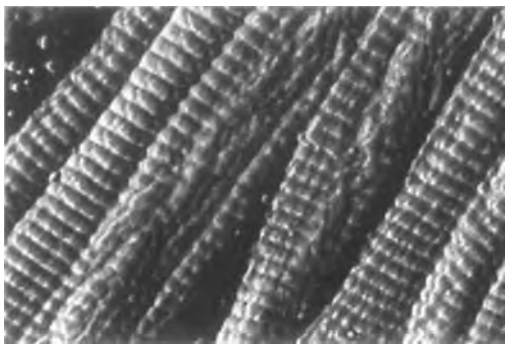

Figure 7. Atomic force microscopic $2.3 \times 1.4\,\mu m$ image of reconstituted microfibrils of bovine dermal collagen. The specimen was fixed in 2.7% glutaraldehyde for 0.6 ks. (After Baselt et al., 1993 [28], with permission.)

an imaging limitation of the AFM. AFM observation, however, is advantageous when examining, without any specimen preparation, cryoprotectants, stainings, embedments, or coatings. It is also possible to make examinations under water by this method.

Dental caries is a multifactorial disease that is a progressive destruction of enamel, dentine and cementum initiated by microbial activity at the tooth surface, even though this explanation is oversimplified. The crystalline phase is biologically mineralized tissues, such as bone and enamel, has a structure similar to hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$] and fluoroapatite [$Ca_{10}(PO_4)_6F_2$]. High resolution electron microscopy (HREM) has been an invaluable technique in the study of the mineralized tissues, the structure of biological macromolecules, their interactions and arrangements of cells. Featherstone and Nelson [29] showed a HREM image of the stoichiometric composition of a synthesized HAP crystal with its *c*-axis oriented parallel to the [0 0 1] and its *b*-axis oriented parallel to the [0 1 0]. The former exhibited a lattice image with hexagonal symmetry and the latter represented it with orthorhombic symmetry. They confirmed these structures by comparing with corresponding projections of the apatite structure and with computer-simulated lattice images.

Thereafter, Brès et al. [30] examined irradiation damage of human enamel during observation by HREM at 300 and 400 kV. Their specimens for HREM were sliced using an ultramicrotome, without decalcification and staining, and HREM images were taken parallel to various orientations. They reported that orientation-dependent damage was in the form of mass loss from voids or uniform destruction of crystal structure on the basis of their superb images and analysis including computer image simulation and optical diffraction. A beam-induced diffusion of Ca and O atoms created CaO crystal outgrowths on the enamel surface and crystal patches inside the bulk crystal.

Periodontal disease is caused directly or indirectly by microorganisms in dental plaque. Bacterial growth in the plaque will take up some phosphate from the saliva which is saturated with respect to hydroxyapatite; hence, calcium phosphate is deposited on the teeth surface in the form of calculus. Furthermore, it is thought that the mineralizing process will be accelerated by nucleation of an organic material on the surface of the tooth. Hayashi [31] showed an initial stage of crystallization of calculus on the surface of human enamel by HREM. Ultrathin sections were prepared by cutting with an ultramicrotome after extraction of a human mandibular impacted third molar after extraction and fixation. Because HREM observation was performed with unstained ultrathin sections, it was possible to analyze the HREM images coupled directly with SAED patterns. His observation revealed that calculus, identified as hydroxyapatite needle-like crystals from the SAED patterns, were nucleated coherently on the surface of enamel crystal. Therefore, these crystals of calculus were rigidly formed on the enamel surface and were grown by delivery of constituents from saliva.

Magnetic resonance imaging (MRI) has been currently and widely applied in clinical medicine and dentistry to obtain important diagnostic information, for example, high quality cross-sectional

images of the body using magnetic fields and radiofrequency waves. Lockhart et al. [32] have attempted an in vitro study of an application of three-dimensional MRI to the diagnosis of pulpal pathosis, because dental radiographs which are the most popular technique in dentistry provide two-dimensional imaging only. They used extracted human teeth for MRI after taking radiographs to examine the extent of caries involvement. Multislice imaging allowed for the collection of eight cross-sectional slices at 1.0 mm intervals in coronal and four in apical directions from a central point. The results obtained showed the outlined shape of a tooth including periodontal membrane and internal form of pulp chamber with a high degree of accuracy, thus suggesting the future possibility for accurate diagnosis and treatments of endodontic and periodontal diseases. For example, Fig. 8 shows a cross-sectional image of a molar with MRI taken by Baumann et al. [33]. A texture within the pulp tissue can be seen clearly. Figure 9 exhibits a three-dimensional image of a molar. This suggests that the MRI is able to reproduce a three-dimensional whole configuration of a tooth and a cross-sectional shape of pulpal chamber with a high degree of accuracy using computerized image processing.

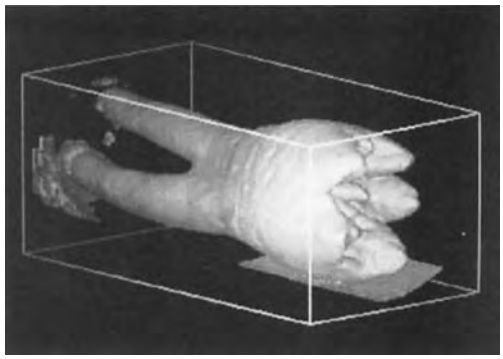

Figure 9. Magnetic resonance microscopic three-dimensional image of the human molar. (After Baumann et al., 1993 [33], with permission.)

Both scanning acoustic microscope (SAM) and scanning laser acoustic microscope (SLAM) have been employed to provide qualitative and quantitative information concerning the material being tested nondestructively. The qualitative information simply provides the morphology in nature and map of the distribution of changes in elasticity and density of a hard tissue on a microscopic scale. Katz and Meunier [34] showed a detailed structure of both human and canine single osteons and osteonic lamellae at a resolution down to approximately 1.7 μm which was well within the thickness of a lamella. When the SLAM is operated in an interference mode, it is possible to obtain the specimen's elastic properties on a

microscopic scale (i.e., quantitative information).

In MRI, SAM and SLAM, the specimens are not necessarily prepared according to the biological treatments such as dehydration, fixation and chemical staining and, therefore, artifacts are not necessarily received. This is thought to be the most advantageous detail compared with other imaging techniques except, of course, for high resolution which is required to distinguish neighboring object points.

10.5 Applications of Microscopy for Characterization of Biomaterials

10.5.1 Characterization of Electrochemical Events on the Surface of Metallic Biomaterials

Surface characterization of metallic biomaterials is particularly important, because surface interactions with surrounding tissue and body fluids lead to various biological and electrochemical events in relation to the biocompatibility and degradation of the implanted devices. The biological events are induced by the release of constituents from corrosion products formed on the surface of a metallic implant in the body. This release of cations is governed as a function of the corrosion rate or oxidation rate of the constituents and of the solubility of the oxide, or first formed corrosion products on the surface of the implant. It is necessary, therefore, to examine the corrosion layer and those factors affecting the corrosion process, so that reactions at the interface between metallic implant and tissue are capable of being minimized, hence reducing inflammation, pain and other problems experienced by the patient.

Electrochemical reactions are examined using anodic polarization, linear polarization and impedance spectroscopy as an averaged measurement because the reactions are detected across an entire surface. However, localized electrochemical events such as etching, selective dissolution, stress corrosion cracking, pitting corrosion, and fretting corrosion processes can be analyzed using surface analytical techniques, for example, Auger electron spectroscopy (AES), X-ray photoemission spectroscopy (XPS or ESCA), electron probe microanalysis (EPMA). To examine morphological aspects on the surface, LM and SEM are commonly used.

It is well known that titanium and its alloys have been used with considerable success for clinical implants because of its excellent corrosion resistance as well as desirable mechanical properties. Occasionally, however, titanium compounds are formed in tissue adjacent to the titanium implants. To elucidate a release mechanism of constituents from an implant, characterization of the passive films on titanium and Ti–6Al–4V alloy was performed in the physiological environment realized by Ringer's solution with changes in pH and amino acid additives using AES and replica TEM by Solar et al. [35]. They showed that the electrochemical reaction was generated by growth of the passive film. They also indicated that the effective electrochemical area of each specimen was less than its geometrical area and was

dependent on both pH and surface finishing conditions.

Bianco et al. [36] studied changes in surface topography and local electronic structure of titanium thin films before and after immersion in an in vitro modeling solution which was a modified Hanks' balanced salt solution with 1.5 mM EDTA. Interactions at the interface between titanium and the solution was observed using STM coupled with tunneling spectroscopy (TS). The topography of the immersed thin film of titanium showed little change from the nonimmersed film specimen, whereas spatial change of the local electronic structure was conspicuous. From the experimental results, they suggested that interactions at the interface between titanium and the solution were not induced uniformly on the surface. They supposed that the change was due to the result of the replacement of the hydroxyl group found on the hydroxylated oxide by phosphate groups.

Stainless steel is the most common implant material in orthopedics. Surgical implants are usually required to possess strength levels far greater than that of bone and have an elastic modulus similar to that of bone. Stainless steel, however, is frequently corroded in the human body. Sundgren et al. [37] examined interface characteristics between stainless steel implants and human oral tissue (both hard and soft) using AES with SEM. They found that the thickness and nature of the passivated oxide layer on the implants depended on the location of the implant sites in the oral region. When the implant was placed in hard tissue, thickness of the oxide layer was not affected or increased, and the oxide was incorporated with calcium and phosphorus. By contrast, when the implant located in soft tissue, the thickness of the oxide layer decreased. These changes were interpreted in terms of oxygen pressures and metabolic activity.

Although comprehensive studies on the corrosion resistance of commercial dental gold alloys have been performed, it is not easy to understand their corrosion characteristics completely because these alloys have extremely complex combinations of constituents, frequently containing five or more elements. In these alloys, the overall corrosion resistance is thought to be controlled by the total amount of precious metals (i.e., nobility). Nakagawa et al. [38] examined the effect of microstructure on the corrosion of Au–Cu–Pd and Au–Cu–Ag ternary and Au–Cu–Ag–Pd quaternary alloys using anodic potentiodynamic and potentiostatic polarization tests in deaerated 1% NaCl solution at 310 K. To consummate changes in microstructure associated with phase transformations, a single phase of solid solution and of $L1_0$ type ordered structure was obtained by annealing at 1073 K and at 573 K for appropriate periods, then quenched in ice brine, respectively, in Au–Cu–Pd ternary alloys. A two-phase coexisting microstructure, which consisted of Cu-rich and Ag-rich f.c.c. phases, was also realized by a similar heat treatment in Au–Cu–Ag ternary and Au–Cu–Ag–Pd quaternary alloys. The phase transformation and the associated microstructure as well as changes in crystal symmetry were confirmed by TEM and SAED techniques. They proved that the single phase microstructure of Au–Cu–Pd ternary alloys exhibited high corrosion resistance. The high nobility Au–Cu–Ag ternary alloys also showed high corrosion resistance

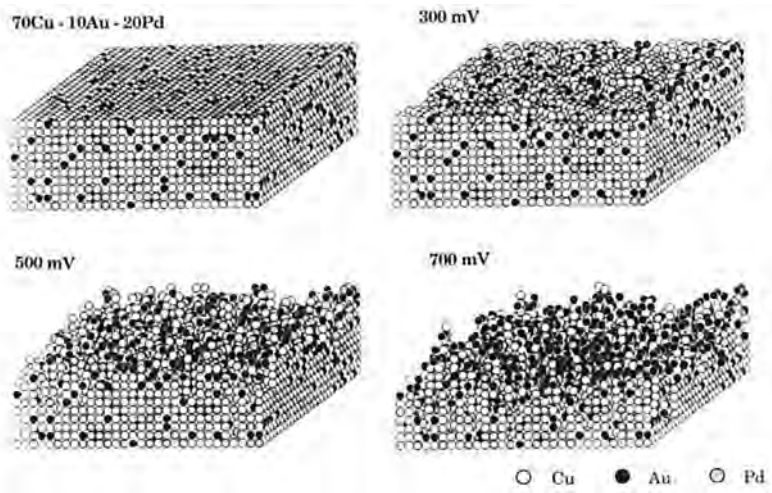

Figure 10. Computer simulated schemes during anodic dissolution of the Cu–10 at.% Au–10 at.% Pd alloy polarized at various potentials. (The figure reproduced newly for the book with courtesy Nakagawa et al., 1993 [39].)

regardless of its two-phase coexisting microstructure. However, the generalized finding was that the two-phase microstructure had lowered the corrosion resistance compared with the single phase alloys. They also found that anodic potentiodynamic polarization curves of the two-phase microstructure could be explained by superimposing the curves of each phase using the principle of additivity. In fact, the potential at which the current density increased significantly corresponded to that of each phase, and the amount of the current density was calculated as the summation of each phase in proportion to their volume fractions.

In noble metal alloys, the preferential or selective dissolution of less noble elements and surface enrichment with noble elements may take place if the alloy is polarized at a lower potential than that of the anodic reaction of the noble elements, as is well known. Nakagawa et al. [39] tried to explain their experimental results by computer simulations of the anodic dissolution process in Au–Cu–Pd ternary alloys using the dissolution model and taking into account the effect of atomic interaction energy. Dissolution probability of those constituents which exhibited the dissolution rate were defined by considering the standard electrode potential of dissolution reaction and anodic interaction between Cu and the other atoms. Figure 10 shows the changes in the surface configurations with increasing polarization potential (i.e., dissolution probability) in a Cu–10 at.% Au–20 at.% Pd alloy. It is possible to observe that significant dissolution occurs and the surface of the alloy becomes rougher with increasing polarization potential. Thus, the computer simulation qualitatively showed a reproduction of their experimental results of anodic potentiostatic polarization concerning the dependence of the anodic dissolution behavior on the polarization potential and alloy composition, and the atomic concentration depth profile of the constituents after anodic polarization. These

results suggested that atomic interaction among the constituents of alloys was an important factor governing the anodic dissolution features of alloys. It is thought that STM and AFM observation is necessary to confirm this dissolution model.

Recently, Gilbert et al. [40] have introduced a new technique capable of imaging highly localized electrochemical currents associated with charge transfer reactions on the surface of metallic biomaterials, using a scanning electrochemical microscope (SECM). This is a nonoptical scanning microscope which can be examined in two different modes: the oxygen reaction rate on the surface of a specimen mode and the ion release and deposition mode. They carried out SECM examinations to evaluate electrochemical reactions or cation release processes in Ni minigrids, an intermetallic compound, γ_1, formed in crystals of dental amalgam and Co–Cr–Mo alloy beads sintered to the main body of a hip joint replacement prosthesis which exhibited significant differences in geometries and corrosion processes. They have emphasized that the SECM is a valuable tool for imaging microelectrochemical processes on the surfaces of metallurgical polished alloy specimens and a wide variety of other surfaces of biological interest where charge transfer occurs.

10.5.2 Coherent Phase Diagram of Au–Cu–Ag, Au–Cu–Pt Ternary and $[Au_x(Ag_{0.24}Cu_{0.76})_{1-x}]_{0.958}$–$Pt_{0.015}$ Quaternary Systems

It is well known that most dental gold alloys containing platinum and palladium exhibit conspicuous age-hardening characteristics. In 1905, an age-hardenable gold–copper–silver–platinum alloy, which we now realize from its composition was hardenable by AuCu ordering, was developed and put on the market for the first time by the S. S. White Dental Manufacturing Co. (USA). It is astonishing to note that age-hardening was being applied in dental practice so early on [41].

The essential components of commercial dental gold alloys are thought to be gold, copper and silver. A knowledge of equilibrium phase diagrams is an important aid in predicting the phase transformations resulting from the aging of alloys; the ordering regions in the Au–Cu–Ag ternary system have not been established with sufficient accuracy. A brief description of the historical background on the determination of the Au–Cu–Ag ternary system is given in [42].

Generally, a great deal of experimental work is needed; hence, long periods are needed to allow a complete evolution to the equilibrium state, also there is much expense involved in the case of precious metal alloys to determine the equilibrium phase diagram of the ternary alloy system. Yamauchi et al. [43] calculated a 'coherent' phase diagram of the Cu–Au–Ag ternary system, using the determined interaction energy parameters to fit only the experimental binary phase diagrams of Au–Cu, Cu–Ag and Ag–Au systems. Even though it was intended to represent only 'coherent' equilibria (i.e., when all the possible phases differ from each other merely by the arrangement of the constituent atoms of copper, silver or gold on a fixed f.c.c. lattice of the disordered solid solution) the calculated phase diagram showed striking similarities with the

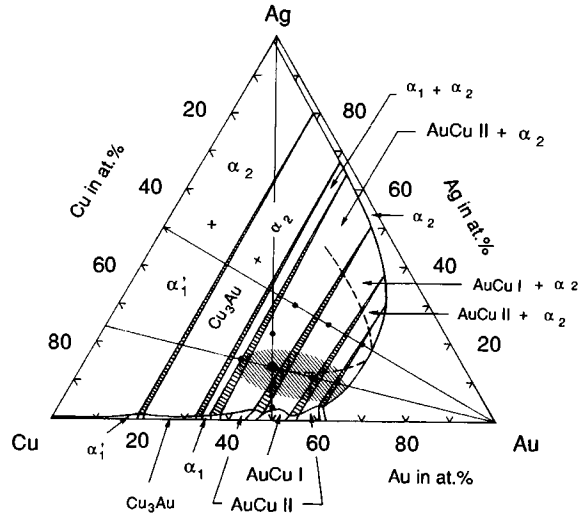

Figure 11. Isothermal section of a plausible coherent phase diagram of the Au–Cu–Ag ternary system at 575 K. (After Hisatsune et al., 1991 [45].)

experimentally derived phase diagram determined by X-ray powder diffraction according to Uzuka et al. [44]. This calculated phase diagram was confirmed to refer to TEM experimental data obtained by Yasuda's group. Figure 11 shows an isothermal section at 573 K of the plausible Au–Cu–Ag ternary phase diagram which was constructed by superimposing the theoretical phase diagram calculated using the cluster variation method [43] on experimental data [45]. In the phase diagram, the shaded area indicates the composition region corresponding to commercial dental gold alloys and the dots show the composition of alloys examined by TEM and HREM.

According to the hypothesis of Allen and Cahn [46], a coherent phase must be metastable and must be unstable in the presence of the incoherent phase; the coherency strain must also be present in the coherent multiphase structure, and dislocation must be visible at the interfaces with the incoherent phase to reduce coherency strain. They showed that the coherent phase diagram of the Fe–Al binary system could be obtained by TEM and SAED, as long as the study satisfied their hypothesis. A coherent phase diagram gives us more effective information to predict phase transformations related to age-hardening in an alloy system than an incoherent equilibrium phase diagram.

Figure 12 is part of the coherent phase diagram of Au_x–$(Ag_{0.24}Cu_{0.76})_{1-x}$ section in the Au–Cu–Ag ternary system which was determined by means of TEM bright- and dark-field imaging coupled with the SAED technique, because this section passes through the composition region of commercial dental gold alloys, as seen in the shaded area of Fig. 11 [47]. The formation region of long period superstructure of AuCuII appears coexisting with a silver-rich disordered f.c.c. α_2 phase. The Cu_3AuII long period superstructure was also found in the $Cu_3Au + \alpha_1 + \alpha_2$ three phases coexisting region. Here, the α_1 phase is a Cu-rich disordered f.c.c. structure. In relation to this system, a coherent

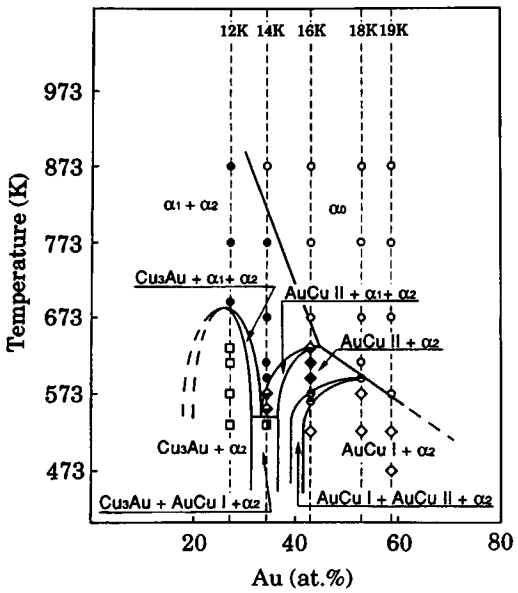

Figure 12. Coherent phase diagram of the Au_x–$(Ag_{0.24}Cu_{0.76})_{1-x}$ pseudobinary section in Au–Cu–Ag ternary system. (After Nakagawa and Yasuda, 1988 [47].)

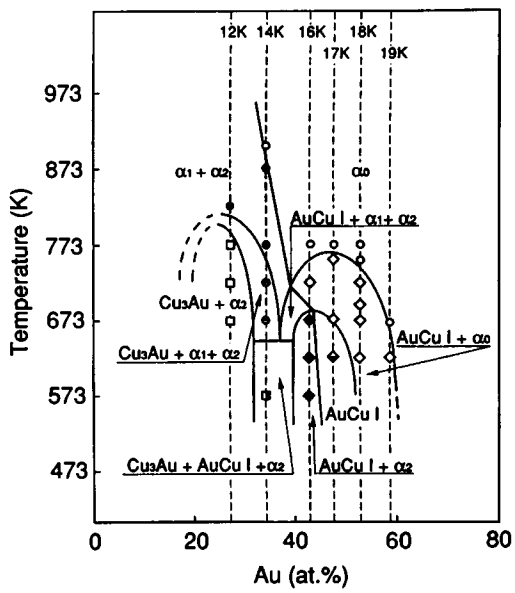

Figure 13. Coherent phase diagram of the $[Au_x$–$(Ag_{0.24}Cu_{0.76})_{1-x}]_{0.985}$–$Pt_{0.015}$ pseudobinary section in Au–Cu–Ag–Pt quaternary system. (After Iwanuma, 1994 [48], with permission by his supervisor.)

phase diagram of more complex quaternary alloys $[Au_x$–$(Ag_{0.24}Cu_{0.76})_{1-x}]_{0.985}$–$Pt_{0.015}$ pseudobinary section in the Au–Cu–Ag–Pt system was also determined recently using TEM and SAED by Iwanuma [48], as shown in Fig. 13 in which any long period AuCuII superstructure cannot be detected. The coherent phase diagram of AuCu–Pt pseudobinary section was determined also using TEM and SAED by El Araby et al. [49]. They showed that the AuCuII ordered region disappeared on the phase diagram in the composition range over approximately 1.3 at.% Pt.

A HREM coupled with SAED is an indispensable technique to identify a minor phase in multiphase structure for the determination of a coherent phase diagram. For instance, Yasuda et al. studied structural aspects of the AuCuII ordered phase associated with order twinning in AuCu–3 at.% Ag [50] AuCu–9 at.% Ag [51] and AuCu–14 at.% Ag [52] alloys of HREM and SAED. The α_0 phase which was predicted from the phase rule could be found adjacent to the tip of the microtwin platelets when they were in contact with other orientation variants of the microtwin platelets as an inevitable consequence of strain accommodation in AuCu–3 at.% Ag alloy [50]. In AuCu–9 at.% Ag alloy, they observed that a characteristic mosaic structure consisted of cuboidal blocks of the α_2 phase enclosed by two different orientation variants of the AuCuII twinned ordered phase by HREM [51]. Their results revealed the atomic arrangement of each phase, the interfacial structure between the coexisting phases on the scale of interatomic distance and strain field induced

by order twinning at corners in the cuboidal α_2 phase.

10.5.3 Structural Aspects Associated with Phase Transformation and Age-hardening Mechanisms in Dental Gold Alloys

In dental gold alloys, age-hardening is induced mainly by AuCu ordering. Microstructural changes related to AuCu ordering and two-phase decomposition were studied by TEM, HREM and SAED in Au–Cu–Ag ternary alloys [50–52]. In Au–Cu–Ag ternary alloys, four distinguishable phase transformations occurred depending on the silver content and on the annealing temperature: (a) the formation of the AuCuI and/or AuCuII long period ordered platelets and its twinning characterized by a stair-step made by a nucleation and growth mechanism (N–G process); (b) AuCuI and/or AuCuII ordering and two-phase decomposition promoted by the N–G process; (c) the ordering resulting from spinodal decomposition; and (d) the formation of the lamellar structure developed from grain boundaries by discontinuous precipitation.

The HREM study showed that process (a) was brought about in a composition located outside of the miscibility gap of two-phase decomposition in Au–Cu, that is, low content Ag alloys in the AuCu–Ag pseudobinary system [50]. Changes in microstructures induced by process (b) were complex; for example, two types of precipitate, spindle type and chain type, were formed by the N–G process upon annealing above the critical temperature for ordering, T_c. Below the T_c, these precipitates changed to a sandwich structure consisting of cuboidal blocks of α_2 phase and AuCuII ordered thin platelets along two of their three faces, and only their lateral faces were not decorated and connected directly with the α_1 matrix. In a low silver content alloy, AuCu–5.6 at.% Ag, the α_2 phase was formed as finely dispersed precipitates, sometimes as small as 10 nm × 2 nm, coexisting with AuCuI and/or AuCuII ordered phase [53]. In process (c), below the spinodal temperature, the modulated structure was generated in the early stage of aging, then the cuboidal blocks of the α_2 phase were completely sandwiched by the AuCuII ordered thin platelets [52].

Although there are four types of phase transformation giving rise to age-hardening, only two types of phase transformation are reported in commercial dental gold alloys. The age-hardening characteristics of commercial dental gold alloys are also studied by Yasuda's group using TEM, SAED, HREM, electrical resistivity measurements, hardness tests and X-ray diffraction. In an Au–21.8 at.% Cu–8.8 at.% Pt–8.8 at.% Pd alloy, age-hardening occurred in two stages. The first stage arose from the nucleation of AuCuI ordered platelets and was characterized by a slow growth rate of the ordered nuclei [54]. In the second stage, simultaneous ordering and precipitation took place. An alternating lamellar structure consisting of AuCuI ordered platelets and platinum-rich f.c.c precipitates was identified by TEM and SAED. Studies for elucidating age-hardening mechanisms on a series of commercial dental gold alloys were performed, since it was expected that the age-hardening mechanism varied greatly

depending upon the concentration of gold in the alloys.

The two alloys studied were Au–26.5 at. % Cu–18.2 at. % Ag–7.9 at. % Pd (16 K/S) and Au–25.3 at. % Cu–27.4 at. % Ag–7.6 at.% Pd (14 K–S) [55, 56]. In these alloys, two stages of AuCuI ordering could be distinguished by TEM and SAED studies of isochronal aging of a supersaturated solid solution. In the first stage, ordering of a metastable AuCuI′ ordered phase formed as a stepwise arrangement of platelets situated on the {1 0 0} planes. Prolongation of the aging period caused the formation of a lamellar structure composed of the equilibrium AuCuI ordered and a silver-rich disordered f.c.c. phases. The metastable AuCuI′ ordered platelets were formed prior to the equilibrium AuCuI ordered phase. The AuCuI′ platelet formation was accompanied, in the 16 K–S alloy, by a contraction of approximately 0.07 along the *c*-axis of the AuCuI′ in the surrounding matrix. In the 14 K–S alloy, the contraction along the *c*-axis was approximately 0.06. The strain introduced by the tetragonality of the AuCuI′ structure led to substantial hardening in the early stages of aging.

Thereafter, a different type of age-hardening mechanism was found in a commercial dental gold alloy, Au–31.7 at.% Cu–8.1 at.% Pd–5.3 at.% Ag (18 K–S) [57]. The X-ray and SAED studies as well as TEM showed that Au_3Cu $L1_2$ type superlattice with thermal antiphase domain boundaries (APBs) was formed by aging at 673 K. It was thought that the hardening arose through the mechanism of antiphase domain size effect. The $L1_0$ type AuCuI superlattice was also formed in regions adjacent to the Au_3Cu ordered phase in the later stages of aging below 623 K. The TEM micrographs showed that the AuCuI ordered platelets were formed in the Au_3Cu ordered matrix along ⟨1 0 0⟩ directions. Thus, it was concluded that the hardening should be attributed not only to the APBs size effect, but also to the elastic strain field induced by the formation of the ordered AuCuI platelets in the aging temperature range below 623 K.

Although the hardening mechanism in dental gold alloys was thought to be attributed to a coherency strain field at the interface between the AuCuI ordered platelets and the surrounding matrix, the configuration of the interface, that provides direct evidence of the presence of the coherency strain fields, could not be deduced by conventional TEM. Therefore, HREM coupled with SAED was employed to elucidate structural configuration of the interface between the AuCuI and Au_3Cu ordered phases in the 18 K–S alloy [58]. An HREM image taken from the specimen aged at 673 K for 1.8 Ms with the incident electron beam parallel to the [1 0 0] direction showed that the square pattern of bright dots which had the same configuration and scale as the projection of the copper columns in Au_3Cu ordered structure. From this configuration it was clearly evident that the copper columns were at the correct positions with respect to the basic f.c.c. lattice (i.e., at each corner of the square). A shift in the arrays of the bright dots observed across the interfaces were composed of the APBs. The presence of APBs introduces a local change in chemical composition by excess atoms with respect to the stoichiometric composition of an ordered phase. Then, these excess atoms will be segregated along the

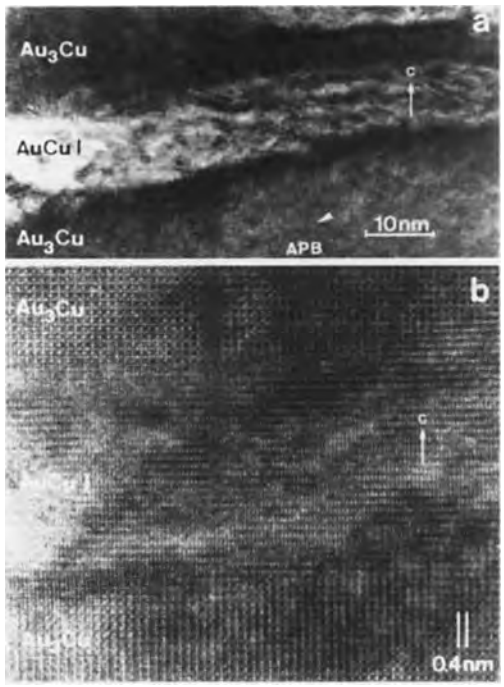

Figure 14. Bright field high resolution electron microscopic images of a commercial dental gold alloy (18 K–S) aged at 573 K for 1.8 Ms. (a) Only the superlattice reflections were selected for imaging; (b) all reflections up to 220_{fcc} were selected for imaging. (After Yasuda et al., 1986 [58].)

APBs. This segregation contributed to the hardening as well as to the higher energy at the APBs. When aging was carried out below 623 K, the AuCuI ordered platelets were formed in regions adjacent to the Au_3Cu ordered matrix. Figure 14a was produced by using 0 0 1, 1 0 0, 1 1 0 and equivalent superlattice reflections, the fundamental reflections being excluded, and contain an interface between the AuCuI platelet and the Au_3Cu ordered matrix of a specimen aged at 573 K for 1.8 Ms. Only one-dimensional resolution is observed in the AuCuI ordered platelet. For the HREM image in Fig. 14b, the f.c.c. reflections were also included in the imaging aperture to show in detail the arrangement

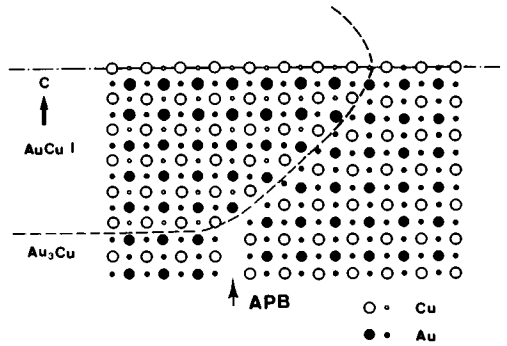

Figure 15. Schematic representation of an AuCu(I) platelet in an Au_3Cu matrix for axial ratio c/a of 0.9; an antiphase domain boundary (APB) is induced automatically if copper continuity is required along the center of the platelet (large circles are at level 0; small circles are at level 1/2). (After Yasuda et al., 1986 [58].)

of the atom columns along the interface between the AuCuI ordered platelet and the Au_3Cu ordered matrix. In spite of the disturbance caused by the presence of strain and strain contrast, the interface is clearly visible due to the small difference in atomic distance between the AuCuI and Au_3Cu ordered phases. It is clear that the amount of elastic strain increases in proportion to the thickness of the AuCuI ordered platelet, that is the length along the c-axis, within the range of the elastic limit.

If, as shown schematically in Fig. 15, it is assumed that at the top of such a platelet, the pure copper (0 0 1) planes in AuCuI coincide with the mixed gold and copper planes in Au_3Cu, then with an axial ratio $c/a = 0.9$ for a platelet with a halfwidth of 5 AuCuI unit cells, the pure copper planes will now coincide with the pure gold planes. For a c/a ratio of 0.945 which was the measured value from the diffraction patterns, the width of the AuCuI platelet will be 18 or 19 unit cells thick. This explanation is in good agreement

with the experimental observations; indeed, such a mismatch of the APB is observed in Fig. 14a as is indicated by the arrow head. Thus, it was concluded that the AuCuI ordered platelets, being coherent with the Au_3Cu ordered phase as matrix, gave rise to a considerable amount of elastic strain which could be a major contribution to the age-hardening in dental gold alloys. It was the first time to date that the atomic configuration in ordered phases induced by aging was produced and analyzed in commercial dental gold alloys.

10.6 Concluding Remarks

This section has reviewed some applications of microscopy which evaluate or characterize materials according to the required scale in the field of biomaterials science. A large number of papers in this field appear annually in the literature, the subject of which varies according to the investigator's background: that is, leanings towards physics, chemistry or biology, as well as clinical evaluation by clinicians in medicine and dentistry. In this article, we classified such contributions into two parts at the interface of an implant and surrounding tissue. In other words, biomaterials science is composed of a biological scientific approach and materials scientific approach, thus making the subject very much an interdisciplinary science. Clearly, from the contents of this contribution, the reader will appreciate that the discussion is selective and represents our special interests. However, from the references cited, the reader will be able to make further excursion into this fascinating domain.

Handbook of Microscopy
S. Amelinckx, D. van Dyck, J. van Landuyt, G. van Tendeloo

11 Carbon

11.1 Introduction

In view of its industrial importance in general, and in particular in the field of nuclear energy, carbon has been the subject of a large amount of research applying a wide range of physico-chemical methods. Among these microscopy holds a prominent place, since the morphology, microstructure, and texture are important parameters for the behavior of carbon, mainly as graphite.

We shall limit ourselves in this contribution to the description of a number of representative features observed by means of various microscopy methods, also illustrating the power of these techniques in this particular field of research.

11.2 The Different Forms of Carbon

11.2.1 Graphite

Elemental carbon occurs in different solid forms. The low temperature, low pressure phase is graphite (see, for example, Marsh [1]); its structure consists of planar hexagonal honeycomb networks of sp_2-bonded carbon atoms (Fig. 1a). The stacking of the layers in normal hexagonal graphite ($a = 0.2456\,\text{nm}$, $c = 0.6696\,\text{nm}$) can be represented by the sequence ABAB.... However, a rhombohedral variety, represented by the sequence ABCABC... occasionally occurs, in particular in heavily deformed graphite. Synthetic graphites are often orientationally disordered (turbostratic); the material cleaves very easily along the basal planes, since the bonding between the layers is of the weak Van der Waals type.

11.2.2 Diamond

The high temperature, high pressure form of carbon is cubic diamond ($a = 0.3567\,\text{nm}$). This structure consists of a spatial network of tetrahedra formed by sp_3-bonded carbon atoms (Fig. 1b), forming an f.c.c. lattice, the stacking sequence in terms of (111) layers being ...AαBβCγ.... Also a hexagonal form (Londsdaleite), having a wurtzite-type structure with stacking sequence ...AαBβ... is formed under special circumstances (e.g., in meteorite craters) [2]. In the past, diamond has been synthesized under high pressure and temperature in the presence of various catalysts (for a review,

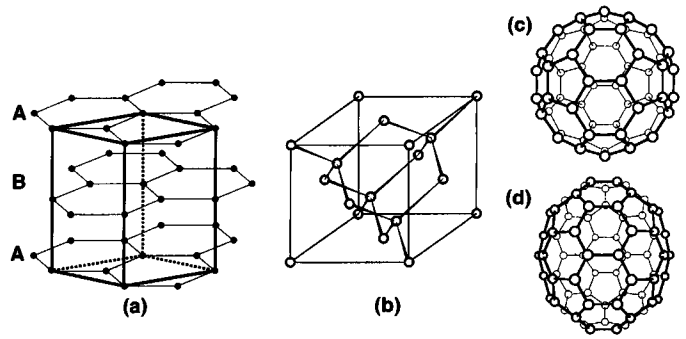

Figure 1. The different forms of solid elemental carbon: (a) graphite: sp_2-bonding, (b) diamond: sp_3-bonding, (c) fullerenes: C_{60} and (d) C_{70}.

see, e.g., Wilks and Wilks [3]). More recently, low pressure methods based on plasma-assisted chemical vapor deposition (CVD) have been developed, allowing the deposition of thin films of diamond on a crystalline substrate (for example, silicon) (see, e.g., references [4–7] and [3] for a review). The microstructure of these films is remarkable and important for the applications concerned.

11.2.3 Fullerenes

As well as these two forms of elemental carbon, a third form was discovered recently. Under certain circumstances, carbon has been found to form closed cage-like molecules [8], which give rise to predominantly Van der Waals bonded molecular crystals [9]. Such molecules are found in the soot produced in an electric arc between graphite electrodes under the reduced pressure of helium [9]. The most abundant species in the soot are C_{60} and C_{70}. Models of two of the simplest among these globular molecules, called fullerenes, are shown in Figs. 1c and d. They can be extracted from the soot by organic solvents and can be separated by chemical methods such as liquid phase chromatography, and then purified by selective sublimation [10]. C_{60} and C_{70} were studied initially because they were most readily available in appreciable quantities.

Owing to the initially very limited availability of pure, crystalline C_{60} and C_{70}, the structure and microstructure of these molecular crystals were initially studied almost exclusively by means of electron microscopy [9, 11–14] and X-ray diffraction [9, 15–17], and to a lesser extent by means of atomic force and scanning tunneling microscopy (especially for the observations of thin films) [18–24], whereas scanning electron microscopy was used to study the morphology (Fig. 2)

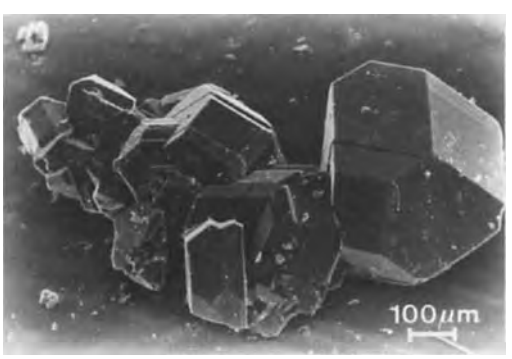

Figure 2. Scanning electron microscopic (SEM) image of sublimation-grown C_{60} single crystals (Van Tendeloo et al. [14]).

(for example, references [14, 25]). The crystal structures and phase transitions upon heating or cooling of fullerene crystals are reviewed in Fisher and Heiney [26].

The molecule C_{60} is the most symmetrical and most spherical fullerene; it is a globular cage consisting of 20 hexagonal and 12 pentagonal edge-shearing meshes. Each pentagon is surrounded by five hexagons and each hexagon by three pentagons and three hexagons (Fig. 1c). All closed-cage fullerenes contain a mixture of hexagons and pentagons; they satisfy Euler's rule for closed polyhedra (Appendix A, Sec. 11.7.1 of this Chapter). The number of pentagons is invariably 12 because it is the 'closure condition', i.e., twelve is the number required to cause a total convex curvature of 4π (Appendix B, Sec. 11.7.2 of this Chapter). The C_{70} molecule is an elongated, ellipsoidal cage differing from C_{60} by the presence of one more 'belt' of hexagons (Fig. 1d). Whereas the molecular point group symmetry of C_{60} is I_h, that of C_{70} is only D_{5h}.

11.2.4 Nanotubes

As a by-product of fullerene production by the electric arc method, it was recently discovered by means of transmission electron microscopy (TEM) that carbon often forms fine tubular fibers, with diameters of the order of nanometers and lengths of up to micrometers [27]. Such fibers have potential applications and have therefore been studied extensively (reviewed in references [28–30]). Owing to their small size, individual fibers can only be observed conveniently by electron diffraction and electron microscopy.

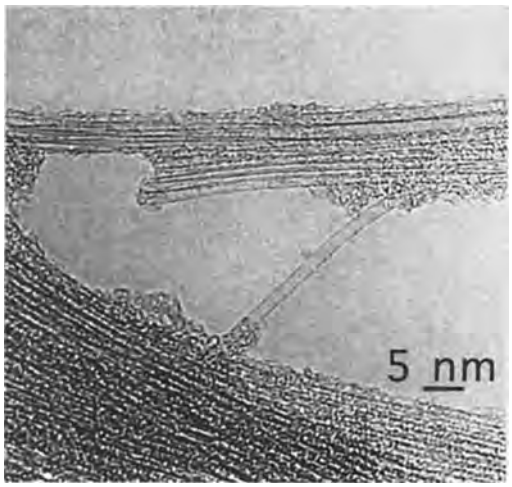

Figure 3. A single wall carbon tube (TEM); some bundles of parallel, single wall tubes are also present.

These fibers are either concentric cylinders of graphene sheets [27] or multiturn scrolls made of a single graphene sheet or a mixture of both [31, 32]. Single layer cylindrical fibers (Fig. 3) have recently been produced via a catalytic method, introducing the transition metal catalyst in the graphite electrodes of the electric arc [33–35]. Even more recently, high yields of single sheet tubes have been obtained by laser evaporation in an oven at 1200°C of a carbon target containing a small amount of transition metal atoms such as nickel or cobalt [36, 37]. Without a catalyst, the arc-grown tubules are usually multilayered and often contain imperfections, a number of which will be discussed below.

Under adequately chosen conditions, helix-shaped carbon fibers are produced via the catalytic decomposition at relatively low temperatures (~600–800°C) of hydrocarbons (Fig. 4) [38, 39]. Under particular conditions, conically wound, cylindrically shaped solid needles of carbon can be produced (Fig. 5) [40, 41].

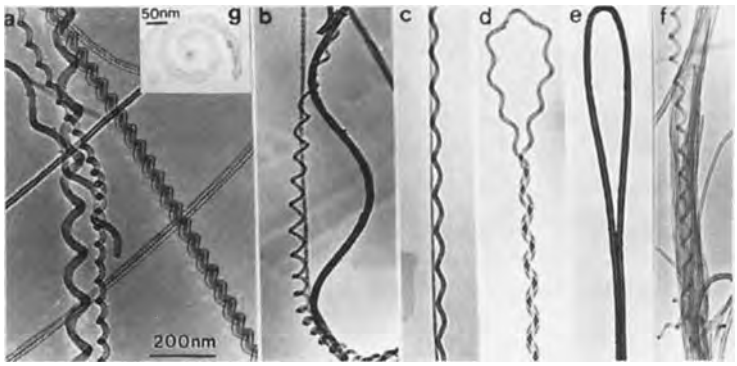

Figure 4. (a) to (g) Helix-shaped carbon tubules produced by the catalytic method and observed by TEM. Note the variety of shapes (Amelinckx et al. [212]).

11.3 Graphite

11.3.1 Specimen Preparation

Specimens with a uniform thickness over large areas and suitable for TEM diffraction contrast studies can easily be prepared by the repeated cleavage of single crystals (as occur in the Ticonderoga limestone, USA). Pieces of adhesive tape are hereby stretched over flat glass microscopy slides in order to keep the tape flat, and subsequently pressed with the adhesive coating against both sides of a graphite flake. The slides are repeatedly pulled apart avoiding shearing. Very thin flakes then adhere to the tape. Dissolving the glue in an organic solvent liberates these flakes, which then float in the liquid and can be deposited on standard grids.

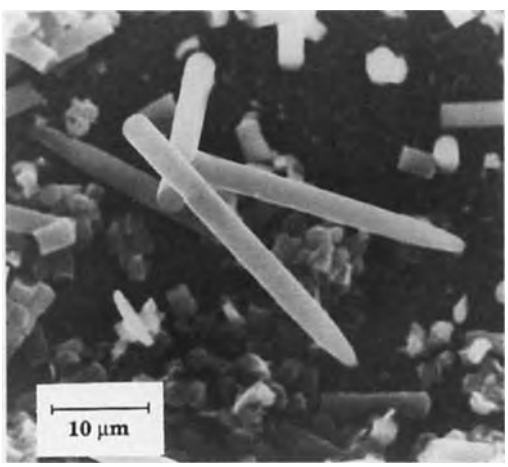

Figure 5. SEM image of conically wound graphite needles produced from CO on an SiC substrate (Amelinckx et al. [40]).

11.3.2 Transmission Electron Microscopy (TEM) Studies

Owing to pronounced cleavage, specimens are invariably parallel to the basal plane. Since the glide planes of dislocations are also parallel to the (0001) plane, the geometry of the specimen lends itself particularly well to a study of basal plane dislocation configurations. A number of these are described in Chap. 4.1, Sec. 1.1.18 of Vol. 1 of this Handbook and in more detail in Amelinckx et al. [42]. Basal plane glide dislocations are always dissociated in two partials of the Shockley type with Burgers vectors $A\sigma$ and σB, according to the equation $AB = A\sigma + \sigma B$, using the notation illustrated in Fig. 6.

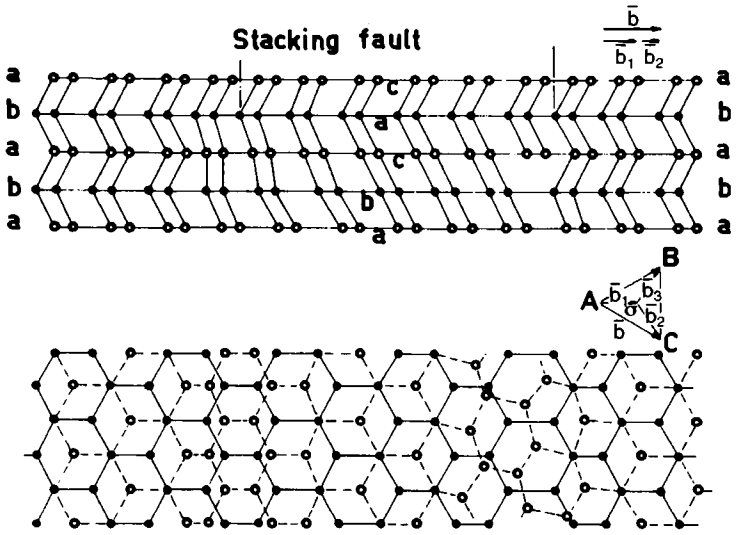

Figure 6. Schematic cross-sectional and plane view of a glide dislocation ribbon in graphite. A ribbon of intrinsic stacking fault separates the partial dislocations. A reference triangle for denoting Burgers vectors is shown as well (Amelinckx et al. [42]).

Imaging under two beam conditions with a $30\bar{3}0$ type active reflection reveals the three families of partials with Burgers vector $\pm A\sigma$, $\pm B\sigma$, and $\pm C\sigma$ (Fig. 7). These conditions were used to image single dislocation ribbons and study the variation of their width d with the angle ϕ enclosed by the direction of the total Burgers vector AB of the dislocation pair and the direction of the ribbon (Fig. 8). From

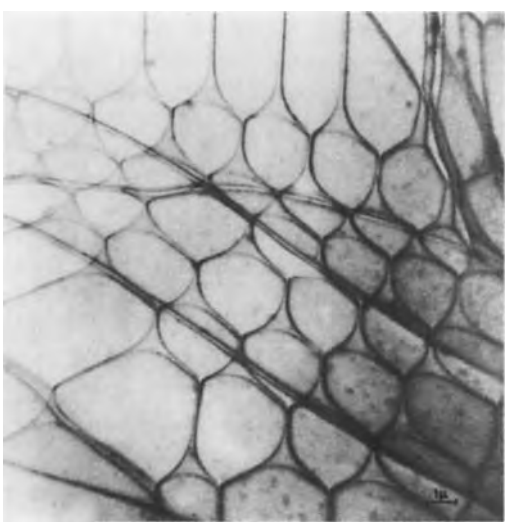

Figure 7. Network of partial dislocations in the basal plane of graphite observed in two-beam bright field diffraction contrast (TEM) (Amelinckx and Delavignette [44]).

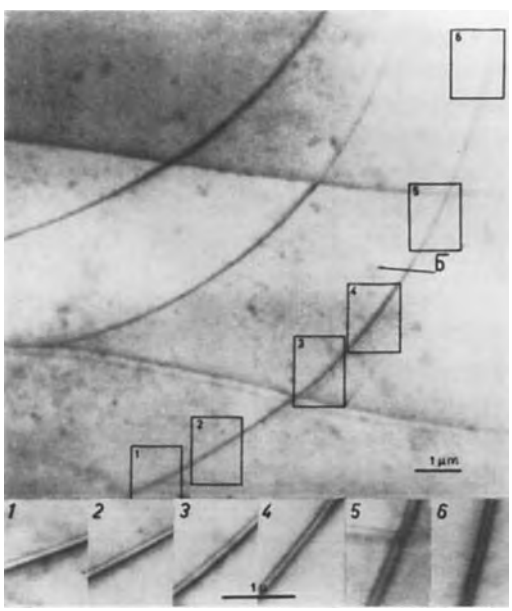

Figure 8. Curved single ribbon of partials in graphite. Note the variation in ribbon width with the orientation of the ribbon (TEM) (Delavignette and Amelinckx [43]).

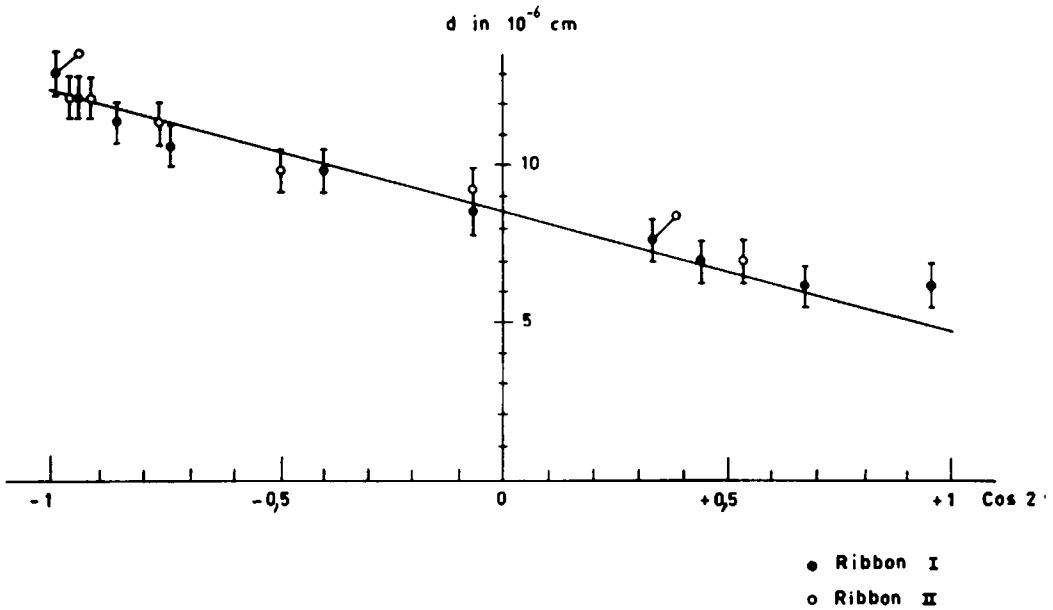

Figure 9. Plot of the ribbon width d as a function of a character of the dislocation ribbon: $\cos\phi$. According to Eqs. (1) and (2), the graph is a straight line of which the slope yields ν and the intercept d_0. This allows us to compute γ/μ from Eq. (2) (Amelinckx and Delavignette [43]).

this variation the stacking fault energy γ can be deduced, as well as the effective value of Poisson's ratio ν, as was shown for the first time in graphite [43]. This method is based on the equations

$$d = d_0\left[1 - \frac{2\nu}{(2-\nu)}\cos 2\phi\right] \qquad (1)$$

$$\gamma = \frac{\mu \boldsymbol{b}^2}{8\pi d_0}\left(\frac{2-\nu}{1-\nu}\right) \qquad (2)$$

(Fig. 9), where μ is the shear modulus and $\boldsymbol{b}$ the Burgers vector of the partial dislocations. From the linear plot of d versus $\cos 2\phi$, such as in Fig. 9, d_0 is deduced from the intercept and ν from the slope; γ/μ then follows from Eq. (2). The underlying theory is found in Amelinckx et al. [42]. It should be noted that to deduce the real ribbon width from the image the sideways image shift should be taken into account, which can either be in the same sense for both partials, or in the opposite sense; in the latter case it can be either inwards or outwards, leading respectively to an apparently smaller or larger width (see Chap. 4.1, Sec. 1.1.18 of Vol. 1 of this Handbook).

The Burgers vector of individual partials is determined using the image extinction criterion $\boldsymbol{g}\cdot\boldsymbol{b} = 0$. Partial dislocations go out of contrast for reflections of the type $11\bar{2}0$, i.e., for reflections of the 'second' hexagon. The 'absent' partial dislocation has a Burgers vector that is perpendicular to the active diffraction vector (Fig. 10b). One image extinction is sufficient, since in the particular case of graphite the Burgers vectors of glide dislocations must be parallel to the basal plane [44].

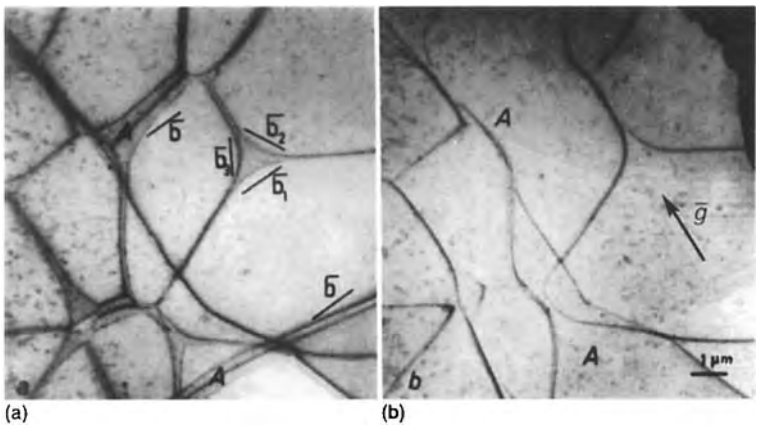

Figure 10. Extinction of partial dislocations in a network situated in the basal plane of graphite. Note the simultaneous extinction of the three partials in the triple ribbons at A (TEM). (a) All dislocations in contrast. (b) One set of dislocations is extinct (Amelinckx and Delavignette [44]).

Imaging in a $10\bar{1}0$ type reflection (i.e., in the first hexagon) either in bright field (BF) or in dark field (DF) reveals the stacking fault areas, as in Fig. 10a, as darker areas. This figure reveals two features of particular interest. The extended dislocation node, consisting of three partial dislocations forming a triangular area limited by curved partial dislocations, provides an alternative method to deduce the stacking fault energy from the smallest radius of curvature of the partials. The theoretical basis of this measurement is discussed in the literature [45, 46].

The second feature is the 'triple ribbon' in A, consisting of three parallel partials separated by two strips of stacking fault [43, 44]. The simultaneous extinction of the three partials in the triple ribbon of Fig. 10b leads to the conclusion that the three partials have the same Burgers vector, which is indicated in Fig. 10a [44]. This does not exclude the fact that they have different line images (Part IV, Chap. 1, Sec. 1.1.18 of Vol. 1 of this Handbook). Models for such triple ribbons, which were first discovered in graphite, are discussed in Part IV, Chap. 1, Sec. 1.1.20 of Vol. 1 of this Handbook and Amelinckx et al. [42]. They are very sensitive probes for measuring the stacking fault energy since they are wider than single ribbons. They also make it possible to observe the effect of surface steps, such as XY, on the ribbon width, as is evident in Fig. 11. The proximity of a surface decreases the repulsive force between the partials without affecting the magnitude of the stacking fault energy, which determines the attractive interaction; as a result, the total width decreases as the ribbon approaches the surface. On determining the stacking fault energy from ribbon widths, the widest ribbon should therefore always be used.

Graphite foils often contain twist boundaries situated in the (0 0 0 1) plane [42]; these possibly result from deformation during specimen preparation, but they must be frequent in 'turbostratic' graphite. They consist of a network of extended and contracted nodes (Fig. 12) formed by the intersection of two families of ribbons with different total Burgers vectors. In Fig. 12b the faulted areas, which are on the concave side of the partials, show up brighter, which is rather exceptional since this requires the faulted area to be close to a

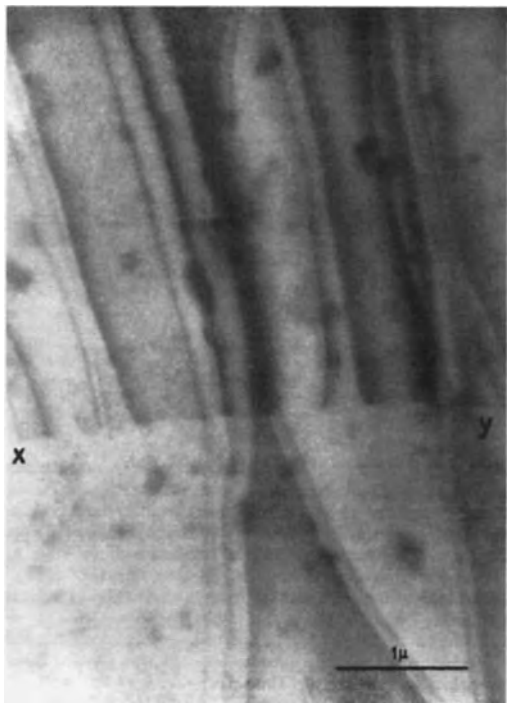

Figure 11. Triple ribbon in the (0001) plane of graphite passing under a surface step XY, hereby changing its width (TEM) (Amelinckx et al. [42]).

surface (see Part IV, Chap. 1, Sec. 1.1.18 of Vol. 1 of this Handbook). The partial dislocations in such a network have a predominantly screw character in agreement with the twist character of the boundary.

In graphite heated in vacuum to about 3000°C and subsequently quenched, circular faulted loops can be observed in the basal plane (Fig. 13) (see, for example, Amelinckx et al. [42]). They are attributed to the precipitation of vacancies into disks followed by collapse of the adjacent lattice planes. The Burgers vectors of these loops were shown to be inclined with respect to the basal plane, showing that on collapsing a lateral offset takes place. Also, heavily neutron-irradiated and subsequently annealed graphite was shown to contain loops of a similar type using the method described in Part IV, Chap. 1, Sec. 1.1.18 of Vol. 1 of this Handbook.

In bromine-intercalated graphite the boundary between the intercalated and the pristine regions is formed by a

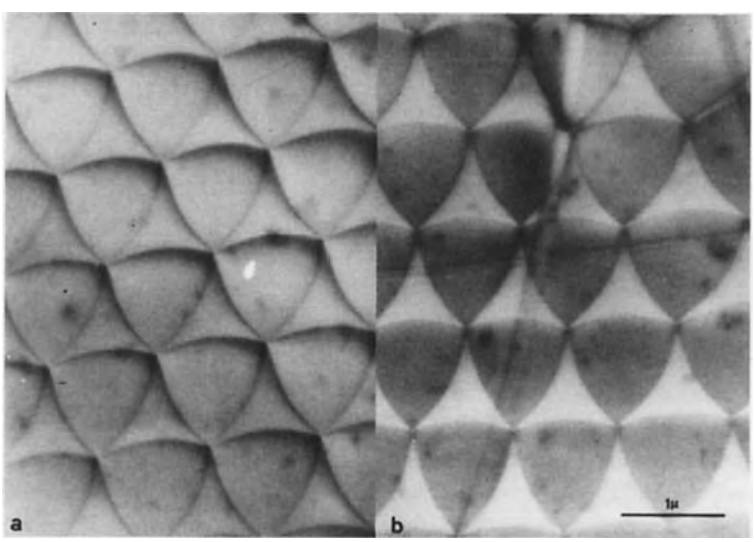

Figure 12. Network of contracted and extended nodes in graphite under two different two-beam diffraction conditions. In (a) line contrast, and in (b) the faulted areas show up bright because the network is close to the surface (TEM) (Amelinckx et al. [42]).

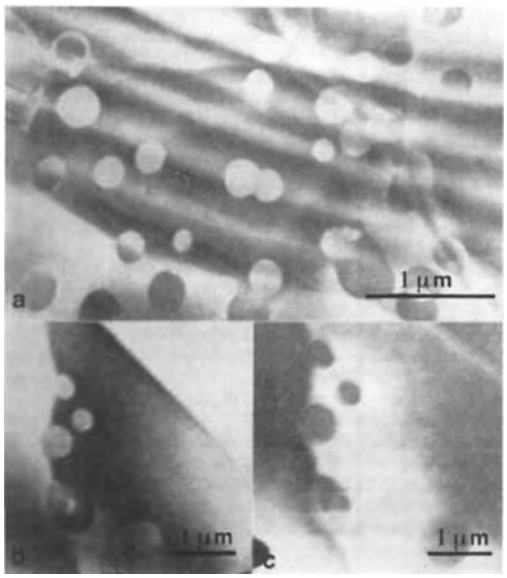

Figure 13. (a) Circular dislocation loops in the (0 0 0 1) plane, formed from quenched-in vacancies in graphite. Note the fault contrast inside the loops (TEM). The fault contrast is inverted between (b) and (c), which represent the same area (Amelinckx et al. [42]).

particular type of dislocation which can be revealed in TEM and of which the motion can be studied in situ [47, 48]. It was shown by TEM that the bromine enters the graphite preferentially along stacking faults.

11.3.3 Optical Microscopy

Conventional optical reflection microscopy and interference microscopy (so-called Fizeau fringes [49]) have been used to study the surface oxidation of graphite by oxidizing agents (e.g., O_2) (see Thomas [50] for a review). The surface is found to oxidize by the lateral removal of C-layers nucleated at preferential sites which are interpreted as the emergence points of nonbasal dislocations [50]. Even single vacancies are held potentially responsible for the nucleation of pits [50]. The effect of metallic catalyst particles on the oxidation behavior was also studied (see, e.g., Hennig [51, 52] and Thomas [50] for a review). Nonbasal dislocations have been revealed by etching and studied by optical microscopy of (0 0 0 1) surfaces in references [53, 54].

11.3.4 Scanning Tunneling Microscopy

Scanning tunneling microscopy (STM) allows us to reveal the surface of graphite at the atomic level (Fig. 14). It turns out that, against intuitive expectation, the honeycomb structure is not revealed but the image is instead a close-packed hexagonal array of dots with lattice parameter a [55]. This is interpreted by assuming that the geometry of the two

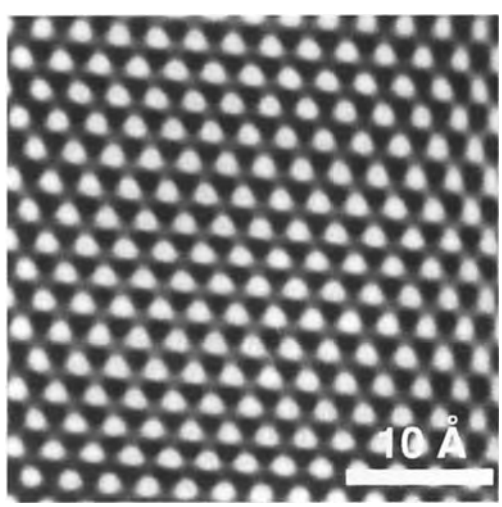

Figure 14. STM image of the (0 0 0 1) surface of graphite. Only half of the surface atoms are imaged (Kelty and Lieber [58]).

uppermost layers is revealed. Two types of graphite surface atoms have then to be considered. Half of the surface atom has a neighbor at $c/2$ along the c-direction, the other half has not; the first neighbor along the c-direction is at a distance c. This is obvious from the atomic structure of graphite (Fig. 1a). It appears that only one kind of surface atom is actually revealed (Fig. 14) [56]. Furthermore, large vertical corrugations have been observed on STM images of graphite surfaces in air. It was argued that this effect could be attributed to elastic interactions between the graphite surface and the STM tip through a layer of contamination [57]. It was found that images of clean graphite surfaces in vacuum do not show such corrugations.

Stage 1 potassium-intercalated graphite (KC_8) has been imaged by means of STM [58]. A $2a$ superlattice was detected. The presence of the potassium ions causes the graphite layers to become stacked A–A instead of A–B as in pristine graphite; nevertheless, not all carbon sites show up as identical peaks. Elastic deformations of the graphite surface are not held responsible for the observed period doubling in the image; this is attributed to electronic effects associated with the ordering of the potassium ions (Fig. 15).

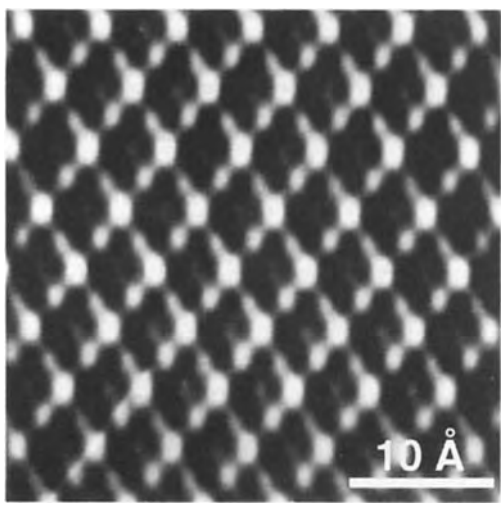

Figure 15. STM image of (0 0 0 1) surface of graphite intercalated with potassium (C_8K); note the period doubling in the image (Kelty and Lieber [58]).

11.4 Diamond

11.4.1 Natural Diamond

The microscopic characterization of diamond as a gem is one of the subjects treated in Chap. 1.7 of this Volume; in the following paragraph we treat the materials science aspects.

Natural diamonds have been studied extensively by means of optical surface methods by Tolansky and co-workers (see, for example, reference [59]). They discovered the presence of 'trigons' and shallow triangular pits on natural (1 1 1) faces (Fig. 16). These were interpreted by a number of authors as etch figures [60], and by others as growth features [61]. The methods used were phase contrast reflection optical microscopy (Fig. 16a) and multiple beam interferometry in monochromatic light (Fig. 16b) [49, 61]. Fizeau-type fringes (Fig. 16b) were produced using an interferometer consisting of an optical flat pressed against the surface to be studied, both being silvered to about 80–90% transmission. In this manner, surface steps of only a few nanometers high can be detected and measured optically by multiple beam interferometry, but the lateral resolution

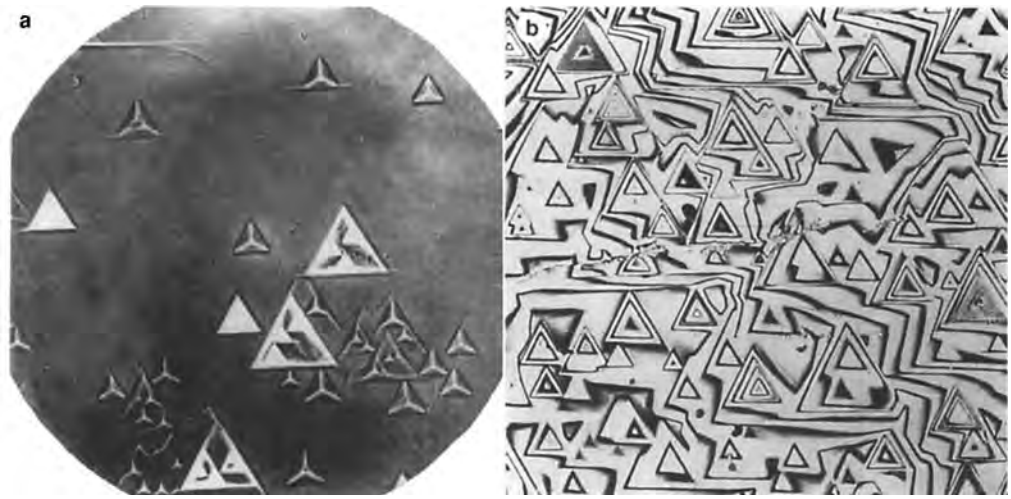

Figure 16. Trigons in diamond on a (1 1 1) face, (a) imaged by means of phase contrast reflection optical microscopy, and (b) by means of multiple beam interferometry (Tolansky [61]).

is of course limited to that typical of optical microscopes (Part I, Chap. 1 of Vol. 1 of this Handbook). The same techniques were used to study the anisotropy of the abrasion rate along different directions on several crystal faces (see, e.g., Wilks and Wilks [62], or Wilks and Wilks [3] for an overview), a problem of technical importance.

X-ray topography has been used extensively to study dislocations by Lang and coworkers (for overviews, see Part II, Chap. 5 of Vol. 1 of this Handbook and references [63, 64]). Owing to their high degree of perfection, natural diamonds make appropriate samples for X-ray topography, which is a low resolution method (Fig. 17). Natural diamond was found to contain very few dislocations (Fig. 18).

Diffraction contrast TEM has also been used in the study of dislocations in natural diamond; in particular the weak beam method was applied to study the splitting in partial dislocations and to derive the stacking fault energy [65, 66].

TEM studies led to the discovery of so-called nitrogen platelets (Fig. 19) [67–71], which are essentially Guinier–Preston zone-like precipitates containing layers of nitrogen atoms, which in dispersed form

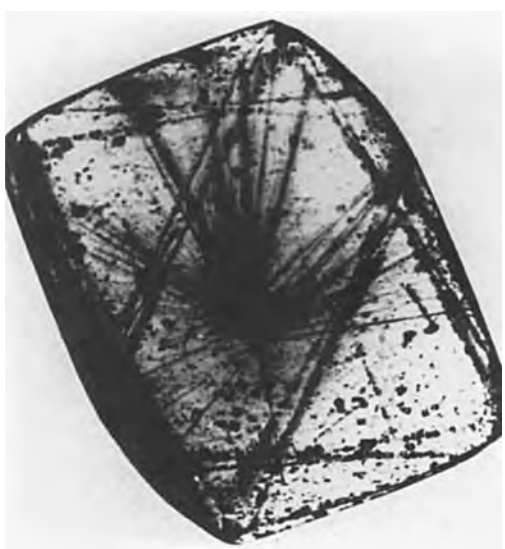

Figure 17. X-ray topograph of a diamond containing dislocations radiating in all directions from an internal flaw (Lang [63]).

Figure 18. X-ray topographs illustrating the perfection of certain diamonds (Lang [63]).

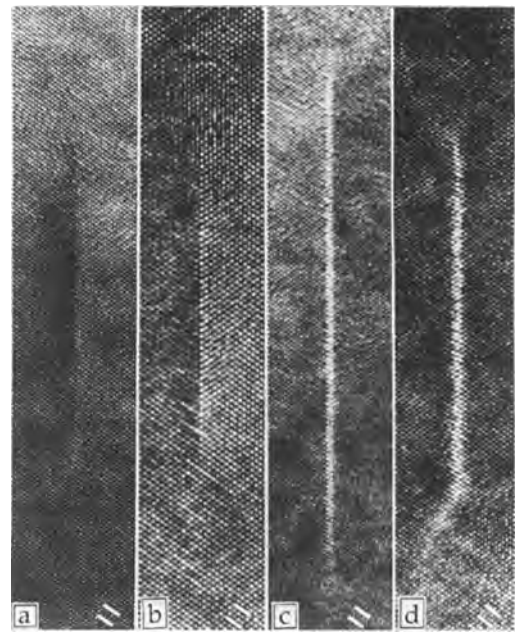

Figure 20. (a) to (d) High resolution images of nitrogen platelets in diamond (HREM) (courtesy of W. Luyten).

are responsible for the yellow color of 'cape' diamonds. High resolution images (Fig. 20) have been used to determine the atomic structure [72, 73] by comparing simulated images of various proposed models with the observed images.

Some natural diamonds contain tiny octahedral-shaped cavities called voidites [74–80]. In TEM they sometimes produce a strain pattern, proving that the voidite causes stress in the surrounding diamond matrix. Moiré patterns (Fig. 21a) give information on the lattice parameters of the material enclosed in the void relative to the lattice parameter of diamond. A peculiar form of double diffraction allows us to deduce indirectly the single crystal diffraction pattern of the material in the void [81], which is found to be a form of solid nitrogen.

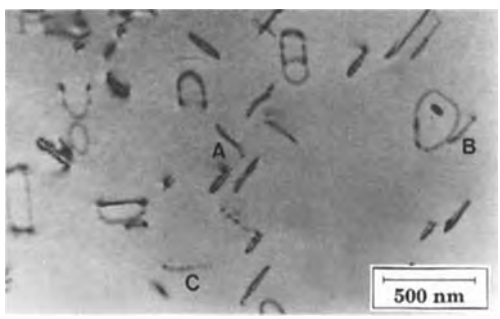

Figure 19. Diffraction contrast image (TEM) revealing nitrogen platelets in diamond. The platelets are situated in cubic planes (courtesy of W. Luyten).

Concentric growth layers can be observed in many natural diamonds by means of cathodoluminescence using a scanning electron microscope (see, e.g., Goldstein and Yakowitz [82]). These patterns are due to slight variations in the impurity contents of the material out of which the diamond has grown (blue ground). Since no two diamonds have identical growth patterns, the

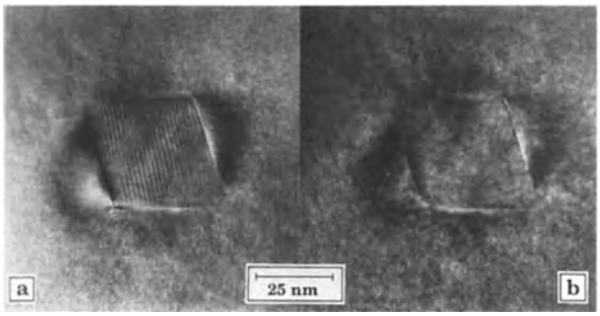

Figure 21. (a), (b) Voidites in natural diamond. Note the presence of Moiré fringes in (a). The strain field in the surrounding diamond matrix is imaged as well (Luyten et al. [81]).

cathodoluminescence pattern can be used as a 'fingerprint' for a given stone in forensic applications. Since dislocation lines or centers located close to them act as recombination centers, they emit light in cathodoluminescence (Fig. 22). For a general review of defects in diamonds, we refer to Wilks and Wilks [3].

11.4.2 Synthetic Diamond

A synthetic diamond single crystal grown by means of the high pressure, high temperature method, is shown in Fig. 23, as observed in SEM.

In recent years, with the discovery of plasma enhanced, low pressure, chemical vapor deposition methods to grow epitaxial layers of diamond, the way was opened for the application of diamond films in solid state electronics and in the wear protection of tools [3–7]. This has triggered a number of studies on the degree of perfection of such layers using high resolution electron microscopy (HREM) (e.g., references [83–97]). The films are often prepared by epitaxial growth on a (1 1 1) silicon single crystal base, in view of applications in microelectronics. Owing to the lattice misfit with the substrate, the diamond layers are often heavily faulted. Specimens consisting of a free,

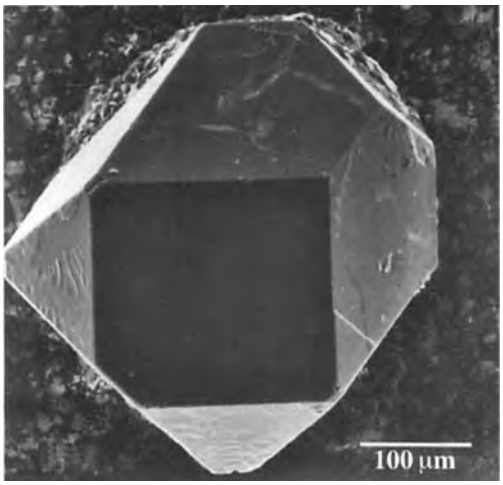

Figure 23. Synthetic diamond prepared by the high pressure, high temperature method (SEM).

unsupported diamond film of uniform thickness parallel to a (1 1 1) face can easily be made by selectively dissolving the silicon base. Such studies revealed the occurrence of various defects related to the relatively small stacking fault energy of diamond.

The most prominent defects are twin boundaries (Fig. 24). Frequently sequences of the order of ten parallel interfaces, separating relatively narrow twin lamellae, can be observed edge-on. Attempts to measure the lattice relaxation along such twin interfaces were inconclusive [97]. Steps in twin boundaries, forming twinning dislocations, are often found as well. Twin boundaries, inclined with respect to the foil surface, separate overlapping, twin-related crystal parts (Fig. 25). In the overlap region a coincidence dot pattern is observed in the HREM image, exhibiting a triple period compared to that of diamond; owing to double diffraction, the diffraction pattern also exhibits the same spacing tripling (Fig. 25) [97, 98].

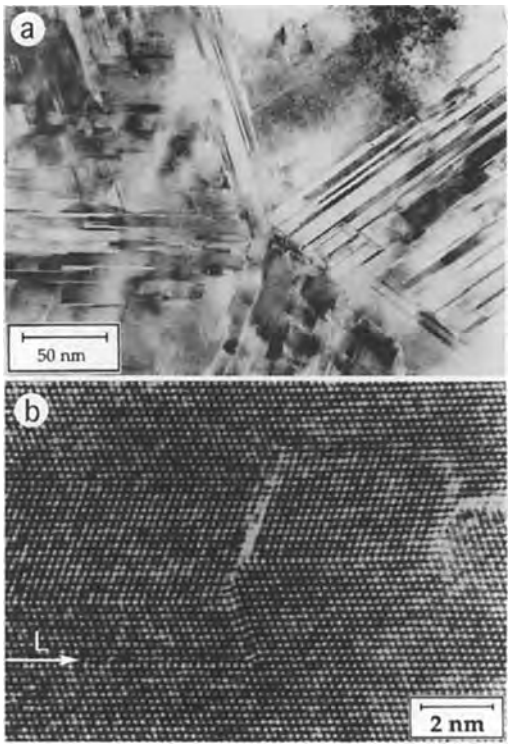

Figure 24. Low magnification, high resolution image along the [1 1 0] zone of a free synthetic diamond flake prepared by plasma-enhanced CVD on a silicon substrate. Note the high concentration of twins and stacking faults on the (1 1 1) planes (HREM). (a) Five twin-related grains forming a disclination along their common line. (b) Twins and a Lomer–Cottrell barrier in L (Luyten et al. [97]).

Glide dislocations on the (1 1 1) planes are dissociated in Shockley partials connected by a strip of intrinsic stacking fault. Such a configuration (Fig. 26) can be used to deduce the stacking fault energy. The value obtained in this way was $\gamma = 209 \pm 26\,\mathrm{mJ\,m^{-2}}$, to be compared with that deduced from natural crystals by the weak beam method ($\gamma = 279 \pm 41\,\mathrm{mJ\,m^{-2}}$ [65]). This discrepancy was attributed to surface effects in the weak beam case, where the dislocations are parallel to the surfaces (see Sec. 11.3.2 of this Chapter).

11.5 Fullerenes

11.5.1 C_{60} Crystal Structures: Phase Transitions

The room temperature structure of solid C_{60} of sufficient purity is a face-centered arrangement (cubic, $a_0 = 1.41$ nm) of quasi-spherical molecules with radius $r = 0.353$ nm (see, for example, Heiney et al. [17]). The apparent sphericity results from the (almost) free rotation of the molecules at room temperature.

It was found by electron diffraction and microscopy that crystals grown from a solution were faulted hexagonally closed-packed, but transform in situ into a faulted face-centered cubic structure, presumably as a consequence of evaporation, in the microscope vacuum, of solvent molecules (Fig. 27) [11].

As a result of the particular ratio of the lattice parameter and the radius of the 'spherical molecules', the $h\,0\,0$, $0\,k\,0$, and $0\,0\,l$ reflections are accidentally extinct even for h, k, and l: even, as was demonstrated by means of X-ray diffraction [99] and electron diffraction [100] (Fig. 28). This may lead to a sensitive method to study the phenomena that cause a change of this ratio and thus lead to the appearance of these reflections, for h: even (k: even or l: even) [101].

Figure 29 shows an HREM image of a perfect C_{60} crystal seen along the [110] zone. At 255 K an orientational phase transition occurs; the structure remains cubic but the symmetry decreases; the highest symmetry space group $Fm\bar{3}m$ is reduced to the subgroup $Pa\bar{3}$, the three fourfold axes being replaced by twofold axes [16, 17, 102]. The symmetry transla-

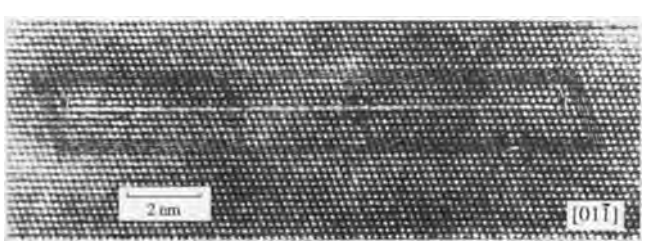

Figure 26. Glide ribbon consisting of Shockley partials separated by an intrinsic stacking fault (Burgers circuits are outlined). Such ribbons are used as probes to measure the stacking fault energy (HREM) (Luyten et al. [97]).

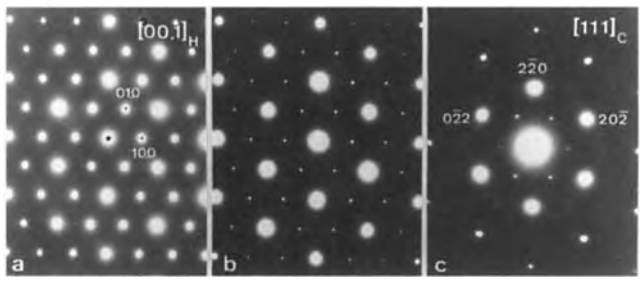

Figure 27. Evolution at room temperature in the microscope of the diffraction pattern of a crystallite of C_{60} grown from an organic solvent. The diffraction patterns all refer to the same area of the crystallite after increasing time intervals in the microscope. (a) Predominantly hexagonally packed. tions of the type $1/2\langle 110\rangle$ are lost since the lattice becomes primitive with approximately the same lattice parameter. A single crystal is hereby fragmented in two orientation variants related by a 90° rotation about a cubic axis. Moreover, each orientation can occur in four translation variants, having the lost symmetry translations as displacement vectors. The electron diffraction patterns of Fig. 30 prove the presence of two orientation variants [14, 103]. In particular they illustrate the loss of fourfold symmetry of a single variant; the symmetry breaking superstructure spots are somewhat weaker than the basic spots. In Fig. 30c two orientation variants are present in the selected area. The corresponding orientation domains can be imaged by making dark field images in superlattice reflections. The domain walls are found to coincide often with (111) twin interfaces [14, 103].

At still lower temperatures, certain crystals were found to exhibit a further superstructure with a lattice parameter $2a_0$ [104]; however, this was not confirmed by X-ray diffraction [105].

X-ray and neutron diffraction have shown that the $Pa\bar{3}$ superstructure is due to the 'freezing in' of the molecules in four different orientations, each of the four primitive sublattices of the face-centered cubic lattice being occupied by molecules

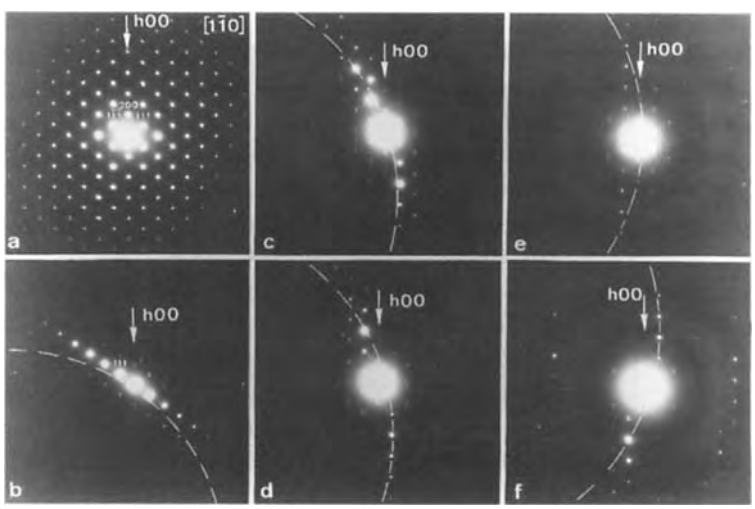

Figure 28. Room temperature diffraction experiment on C_{60} showing the extinction of the $h00$ diffraction spots with h: even. (a) to (f) On gradually tilting, Ewald's sphere is swept through the row of $h00$ nodes (indicated by an arrow), without exciting 200, 400, etc., although such reflections are allowed in the f.c.c. lattice. In (a) such reflections are produced by double diffraction (Amelinckx et al. [100]).

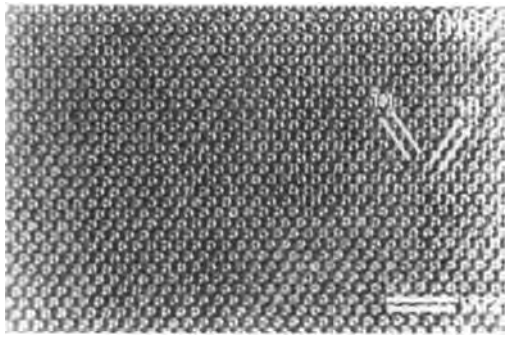

Figure 29. High resolution image of a perfect C_{60} crystallite as viewed along [1 1 0] (Muto et al. [107]).

having the same orientation [17]. The relative orientations of adjacent molecules are determined by a simple packing principle: parts of the cage surface where there is an accumulation of electric charge face parts of the neighboring cage where there is a deficiency of electric charge, thus minimizing the total coulomb energy.

11.5.2 Defects in F.C.C. Crystals of C_{60}

Crystals of the room temperature form of C_{60} exhibit the same kinds of defects as are typically found in f.c.c. alloys with a very

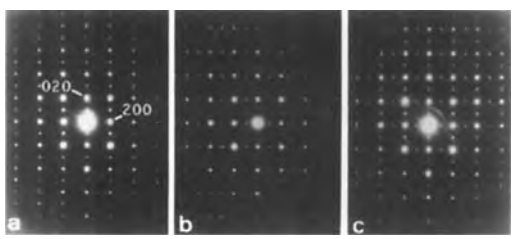

Figure 30. [0 0 1] zone diffraction pattern of the simple cubic low temperature phase of C_{60}; note the twofold rotation symmetry of the pattern due to the presence of weaker superstructure spots. In (a) one variant is revealed, in (b) the second orientation variant is selected, and in (c) both variants are present in the selected area (Van Tendeloo et al. [14]).

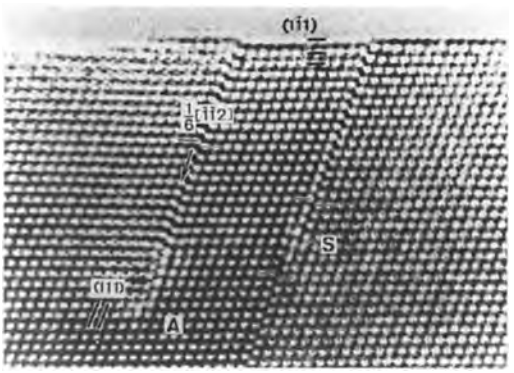

Figure 31. Stacking fault (S) and Frank dislocation and its associated fault (A) in C_{60}; zone axis [1 1 0] (Muto et al. [107]).

small stacking fault energy, the molecules playing the role of the atoms in the alloys [13, 14, 103, 106, 107]. Growth phenomena on the surface of single crystals were observed by optical microscopy [108].

The dominant defects revealed by HREM are coherent twin interfaces and stacking faults on (111), both intrinsic and extrinsic, and their combined configurations, with partial dislocations such as Lomer–Cottrell locks, and Shockley and Frank dislocations (Fig. 31) [107]. Owing to the exceptionally small stacking fault energy, defects resulting from the intersection of intrinsic stacking faults can also be formed, as shown in Fig. 32: these defects are linear arrays of 'fractional' vacancies.

11.5.3 C_{70} Crystal Structures: Phase Transitions

At room temperature, vapor grown crystals of very pure C_{70} (>99.9%) exhibit, even within the same batch, two different morphologies [109]. The majority of the crystals is cubic, but a minority has a

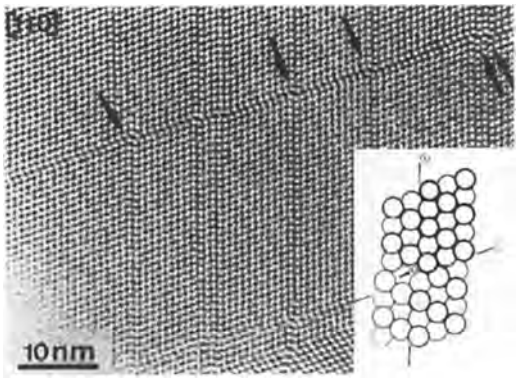

Figure 32. Intersecting stacking faults in C_{60} (zone axis [1 1 0]). Inset: model for the intersections (Van Tendeloo et al. [103]).

hexagonal habit. The corresponding room temperature structures, as deduced from electron diffraction and HREM, are face-centered cubic and hexagonally close-packed, both structures being heavily faulted respectively on $(1\,1\,1)_{f.c.c.}$ or $(0\,0\,0\,1)_{h.c.p.}$ planes (Fig. 33) [103, 110].

As first shown by means of in situ low temperature electron diffraction, the two types of crystal undergo orientational phase transitions on cooling. At liquid nitrogen temperature, the c/a ratio of the h.c.p. form is $c/a = 1.82$, which corresponds to the axial ratio for an h.c.p.

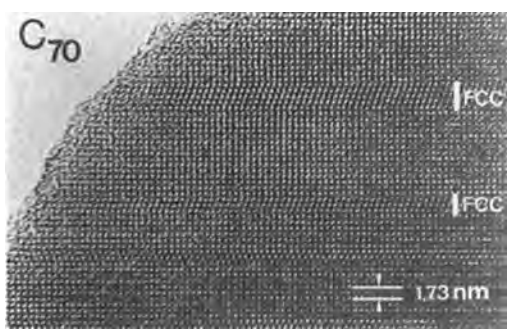

Figure 33. Room temperature HREM image along $[1\,1\,0]_{f.c.c.}$ of a crystallite of C_{70} exhibiting a mixture of hexagonal and cubic stacking (Muto et al. [107]).

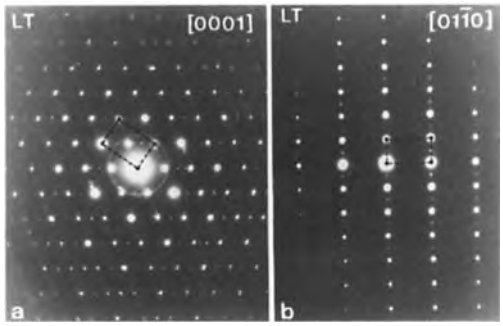

Figure 34. Electron diffraction patterns of the low temperature phase of the hexagonal form of C_{70}. (a) [0 0 0 1] zone and (b) [0 1 $\bar{1}$ 0]. Note the parameter doubling (Van Tendeloo et al. [110]).

stacking of ellipsoids of revolution with their long axis parallel to c and with an aspect ratio corresponding to that of C_{70}. Moreover, the a-parameter of the h.c.p. basic lattice is doubled along one direction, breaking the hexagonal symmetry (Fig. 34a). The lattice can be described either as monoclinic with $\beta = 120°$ or as C-face-centered orthorhombic. It was shown that in this low temperature phase the ellipsoidal C_{70} molecules are h.c.p. with their long axis parallel to c and orientationally ordered within the layers according to the same principle as mentioned above for the low temperature phase of C_{60} [103, 109, 110]. As the temperature rises above 276 K, the superstructure spots disappear, but the c/a ratio remains roughly the same. This was interpreted as resulting from the rotation of the molecules about their long axis, which still remains parallel to c. At around 337 K, the c/a ratio decreases rapidly and approaches a value close to that for the packing of spheres ($c/a = 1.63$). This was taken to mean that the molecules now freely rotate, hereby simulating a spherical shape. Two different stacking modes of the same

ordered layers, one of them leading to doubling of the *c*-parameter (Fig. 34b), were observed in the low temperature phase, suggesting the possibility of orientational polytypism [110].

The f.c.c. stacked form of C_{70} has a low temperature form which is slightly rhombohedral, with a temperature-dependent rhombohedral angle, the long axis of the ellipsoids being oriented along the long diagonal of the elongated rhombohedron. The transformation temperature is slightly above room temperature. By varying the electron beam intensity, the crystal structure can be switched in situ from rhombohedral to f.c.c. and vice versa [103, 107]. The f.c.c.–rhombohedral transition gives rise to four orientation variants corresponding to the four possible orientations of the ⟨1 1 1⟩ direction, which becomes the long diagonal of the rhombohedral phase. A single crystal of f.c.c.-stacked C_{70} thus breaks up in a twinned domain structure on cooling; this was shown by optical microscopy (Fig. 35a) and on a finer scale by AFM, as shown in Fig. 35b [23].

These results are in good agreement with those of other techniques, such as X-ray diffraction [111–117], neutron diffraction [118], and NMR (nuclear magnetic resonance) observations [119, 120]. However, considerable undercooling of the different phases and the existence of several metastable phases (such as the h.c.p. phase at room temperature) complicated the interpretation of the experiments considerably [115, 121].

11.5.4 Intercalated C_{60}

Intercalates of C_{60}, such as $C_{60}(I_2)_{2-x}$ [122] and Rb_6C_{60} [123], were imaged by means of HREM. The iodine enters the C_{60} as a neutral molecule. The in situ deintercalation of $C_{60}(I_2)_{2-x}$ by the loss of I_2 molecules in the microscope vacuum was studied in detail and shown to proceed by the migration of dislocation-like defects bordering the intercalated areas, causing a shear over $\frac{1}{2}c$ along a prismatic plane of the simple hexagonal structure, followed by relaxation along a direction normal to this prismatic plane. In the wake of the moving dislocation, the AA stacking of the simple hexagonal structure of the C_{60} matrix of the intercalate is transformed into the ABC... stacking of the f.c.c. structure of pristine C_{60} (Fig. 36) [122]. This mechanism explains the orientation relationship between the intercalated and the pristine phases.

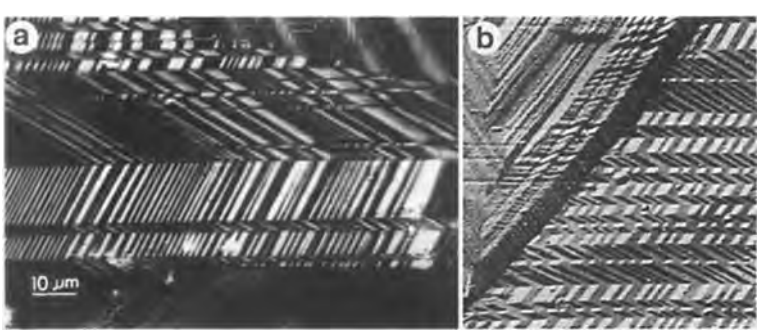

Figure 35. Domain structure in rhombohedral C_{70} crystallites as revealed by means of (a) optical microscopy and (b) AFM (Verheyen et al. [23]).

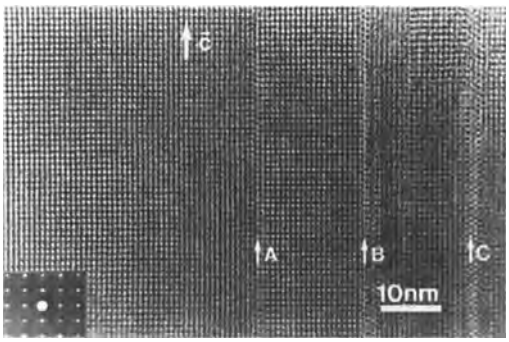

Figure 36. Prismatic faults and bands A, B, C of partly disintercalated simple hexagonal $C_{60}(I_2)_{2-x}$ in HREM. Inset: corresponding diffraction pattern; note the streaking (Zhang et al. [122]).

In Rb_6C_{60} and in similar alkali-doped C_{60} intercalates, the alkali atoms are ionized and form well-defined superstructures. These compounds are very sensitive to the humidity of the air. Handling the sample in view of its preparation as a microscope specimen and of its subsequent insertion in the microscope requires special precautions. An inexpensive, but nevertheless efficient method, making it possible to keep the material under a protective gas atmosphere during all these operations, was described in Zhang et al. [123]. HREM images of the Rb_6C_{60} intercalated at two different defocus conditions are reproduced in Fig. 37 and compared with the structure model.

Atomic resolution STM studies of K_xC_{60} and Ca_xC_{60} thin film intercalates show the dependence of the surface structure on the potassium or calcium concentration [19, 124]. C_{60} molecules are revealed as featureless 'domes' in STM images of pure C_{60} films at room temperature, due to the rapid rotation of the molecules. However, images obtained from Ca_xC_{60} thin films clearly show intramolecular features for some values of x, reflecting the cage structure of each individual molecule, and thus indicating that the molecules have a fixed orientation

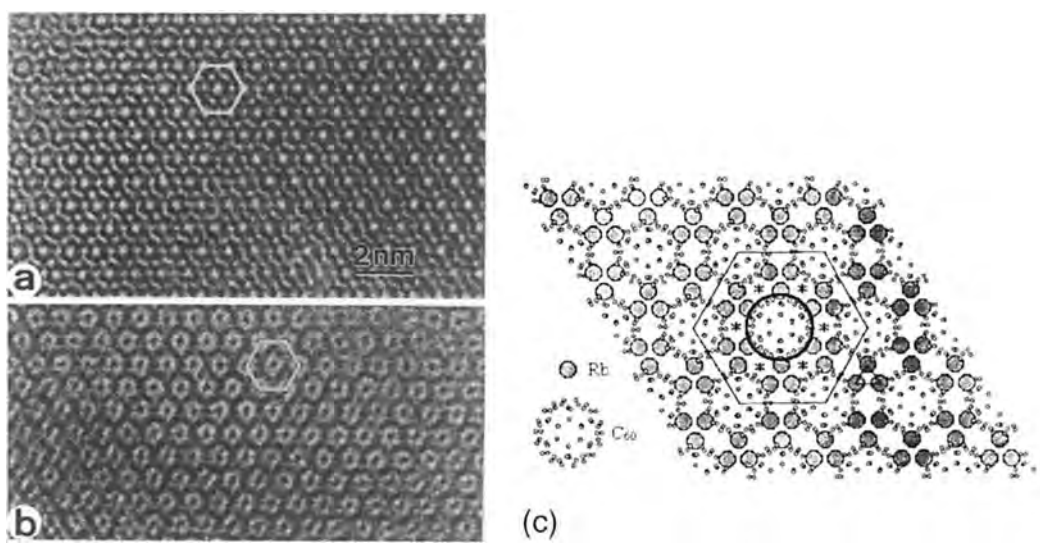

Figure 37. HREM along [1 1 1] of rubidium intercalated C_{60}, compared with (c) a schematic diagram of the structure. Images (a) and (b) were taken at two different defocus values (Zhang et al. [123]).

(similar observations are reported for C_{60} films at 4.5 K [125]). The positions of the potassium ions could not be imaged directly, since the STM images were found to show the changes in the electronic structure due to the potassium intercalation, rather than the real structure of the film surfaces.

11.5.5 C_{60} and C_{70} Thin Films

Epitaxial thin films of C_{60} and C_{70} have been prepared by vapor deposition on cleaved surfaces of many substrates, such as metallic, semiconducting, and layered semiconducting materials. Atomic resolution AFM and STM are well suited for the surface structure determination of the first monolayers, revealing the growth mode, structure, defects, and orientational degrees of freedom of the fullerene molecules [18–24, 126, 127]. TEM and electron diffraction can be used successfully to study the structure and quality of somewhat thicker films [128–134] and to obtain the orientation of the overlayer on the substrate surface [135, 136]; no observations of cross-sectional samples have been reported to date. At present, the best quality films have been obtained on one of several lamellar substrates such as GeS (0 0 1), GaSe (0 0 0 1), MoS_2 (0 0 0 1), and mica (0 0 1).

Germanium sulphide (GeS) is a particularly interesting substrate for the deposition of C_{60} films. It cleaves easily along the (0 0 1) plane and then exhibits a surface that is grooved along one direction [137]. The distance between the grooves happens to be precisely half the equilibrium separation of close-packed rows of C_{60} molecules, making it possible to obtain good epitaxial layers by systematically 'filling' every other groove. The orientation relationship is then $[1\,1\,1]_{C60} // [0\,0\,1]_{GeS}$ and $[1\,0\,\bar{1}]_{C60} // [0\bar{1}0]_{GeS}$ [136–138]. The geometry of the epitaxy may induce 'antiphase boundaries', either by missing out two grooves instead of one, or by a lateral shift of the sets of occupied grooves (Fig. 38). These features were found by means of TEM, which is a well-established method of obtaining the orientation relationship from a composite foil: substrate plus film. Antiphase boundaries were revealed in HREM [136].

11.6 Carbon Nanotubules and Nanoparticles

11.6.1 Introduction

Carbon nanotubules generally consist of a concentric packing of hollow, cage-like carbon configurations. Carbon nanoparticles are spherical or polyhedral shaped [139], whereas carbon nanotubes are cylindrical structures, closed by caps and with lengths several orders of magnitude larger than their diameter [27]. The structure of the caps (Fig. 39b) can be considered as graphene sheets, in which the removal or the insertion of 60° wedges, generating disclinations in the graphene sheet, causes curvature of the otherwise flat layers. The cylindrical part, on the other hand, consists of elastically deformed graphene sheets (Fig. 39a).

Experimental techniques such as X-ray diffraction, which probe the average structure of a macroscopic quantity of material,

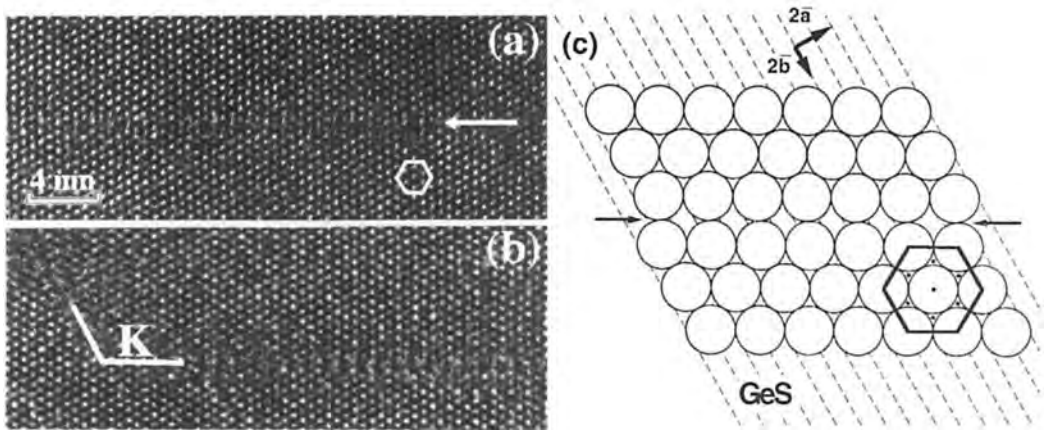

Figure 38. (a) and (b) Out-of-phase boundaries in epitaxial films of C_{60} on a (0 0 1) cleavage face of GeS (the zone axis is $[1\,1\,1]_{C60}$; the lattice of GeS is not resolved) (HREM). The hexagon connects the centers of C_{60} molecules of the first monolayer, as also indicated in (c). Note that only one third of the bright dots correspond to the centers of molecules of the first monolayer (A-type layer). The other dots represent the centers of the molecules of the B-type and C-type monolayers. (c) Schematic representation of the out-of-phase boundary (Bernaerts et al. [136]).

are not well suited for the study of such carbon materials. SEM is able to show the morphology of the material [140–143]. AFM [144, 145] and STM [144, 146, 147] were used to study the external shape and the atomic structure on the surface of the tubes. However, most structural information about carbon nanotubes results from the application of TEM techniques, such as high resolution imaging and electron diffraction, although TEM is not able to show the individual carbon positions due to the absence of well-defined atomic columns [27, 30–32, 148–159].

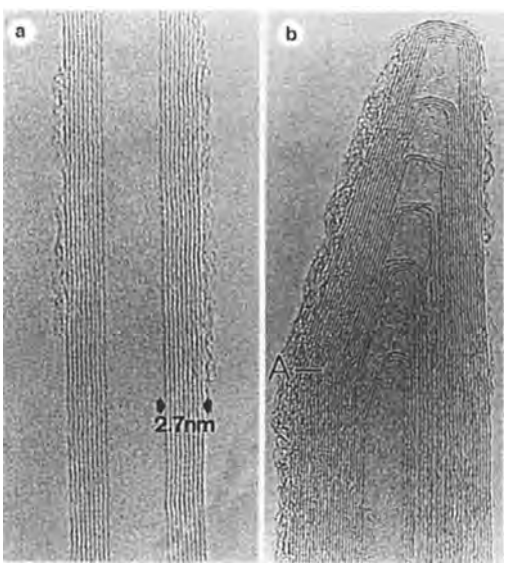

Figure 39. Multishell carbon nanotubes prepared by the arc discharge method and imaged by means of {0 0 0 2} lattice fringes ($d_{0002} = 0.344$ nm). (a) Straight tube. (b) Terminal caps (Zhang et al. [153]).

Until recently, there were two major routes for the production of carbon nanotubes: nucleation from a carbon plasma in an electric arc [27, 141, 143, 160, 161] or the catalytic decomposition of hydrocarbons [39, 162, 163], each having several variants. The catalytic method is very similar to the production of mesoscopic carbon fibers, already known for a long time (see, for example, references [164–168]). Very recently, variants of these methods leading to single-walled tubes have become available [36, 37]. First we will discuss observations of perfect structures and finally observations of structural defects

in these carbon configurations will be shown.

The hollow channel inside the carbon nanotubules can be filled with various materials, as was observed by TEM [169–176]. The filling takes place either during production of the tubules, or by opening the tip of the tubes by a chemical reaction and subsequently filling them with liquid phase, due to capillary forces. Owing to the small space available inside the channel, the crystal structure of the filling material can be different from that of the normal bulk material.

11.6.2 The Microstructure of 'Perfect' Carbon Particles

The structure of a single shell carbon cage is completely determined by the positions of the pentagons in the otherwise hexagonal graphene layer [177, 178]. A carbon nanotube consists of a cylindrical 'body', exclusively containing hexagons, terminated by two caps, each containing six pentagons. The aromatic structure of the cylindrical body is completely determined by only three parameters: the length L and the radius r, giving the dimensions of the tube, and the chiral angle θ, representing the orientation of the graphene network with respect to the tube axis [27] (negative chiral angles are allowed, taking into account the hand of chiral tubes). L and r can easily be obtained from HREM images; the chiral angle θ can be determined from the electron diffraction patterns. The sign of θ and thus the hand of the tubes can be obtained from diffraction contrast images observed under a suitable incidence direction of the electron beam. For more theoretical purposes, it may be suitable to replace r and θ by the pair of integers, the Hamada indices (n, m) (see Appendix C).

Determination of the Radius r and Length L: High Resolution Electron Microscopy (HREM) Images

Generally, images of carbon nanotubes are recorded with the tube axis normal to the electron beam (normal incidence), showing the two walls and the hollow central channel (Fig. 39). The main features are the {0002} lattice fringes imaging the edge-on view of the graphene layers in the tube walls [27]. The fringe spacing is 0.344 nm, compatible with the (0002) interplanar distance in turbostratic graphite [179]. Since most tubes are relatively small (<10 nm), and since carbon is a weak electron scatterer, carbon nanotubes can be considered as thin, weak phase objects. At Scherzer defocus, HREM images of such samples show dark contrast at sites with a high projected electron density. The dark fringes can thus be directly associated with graphene layers seen edge on. The number of layers in a tubule and the radii of the tubes can thus be readily determined. Image simulations confirm that the dark {0002} fringes correspond to the graphene planes (for Scherzer defocus) [153, 180, 181], but measuring the distance between the fringes in an image of a single shell tube is not a very accurate method for the determination of r, as was shown in Wang and Zhou [182].

HREM images with two-dimensional resolution sometimes show $\{1\,0\,\bar{1}\,0\}$ fringes (spacing 0.21 nm) in the central and wall region (Fig. 40). The orientation of this

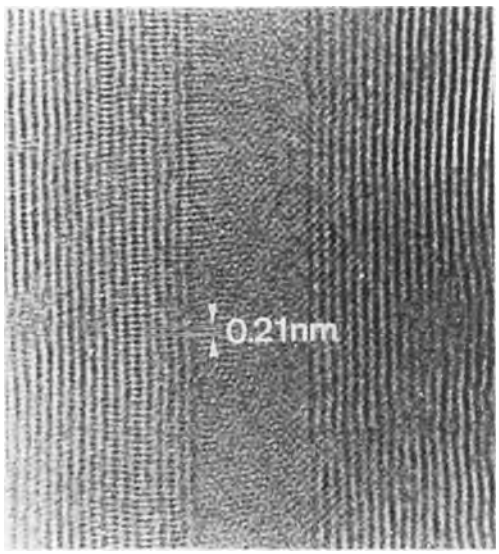

Figure 40. High resolution image of a multishell tubule exhibiting, next to the {0 0 0 2} fringes, $\{1\,0\,\bar{1}\,0\}$ fringes ($d_{10\bar{1}0} = 0.21$ nm) (Zhang et al. [153]).

pattern with respect to the tube axis can be used to determine the chiral angle [153]. By examining the contrast and symmetry of the *hk*.0 fringes, it is possible to draw some conclusions about the cross section of the tubules [183, 184]: for a perfectly cylindrical tubule, the angle between the electron beam and the graphene layers changes continuously as a function of the projected distance to the tubule axis. Consequently, the appearance of the $\{1\,0\,\bar{1}\,0\}$ fringes in the HREM image is expected to change continuously as a function of the distance to the tubule axis. For tubules with a polygonized cross section, however, large parts of the tubule have the same orientation with respect to the electron beam, independent of the distance to the tubule axis, and the fringe contrast is expected to be constant along strips parallel to the tubule walls. As shown by Fan and Bursil [181], it is in principle possible to determine the chiralities of every single shell tube in a multishell tubule from HREM images exhibiting $\{1\,0\,\bar{1}\,0\}$ fringes, as long as the number of layers is small. The power spectrum of the digitized image is obtained by fast Fourier transformation, clearly revealing the different chiralities in a multishell tubule. By allowing only the spots corresponding to a specific chirality to contribute to the reconstructed image (obtained by inverse Fourier transformation), the chirality can be assigned to a specific layer of the multishell tuble. However, the high resolution required, problems with radiation damage, deviations from normal incidence, and defects in the carbon structure severely limit the practical use of such images for the structure determination of carbon nanotubes.

The outer radius and length of nanotubes can also be determined from AFM or STM images of tubes firmly attached to a substrate such as silicon [145–147]. Owing to the dependence of the images on the shape of the AFM or STM tip, the most accurate results are obtained from height measurements, rather than from the lateral dimensions of the tube images. Atomic resolution images allow the determination of the helicity, but only of the outermost tube.

Determination of the Chiral Angle θ: Electron Diffraction (ED) Patterns

The chirality of carbon nanotubes can be derived from HREM, AFM, or STM images, although with many practical difficulties and limitations. High resolution Moiré patterns, due to overlap of the top and bottom parts within the projected area of the channel, can provide an alternative means of determining the chiral angle

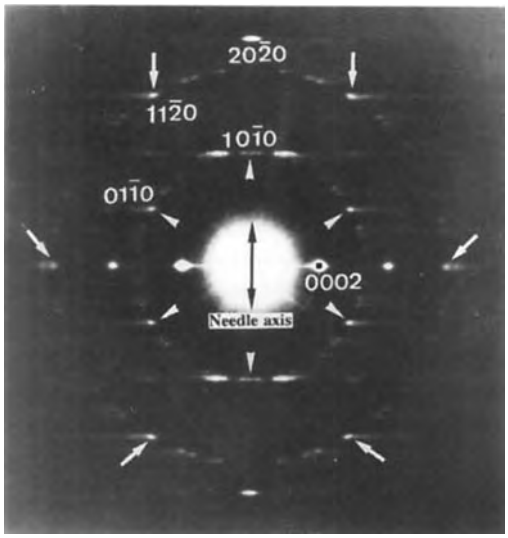

Figure 41. Electron diffraction pattern of a multishell nanotubule made under quasi-normal incidence. Note the weak spots due to chiral tubes; most of the tubes are achiral, however, as deduced from the relatively higher intensity of the spots indicated by arrows (Zhang et al. [155]).

[184]. However, these HREM techniques require normal incidence of the electron beam, a condition that cannot be recognized from the images alone. Electron diffraction (ED) patterns obtained from an isolated tubule (Fig. 41) give both the angle of incidence of the electron beam and the chiralities present in the tubule [see Eqs. (3) and (4)]. The tubule that produced Fig. 41 was largely achiral, as deduced from the main spots (arrowed), but weaker spots with the same spatial frequency are split, proving the presence of chiral components.

The interpretation of ED patterns developed for carbon nanotubules can also be applied to that of other cylindrical structures such as chrysotile serpentines [185] or cylinders of MTS_3 misfit layer compounds [186]. (M = Pb, Sn, ...; T = Nb, Ta, ...)

The helicity θ of a carbon nanotube can conventionally be defined as the smallest angle enclosed by the C–C bonds and the needle axis [sometimes it is defined as $\pi/(2-\theta)$]. In achiral tubes θ is zero for zigzag or parallel tubes and 30° for armchair or normal tubes. As a result of the hexagonal symmetry of the graphene sheets, other C–C bonds enclose an angle $(\theta + 60°)$ or $(\theta - 60°)$ with the tubule axis.

A simple intuitive interpretation of ED patterns valid for normal beam incidence was given by Iijima [27]. The stacking of the graphene layers in the wall regions is represented as a row of equidistant $0\,0\,0\,l$ (l:even) reflections. The hexagonal lattices of the layers in the top and bottom part of the tubule causes hexagonal sets of $hk.0$ spots in the diffraction pattern. For nonhelical tubes, the patterns of the top and bottom parts superpose and only one hexagonal pattern is visible. For helical tubes, the hexagonal $hk.0$ pattern is rotated with respect to the $(0\,0\,0\,l)$ row; the pattern corresponding to the top part is rotated in one sense, while the pattern of the bottom part is rotated in the other sense. Consequently, two hexagonal sets of spots are visible in the ED pattern, their angular separation being a measure for the chirality θ of the tube. Owing to the cylindrical nature of the tubes, the $hk.0$ spots are clearly streaked outwards, away from the tubule axis, as explained in more detail below and in Appendix D (Fig. 41). Diffraction patterns observed for single shell carbon nanotubes show the same features, only the $0\,0\,0\,2$ spots are absent [33, 187].

This intuitive interpretation is only valid for normal incidence, and cannot explain the behavior of the spots upon tilting the tube. Moreover, using patterns

not obtained under normal incidence, the method for measuring the chirality will give inaccurate results if not corrected for inclination [188]. Therefore consideration of the complete three-dimensional diffraction space is necessary [155].

Construction of diffraction space: It is possible to imagine several structural models of multiwall carbon nanotubes, either 'scroll' type or concentric cylinder type, for the construction of diffraction space. We call 'ideal' a scroll in which the layers forming the successive turns are superposed without relaxation of the atomic structure of the layers, in particular the interlayer spacing being rigorously conserved. The increase in length of successive turns ($2\pi \times$ layer thickness per turn) is then accommodated by a continuously increasing relative shear of successive curved, but otherwise undeformed layers. In a 'real' scroll this shear is not uniform since atoms in one layer tend to occupy 'hollows' in the underlying layer, leading to strips of good fit separated by partial edge dislocations of the type presented in Fig. 6 parallel to the fiber axis [153]. If these dislocations are arranged in radial planar walls, the scroll acquires a polygonal cross section. If, on the contrary, the dislocations are roughly randomly distributed (with the same average spacing) along the turns, the scroll's cross section remains to a good approximation a circular Archimedian spiral. In the latter case it is justified to consider the stacking of the tangential c layers as disordered by random shifts parallel to the layers, the shift vectors being determined by the Burgers vectors of the partial dislocations. We discuss the geometry of diffraction space for these two extreme cases. The case of achiral tubules, consisting of concentric tubes, can be modeled, as far as the diffraction effects are concerned, as real scrolls. Chiral tubules are considered separately.

1. Ideal scroll—We first discuss the diffraction space of ideal scrolls using a model similar to that used in the literature [189]. Figure 42a shows two successive

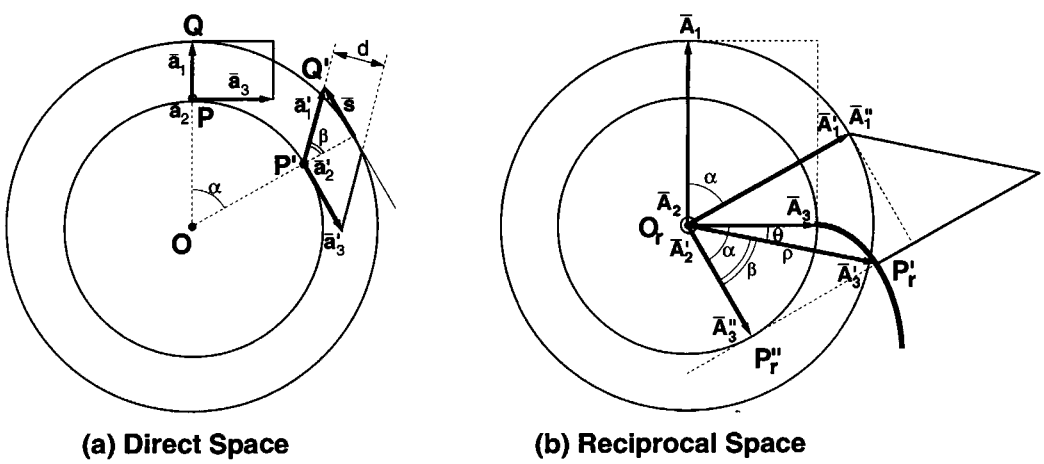

Figure 42. Illustration of the notations used for the derivation of diffraction space for an ideal scroll: (a) direct space; (b) reciprocal space.

layers in the cross section of an achiral circular cylindrical tubule. Let the unit cell of the structure at P be constructed on the base vectors $(\boldsymbol{a}_1, \boldsymbol{a}_2, \boldsymbol{a}_3)$. On rolling over an angle α in such a way that $\overline{PP'} = \overline{QQ'}$, the relative shear is $\boldsymbol{s}$ for two successive layers. The unit mesh $(\boldsymbol{a}_1, \boldsymbol{a}_3)$ is sheared over an angle β. The new base vectors are $(\boldsymbol{a}'_1, \boldsymbol{a}'_2, \boldsymbol{a}'_3)$. The vector $\boldsymbol{a}_2 = \boldsymbol{a}'_2$; $\boldsymbol{a}'_1$ encloses an angle β with the radial direction, $\boldsymbol{a}'_3$ is tangential to the inner circle and is thus parallel to the direction of shearing.

Since the tube is assumed to be achiral, our geometrical considerations can be limited to a plane normal to the fiber axis; the problem is then reduced to two dimensions. Let the reciprocal unit mesh of $(\boldsymbol{a}_1, \boldsymbol{a}_3)$ be $(\boldsymbol{A}_1, \boldsymbol{A}_3)$ (Fig. 42b). After rolling over an angle α this unit mesh occupies the orientation $(\boldsymbol{a}'_1, \boldsymbol{a}'_3)$ in direct space and $(\boldsymbol{A}''_1, \boldsymbol{A}''_3)$ in reciprocal space. However, we have hereby as yet ignored the shear $\boldsymbol{s}$ over an angle β. Taking this into account the unit mesh in reciprocal space becomes $(\boldsymbol{A}'_2, \boldsymbol{A}'_3)$, where $\boldsymbol{A}'_3$ is perpendicular to the plane $(\boldsymbol{a}'_1, \boldsymbol{a}'_2)$ and has a length equal to the universe of the direct space interplanar distance between these planes. From Fig. 42b $|\boldsymbol{A}'_3| = 1/d$; $d = |\boldsymbol{a}_3| \cos\beta$ and hence $|\boldsymbol{A}'_3| = |\boldsymbol{A}_3|/\cos\beta$.

It is our objective to find the geometrical locus of the reciprocal lattice node P'_r at the endpoint of $\boldsymbol{A}'_3$. We note that $\overline{P'_r P''_r} = |\boldsymbol{A}_3| \tan\beta$ and that the arc $\overline{A''_3 A_3} = |\boldsymbol{A}_3|\alpha$. Since, moreover, $|\boldsymbol{s}| = 2\pi|\boldsymbol{a}_1|(\alpha/2\pi) \equiv |\boldsymbol{a}_1|\alpha$ and, moreover, $\tan\beta = |\boldsymbol{s}|/|\boldsymbol{a}_1|$ (from Fig. 42a), $\tan\beta = \alpha$ and hence $|\overline{P'_r P''_r}| = |\overline{P''_r A_3}|$, from which we conclude that the geometrical locus of P'_r is described by a point on the straight line $P'_r P''_r$ when the latter rolls without sliding on the circle with radius $O_r A_3$. Such a curve is called the evolute of a circle. The reciprocal lattice nodes corresponding to families of lattice planes parallel to the axis of the fiber thus describe circle evolutes.

In the system of polar coordinates (ρ, θ) with origin in O_r, the locus of the point P'_r is obtained as follows, $\theta = \alpha - \beta$ and $\rho = |\boldsymbol{A}'_3| = |\boldsymbol{A}_3|/\cos\beta$ (from Fig. 42b); since $\tan\beta = \alpha$ and $\cos\beta = (1 + \alpha^2)^{-1/2}$, we finally have $\theta = \alpha - \arctan\alpha$ and $\rho = |\boldsymbol{A}_3|\sqrt{1 + \alpha^2}$, which is the equation of a circle evolute in polar coordinates with α as a parameter. If α is large enough, approximately $\theta = \alpha - \pi/2$ and $\rho = A_3\alpha$ or $\rho = A_3\theta + const$, which represents an Archimedean spiral with a separation A_3 between successive turns.

2. Real scrolls and tubules—In real scrolls and even more so in achiral tubules consisting of concentric tubes, the structures in successive turns (tubes) are no longer always shifted systematically over the same displacement vector as was the ideal case for homogeneous shear, but such shifts, parallel to the outer planes, are now random. As a result, the scroll (or tubule) can now be assumed to consist of volume elements of one-dimensionally disordered c-layers (as in graphite), which are always at a tangent to the scroll wall (see Fig. 43). The diffraction space of one such volume element then consists of a two-dimensional array of *hk*.0 nodes of the layer structure in a plane parallel to the fiber axis. Except for the origin, all such nodes are streaked along a direction normal to the (0001) layer plane, i.e., along c^*. Only the $000l$ row consists of sharp nodes since $000l$ reflections are not affected by shifts parallel to the $(000l)$ planes; these nodes describe circles with radii lc^*.

If the one-dimensional disorder is not completely random, reinforcements will

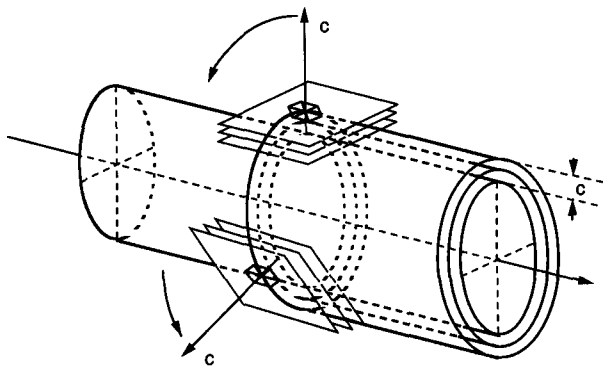

Figure 43. Model used in deriving diffraction space for a real tubule (or scroll) (Zhang et al. [155]).

occur in the streaks; these correspond to preferred periodicities in the arrangement of layers. In monolayer tubules the streaking of the *hk*.0 nodes, as well as that through the origin, is due to the 'shape' effect, i.e., to the extreme 'thinness' of the layer or, stated otherwise, to the two-dimensional nature of the tangent 'volume' elements.

The reciprocal space of the scroll (or tubule) now consists of the geometrical loci traced out by the reciprocal space of one such block on rotation about an axis through the origin parallel to the fiber axis. The streaks hereby generate 'disks' or 'coronae' of diffuse scattering sharply limited inwards by the circles described by the *hk*.0 nodes, and fading outwards. A schematic view of the reciprocal space for an achiral scroll (or tubule) is shown in Fig. 44. An intuitive direct space model for diffuse intensity is discussed in Appendix D.

As an ideal scroll or a multilayer tubule is assumed to become more real, the set of evolutes evolves into the coronea of diffuse

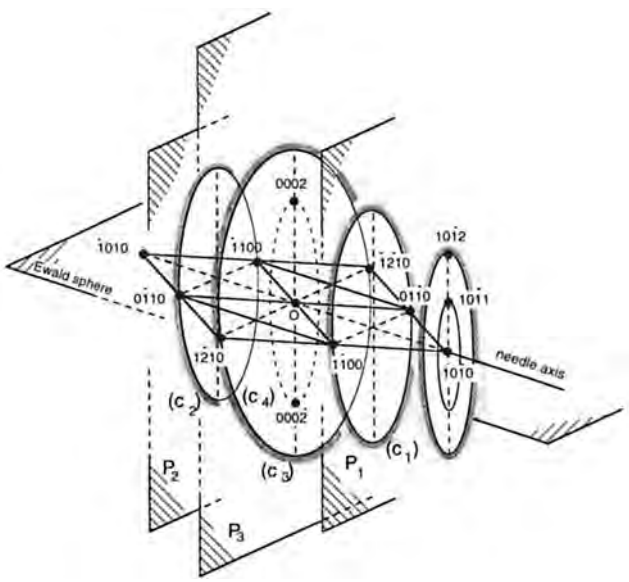

Figure 44. Schematic representation of diffraction space for an achiral tubule. Each node describes a circle in diffraction space (Zhang et al. [155]).

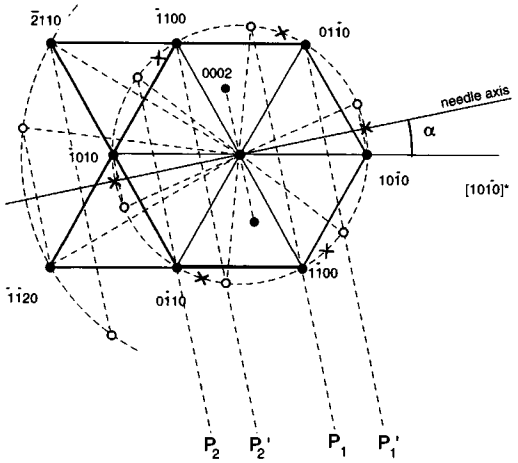

Figure 45. Schematic representation of spot doubling (full and open circles) characteristic of the diffraction space for a chiral tubule (Zhang et al. [155]).

scattering. The diffraction patterns of multilayer carbon fibers can satisfactorily be interpreted on a real model. In achiral tubes the situation is degenerate in the sense that two (or more) nodes give rise to a single 'coronae'. In chiral tubes this degeneracy is lifted and each node describes its own circle (and coronea) obtained by rotation about an axis parallel to the needle axis of Fig. 45.

The diffraction pattern for an arbitrary orientation of the tubule is found by considering the intersection of Ewald's sphere (plane) with the diffraction space. Both the tilt angle α and the true helicity θ can be found from a single diffraction pattern by means of the following relations [188]

$$\tan\theta = \frac{\cos\phi_1 - \cos\phi_2}{\tan\gamma(\cos\phi_1 + \cos\phi_2)} = -\frac{\tan\left(\frac{\phi_1 - \phi_2}{2}\right)\tan\left(\frac{\phi_1 + \phi_2}{2}\right)}{\tan\gamma} \qquad (3)$$

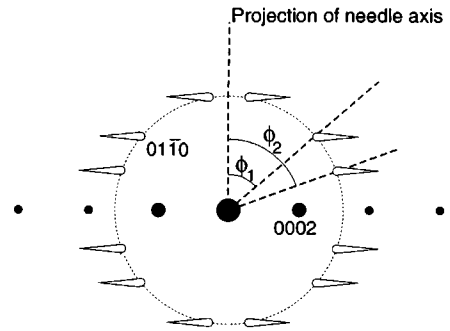

Figure 46. Illustration of the symbols used in Eqs. (3) and (4).

and

$$\cos\alpha = \frac{\cos(\gamma - \theta)}{\cos\phi_1} \equiv \frac{\cos(\gamma + \theta)}{\cos\phi_2} \qquad (4)$$

with ϕ_1 and ϕ_2 the measured angles in the inclined position between the spots of the doublet and the projected tube axis (Fig. 46); γ is the angle for the considered spots in the case of an achiral tube at normal incidence. At normal incidence $\gamma = 0$, 30°, 60°, or 90°, depending on whether spots of the first or second hexagon are considered.

The Hand of Chiral Tubes: Diffraction Contrast Dark Field Images

ED patterns are insensitive to the hand of chiral tubes, as are the HREM images of {0002} fringes. However, for specific incidence angles of the electron beam (for example, tilt-angle $\alpha = \theta$), Ewald's plane is tangential to one of the *hk*.0 circles in diffraction space leading to the coincidence of two reflections. Dark field diffraction contrast images taken in the coinciding *hk*.0 reflection, which is located on the line perpendicular to the row of *c*-reflections (see Fig. 47a), allows the determination of the hand of chiral nanotubes (it

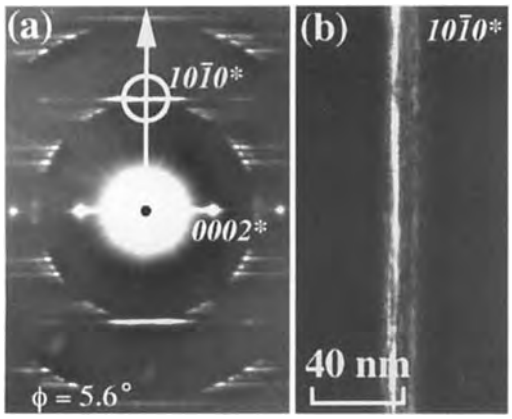

Figure 47. (b) Tilted dark field image used to determine the hand of chiral tubules and (a) the corresponding diffraction pattern (Bernaerts et al. [189a]).

must be stated that a clear definition of the hand of a tube is required: by convention, we will define the hand of a chiral tube as that of the helical string of hexagons through a given point of the cylindrical surface which encloses the largest angle with the tubule axis, i.e., which has the smallest pitch) [189, 190]. For specific tilting angles, and by selecting the appropriate diffraction spot (as indicated on Fig. 47a), the brightness of both walls in the dark field diffraction contrast image differs; which wall is the brightest depends on the sense of tilting and on the chirality of the tube (Fig. 47b). This dark field technique can be used for multishell, multichiral tubes, and is able to provide a map of the distribution of the chiralities inside a multishell tubule, although with relatively poor resolution [189a].

A similar technique was used in the past to determine the hand of chiral tubular textures such as tobacco mosaic virus [191], MoS_2 tubes [192], and the hand of screw dislocations [193].

11.6.3 Carbon Onions

Intense electron irradiation of the carbon clusters results in considerable changes in the carbon network and can be a problem for high resolution observations. However, experiments in which the carbon nanotubes are intentionally irradiated were performed by Ugarte [194–196]. After very intense irradiation, the carbon nanotubes transformed during the first stage from cylindrical structures into amorphous material consisting of graphene tube fragments. Longer irradiation transformed this material into spherical particles, which are concentric stackings of spherical cages with systematically increasing diameter: so-called carbon onions (Fig. 48a). The innermost cage is of the same size as fullerene globular molecules such as C_{60}. From careful comparison between simulated and experimental images, it was concluded that such carbon onions are spherical in contrast to cage-like single shell C_n globular particles, which would be polyhedral [180]. The Van der Waals interaction between different layers in a carbon onion favors the spherical shape above the polyhedral shape [198]. The relative orientation of the single shell molecules forming the onion was found to be random [180].

A quite remarkable phenomenon was recently discovered: carbon onions can apparently be used as nanoscale pressure cells, capable of sustaining pressures (~50–100 GPa) and temperatures high enough to transform graphite into diamond under equilibrium conditions [199a]. Carbon particles such as nanotubes, when electron irradiated in situ (at temperatures of the order of 750°C)

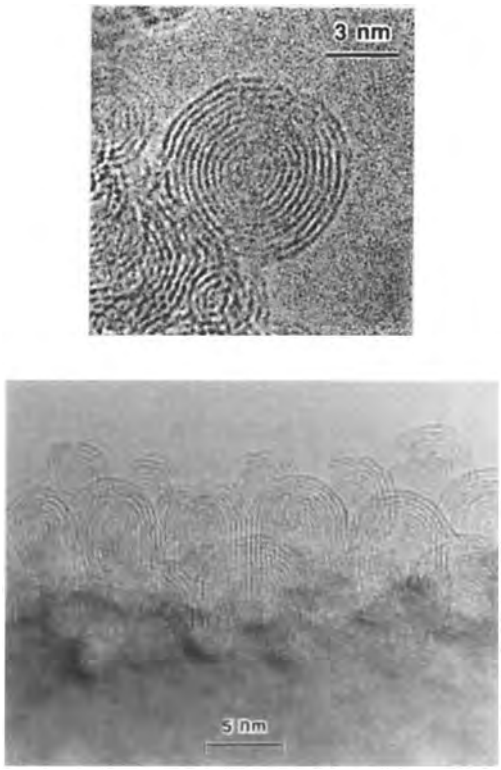

Figure 48. (a) Carbon onions containing several concentric shells (Ugarte and de Heere [197]), (b) Onions formed under intense electron irradiation at the surface of diamond. There is a directional correlation of the epitaxial onion-like graphitic particles and the diamond substrate. The (00.1) plane of graphite is well aligned with one family of (111) planes of diamond [199b]. (Courtesy of S. Iijima)

in a high voltage (1250 kV) microscope, transform into large onions, containing numerous (>15) concentric spherical shells. The increased atom mobility due to the combined effect of electron irradiation and high temperature allows the radiation damage to anneal out as it is formed. The pressure in the central part of the onion can be deduced from the systematic decrease in c-spacing (from 0.32 nm down to 0.22 nm) towards the center, as observed by HREM. On prolonged irradiation at temperatures between 650 and 750°C, the central cavity becomes filled with a nanocrystal of diamond, identified by high resolution imaging and electron diffraction. Irradiation at room temperature produces radiation damage, but no diamond.

Recently [199b] the transformation of sp_2 bonded graphitic structure was studied 'in-situ' using the electron microscope simultaneously as a heat source, as a small accelerator and as an imaging device. A thin chip of diamond was irradiated at 200 keV at an electron dose rate of about 10^7 el/nm^2 sec ($\sim$ 150/cm^2). After a total dose of about 10^9–10^{10} el/nm^2 high resolution images of the thin edge of the specimen exhibit 'onions' containing 4–10 graphitic shells, superposed on the diamond lattice image (Fig. 48b).

This nanostructure appears to be due to the dynamic equilibrium between on the one hand the production of atom displacements resulting from electron excitations, rather than from the direct impact of electrons, and on the other hand the thermal energy and the charging effect favouring atomic migration and restructuring along the surface. It should be noted that the carbon displacement threshold in diamond is 80 eV corresponding to an electron energy of 330 keV, which is above the operating electron energy of the microscope. It is further noted that these graphite particles are not stable under less intense electron irradiation, such as used in high resolution electron microscopy (of the order of 10^6 el/nm^2 sec). This is a consequence of the smaller carbon displacement threshold in graphite which is only about 30 eV (corresponding to $\sim$ 140 keV).

11.6.4 Defects In and Deformation of Carbon Nanotubules

Radiation Effects

Recently, more attention is being given to the study of defects in carbon particles. During HREM observations, defects are induced by the intense electron radiation. Therefore useful observations can only be made for a short time and with relatively low electron energies. Recently, it was found that heating the sample to 300°C during observation, limits the effect of radiation, even for electron energies of 1.25 MeV, due to the higher defect mobility in the carbon network [200].

Deformation of Carbon Nanotubes

Elastic bending and the resulting deformation of the tubes under the influence of external forces were recently studied by HREM [154, 201, 202]. The inner rim of the tubules, which is under compressive stress, was found to exhibit a number of kinks, depending on the bending angle. Although the graphite layers are locally severely deformed, the elastic limit is not exceeded, as was proven by a TEM experiment which showed complete restoration of the original shape, in agreement with molecular dynamics simulations.

The radial deformation of carbon nanotubes was revealed by careful analysis of 0002 fringe images of juxtaposed tube pairs [203]. The slightly deviating interfringe spacing in the contact region was attributed to elastic deformation of the two nanotubes due to the Van der Waals attraction between them.

'Fully collapsed' carbon nanotubes have been identified by TEM in soot prepared by the carbon arc method [204]. The cross section of these multilayer tubes is not circular but consists of a flattened ribbon like part where the graphite layers are parallel, terminated on both sides by strongly curved borders. Such a shape would result when a circular multishell tubule is completely flattened; it is stabilized by the Van der Waals attraction between the parallel flattened parts. The shape was deduced from the presence of twists and from in situ rotation experiments around the length axis.

Very recently [205], low magnification transmission electron microscopy has been used to estimate Young's modulus of single multishell nanotubes. It is found that tubes supported from one end only, as in a cantilever, vibrate constantly, independently of the intensity of the electron beam. This phenomenon is attributed to the thermal energy associated with the ambient temperature. Focussing of the vibrating end is then impossible. However, the extreme positions, i.e., the vibration amplitude, can be recorded as a function of temperature in a heating holder. From this temperature dependence, Young's modulus can be estimated. It is found to be in the TPa range, which is much larger than that of carbon fibers used hitherto for the reinforcement of composite materials.

Pentagons and Heptagons

Pentagonal meshes in the hexagonal graphene network are necessary to close the carbon cage (Fig. 39). Also, the presence of heptagonal meshes has to be inferred from the observed negative curvature in certain parts of the graphene layers. The effect of pentagons and heptagons on

the external shape of a tube was observed by TEM [148, 149, 152, 157, 206, 207] and AFM [145]. A pair consisting of a heptagon and a pentagon in diametrically opposed positions causes a tube to be bent over an angle of approximately 30°, and can induce a change in the radius and helicity [189, 208–210].

A pentagon–heptagon pair in adjacent positions in a graphene sheet forms a pair of 60° disclinations of opposite sign. Such a pair of disclinations is equivalent to an edge dislocation having its supplementary 'half-line' parallel to the line connecting the centers of the two disclinations. Such defects can therefore account for changes in the diameter of straight cylindrical tubules; they would topologically be necessary in seamless conical tubes having semi-apex cone angles different from those given by Eq. (9). Shape and size changes of tubules, as observed by means of {0 0 0 2} fringes, have been explained by assuming combinations of pentagons and heptagons [149].

Helically Coiled Tubules

The periodic insertion of heptagon–pentagon pairs in diametrically opposed sites on the tubule can transform a straight carbon nanotube into a torus or into a helically coiled tubule, which were theoretically shown to be energetically stable structures [211]. Such structures are believed to be observed in the material deposited during the thermal decomposition of hydrocarbons, using finely dispersed metal particles supported by amorphous silica as a catalyst [38, 39]. TEM observations revealed that the deposited material contains a large number of multishell carbon nanotubes, a significant fraction being regularly helically coiled (Fig. 4). The radius R of the helix ranges from 8 nm to a few hundred nanometers; the pitch p of the helix ranges from 20 nm to a few hundred nanometers. A method to derive these parameters for a helix in an arbitrary orientation is described in Bernaerts et al. [159]. The handedness of the helix can be derived by observing the helical tube with the incident electron beam inclined with respect to the helix axis. The difference in shape of the helix parts on both sides of the helix axis and knowledge of the tilt direction enables us to determine the handedness of the helix; a method that is more or less similar to one of the methods to determine the handedness of chiral tubes.

A model for the diffraction space of helically coiled nanotubes is summarized in Appendix E. In the diffraction pattern, the 0 0 0 l reflections become arcs; their angular extent depending on the shape of the helix and on the tilt angle of the helix axis with respect to the electron beam. This was confirmed by ED and TEM images, and the model is in agreement with diffraction contrast dark field images such as shown in Fig. 49 [159]. For a perfectly helically coiled tubule, a continuous intensity distribution is expected in the 0 0 0 l arcs. However, experimental ED patterns obtained from a single turn of the helix clearly show that the 0 0 0 l arcs have a spotty appearance if a single turn of the helix is selected (Fig. 50d), indicating that the helices are polygonized. This was confirmed by TEM images [159]. The bending angle was found to be approximately 30°, the same value as expected for a tube with a heptagon–pentagon pair inserted in diametrically opposed sites in the graphene network of the tube

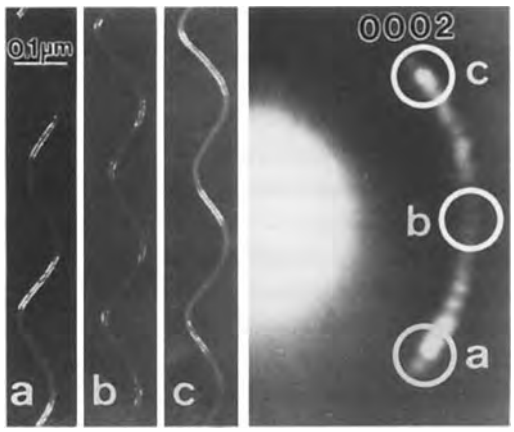

Figure 49. Diffraction contrast dark field images (a), (b), and (c) made in different parts of the 0002 diffraction arcs of a helical tubule, as indicated in the diffraction pattern. The two walls are revealed as bright segments (Bernaerts et al. [159]).

[205, 206]. Based on morphological observations and on the observations of catalytic particles in association with the tubules, a growth model accounting for the helical shape could be proposed [212].

Cross Section of Tubules

Most HREM images of carbon nanotubules show the same number of fringes in both walls. Therefore Iijima concluded that the tubules must be concentric stackings of closed cylindrical tubes: the 'Russian doll' model [27]. However, this model often seems to be oversimplified for two reasons: (i) the cross section of a considerable fraction of the multishell tubules deviates from circular, and (ii) there are indications that some tubes are not a concentric arrangement of closed tubes, but are, at least in part, scrolls. This was concluded from the presence of anomalous interfringe spacings [32] (Fig. 51).

As already mentioned, it is impossible for a given graphene layer in a carbon nanotube to remain in register with the structure of the previous layer due to the circumference difference $2\pi(c/2) = \pi c$, even if both tubes have the same chirality.

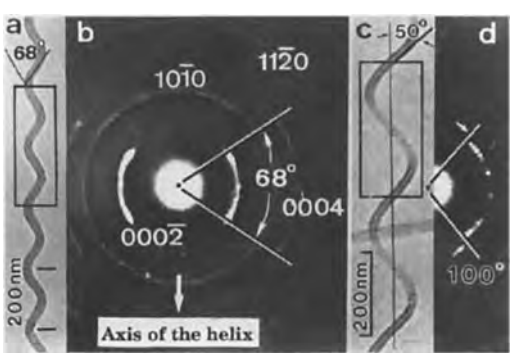

Figure 50. Electron diffraction pattern of a polygonized helical tubule. In (a) and (b) several turns are included in the selected area, whereas in (c) and (d) only one turn is included (Bernaerts et al. [159]).

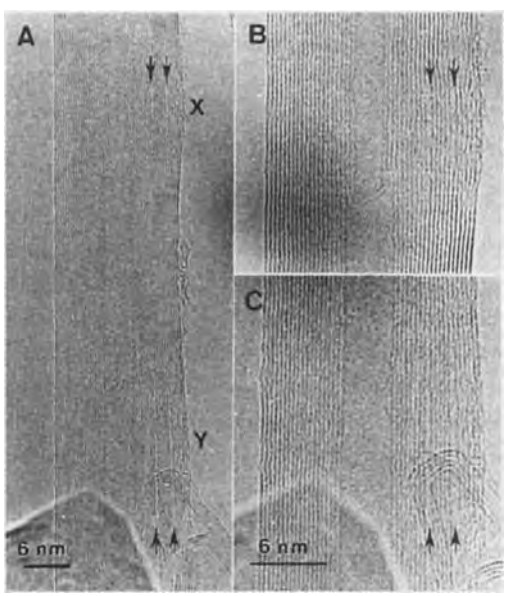

Figure 51. Anomalously spaced lattice fringes, indicated by arrows, in a multishell tubule attributed to dislocations terminating scroll parts in the tubule. (B) and (C) are magnified parts of X and Y in (A) (Amelinckx et al. [32]).

The cross section of a tubule can be circular or polygonized, as stated above. However, from the two-dimensional projected images obtained by TEM, it is not straightforward to distinguish between both cases, if the electron beam is not parallel to the tubule axis. From images taken at normal incidence, in combination with extensive tilting about the tube axis, it is clear that a considerable part of the tubules has a cross section deviating from a circular one, especially close to the cap of the tube (see, for example, Li et al. [213]). Liu and Cowley [156, 158] concluded from nanodiffraction patterns that some nanotubes have a polygonized cross section, and interpreted HREM images of tubes exhibiting some extra wide, singular 0002 interfringe spacings in one wall, such as in Fig. 51, as being an indication of polygonized tubes (this feature was reinterpreted more recently, however [32]). Furthermore, AFM and STM observations confirmed that tubes with circular, as well as with polygonal cross sections exist [144, 145]. Recently, TEM images were obtained from tubes viewed along their axis by embedding the tube containing soot in an epoxy resin and by subsequently sectioning the samples with ultra microtomy (UMT) [154, 214, 215]. Although it is difficult to distinguish between cross sections of cylindrical nanotubes and more or less spherical nanoparticles, these images are in agreement with the AFM and previous TEM results.

By recording ED patterns and HREM images of the same tubule, the number of different chiral angles observable in the ED patterns are found mostly to be much smaller than the number of layers in the tubule (observations of monochiral tubes of more than 10 layers were reported), suggesting that such tubules may be scrolls. Furthermore, intercalation experiments revealed that metal atoms can penetrate and destroy the layer structure of the tubes [31]. These two results are unlikely for the Russian Doll model for carbon nanotubes, and an alternative model was proposed: carbon nanotubes can consist, at least partly, of one or more graphene sheets rolled into scrolls, thus leading to a cross section similar to an Archimedian spiral [32]. (This model was also proposed in the past for carbon fibers [164].) All turns of a scroll have of course the same chirality. A terminating or starting scroll introduces an edge dislocation in the tubule wall, and it was argued that the deviating graphene layer distance in the close neighborhood of these edge dislocations causes the singular 0002 fringe spacings observed in some HREM images [32] (Fig. 51). For the configurations of the edge dislocations to be as expected on theoretical grounds, the number of fringes must remain equal in both walls. Furthermore, terminating 0001 layers were observed in HREM images taken for normal incidence [145] and in cross-sectional images [154, 214–216].

11.6.5 Conically Shaped Carbon Configurations

Cylindrical carbon nanotubes are observed to be closed by dome-shaped caps or by conical caps depending on the configuration of the pentagons in the graphene structure (Fig. 39b). STM [217], SEM, and TEM [40, 41] observations

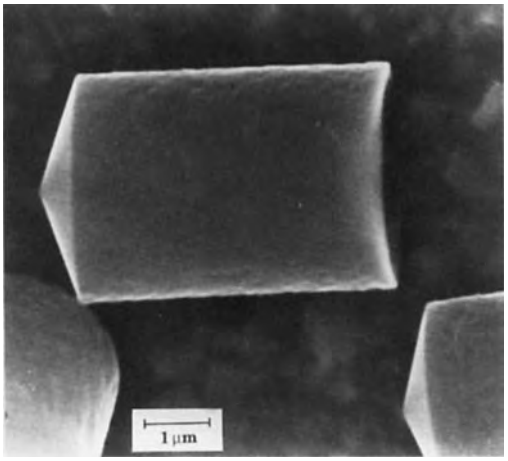

Figure 52. SEM image of a conically wound carbon needle formed by the decomposition of CO on an SiC substrate. The fracture surfaces show the conical character of the needle (TEM). The semi-apex angle is ~70° (Amelinckx et al. [40]).

showed the existence of isolated, conically shaped carbon structures (Fig. 52), and 'bamboo shaped' carbon nanotubes consisting of a string of conical structures were observed by HREM [218]. As shown in Appendix F and in the literature [40, 41, 217], only certain semi-apex angles are allowed for seamless cones. Different semi-apex angles correspond to a different number of pentagons in the tip of the cone. Cone angles slightly deviating from these specific values were seen to occur in conical graphite whiskers [40, 41]. Since for these observed semi-apex angles no seamless cones are expected, the whisker was found to consist of a conical graphene plane, helically wound around a 'disclination' with a fivefold carbon ring core. Each turn of a conical scroll is rotated with respect to the previous turn over an angle $\theta = 2\pi \sin \phi_0$ (ϕ_0 being the semi-apex angle of the cone) about the local c-direction. This rotation of each successive layer with respect to the previous one explains the peculiar diffraction effects observed for such conical whiskers, as shown in Luyten et al. [41].

The diffraction pattern of conically wound single fibers, the incidence beam being parallel to the cone axis, is much more complicated than that due to cylindrically wound fibers [219]. The most prominent feature is the presence of two rows of equidistant sharp $000l^*$ reflections through the origin, enclosing an angle $2\phi_0$. These rows are perpendicular to the projected wall directions. They are, moreover, both shifted along their length towards the origin, as a result of 'refraction' of the electron beam at the walls of the cone. The other reciprocal lattice node points generate loci which are spherical spirals, i.e., curves situated on spheres of constant spatial frequency.

In general each node generates a spherical spiral, but in cases of high symmetry and for special values of ϕ_0, all nodes of a given spatial frequency may generate a single spiral. For a detailed discussion, we refer to Amelinckx et al. [219].

11.7 Appendices

11.7.1 Appendix A: Euler's Rule

C_{60} and C_{70} are convex polyhedra which obey Euler's topological rule, i.e.,

$$V + F - E = 2 \tag{5}$$

where V is the number of vertices, E the number of edges, F the number of faces, h the number of hexagons, and p the number of pentagons in one polyhedron. For this particular case, it can be derived very

simply. Obviously for the number of edges

$$5p + 6h = 2E \tag{6}$$

with each pentagon contributing five edges and each hexagon six edges; however, since each edge belongs to two faces we have counted the number of edges twice. The number of faces is obviously

$$F = p + h \tag{7}$$

Since each edge connects two vertices and along each vertex three edges come together,

$$E = (3/2)V \tag{8}$$

because again we have counted each edge twice. Eliminating p and h between (6), (7), and (8), keeping in mind that $p = 12$ (see App. B), leads to (5). This relation is quite generally valid for convex polyhedra, also if more than three edges come together in a vertex.

11.7.2 Appendix B: Curvature Introduced by Pentagonal Meshes

The introduction of a pentagonal mesh in a hexagonal honeycomb network can be modeled using a continuum model as the extraction of a 60° wedge followed by closing of the resulting gap, i.e., as the introduction of a negative 60° disclination. The planar sheet is hereby deformed into a cone with a semi-apex angle ϕ_0 related to the extracted wedge angle θ (θ, e.g., 60°) by the relation [40]

$$\theta = 2\pi \sin\phi_0 \tag{9}$$

This cone covers a solid angle Ω_0 in units 4π

$$\Omega_0 = \frac{1}{2}\int_0^{\phi_0} \sin\phi \, \mathrm{d}\phi = \frac{1}{2}(1 - \cos\phi_0) \tag{10}$$

Of more direct interest is the cone formed by the local normals to this first cone. The corresponding solid angle Ω_n is given by the same equation [Eq. (10)], but the integration limits are different

$$\Omega_n = \frac{1}{2}\int_{\pi/2}^{\pi/2-\phi_0} \sin\phi \, \mathrm{d}\phi$$

$$= \frac{1}{2}\sin\phi_0 = \frac{\theta}{4\pi} \tag{11}$$

For $\theta = 60°$, $\Omega_n = 1/12$, i.e., twelve pentagons are necessary to form a closed cage fullerene. The simplest polyhedron is the pentagon dodecahedron which contains exclusively 12 pentagons.

11.7.3 Appendix C: Relation Between r, θ, and (n, m) for Chiral Tubes

The atomic structure of the cylindrical part of a seamless single shell carbon nanotube is determined by the radius r and the chiral angle θ. Consider a line along the complete circumference of the tube and perpendicular to the tube axis; let the starting point A and the endpoint A′ of the line coincide (Fig. 53). By cutting the tube along a line parallel to the tube axis and through A (and A′), the tube can be unfolded to a flat, two-dimensional graphene sheet. The segment AA′ is then defined as the chiral vector $\boldsymbol{c}_\mathrm{h}$; it connects two crystallographically equivalent sites on the graphene sheet. This chiral vector $\boldsymbol{c}_\mathrm{h}$ completely characterizes the geometry of the tube [178], and by specifying $\boldsymbol{c}_\mathrm{h}$ in terms of the unit lattice vectors of the honeycomb lattice ($\boldsymbol{a}_1$ and $\boldsymbol{a}_2$), the integer Hamada indices (n, m) are obtained by the relation

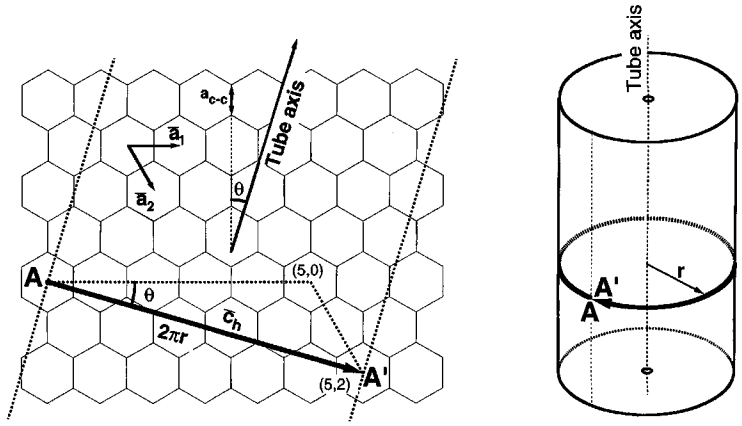

Figure 53. Schematic representation of the relation between r, θ, and (n, m) for a cylindrical carbon nanotube. Wrapping up of the graphene sheet in such a way that A coincides with A′ leads to the formation of a tube.

$\boldsymbol{c}_h = n\boldsymbol{a}_1 + m\boldsymbol{a}_2$ (Fig. 53) [178, 220]. The Hamada indices are generally used for theoretical work, while the radius r and the chiral angle θ can be determined experimentally. The radius r of a tube with Hamada indices (n, m) is given by the following relation

$$2r = \frac{\sqrt{3}}{\pi} a_{C-C} \sqrt{m^2 + mn + n^2} \tag{12}$$

and the chiral angle θ can be found from

$$\tan\theta = \frac{\sqrt{3}n}{2m + n} \tag{13}$$

with $a_{C-C} = 0.142\,\text{Å}$ (0.0142 nm), the nearest neighbor carbon–carbon distance [178]. Conversely, the measurement of r and θ for a monochiral tube allows m and n to be obtained from the relations

$$n = 2\sqrt{\frac{x}{y^2 + 3}} \tag{14}$$

and

$$m = \sqrt{\left(\frac{x}{y^2 + 3}\right)}(y - 1) \tag{15}$$

with

$$x = \frac{4r^2\pi^2}{3a_{C-C}^2} \tag{16}$$

and

$$y = \frac{\sqrt{3}}{\tan\theta} \tag{17}$$

11.7.4 Appendix D: Intuitive Direct Space Model for the Origin of Streaking in the Diffraction Patterns of Cylindrical Tubules

As far as diffraction is concerned, a tubule can be modeled as represented in Fig. 43, where the volume elements at a tangent to the tubes contain either a single graphene sheet (in monoshell tubes) or several random phase, disordered sheets. Within these sheets the tangential repeat distance along the normal to the cylinder axis is assumed to be a. It is thus possible to model the main diffraction effects due to the cylindrical curvature by considering each of these volume elements as a planar grating tangential to the cylinder and consisting of an array of equidistant, infinitely long scattering lines with separation a parallel to the tube axis. The problem is then reduced to two dimensions, as shown in Fig. 54a, representing a section

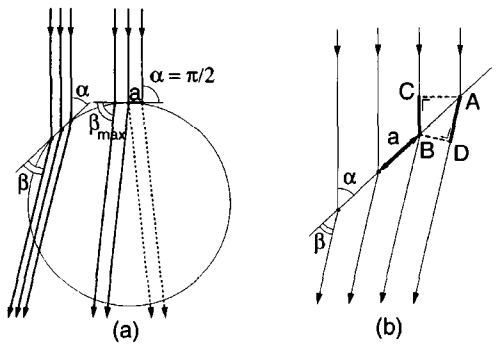

Figure 54. Direct space construction explaining the streaking of *hk*.0 spots in the diffraction patterns of carbon nanotubes. (a) Model for the circular monoshell tube. (b) Illustrating the derivation of the diffraction condition for a planar grating of parallel lines.

perpendicular to the tube axis. If we consider one such position of the grating (Fig. 54b), the diffraction condition expresses that intensity maxima occur if the path difference Δ of waves diffracted by successive 'lines' is an integer number of wavelengths λ

$$\Delta \equiv \mathrm{AD} - \mathrm{BC} = n\lambda$$

or

$$a(\cos\beta - \cos\alpha) = n\lambda \tag{18}$$

which is simply one of the three celebrated von Laue conditions. Under normal incidence ($\alpha = \pi/2$), the angle β is maximum, i.e., $\beta = \beta_m$, which is constant for a given reflection [$\beta_m = \arccos(n\lambda/a)$]. Hence Eq. (18) can be written as

$$\cos\beta - \cos\beta_m = \cos\alpha \tag{19}$$

Since $(\beta - \beta_m)$ is quite small, Eq. (19) can be rewritten as

$$\cos\alpha = (\beta_m - \beta)\sin\beta_m \tag{20}$$

or finally

$$\beta = \beta_m - \frac{\cos\alpha}{\sin\beta_m} \tag{21}$$

It is clear that as α decreases ($\cos\alpha$ increases), β also decreases for constant β_m, i.e., for a given reflection. At the same time, the intensity decreases with decreasing β since the incident intensity is proportional to $\sin\alpha$ and since, moreover, the atomic scattering factor also decreases with increasing scattering angle, i.e., with decreasing β. The reflection thus becomes elongated, fading out towards higher spatial frequencies. The interference between the beams diffracted by the two walls causes a quasiperiodic variation of the intensity, which is described exactly by Bessel functions [221, 222].

The smallest angle, α_{lim}, for which a diffraction maximum is still possible, is determined by the requirement that $\cos\beta \leqslant 1$, i.e., by $\cos\alpha_{lim} + \cos\beta = 1$ [from Eq. (19) or by $\cos\alpha_{lim} = 1 - \cos\beta_m$]. For this α value, β is zero and the diffracted beam is parallel to the planar diffraction grating. For smaller values of α some kind of 'total reflection' occurs, possibly contributing to the streak as well.

It is also worth noting that for small values of α (i.e., for grazing incidence), refraction of the electron beam occurs according to Snell's law. The latter phenomenon leads to observable features for *c*-reflections in the diffraction pattern of multishell tubules. The index of refraction being very close to one, the effect results in a small elongation of the $000l$ reflections along c^*.

An exact kinematical diffraction theory for the diffraction by helically arranged diffraction centers in single shell and multishell cylindrical tubules is formulated in the literature [218, 219].

11.7.5 Appendix E: Reciprocal Space of Helically Coiled Nanotubules[1]

Let us consider a coiled multilayer tubule with inner radius r of which the guiding circular helix is given in Cartesian coordinates by $x = R\cos\theta$, $y = R\sin\theta$, $z = (p/2\pi)\theta$ (R is the radius of the cylinder on which the helix is wound, p the pitch of the helix, and θ is the azimuth of the considered point); moreover, $\tan\phi_0 = (p/2\pi R)$, where ϕ_0 is the slope of the helix.

The geometry of the diffraction space of such a tubule (i.e., the loci of the reciprocal lattice nodes) can be obtained by considering the helical tube as consisting of short, straight, finite segments of tube of which the axis is always at a tangent to the guiding helix and is thus systematically varying in direction. The geometrical locus of the local axis of all such segments is a cone of revolution with semi-apex angle ϕ_0, with its apex in the origin and its axis parallel to the z-axis.

The geometry of diffraction space is now assumed to be the superposition of the loci contributed by all such elementary segments. The latter loci are approximated by those discussed above for infinitely long, straight tubules. In particular the loci of the $0\,0\,0\,l$ nodes, which are the prominent features, are circles centered on the origin of reciprocal space O_r with radii lc^* and situated in planes normal to the axis of the considered segment. The set of such circles in planes normal to the generators of the above-defined cone completely fill a spherical band limited by parallel circles on both sides of the equator of the sphere with radius lc^* centered on O_r; it extends in latitude from $-\phi_0$ to $+\phi_0$.

If the helix is not circular, but 'polygonized', the elementary segments are connected by bends caused by the presence of a pentagon–heptagon pair in diametrically opposite positions. In the diffraction space, the equatorial band now breaks up in discrete circles. The diffraction pattern obtained by intersecting diffraction space with Ewald's sphere (a plane) then consists of two $0\,0\,0\,l$ arcs broken up in discrete spots of which the density increases towards the extremities (Fig. 50d). The angular range of the arcs, as seen from the origin, is $2\phi_0$ at normal incidence of the electron beam, but it becomes larger with inclined incidence. For a full discussion we refer to Bernaerts et al. [159].

11.7.6 Appendix F: Semi-Apex Angles of Conical Tubes

Equation (9) determines a number of discrete semi-apex angles ϕ_0, which allow the formation of seamless conical tubes; this will be the case if $\theta = k\,60°$ (k: integer), i.e., for $\phi_0 = \arcsin(k/6) = 9.59°$, $19.47°$, $30°$, $41.81°$, $56.44°$, and $90°$ corresponding to $k = 1$–6. The acute extremity of such a seamless conical tube with a semi-apex angle ϕ_0 belonging to this series of special values [Eq. (9)] can be closed by means of a fullerene cap containing the adequate number N of pentagons. This number is given by $N = 6(1 - k/6)$. For instance, $k = 1$, i.e., the sharpest semi-apex angle

[1] Bernaerts et al. [159].

of 9.59° corresponds to a cap with $N = 5$ pentagons, whereas with $k = 5$, corresponding to the bluntest cone, a single pentagon ($N = 1$) is sufficient.

In Fig. 39b the measured semi-apex angle is, within experimental error, equal to the theoretical value of 9.59°. The cone is formed because of the presence in A of one pentagon (in each sheet!); the configuration is therefore asymmetrical. For closure of the cone, caps containing five pentagons are required in each of the concentric sheets.

Seamless cones (and also low energy scrolls) can only be formed for the specific angles given above. In Fig. 52 the semi-apex angle is ~70°, which is not one of these specific angles; as a result, misfit occurs between successive sheets. Nevertheless, the nearest ideal case corresponds to $k = 5$, i.e., one pentagon is required along the axis [40].

The pentagons in the caps are whenever possible arranged so as to be all 'isolated', i.e., surrounded by hexagons. This pentagon isolation rule is fulfilled in the cage fullerenes such as C_{60} and C_{70}.

12 Composite Structural Materials

12.1 Introduction

By the term 'composites' we mean materials fabricated from two distinct constituent phases, which after fabrication have retained their chemical, physical, or geometrical identity. Examples are silicon carbide fibers in a silicon carbide matrix, silicon carbide particles in an aluminum alloy matrix, and carbon fibers in a polymer matrix. As illustrated by these examples, constituent phases may be a ceramic, a metal, or a polymer phase. The motivation for the development of these materials is to create materials with a unique combination of properties that cannot be found among the monolithic materials. These properties include physical (e.g. electronic, magnetic, and optical), chemical, or mechanical properties. Here we consider only composites intended for structural applications, where mechanical properties such as strength, stiffness, toughness, and creep resistance play an important role. Usually a composite consists of a contiguous phase, the 'matrix', and a discrete phase, the 'reinforcement phase', which may be composed of particles, platelets, short or long fibers. Composites are often classified according to the nature of the matrix phase and thus are described as metal matrix (MMC), polymer matrix (PMC), and ceramic matrix composites (CMC).

To understand composites fully, a knowledge of their microstructure is indispensable. The relative amount of the reinforcement phase, its distribution in the matrix, and the state of the matrix–reinforcement interface are key parameters for the understanding of the material's behavior. It makes sense to use the simplest and most widely available techniques first. Light optical microscopy (LOM) and scanning electron microscopy (SEM) provide a wealth of information about a material. However, in order to relate the observations to properties, a quantitative description of the microstructure is needed, and hence quantitative image analysis techniques are required. A brief introduction to this subject is given here, as it is not provided elsewhere in these volumes.

12.2 Sample Preparation

12.2.1 Purpose

The purpose of sample preparation has been described well by Clyne and Withers [1]: 'The aim of metallographic preparation

is to prepare a surface such that one or more of the following features can be clearly delineated without unnecessary distortion or the introduction of new features not originally present:

- distributions of reinforcement size, shape, orientation and location;
- matrix grain structure, presence of precipitates, etc.;
- information relating to crystallographic texture and distribution of plastic strain.'

This task is often difficult, due to the large difference in properties between the matrix and the reinforcement material. Artifacts, such as matrix smearing, reinforcement cracking, fiber pull-out, or interface damage, can easily be introduced into the material if proper care is not taken.

Detailed instructions for preparation are hard to find, except for the more intensively studied systems. Several authors, however, give general instructions on composite material sample preparation [1, 2].

12.2.2 Sectioning

The aim of sectioning is to produce a specimen with dimensions that allow further handling, near or exactly at the plane of interest. This stage of the preparation process involves the highest risk of damaging the specimen.

In hard reinforcement–ductile matrix systems, the matrix microstructure is vulnerable to change by excessive deformation introduced by the cutting operation. For thermoplastics with a low melting point (e.g. poly(ethylene) or poly(propylene)), excessive heat generation during cutting can melt the matrix, thus completely altering the microstructure. The use of abundant fluid cooling is advised, both for cooling and for rapid removal of cutting debris from the cutting slit. Burring and reinforcement pull-out at the edges can be minimized by mounting the specimen in resin prior to cutting (see Sec. 12.2.3 of this Chapter).

CMCs are normally cut with low-concentration diamond wafering blades, because they deliver an increased load per abrasive particle at the specimen–blade interface, which helps overcome the ceramic's hardness [3]. Blades having large abrasive particles and blades with fine abrasive particles are available. For brittle, surface-sensitive materials that can be damaged by coarse diamond particles, blades with finer particles are recommended.

For most MMCs the least deformation is introduced by using a low-speed diamond wire saw, or spark erosion. However, these techniques are slow. Cut-off wheels (diamond or ceramic impregnated) are quicker, but cause more matrix material to be deformed. Consequently, the first grinding step should be prolonged to remove the deformed layer.

For some PMCs, water-jet cutting or laser cutting procedures are the only means to produce a clean cut and a representative cross-section.

12.2.3 Mounting

Mounting has several purposes. One is to facilitate the further handling of the specimen during either manual or automatic preparation, by giving it a suitable

size and shape. The mounting also supports fragile specimens and ensures good edge retention. The abrasive properties of the mounting resin should be similar to those of the composite, otherwise edges will be damaged by the uneven removal of material. With temperature-sensitive materials, one must take care that the heat generated by the setting of the resin does not cause damage.

Specimens that are porous and cracked (e.g. not fully dense CMCs, or fiber composites that have not been completely infiltrated) should be impregnated with a low-viscosity resin to fill the pores. Otherwise, grinding and polishing debris may accumulate in the pores, extensive reinforcement breaking and pull-out may occur in the neighborhood, and bleeding out of etchant from the pores may reduce the quality of observation after sample preparation. The use of vacuum impregnation is highly advisable. In this case, resin is poured under vacuum into the mold containing the specimen, resulting in better infiltration of the open areas by the resin.

12.2.4 Grinding

The aim of grinding is to remove the damaged layer and the surface relief caused by sectioning, and to obtain a planar surface. Grinding is a multistep procedure; the optimum number of grinding steps and the abrasives used depend on the material. The most common abrasives are diamond and silicon carbide. The latter is usually bound to a paper substrate; abrasive particle sizes range from approximately 100 to 4000 mesh. Diamond is used either mounted in metallic or polymer substrate (grinding wheels) or suspended in a liquid on a rotating disk (lapping). Diamond powder sizes range from 10 to 100 μm.

If the cutting procedure does not introduce much damage in the sample, one step using a fine grinding medium (20 μm diamond or 600 mesh SiC) may be sufficient. Otherwise, several steps are necessary, progressing from coarser (sometimes as coarse as 100 μm diamond or 180 mesh SiC) to finer media (10 μm diamond or 4000 mesh SiC). If the matrix is ductile or heat sensitive, a high water flow is recommended for cooling and the removal of debris. Between steps, the sample must be cleaned thoroughly to remove all diamond or SiC that might still adhere to the surface.

When grinding and polishing MMCs, the use of automated machinery is recommended, because of the higher reproducibility of results, and the high and even pressure that can be applied. Grinding times should be kept to a minimum (at most a few minutes), and the sample should be lifted frequently from the grinding surface to avoid excessive heating and debris pile-up. Most authors recommend the use of high pressure. In the case of composites containing SiC particulate reinforcement, grinding with SiC papers can introduce foreign SiC particles from the grinding paper into the sample.

For PMCs, the grinding pressure should be minimal to avoid distortion of the matrix and pull-out of the fibers.

For composites made of hard, brittle materials, such as CMCs, it is preferable to achieve gross material removal during sectioning rather than by grinding with coarse abrasives. The properties of the

composite's most brittle constituent dictate the selection of the abrasive size. CMCs are ground using diamond abrasives (15–45 μm), either fixed (diamond wheels) or free (lapping substance). One way of grinding CMCs is to use 40 and then 20 μm nickel-bound diamond wheels, followed by 30 and then 10 μm plastic-bound diamond wheels. The change from nickel-bound to plastic-bound diamond wheels requires a step back in the coarseness of the abrasive particles because the nickel-bound wheels are more aggressive than the plastic-bound ones, thus creating more damage in the composite.

Another technique that is suitable for grinding CMCs is power lapping [3], where a load is applied on the specimen during lapping. This introduces less damage into the material than grinding, and appears to be the best method to maintain the specimen's flatness, especially when the constituent phases are of very different hardness.

12.2.5 Polishing

The aim of polishing is to obtain an optically flat surface, which presents the true microstructure of the material to the observer.

Mechanical polishing is done using cloths impregnated with fine diamond suspensions. Napless or low nap cloths are preferred, as these tend to give minimal surface relief during polishing. They are, however, more prone to contamination by polishing debris, so an adequate lubricant flow is necessary if the matrix is ductile, and cloths should be cleaned well after use. Sometimes, a diamond slurry is used on a ground-glass plate substrate for coarse polishing. Polishing is done in several steps, using decreasing diamond sizes (starting sizes range from 6 to 9 μm; final sizes range from 0.5 to 1 μm). A final step can consist of a short polish with colloidal silica.

For MMCs, the polishing-wheel velocity is usually kept low, and high pressure is applied to the samples. Polishing times range from 5 to 1 min per step, the first steps usually being longer. As an alternative, and for PMCs, low pressure can be applied, and the polishing times made longer (10–45 min per step). Samples are thoroughly cleaned between polishing steps.

For CMCs, the highest material removal rate is obtained with mechano-chemical polishing [3] (fine diamond abrasive suspended in a chemically corroding fluid), using automated specimen preparation with high pressure on the composite. The increased applied load enhances the chemical activity of the polishing mixture due to frictional heating. Long polishing times tend to increase the phase relief within the CMCs and should be avoided. A typical two-step polishing procedure for CMCs is the use of a nylon cloth with a 3 μm diamond solution followed by the use of a high-nap cloth with OPS solution (0.1 μm silica suspension, pH $\simeq$ 8).

Anodic electropolishing can be used for aluminum matrix composites. Of course, it is necessary that good electrical contact can be made with the back of the sample.

12.2.6 Etching

The aim of etching is to enhance the visibility of microstructural features by bringing them into a chemical environment where the features one wants to

observe react differently from the rest of the material. In many cases, the material contrast between matrix and reinforcement is sufficient to make further etching unnecessary for the study of the reinforcement distribution. Etching, however, can reveal grain-structure details such as grain boundaries, the texture of phases, the state of crystallization, and the chemical segregation within a phase.

For MMCs, the classical etchants and etching techniques used for the unreinforced matrix metal can be applied. Problems arise if the matrix–reinforcement interface is attacked preferentially to the grains and grain boundaries; reinforcement dropout and highly uneven etching can result. If the material is slightly porous, etchant bleeding from the pores can severely deteriorate the sample quality. However, the latter problem becomes an advantage when one is interested in locating pores.

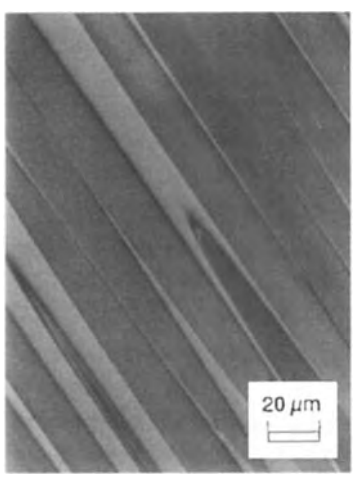

Figure 1. Glass–epoxy composite cross-section (LOM, ×500). The glass fibers were etched for 45 min using a solution of 10 g chromium oxide in 90 ml distilled water, resulting in an improved contrast between fiber and matrix.

For PMCs, etching is only used in special cases where the contrast is low. However, contrast between the matrix, the fibers, and the embedding resin is necessary, especially for quantitative image analysis. In the case of glass-fiber-reinforced epoxies and polyesters, different etching procedures have been described [4]. Figure 1 shows a glass epoxy composite etched in a chromic acid solution.

Sometimes the residual glass in the matrix of CMCs is etched with HF solutions in order to reveal the development of crystalline phases.

12.3 Quantitative Microstructural Analysis

12.3.1 Introduction

Quantitative microstructural analysis (in metallurgy also called quantitative metallography) is based mainly on classical geometrical and statistical concepts, and has a history of well over a century [5, 6]. In the last few decades, the concept of fractals has been introduced; this has found some application in describing and measuring the shape of microstructural constituents, a field which is still expanding rapidly. The advent of cheap and powerful computers has spawned the field of automated image analysis [7, 8], where the often tedious procedures are carried out by a computer. Automated image analysis has greatly facilitated the quantification of microstructures, but the specimen-preparation requirements are even more strict than for manual operations, because computers are often unable

to differentiate artifacts introduced by errors in grinding and polishing. As they become more affordable, techniques taken from medical imaging (tomography) may begin to find application in image analysis. The same applies to artificial intelligence systems, which not only quantify a microstructure but also interpret it. The importance of metallography for composite materials lies mainly in the measurement of the reinforcement distribution parameters, and of the state of the matrix–reinforcement interface.

Here, attention is given to some geometrical parameters that can be estimated from the study of plane sections through the material. Some material parameters, such as the amount of fiber fracture and fiber aspect ratio, are better determined by selective leaching of the matrix metal and studying the remaining 'naked' reinforcement. The distribution of chemical species throughout the material volume, which can, for example, be measured using electron probe microanalysis (EPMA), is not considered here.

12.3.2 Concepts of Quantitative Microstructural Analysis

There are five basic types of quantity of a microstructure that can be measured (Table 1). To each of these quantities can be added a subscript which indicates the reference for the measurement (Table 2, Fig. 2). When the measurement is related to the entire sample or when no ambiguity exists, no further subscripts are given; otherwise extra subscripts are added to indicate the meaning, for example, $(A_V)_{SiC}$ can be the surface/volume ratio of the SiC phase in a composite system.

A number of fundamental relations can be proven to exist between these quantities. The relations can be used to calculate microstructural properties that are difficult to measure from quantities that can more easily be measured:

$$V_V = A_A = L_L = P_P$$

$$S_V = (4/\pi)L_A = 2P_L$$

$$L_V = 2P_A$$

$$P_V = \tfrac{1}{2}L_V S_V = 2P_A P_L$$

These relations are general. That is, they apply in principle to all microstructures, whatever their geometry. It must be kept in mind, however, that they only hold exactly for 'true' geometrical properties. The values that are used in practice are obtained by measuring, and are thus subject to two types of error: random error and systematic error (or bias). The former is inherent to all sampling and measuring procedures, and can be reduced by increasing the number of samples or measurements. The latter is introduced by

Table 1. Types of quantity of a microstructure that can be measured

Type	Example	Notation
Volume	Volume of a phase	V
Area	Grain boundary area	A
Length	Perimeter of an inclusion	L
No. of entities	No. of inclusions	N
No. of points	No. of points of a grid located on inclusions	P

Table 2. Quantities related to microstructure

Relative quantity	Meaning	Example
V_V	Volume per unit volume	Volume fraction of a phase
A_V	Area per unit volume	Interface area per unit volume
L_V	Length per unit volume	Dislocation line length per unit volume
N_V	No. per unit volume[1]	No. of inclusions per unit volume
P_V	Points per unit volume[1]	
A_A	Area per unit area	Area fraction of a plane section occupied by a phase
L_A	Length per unit area	Particle perimeter per unit area
N_A	No. per unit area[1]	No. of cracks per unit area
P_A	Points per unit area[1]	No. of grain boundary triple points per unit area
L_L	Length per unit length	Fraction of the length of a line lying on a phase
N_L	No. per unit length[1]	No. of inclusions crossed by a line of unit length
P_L	Points per unit length[1]	No. of grain boundaries crossed by a line of unit length
P_P	Points fraction[1]	Fraction of points of a grid falling on a phase

[1]The difference between N and P quantities is not always clear. In general, P will be used when point-like features are counted, and N when the counted entity has a non-zero dimension (which is not considered relevant for the measurement). Also, P_V, P_A, and P_L generally concern point-like features of the microstructure, while P_P concerns points of some grid superposed on the microstructure.

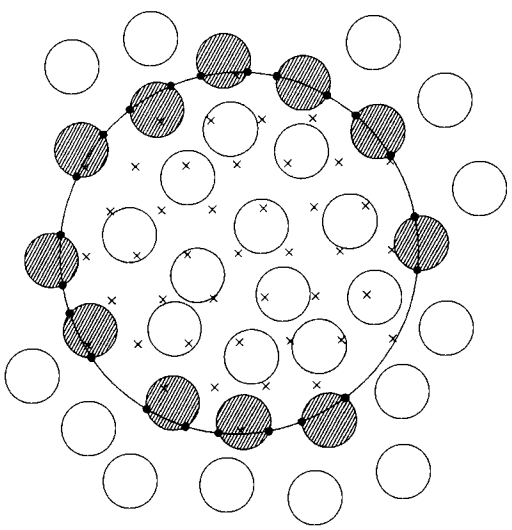

Figure 2. Different point and feature-counting measurements. Circles are the second-phase particles, the background is the matrix. The large circle and the crosses are a measuring line and grid projected onto the microstructure. P_L, the number of interfaces crossed per unit line length (number of black dots divided by the perimeter of the large circle); N_L, the number of inclusions intersected per unit line length (number of hatched particles divided by the perimeter of the large circle); P_P, the fraction of grid points that lie on particles (number of crosses inside particles divided by the total number of crosses).

incorrect sampling procedures, and cannot be reduced by repeated measuring. The above relations are valid for the expected value of the measured quantities, which is approximated by the mean of all unbiased measurement results.

The risk of measurement bias is smaller if the microstructure is 'random', that is if any section taken from the sample is equally well representative of the entire microstructure. Otherwise, the experimenter should carefully select those sections that are most representative of the quantities he wants to measure, and check the results for consistency with the assumptions that were made when choosing the section.

12.3.3 Sources of Error

12.3.3.1 Specimen Preparation Errors

Several possible causes of error have already been mentioned in the section on

specimen preparation:

- Matrix melting/deformation/cracking.
- Reinforcement deformation/cracking/pull-out.
- Interface cracking.
- Reinforcement hidden by smeared matrix material.
- Introduction of SiC from the grinding paper.

12.3.3.2 Sampling Errors

These errors are introduced when the section being studied is not representative of the material. A common cause of this kind of error is when the orientation distribution of microstructural constituents is not homogeneous. A typical example is a matrix with aligned fibers. The fiber volume fraction, for example, is more accurately measured in a transverse section. An experimenter must decide if the quantity of interest is best represented by a transverse or a longitudinal section.

Another cause is when the scale of certain features is larger than the measured area. If, for example, the edges of a composite are depleted of reinforcement, this will go unnoticed if only a few small areas in the middle of the sample are studied.

A third and very important cause is operator bias. An operator can bias results by his choice of measurement areas: if only sites 'that look nice' are selected, certain material characteristics are more or less unconsciously ignored. Results can also be biased by the operator's interpretation of certain unclear phenomena. If a measuring grid point falls on a particle edge, one operator may mark it as 'in' and another as 'out', thus influencing the result of the counting. If an inclusion is of a slightly different shade of color than most others, one operator may judge it to be a foreign inclusion, while another will count it as a piece of reinforcement. Such errors are best avoided by having several operators repeat the same measurement.

It is absolutely necessary that the greatest care is taken to avoid all biasing during sampling. Sampling regions and sectioning directions should be chosen considering all factual information and reasonable suppositions about the material at hand, and all results obtained should afterwards be checked against such suppositions. Moreover, as much true randomness as possible should be introduced into choices between equivalent sections and areas to be measured.

12.3.3.3 Errors Due to Image Analysis

Metallography by image analysis is sensitive to some kinds of error caused by the nature of the image processing hardware. The basic unit of an image in a computer is a pixel; a pixel has one color as its attribute. Pixel size is determined by the nature of the image-recording device and the magnification used to record the image. Any image information that is smaller than the pixel size is lost. Also, information on objects that are only a few pixels in size is very approximate; in particular, information on shape and perimeter is error prone. Therefore, to minimize this error, the objects studied should at least be several tens of pixels in size (Fig. 3).

It is generally the case that pixels associated with a phase do not all have the same color attribute, but a range of attributes. In order for the system to be able to

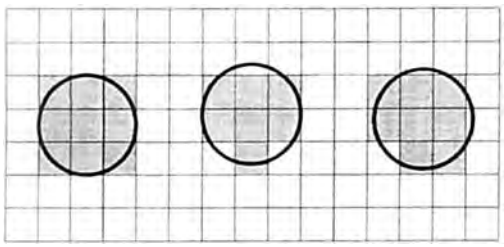

Figure 3. Very small objects cannot be represented accurately on a grid of pixels. The same small circle is represented by 7, 8, or 9 pixels, depending on its position relative to the pixel grid. Information on shape and perimeter is lost.

recognize the phases, the operator must decide which range of color values is to be associated with which phase. This is done by setting threshold values in the color spectrum. This process can easily lead to biasing error due to operator habits or optical illusions. This is particularly important in edge detection because, due to the analog nature of most recording devices, edges that are sharply delineated in the sample are seen as broader and fuzzier in the pixelized image. This fuzziness must be corrected for by applying sharpening filters, and setting appropriate threshold values. Significant errors can be introduced if this is not done correctly (Fig. 4).

Finally, if three phases are present in the system, one dark, one bright, and one of intermediate brightness, a halo effect can occur on the boundaries between the dark and the bright phases: the pixels of intermediate brightness on the fuzzy edge can be falsely interpreted as being of the third phase.

12.3.4 Reinforcement Volume Fraction

The reinforcement volume fraction $(V_V)_r$ is one of the most straightforward quantities to measure in a composite, and is one of the most important parameters governing the bulk properties of the material. There are three ways to determine the volume fraction, and these serve as generic examples for the three classes of measurements on plane sections.

One can determine the fraction of the measurement area that is occupied by the reinforcement $(A_A)_r$. This fraction is equal to the volume fraction or, more precisely, the area fraction is an unbiased estimate of the volume faction [9] (Fig. 5). Consider a cube of material with sides of length L, and a slice through this volume perpendicular to one side with infinitesimal thickness dx and area $A = L^2$. The reinforcement

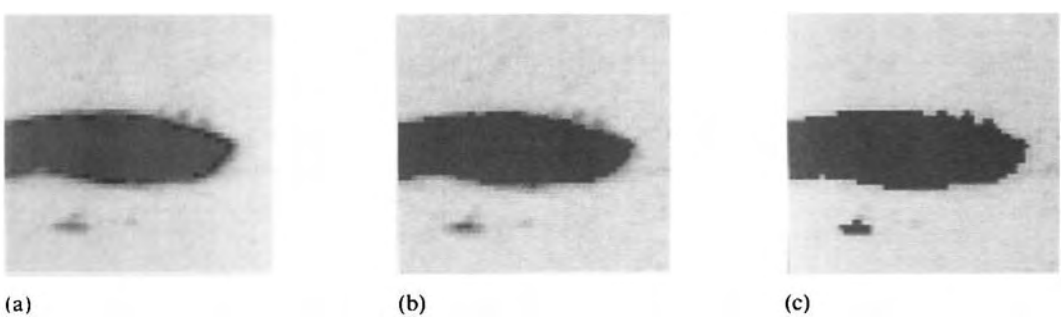

Figure 4. Edge error. The size of an object can vary significantly depending on how much of the fuzzy boundary around it is considered to be part of it.

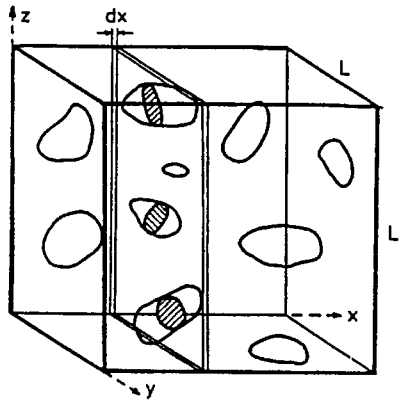

Figure 5. A cube with side L containing second-phase particles. dx is the thickness of an infinitesimally thin slice of the cube.

volume dV in the slice is equal to the area A_r of reinforcement in the slice, times the thickness of the slice:

$$dV = A_r\,dx$$

The total reinforcement volume V_r is the integral of dV over all slices through the cube:

$$V_r = \int_0^L dV = \int_0^L A_r\,dx$$

The average reinforcement area is:

$$\overline{A_r} = L^{-1}\int_0^L A_r\,dx$$

Then:

$$(V_V)_r = \frac{V_r}{L^3} = \frac{\overline{A_r}\cdot L}{L^3} = \frac{\overline{A_r}}{L^2} = (A_A)_r$$

where $(A_A)_r$ is the reinforcement area fraction. This is *areal analysis.*

When one draws an imaginary line segment across the plane section, and measures the fraction of the line length that is drawn over reinforcement areas, then this fraction is equal to the reinforcement volume fraction $(V_V)_r$. This is *lineal analysis.*

When an array of dots is drawn on the plane section, the number of dots that fall on the reinforcement divided by the total number of dots equals the reinforcement volume fraction. This is *point analysis.*

These calculations are, of course, only valid if the areas, lines, and dot grids used introduce no systematic error. This caveat is particularly important for fiber-reinforced composites; in this case the best method is to measure in a plane perpendicular to the fiber direction.

The statistical error of the measurement can be decreased by increasing the number of measurement areas, lines, or points in a section. When using arrays of parallel lines or dots, systematic error can be introduced if the reinforcement has a preferred orientation. This can be avoided by repeating the measurement with the array rotated over a small angle. It is good practice to prepare several sections of the sample for measurement in order to minimize the sampling error introduced by sectioning.

12.3.5 Homogeneity of the Phase Distribution

The failure of composites is greatly influenced by the homogeneity of the reinforcement distribution. Local concentrations of reinforcement can act as crack-generating sites; unreinforced regions are weak spots, where failure may begin.

Inhomogeneity can be described in different ways and can have various meanings. One meaning can be: 'the extent to which the particle/fiber arrangement deviates from a perfectly random arrangement' (or, conversely, a perfectly ordered lattice). This addresses inhomogeneity on the scale of a few reinforcement sizes, looking at how evenly spaced the

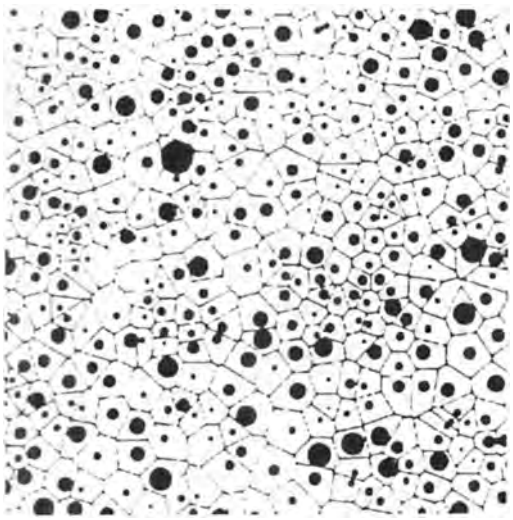

Figure 6. Dirichlet tessellation. Black circles represent reinforcement particles. The image is divided into cells. Each cell comprises the set of points that is closer to the particle enclosed within it than to other particles.

reinforcement is. Another can be: 'the extent to which the reinforcement volume fraction of different sample regions is different'. This addresses inhomogeneity on the scale of the sample, looking at whether there are regions that are less reinforced than others.

One way to address the small-scale inhomogeneity is to use Dirichlet tessellations. A Dirichlet tessellation is a network of polygons in which every polygon contains one particle or fiber, and all points in each polygon are closer to the enclosed particle than to any other particle (Fig. 6). From such a tessellation two parameters can be calculated: Q is the ratio of the observed nearest-neighbor distance to the one expected, and R is the ratio of the variance of the observed nearest-neighbor distance to the expected variance. The values of these parameters allow one to draw conclusions about the reinforcement distribution (Table 3) [10].

Table 3. Interpretation of the Q and R parameters obtained from Dirichlet tessellations

Q	R	Interpretation
<1	<1	Clustered sets
>1	<1	Short-range ordered sets
<1	>1	Sets of clusters with a superimposed background of ordered points

This approach becomes difficult if the sections through the reinforcement have very irregular shapes, as then different possible definitions of the distance from a particle can give rise to different tessellations and different values for Q and R.

A possible measure of large-scale homogeneity h is given by

$$h = \frac{1 - s_f}{f}$$

where f is the nominal volume fraction of reinforcement and s_f is the standard deviation on f [11]. Measuring h involves measuring the local reinforcement fraction over the sample (see Sec. 12.3.2 of this Chapter).

An alternative approach was developed for measuring the homogeneity of the fiber distribution in MMCs prepared by pressure infiltration. In this technique, a preform consisting of stacked fiber bundles, each containing hundreds of filaments, is infiltrated by liquid metal. As the metal tends to separate the bundles rather than to infiltrate between the individual filaments, a structure is formed of regions with a high and rather homogeneous reinforcement fraction, separated by regions containing no reinforcement (Fig. 7a). A measure of the homogeneity of such a

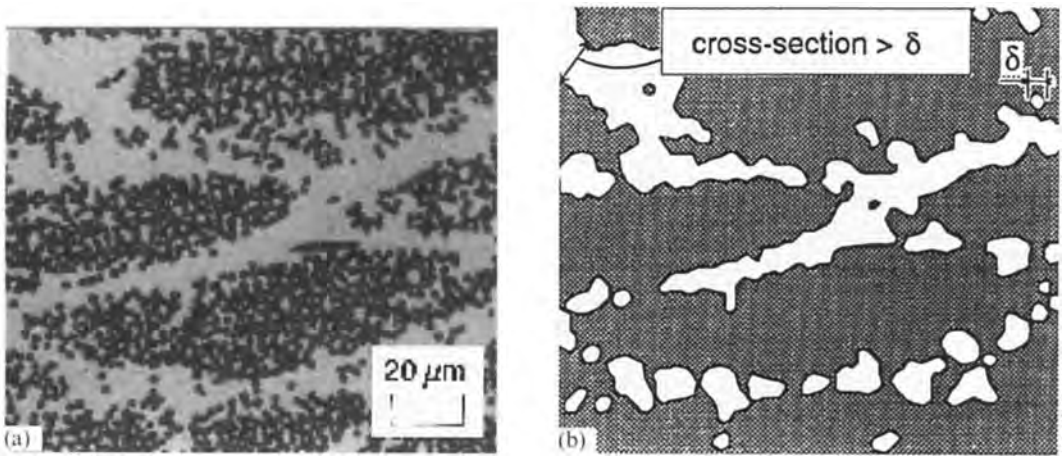

Figure 7. Determination of the unreinforced area fraction U, the ratio of the white area over the total section area, with a resolution of δ. (a) Micrograph of a transverse section through a 6061 aluminum composite reinforced with 50 vol.% SiC fibers. The material was prepared by infiltrating prestacked fiber bundles with liquid aluminum; the aluminum tends to separate the bundles (LOM; no etching). (b) Drawing derived from the micrograph in (a) by image processing. The white areas are regions with a minimum dimension of δ, that is areas which contain no fibers.

fiber distribution is the unreinforced area fraction U in a section. To determine U, a circle of diameter δ is drawn about every point in the section, and the area A of the union of all circles that contain no reinforcement is determined (the white area in Fig. 7b). U is the ratio of A to the total area of the section.

As δ decreases, the fineness of the measurement will increase and U will become larger. This allows one to tune the measurement to the scale of homogeneity one wishes to measure. From the variation of U with δ, information on the fractal geometry of the unreinforced areas can be deduced. δ_{min}, the smallest meaningful value of δ, is the nearest-neighbor spacing of the reinforcement arranged on a perfect lattice [12]. It can be shown [12] that if $\delta = \delta_{min}$, then

$$h = 1 - \sqrt{\frac{1}{1-U} - 1}$$

12.4 Structure of the Constituent Phases

12.4.1 Matrix

For PMCs in the form of a three-dimensional, woven, sandwich fabric, a lightweight foam is used as a core material. Although the foam properties are often neglected in calculations, they do have an influence on the mechanical performance of the sandwich. These properties are determined by the geometry of the foam cells. In order to model and predict the mechanical performance of the foam, it is essential to quantify all the cell dimensions [13]. The fabric is therefore cut at cryogenic temperatures in order to minimize distortion of the cell struts and membranes. The cell dimensions can then be measured from SEM images of the cross-sections (Fig. 8a). At high magnification

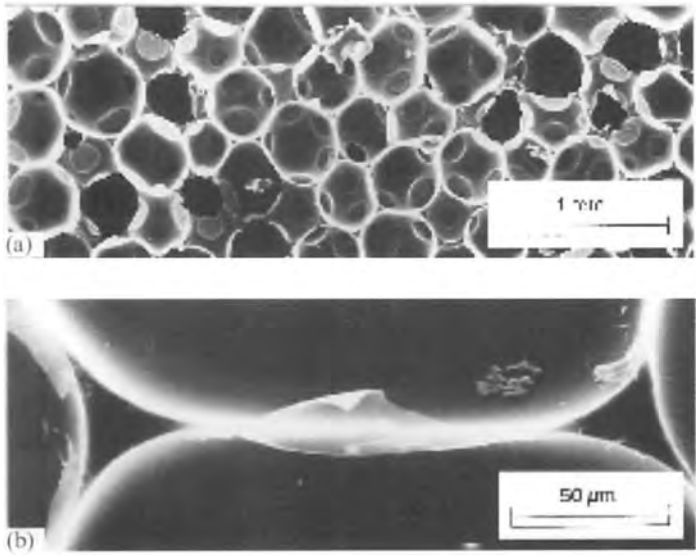

Figure 8. (a) SEM image (×28) of a cross-section obtained by cryogenic cutting of polyurethane foam. (b) SEM image (×500) of a cell membrane and two struts of polyurethane foam.

even the thickness of the membranes can be measured. Using an image like the one in Fig. 8b the thickness of struts and membranes can be measured, although the margin of error is very large. No alternative measurement techniques exist at present.

If polyurethane foam is injected into the core of a composite, the flow of the foam during expansion is strongly influenced (disturbed) by the presence of the pile fibers. From SEM images such as the one shown in Fig. 9, the size of the zone affected and the cell dimensions in the vicinity of the pile fibers can be quantified. This local geometry has a strong influence on the support of the pile fibers during mechanical loading of the sandwich beam.

Glasses and glass-ceramics are often used as matrix in CMCs, because their viscous flow properties at high temperatures allow for relatively easy densification

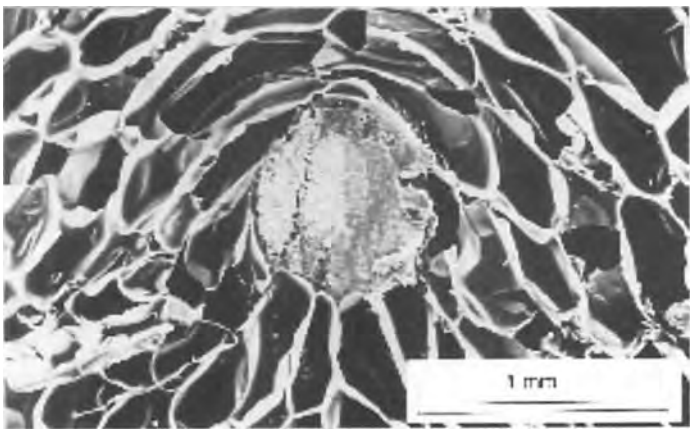

Figure 9. SEM image (×41) of the core of a three-dimensional sandwich fabric panel, containing polyurethane foam. The glass pile fiber in the fabric disturbs the flow of the polyurethane, resulting in a wide variation in the foam morphology.

Figure 10. Microstructure of a BMAS glass-ceramic, heat treated at 1070°C for several hours. Quantitative compositional EPMA indicated the presence of fine, interpenetrating, white celsian and black cordierite crystals, in combination with isolated barium osumilite crystals. A small amount of residual glass surrounds the crystalline phases. Back-scattered electron detector image (×2000).

of the composite. Glasses have an amorphous structure, although they usually show short-range order [14, 15]. Glass-ceramics can first be densified in the glassy state and then subsequently turned into a refractory polycrystalline material by means of an appropriate heat treatment [14–16]. Their properties are very closely related to their microstructure and, more specifically, to: (1) the amount and type of phases present, including porosity; (2) the characteristics of each phase, such as size, shape, and orientation; (3) the elastic modulus mismatch and the thermal expansion coefficient mismatch of the different phases; and (4) the strength of the interface between the phases present [14, 15]. The microstructure of glass-ceramics depends strongly on the processing conditions, such as temperature, holding time, and pressure; several microscopy techniques can be used to illustrate this dependence. The complexity of the microstructure of a $BaO–MgO–Al_2O_3–SiO_2$ (BMAS) glass-ceramic with no reinforcement is illustrated in Fig. 10.

12.4.2 Fibers

In composites reinforced with textiles, which are often used in PMCs and in some CMCs, the geometry of the textile is of primary importance for the mechanical properties and the (de)formability of the composite structure. In models that link this textile geometry to the mechanical properties (stiffness and strength) of the composite, a detailed description of the fabric is necessary. This description is obtained using stereo-microscopy. For a woven fabric, the geometric parameters can be obtained easily. However, for a complex knitted fabric such as the one shown in Fig. 11, a two-dimensional description of the fabric is obtained. The third dimension is obtained by taking into account the relative positions and dimensions of the fiber bundles. Subsequently, the fiber bundles are split up into small, straight segments, each having a specific orientation. These orientations, translated into an orientation distribution function, are used to calculate the elastic properties of the knitted fabric composite [17]. The same technique is used to characterize the deformation behavior (yarn slip, loop

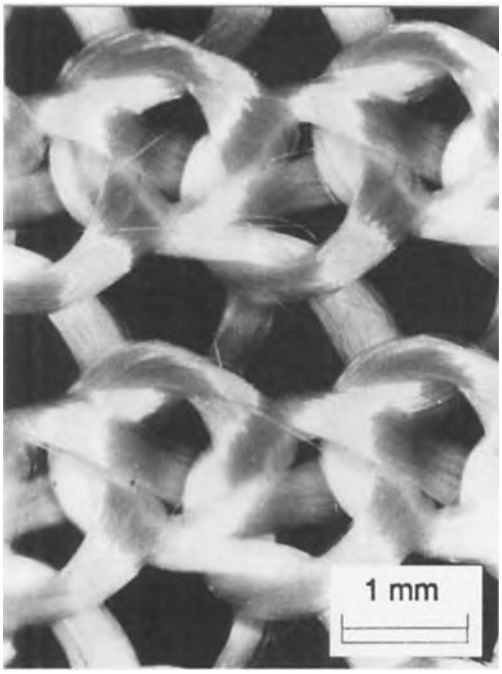

Figure 11. Stereomicrograph (×17) taken from a warp-knitted glass fabric, showing the loop structure.

closing and jamming, and yarn straightening). This is of utmost importance for the application of knitted fabrics in composites, as their main advantage is their high deformability which can be exploited to form complex-shaped parts.

The strength of the ceramic fibers used in CMCs is continuously degraded during processing of the composite, and thus the remaining strength is an important parameter when modeling the properties of the composite. The strength of the fibers in pristine condition or in the fabricated composite can be deduced from fracture mirrors after the composite's failure. A fracture mirror is a smooth, mirror-like region surrounding the fracture-initiating defect in the fiber [18, 19]. The size of the mirror radius a_m can be related to the fiber tensile strength S according to the equation [19, 20]:

$$S a_m^{\frac{1}{2}} = \text{constant}$$

By measuring the fracture mirrors on many pull-out fibers on the fracture surface of a failed composite, it is possible to construct a cumulative probability distribution $P(S)$, which represents to some extent the in situ fiber strength distribution [21]. The fracture surface of a fiber found within a failed Tyranno fiber/BMAS glass-ceramic matrix composite is shown in Fig. 12. Tyranno is a commercial silicon carbide (SiC) fiber containing 1.5–4 wt.% titanium.

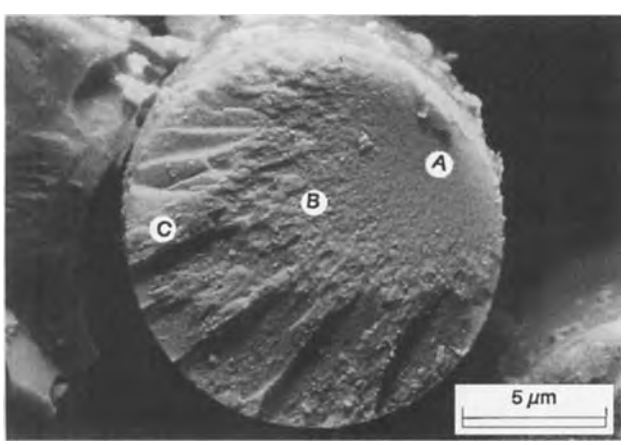

Figure 12. High resolution scanning electron micrograph (HRSEM) of the fracture surface of a Tyranno fiber. Three regions of decreasing smoothness are observed around the fracture-originating flaw: (A) the 'mirror' region; (B) the 'mist' region; (C) the 'hackle' region. The displayed fiber was found on the fracture surface of a Tyranno fiber/BMAS glass-ceramic matrix composite. Back-scattered electron detector image (×5000).

12.5 Structure of Composites

12.5.1 Interaction Between Matrix and Fibers

The crystallinity of thermoplastic polymers and composites is studied using thin slices of the material. The microstructure is revealed by the use of transmitted polarized light. Figure 13a shows a pure polymer: spherulites nucleate at random sites and grow until they meet. The presence of fibers in the molten thermoplastic changes this crystallization behavior: as shown in Fig. 13b, the nucleation points are no longer random, but nucleation starts from the fiber surface. Only in areas of low fiber density will spherulites nucleate in the matrix. The resulting microstructure shows much smaller spherulites. The size of the spherulites has a strong influence on the mechanical properties of the matrix [22]. This is one of the reasons why the mechanical properties, such as the fracture toughness, of the thermoplastic matrix cannot be transferred directly to the composite properties.

In some textile composites, the fabric geometry is stable only after production of the composite. A typical example is the three-dimensional woven sandwich fabric. During production, two skins interconnected by fiber bundles in the third dimension ('pile bundles') are pulled apart to produce a sandwich. The stretching forces applied determine the shape of the pile bundles. This shape (Fig. 14) has an important influence on the compression and shear strength of the core, as well as the stiffness of the core. In order to model these properties, an accurate description of the pile-bundle shape is required. This is obtained by cutting the composite in two orthogonal directions (warp and weft), and examining the shape in both planes

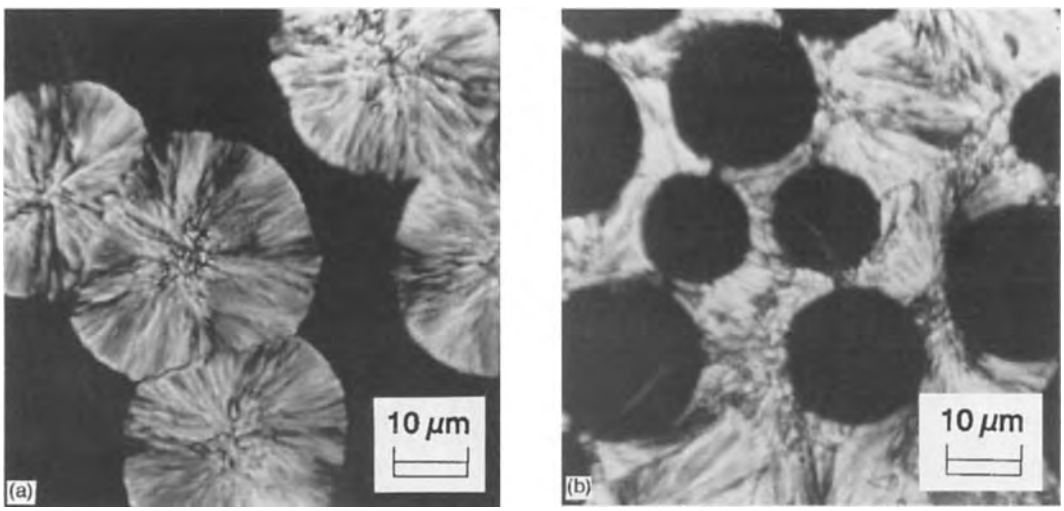

Figure 13. (a) Transmission light microscopy (×1000, using polarized light) reveals the presence of crystalline spherulites in a thermoplastic PAA (Polyarylamide) material which was quenched to freeze at an intermediate stage of the crystallization process. (b) The same technique was used to illustrate the microstructure of a composite with a crystalline thermoplastic PAA matrix. The spherulites nucleate from the surface of the glass fibers (×1000).

Figure 14. SEM image (×10) of the core of a three-dimensional woven sandwich fabric composite. The shape of the connecting pile fibers depends on the production process, and can be quantified using microscopy techniques.

by means of stereo-microscopy. The data from both images are subsequently combined to produce a three-dimensional representation which is used for automatic mesh generation in a finite-element model pre-processor.

SEM techniques are often used to depict microstructural features of CMCs, such as the homogeneity of distribution of the reinforcing phase, the degree of porosity, the development of matrix microcracking, or the structure of the matrix, reinforcement, and interface

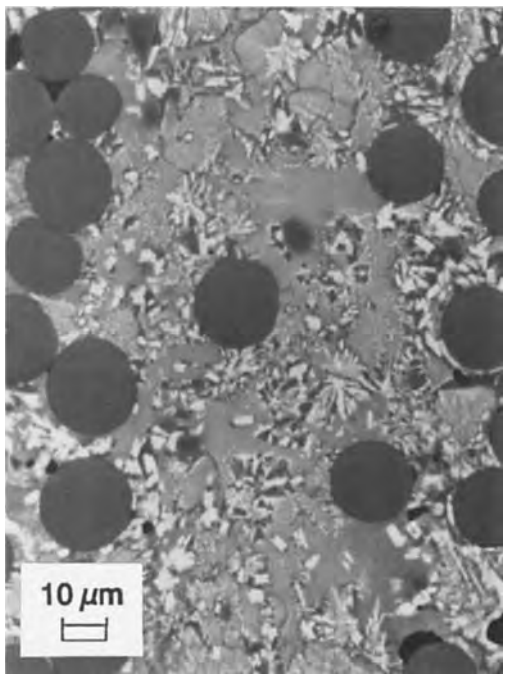

Figure 15. EPMA micrograph (back-scattered electron detector image, ×600) of a Nicalon fiber/BMAS glass-ceramic matrix composite. The matrix consists of barium osumilite, celsian, and cordierite crystals surrounded by residual glass. Fiber-distribution inhomogeneities and matrix porosity are shown.

between them. The microstructure of a Nicalon (commercial silicon carbide) fiber/BMAS glass-ceramic matrix composite is shown in Fig. 15.

12.5.2 Characterization of the Interface

The fragmentation test is commonly used to characterize the interfacial shear strength in PMCs. In this test, a single fiber is embedded in a transparent matrix with a high strain to failure. During loading, the fiber breaks into small fragments. The most commonly used data-reduction

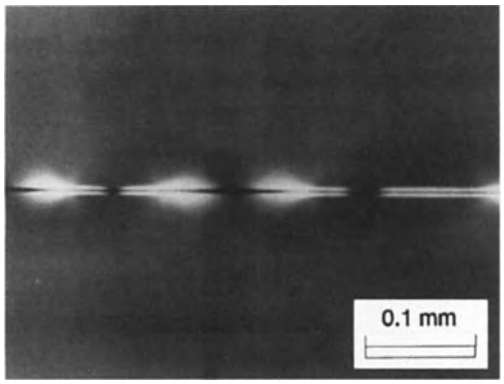

Figure 16. Transmission light microscopy with polarized light (×200) reveals the fiber breaks (dark spots) and the length of the fiber–matrix interface debonding (narrow white fringes close to the fiber) during a single-fiber fragmentation test on a carbon-epoxy composite specimen.

schemes use only the fiber fragment length to characterize the interfacial shear strength. Studies [23] have shown that these data-reduction schemes are not correct. Moreover, it has been demonstrated that, by using transmission microscopy with polarized light, not only the fragment length, but also a debonding length, can be determined. In Fig. 16, the debonded area is revealed by narrow white fringes close to the fiber. The measurement of the debonding length allows a more detailed analysis of the test data, so that a more accurate value of the interfacial shear strength and the interfacial friction stress can be calculated [24].

12.6 Damage Mechanisms

12.6.1 Introduction

Modern engineering materials are required to sustain a reasonable level of damage before complete failure. Sudden brittle fracture without prior warning is not acceptable. This is particularly a problem for CMCs. For the materials engineer it is important to study the microstructural mechanisms by which a composite is able to sustain damage and by which it will ultimately fail. Using the results of such studies, damage tolerance can be designed into the composite.

Some examples of such studies are given below. Microscopy is usually essential to identify the particular damage modes that occur in the various types of composites.

12.6.2 Delamination of Fibrous Composites

PMC and CMC composites are often fabricated from laminae or plies. Each lamina is composed of a single layer of fibers, which have been impregnated with matrix material. Laminae are stacked together with the fibers in the desired relative orientation, and the stack is heat treated so that the matrix forms into a continuous phase. The volume fraction of reinforcement is usually lower between the laminae than within each ply. Hence, the interlaminar volume is often the source of damage in the composite, and delaminations are often an important damage mode in PMCs and CMCs.

In laminated plates, delaminations are created by out-of-plane loads (often due to impact by foreign objects). They are invisible and can grow very quickly during subsequent loading of the part, resulting in stiffness degradation and premature failure of the composite part. This is particularly critical in the very brittle phenolic

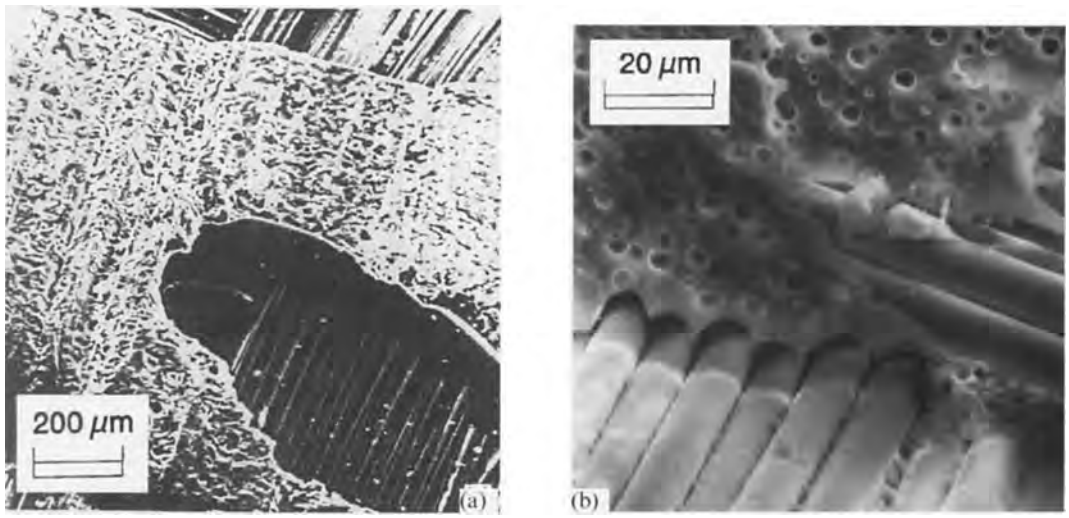

Figure 17. (a) SEM image (×50) of a delamination surface on a woven-glass fabric-reinforced phenolic resin. The delamination jumps from one fabric layer to another. The resin fragments clearly show the imprints of the glass fibers. (b) SEM image (×600) of the same delamination surface, showing that the delamination follows the fiber/matrix interface exactly (although a very thin matrix layer might still be present on the fiber surface).

resin composites [25]. Figure 17a shows a SEM micrograph of a delamination fracture surface of a woven fabric composite. The picture clearly reveals the fabric structure and a block of matrix, while imprints of the next fabric layer are visible in the matrix. The same figure shows that a crack jumps from one layer to the other (this often occurs due to the presence of large voids) and the crack path is near the fiber interface. Micrographs at higher magnifications (Fig. 17b) verify the presence of interface cracks and debonding.

Ply delamination is an important failure mode that occurs in laminated CMCs [15]. Figure 18 presents a central delamination observed in a failed silicon carbide fiber/borosilicate glass matrix composite.

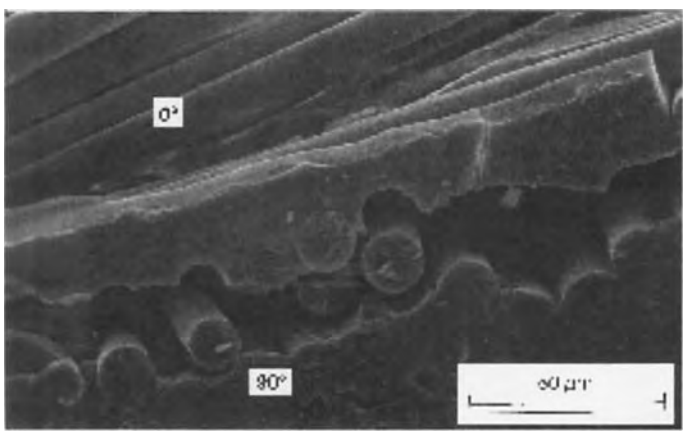

Figure 18. SEM image (secondary electron detector image, ×655) showing the central delamination in a cross-plied composite, consisting of Nicalon (silicon carbide) fibers and a Pyrex (borosilicate) glass matrix. This specimen was tested in three-point bending and the cracks propagated with preferential ease in the glass-rich area between the 0° and 90° plies.

Delamination cracks in cross-plied composites, such as the one shown in Fig. 18, propagate preferentially in the glass-rich layers between the 0° and 90° plies.

12.6.3 Interfacial Failure

The interface between the constituent phases can also be a weak area in a composite. This may actually be desirable in CMCs, but in the other types of composite it is usually not.

The development of damage in carbon-fiber-reinforced PMCs is also influenced by the interface properties. Carbon fibers are treated electrochemically to improve the bonding with the matrix. As a result, the fracture path changes [26], as shown in Fig. 19. In a composite containing untreated fibers, the fracture surface is directly at the fiber surface. Figure 19a shows a clean carbon fiber where the striations are still visible. Increasing the current density during electrochemical treatment results in a shift of the fracture path. In Fig. 19b, a thin resin layer (in this case with an unusual morphology, because the resin is a dual-phase system) is present on the fiber surface. A further increase in the treatment intensity results in a crack which runs through the matrix and the fibers are covered with a large amount of resin. The changes in the crack path have an important influence on the resulting mechanical properties of the composite.

The major drawback of monolithic ceramics for structural applications is their brittleness or, more accurately, their low fracture toughness, which leads to sudden catastrophic failure. A significant enhancement in the toughness of monolithic ceramics can be achieved via CMCs. This is due to the incorporation of a reinforcement (e.g. fibers or whiskers)

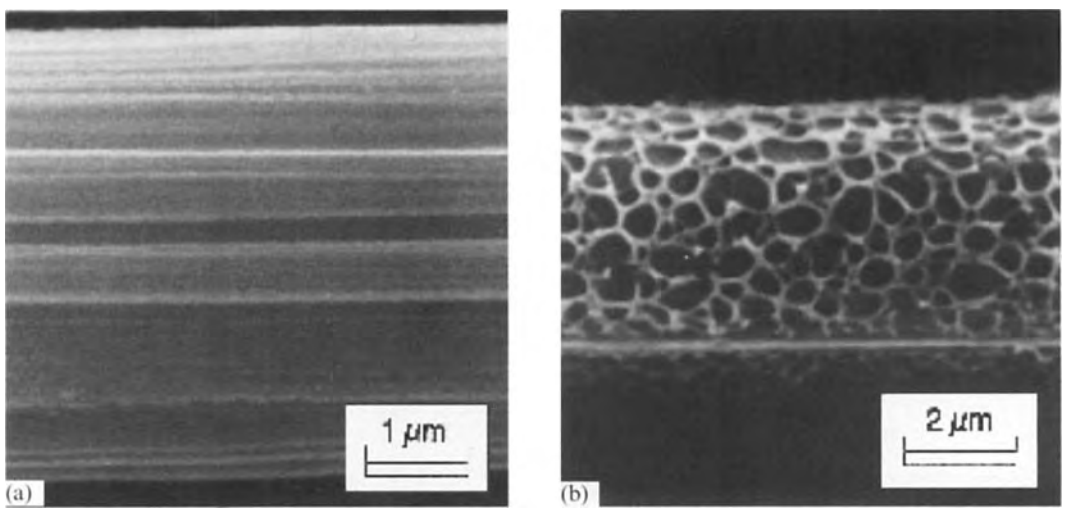

Figure 19. (a) SEM image (×11 400) of a carbon fiber in a fracture surface of a composite containing untreated fibers. The fracture surface has followed the fiber-matrix interface, demonstrating the low interface strength (C-Ep composite). (b) SEM image (×5950) of a carbon fiber in a fracture surface of a composite containing intermediately treated fibers. The low level of the oxidating surface treatment of the fiber creates an interphase between the fiber and the bulk matrix. The fracture surface follows the interphase layer (C-Ep composite).

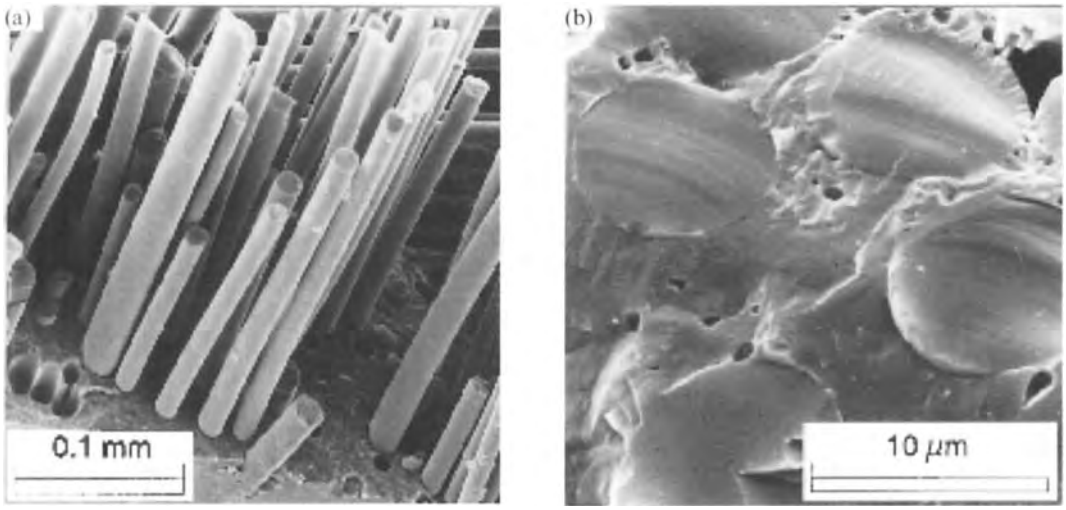

Figure 20. (a) SEM image (secondary electron detector image, ×186) of the fracture surface of a commercial Tyranno (silicon carbide with titanium nitride) fiber/BMAS (barium magnesium aluminosilicate) glass-ceramic matrix composite, the toughness of which is due to the large amount of fiber pull-out. (b) SEM image (secondary electron detector image, ×2620) of the fracture surface of the same composite after a heat treatment (900°C, 16 h), which resulted in degradation of the graphitic fiber-matrix interface. The failure changed from tough to brittle, with no fiber pull-out.

which may introduce into the ceramic matrix fracture energy-dissipating mechanisms, such as fiber-matrix interface debonding, crack deflection, fiber bridging, and fiber pull-out [15, 20, 27, 28]. Whether or not such toughness-enhancing mechanisms will in fact occur depends on the strength of the matrix-reinforcement interface. If the interface bonding between the fibers and the matrix is strong, an oncoming crack will not be influenced by it and this will lead to brittle failure of the composite. On the other hand, weak fiber-matrix bonding can serve as a crack arrestor, increasing substantially the fracture toughness of the composite [27, 28]. The properties of these interfaces need to be controlled closely during the production of CMCs; they may also evolve during service of the material.

The tough behavior of a commercial silicon carbide fiber/BMAS glass–ceramic matrix composite shown in Fig. 20a is characteristic of a class of composites that have a graphitic (C) fiber-matrix interface [27–30]. This interface is formed during hot-pressing of the composite according to the following oxidation reaction [29, 30]:

$$SiC(s) + O_2(g) \leftrightarrow SiO_2(s) + C(s)$$

and is responsible for the increase in the composite's fracture toughness.

Oxidative removal of the carbon interfacial layer followed by oxidation of the fiber surface and strong bonding between the fiber and matrix take place at temperatures above 500°C in air [29–31]. As a result, toughness is strongly reduced and this process severely limits the use of this class of composites at elevated temperatures. Figure 20b illustrates the brittle failure of the composite shown in Fig. 20a after it has been heat treated in air

and the graphitic fiber-matrix interface has been removed.

12.6.4 Particle Fracture

When a MMC reinforced with brittle particles is put under strain, the microscopic deformation cannot be homogeneous as the particles cannot be deformed. The macroscopic deformation of the material must, therefore, be accommodated either by plastic flow of the matrix around the particles, by interface debonding, or by particle fracture. The mechanism depends on the material and the stress state. The latter two mechanisms result in the presence of voids in the material, which can act as nucleation sites for larger cracks which in turn cause total failure.

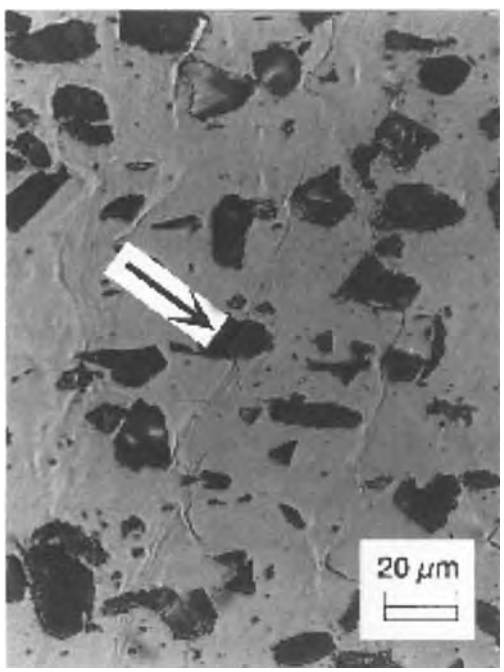

Figure 21. Particle fracture in 6061 aluminum containing 20 wt.% SiC particles. The material was first tempered to a T6 condition, after which the surface of the specimen was polished. Then 2.6% strain was applied, and the specimen was studied under the microscope as strained (LOM, using polarized light and Nomarski interference contrast). Arrow indicates fractured particles; fringes in the background material indicate localized strain.

It is not always clear from the study of fracture surfaces how the failure originated. To find this out, one must study the material during loading itself. One way to do this is by starting with a polished tensile specimen and studying it after different amounts of strain [32]. In this way damage features at the surface can be detected.

Figure 21 shows an Al–SiC composite studied under tensile loading. The particles crack to accommodate the plastic strain of the matrix, and these cracked particles act as nucleation sites for matrix cracks.

12.7 Concluding Remarks

In the present chapter the role of commonly available microscopy techniques such as LOM and SEM has been emphasized. Clearly, there is plenty of scope to use more advanced techniques, especially to characterize the interface between the constituent phases in composites. High resolution imaging and analytical techniques which have been used include transmission electron microscopy coupled with analytical techniques, such as energy dispersive X-ray spectroscopy, electron energy-loss spectroscopy, and Auger electron spectroscopy. For polymer-based composites X-ray photoelectron spectroscopy with high spatial resolution is appropriate because the technique also yields information on the type of bonding at

the interface. Secondary ion mass spectroscopy has also been used.

Internal stresses and strains are often an important characteristic of structural composites due to the differences in the thermal expansion behavior of the two phases. Indeed these play an important role in the selection of the constituent phases, particularly for MMCs and CMCs which are processed at high temperatures. Micro-Raman spectroscopy coupled with optical microscopy has found to be useful for characterizing composites with respect to internal stresses [33].

Finally, the importance of specimen-preparation techniques and quantitative image analysis in the field of composite materials cannot be overestimated.

13 The Structure of Polymers and their Monomeric Analogs

13.1 Introduction

The proposition of writing a short chapter about polymers is a task like that of Sisyphus; since the problem cannot be solved, one may be persuaded of the absurdity of human endeavor. In addition to this, the result is almost certain to create everlasting animosity from respected colleagues whose excellent work has not been included. It is hoped that the reader will understand that only a small representative fraction of work can be included and that the choice is partly dictated by personal interest in and understanding of certain aspects of the field, but also in order to create some continuity within the paper. Only in this way will it be possible to communicate some of the fascinating problems related to this field, in which it is essential for chemists and physicists to work closely together, a field in which molecules can be manipulated in an apparently infinite number of ways to produce specific physical properties. For this reason also, this chapter emphasizes work in which new methods have been developed and innovative materials investigated.

The role of the electron microscopist is to find the equations which relate physical properties to molecular structure and superstructure and to find ways of making these structures visible. The qualitative assessment of an image, however good it is, is usually inadequate for an analysis of the physical properties. Thus quantitative analysis is frequently essential, not only to quantify the results, but also to find an adequate way of varying one parameter so that the data can be used to verify or disprove an equation.

The aim of this chapter is not to present a comprehensive overview of the whole topic (since this is impossible), but rather to highlight specific, characteristic developments and problems in the elucidation of polymer structure and defects, while keeping the mathematics to a minimum. The appropriate references are, however, given. The author hopes that some cross-correlation with other fields can be initiated when it is realized, with the help of interdisciplinary publications such as this book, that many similar problems occur in the solid-state physics of different materials and that science would benefit from an exchange of information and expertise.

The chapter is divided into four major sections: the role of electron microscopy in elucidating structure–property relationships in the major polymer classes; the

use of new microscopic methods to study polymers; electron crystallography of polymers and their monomeric analogs; and high resolution transmission electron microscopy (TEM).

A discussion of experimental high resolution TEM images of polymers and their monomeric analogs has been included because, strangely enough in view of the beam sensitivity and associated difficulties of TEM, some major advances in understanding the structure of polymers have recently been made using this technique. Images and diffraction patterns from polymers frequently do not achieve the quality of their monomeric analogs; polymer crystals tend to be smaller and less perfect. Therefore a study of the appropriate monomeric analogs delivers crucial information about the molecular packing and orientation. The literature has been chosen such that at least one standard textbook is included in each subsection and representative specialized literature is included which gives an extended reference list and an overview of the subject.

13.1.1 Investigation of Polymers by Electron Microscopy

The investigation of polymers by electron microscopy is driven by the desire to improve specific physical properties. The nature of polymeric chains, with their enormous range of molecular architectures, enables an apparently infinite variety of structures to be achieved.

Polymers or macromolecules are found naturally in the form of silk, rubber, wool, cotton, wood, etc., as well as being synthesized to form plastics, fibers, paints, coatings, and liquid crystals. They are giant molecules with molecular weights between 10^3 and 10^6, connected to one another by covalent bonds which may be synthesized to form linear chains, branched chains, or networks. The chains interact through van der Waals forces, while the individual atoms of the chains are linked by covalent bonds.

The type of atoms involved and their specific arrangement and length gives macromolecules their chemical distinctiveness and particular function. The complexities are far too great for a mechanistic deduction of properties from the detailed structure of the constituent molecules, and so a statistical approach has played a dominant role in the treatment of the composition, reactions, and physical properties of polymeric substances [1].

Polymers are particularly difficult to image in both TEM and scanning electron microscopy (SEM) because they are composed primarily of atoms with small atomic numbers and low densities, so that contrast is low. In addition, all aliphatic and some aromatic polymers are beam sensitive, so that they are destroyed almost before the image can be recorded.

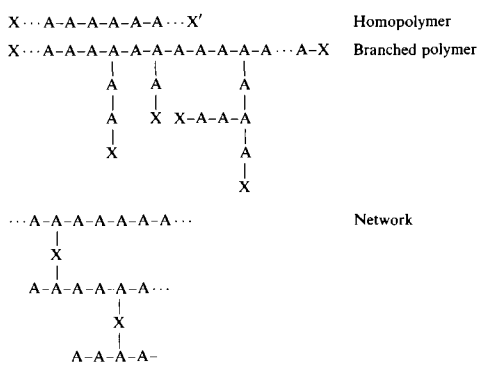
The interaction between the primary beam and the sample leads to many events which generate molecular fragments, secondary electrons, and X-rays. In addition, chemical changes such as cross-linking, degradation, and evolution of gases can occur at a rate dependent on the concentration of the respective species. A further disadvantage in the case of SEM is the nonconducting nature of polymers, which causes both charge and thermal build-up in the sample. If a polymer contains contaminants such as residual solvent, these may degas when placed in a vacuum and

cause polymerization reactions at the sample surface. This can give rise to a contaminating layer. Polymer microscopists have developed methods of preparation, recording, and analysis to cope with these problems, but they are generally specimen specific. For this reason, references have been chosen which clearly reveal the preparative procedures, but these cannot be treated in this article.

13.2 Structure–Property Relationships in the Major Polymer Classes

13.2.1 Homopolymers

Molecules composed of chemically and stereochemically identical units (apart from end-groups) are called 'homopolymers'; molecules with more than one kind of repeating unit are called 'copolymers'. If A represents the structurally repeating unit, and X,X′ are the end-groups, then geometries such as the following are possible:



The number of possible variations in chemical repeating units produces an enormous list of useful polymers. In addition to the many synthetic plastics, chain molecules such as polysaccharides, polypeptides, and nucleic acids can be organized into more complex macromolecular structures of great biological and biochemical importance. The effect of replacing chemical structural units on the physical properties is enormous. For example, if the hydrogen atoms in the linear homopolymer polyethylene are replaced by fluorine atoms, the melting temperature is increased by about 160°C and the coefficient of friction is decreased drastically. Alternatively, if aromatic rings are introduced into the chain backbone, the thermal and oxidative stability is enhanced and very rigid materials can be produced. Such polymers can replace metals in many applications.

The thermodynamics and statistical principles governing the behavior of polymers has been covered extensively by Flory [1]. Both the crystal structure and the superstructural arrangement of the crystalline entities are of paramount importance for the physical properties of these materials, and these are amenable to electron microscopic observation. Therefore homopolymers have been studied extensively by means of electron microscopy and electron diffraction.

13.2.1.1 Single Crystals

A large number of long-chain molecules can crystallize, depending on their molecular architecture and intermolecular forces. The crystals are generally much smaller than those of their monomeric analogs and are therefore inaccessible to light microscopy and X-ray structure

analysis, but are well suited to electron microscopy. The structure of homopolymer single crystals grown from solution and their relation to crystallization kinetics has been described in several books [2–4]. Some polymer single crystals have needle-shaped morphologies, but many polymers form flat or pyramid-shaped lamellar single crystals with a thickness which varies from about 100 to 500 Å and with lateral dimensions of several thousand angstrom or even tens of micrometers. The crystals vary in size, thickness, and shape depending on such factors as solvent, temperature, concentration, and rate of growth. Three typical examples are chosen to demonstrate the role that electron microscopy and diffraction has played in the elucidation of some fundamental problems related to these polymers. They represent the three major types of chain configuration: flexible chains, rigid chains, and helical chains.

Polyethylene

It has been shown by extensive electron microscopic studies [5–8] that polyethylene single crystals grown from dilute solution form hollow pyramids in solution which collapse when transferred to a substrate and form corrugations in the ⟨130⟩ directions in each of the four {110} sectors (Fig. 1b). Since electron microscopy has also played a decisive role in the interpretation of the fold surfaces in polymer single crystals, it is important to review this problem here.

The lateral extension of single crystals in the *ab* direction is generally in the micrometer range, whereas the crystallographic *c* direction, which is also the molecular direction, extends only to 100 Å, which is much less than the molecular length. It is clear, therefore, that the molecule has to fold at the crystal (lamellar) surface and to re-enter the crystal at a later stage during crystallization. The precise nature of this fold and the question of whether the molecule returns to this crystal in an adjacent or nonadjacent position was strongly debated in the literature for many years. Since the molecule emerging from the crystal surface is no longer confined to the closest packing induced by the crystal field, there is obviously a crowding problem at the lamellar surfaces where the molecule emerges. Density measurements clearly indicated that these surfaces consist of an amorphous overlayer [9–11]. This conclusion was supported by other evidence such as enthalpy of fusion and Raman spectroscopy measurements as well as other physical properties [12]. In contrast to this, infrared studies [13] and etching experiments were interpreted as indicating tight folding with strict adjacent re-entry [14].

Neutron scattering evidence from the small and intermediate scattering region of polyethylene single crystals indicated that some adjacent re-entry occurs at {200} growth faces, but that there is stem dilution along {110} growth planes [15, 16].

The role of electron microscopy in this important issue has been that the observation and analysis of sectorized crystals was interpreted for many years as clear evidence for tight folds with strictly adjacent re-entry. However, in a recent detailed comparative investigation of polyethylene and a series of nonfolded *n*-alkanes, it was shown that the relevant features of bright-field images related to the problem above are identical in unfolded *n*-alkanes and in polyethylene. These observations included the phenomenon of sectorization as well as

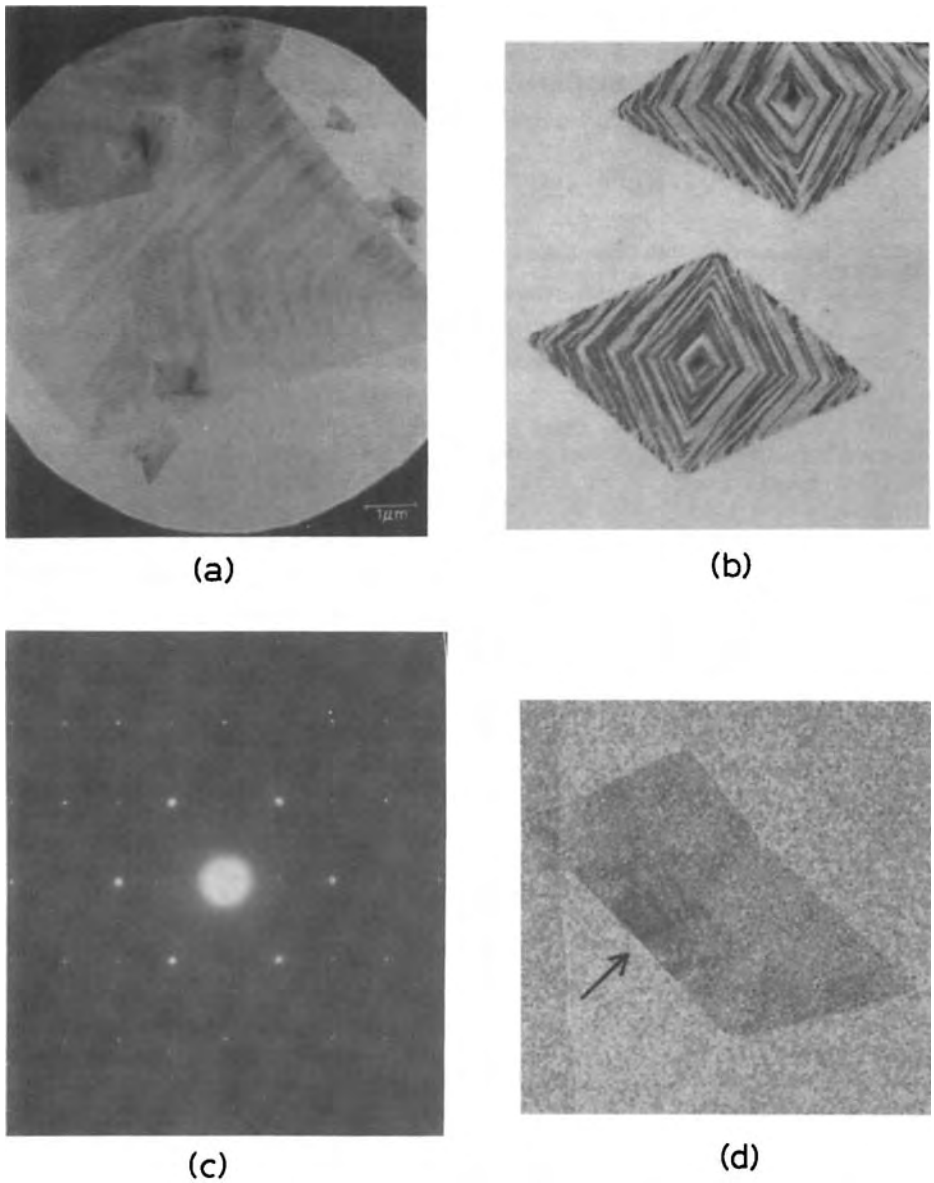


Figure 1. (a) Bright-field electron micrograph of a monolamellar crystal of paraffin n-$C_{82}H_{166}$. Bragg fringes are directed along $\langle 130 \rangle$ in $\{110\}$ sectors. (b) Images from collapsed polyethylene pyramids with Bragg fringes directed along $\langle 1\bar{3}0 \rangle$ in $\{110\}$ sectors. (c) $(hk0)$ diffraction pattern from orthorhombic paraffin crystal in space group $Pca2_1$. (d) Nonplanar crystal habit of n-C_mH_{2m+2} for $m \geqslant 44$ [17].

the orientation of diffraction contrast bands in individual sector domains (Fig. 1b). In addition, high resolution images [17] also demonstrated that the molecular packing of successive bands was similar in alkanes and polyethylene; therefore tight folds with strictly adjacent re-entry need not necessarily be invoked to

explain the observed phenomena in polyethylene. Further studies, in which n-$C_{50}H_{102}$ and n-$C_{60}H_{122}$ were co-crystallized in order to create a disordered surface, established that surface order is not a prerequisite for the phenomenon of sectorized crystallization [18]. A second important issue which was addressed in this investigation is that of chain tilt with respect to the layer normal (clearly the surface area per stem is increased by molecular tilt, thus alleviating the packing problem at the lamellar surface). This phenomenon is related to molecular symmetry, which is *mm* for an odd-numbered n-alkane and $2/m$ for an even numbered n-alkane. The former will pack preferentially in a rectangular array of untilted chains, whereas the latter is required to preserve a center of inversion in the layer packing and gives rise to oblique layers with tilted chain axes. In the case of polyethylene, it was shown that an oblique layer tilt axis occurs along the methylene subcell diagonal, corresponding to one of Kitaigorodskii's $R[\pm 1, \pm 1]$ layers [19]. The direction of this tilt axis was shown to change in each lamellar sector. It was shown that the growth of a three-dimensional lamellar habit from solution must be nucleated by a four-fold twin, where the lamellar sectors meet at the projected diagonals [18].

Poly(ether ether ketone)

Poly(ether ether ketone) (PEEK) is a high performance engineering thermoplastic, the repeat formula of which is $[C_6H_4OC_6H_4OC_6H_4CO]_n$, which has a very high melting temperature. Because of its high temperature/high strength characteristics, its exceptional chemical resistance, and its melt process ability, PEEK is extremely interesting for applications such as reinforced composites, coatings, electrical connectors, etc. In a series of articles describing electron microscopy and diffraction in PEEK, it was shown that the unit cell in the narrow fibrous crystals is orthorhombic ($a = 7.75$, $b = 5.89$, $c = 9.88$ Å) (Fig. 2) and very similar to other aromatic polymers such as poly(*p*-phenylane oxide) (PPO) and poly(*p*-phenylane sulfide) (PPS) [20]. The electron

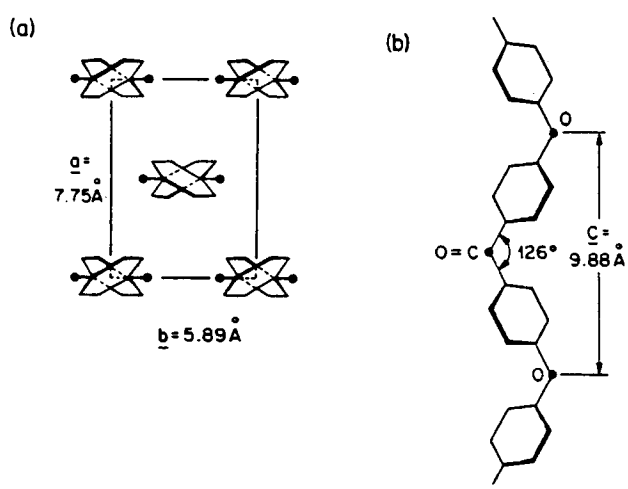

Figure 2. Projection of (a) the unit cell of PEEK along the *c* axis, and (b) the molecular conformation of PEEK along the *a* axis [20].

diffraction results were not consistent with the packing scheme obtained from X-ray results for PPO [21] and PPS [22] in which the molecules are located at the corners and center of an orthorhombic unit cell. The explanation for the puzzling double melting peak observed in these materials was subsequently shown by electron microscopy to lie in a second morphological form, having the same unit cell and *b*-axis preferred growth direction, but in this case the molecule is not parallel to the lamellar normal but inclined to it by 38.1°, leading to {102}-type fold surfaces [23].

Polypropylene

Polypropylene can be synthesized in the isotactic (iPP) and syndiotactic (sPP) forms. Electron microscopy has played a major role in establishing its structure. This includes the determination of the unit cell orientation and preferred growth direction in quadrites and spherulites of iPP [24], the elucidation of the molecular origin of lamellar branching [25], and the determination of the morphology and structure of the γ-polymorph [26]. The structure and defects of sPP were studied by using a combination of X-ray scattering, electron diffraction, and molecular modeling [27] (Fig. 3). The chain in its $(t_2g_2)_2$ conformation was shown to pack in a fully antichiral orthorhombic cell along both the *a* and the *b* axes, with $a = 14.5$ Å, $b = 11.2$ Å, and $c = 7.4$ Å. Crystallization at lower temperatures causes streaking on $\{h20\}$ spots in electron diffraction, indicating defects along the *b* axis consisting of rows of chains displaced by $b/4$. In a subsequent paper on their morphology, these crystals were shown to exhibit transverse fractures, which are associated with an order of magnitude greater thermal expansion along the crystallographic *b* axis with respect to the *a* axis. This has drastic consequences on the mechanical properties [28].

These representative examples of crystal structure and morphology obtained from three major types of macromolecules demonstrate that electron microscopy can provide crucial information about fundamental issues in polymer physics, but that these results have to be viewed in the larger framework of other methods such as X-ray and neutron scattering, differential scanning calorimetry, and density measurements, as well as Raman and infrared data. Fortunately, there has been an increasing tendency towards more collaborative research between scientists from different fields of expertise, a development which is certainly in the interest of polymer science.

13.2.1.2 Bulk Morphology

Linear polymers can crystallize with varying degrees of order. Most polymers crystallize by chain folding to form thin lamellae, the internal structure of which corresponds to that of single crystals. This central core is similar to crystals of a monodisperse oligomer. The essential difference with respect to single crystals from solution is the trajectory of the molecular chain in the noncrystalline regions, since in the bulk these serve to connect the crystalline entities with one another. As flexible molecules form Gaussian coils in the melt [1], the question arises as to how they reorganize during crystallization in order

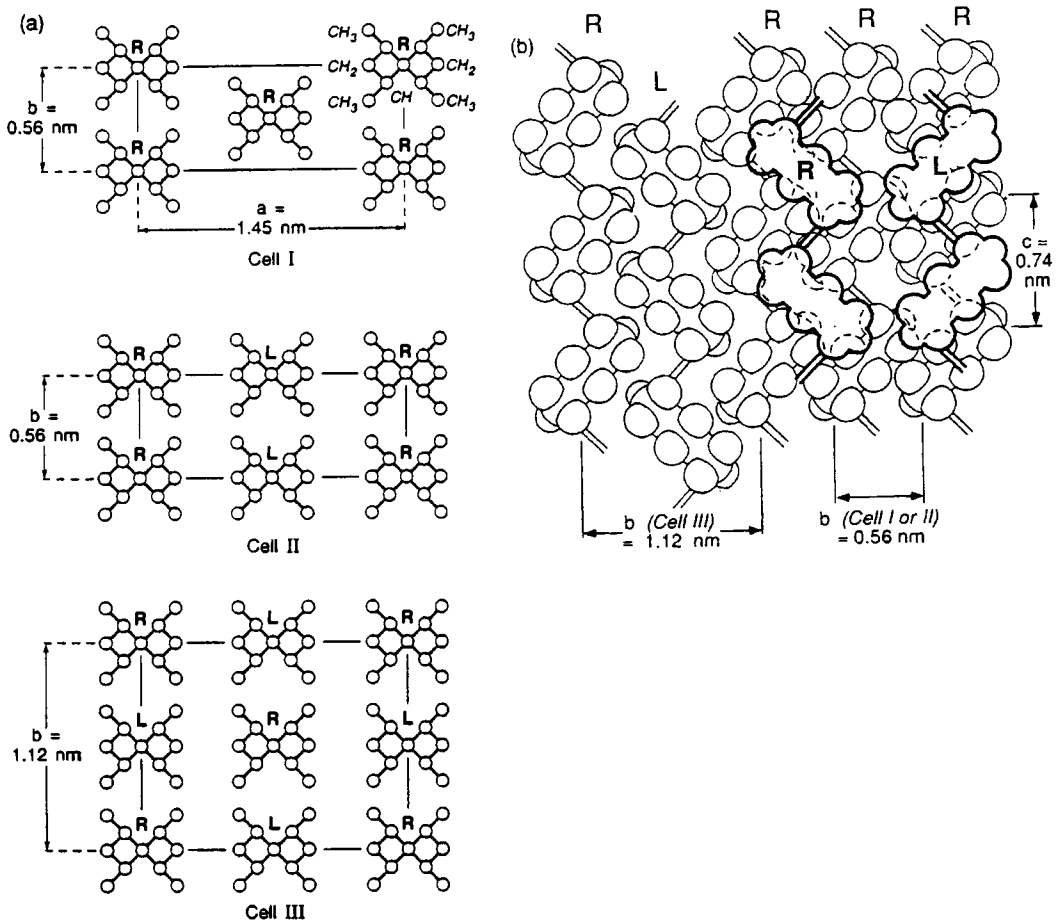

Figure 3. (a) Proposed unit cells for the stable $(t_2g_2)_2$ form of sPP, shown in the *c* axis projection. Cell I: fully isochiral cell, carbon centered. Cell II: Primitive cell with antichiral packing of chains along the *a* axis. Cell III: fully antichiral, body-centered cell. Right- and left-handed helical molecules are denoted by R and L, respectively [27]. (b) Schematic diagram showing the origins of isochiral (RRR) and antichiral (RLR) molecular packing in sPP. While the right-handed molecule can deposit only between a pair of right-handed substrate helices, the left-handed molecule can deposit only directly on top of a right-handed one. The left half shows that only antichiral deposition is possible for a cell III substrate [27].

to form a condensed phase in which lamellae with a typical thickness of about 100 Å are interspersed with amorphous regions. Depending on the crystallization conditions, the lamellae become twisted and radiate from the center to produce a spherulite: the radiating primary lamellae are interspersed with secondary lamellae which crystallize during cooling, and with amorphous chains which are located at the surfaces of both primary and secondary lamellae as well as at the crystal edges. The degree of twist and bend depends on the molecular weight and cooling rate.

Kinetic studies of the crystallization process have shown that the morphology of bulk polymers depends on the crystallization temperature and the rate of

cooling [29–31]. An analysis of crystallization rates in the vicinity of the melting temperature showed that polymer crystallization is a nucleation-controlled process. The details of the nucleation process were first analyzed by Hillig for the nucleation and subsequent growth of small molecules on previously formed substrate [32]. The conclusions can be adapted in a straightforward manner, without recourse to molecular models, for the crystallization of long-chain molecules [33–36]. Undoubtedly, the major type of superstructure observed in bulk polymers is the spherulite. For the detailed elucidation of spherulite morphology by surface replication methods, the work of Bassett represents a major contribution. The technique of permanganic etching [37] has shown the arrangement of crystallites (lamellae) in many bulk polymers, revealing screw dislocations on lamellar surfaces as well as the organization at a superstructural level. Two images of high- and low-density polyethylene prepared by using this method are shown in Fig. 4. Subsequently the superstructural organization of lamellae was studied in other technologically important polymers, notably poly(aryl ether ether ketone) [38] and isotactic poly(4-methylpentene-1). The universal feature was shown to be the crystalline lamellae with branching at, and divergence from, giant screw dislocations, leading to a space-filling (spherulitic) framework of dominant lamellae with the fastest growth direction being radial [39]. Subsequent growth occurs within this framework. The genesis of screw dislocations can be controlled by increasing the undercooling, giving rise to dislocations at the resulting interface. The asymmetry in growth terraces associated with a screw dislocation is expected to give rise to a twist because of lamellar divergence. The well-known appearance of banded spherulites was shown to be linked to the formation of isochiral screw dislocations coupled with the tendency of adjacent lamellae to diverge. The electron microscopic investigation on poly(4-methylpentene-1) combined with differential scanning

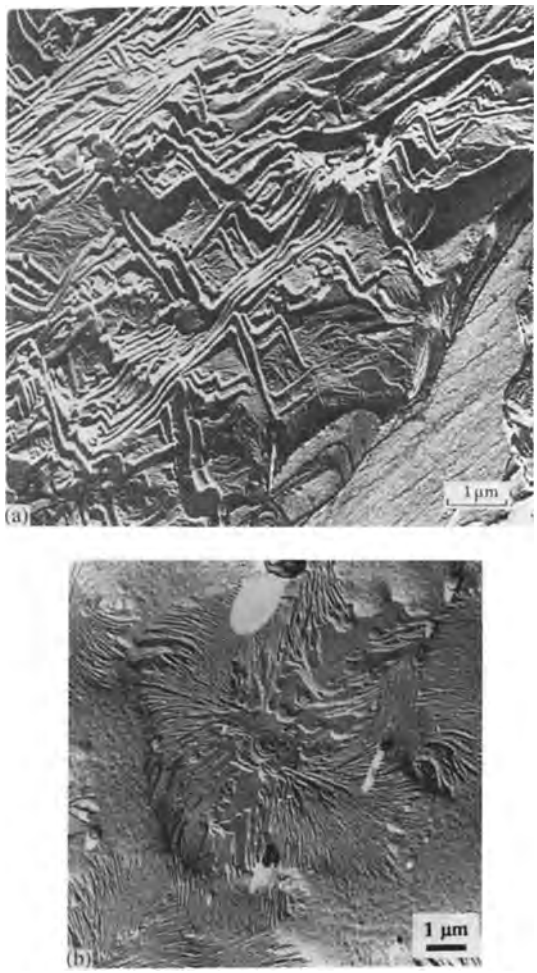

Figure 4. (a) High density polyethylene showing ridged (roof-shaped) lamellae and thin (secondary) lamellae [37]. (b) Embryonic spherulites of linear low-density polyethylene grown at 124°C [39].

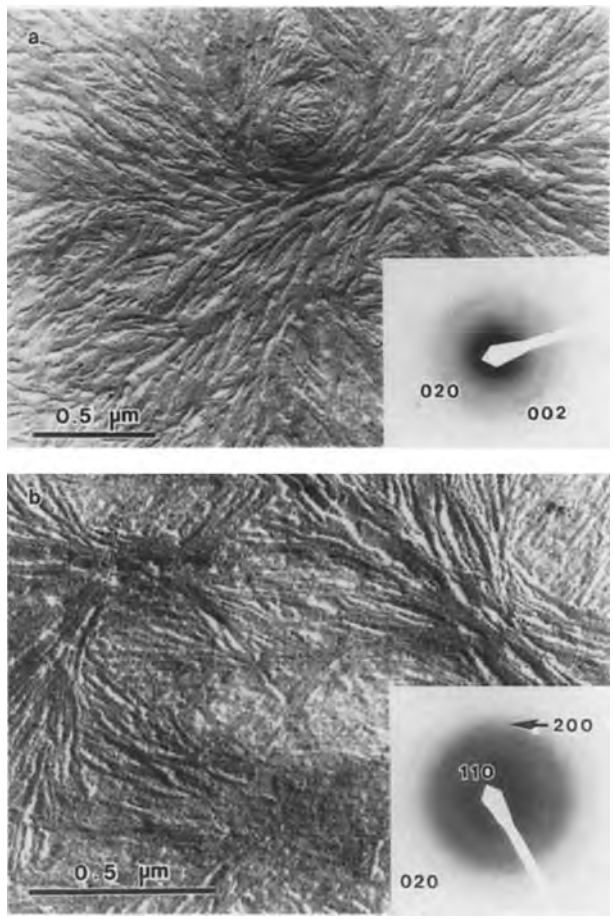

Figure 5. Bright-field transmission electron micrographs and selected-area diffraction patterns from thin PEEK films crystallized at (a) 270°C and (b) 250°C. The diffraction pattern in (a) stems from the lower left-hand region of the field, while that in (b) arises from the central region [41].

calorimetry verified earlier results on polyethylene, poly(aryl ether ether ketone)polypropylene [40], and poly(aryl ether ether ketone) (Fig. 5); that is, that the subsidiary lamellae melt at lower temperatures than the dominant lamellae [41]. Furthermore, subsidiary lamellae deform earlier during tensile drawing. In contrast to the branched copolymers, where many chain branches are expected to be located at the crystal surfaces, thus preventing isothermal crystal thickening, the linear materials have repeatedly shown this phenomenon. Electron microscopic studies on poly(4-methylpentene) revealed that, when already existent lamellae are held slightly below their melting point, local effects at lamellar edges lead to continuous lamellar thickening, thus achieving higher stability and melting points.

While surface replication methods such as these give detailed qualitative information about the morphology and superstructural arrangement of polymer crystallites within the spherulites, a quantitative assessment of crystal growth became increasingly essential as fundamentally different concepts regarding the nucleation and growth of polymer crystallites, as well as their surface morphologies, gave rise to apparently

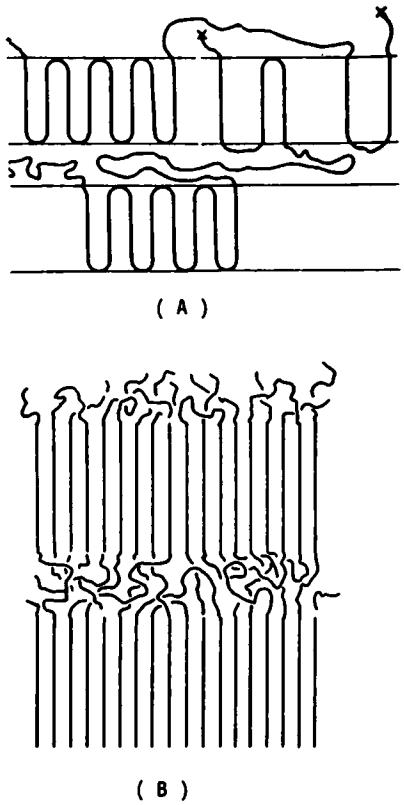

Figure 6. Two examples of proposed models for the structure of the amorphous regions in semicrystalline polymers: (a) central core model with eight adjacent re-entry folds in the cores; (b) 'switchboard' model [42].

insoluble controversies. The sketch shown in Fig. 6 summarizes the molecular trajectory problem [42] which is concerned with the question of whether or not the molecule emerging from the crystal surface returns to the same crystal in an adjacent position with tight folding. The question relating to the number of molecules between crystallites and their conformation in the non-crystalline sequences has direct bearing on: the strength of polymers; their fracture, crazing, and yield behaviors; the glass transition temperature; diffusion; and physical aging [43–45].

For polymeric molecules the temperature interval just below the equilibrium melting temperature is a metastable zone in which nuclei do not form at a detectable rate but in which crystals, once formed, can grow (regime I). Below this metastable temperature zone, nuclei may form spontaneously, either homogeneously or heterogeneously (regime II). As the substance cools further, a high-viscosity zone is reached where the formation of nuclei is again inhibited and growth is again very slow (regime III). Studies of the overall crystallization of spherulites in linear polyethylene over an extended molecular weight range showed that the temperature coefficient of the overall crystallization rate increases by a factor of 2 during the transition from regime I to regime II [46, 47].

From these considerations, and from experimental light scattering evidence, it became clear that the supermolecular organization of lamellae depends on both the undercooling and the molecular weight in a complex manner. This was first demonstrated for linear polyethylene in a light-scattering study by Maxwell and Mandelkern [36] (Fig. 7) and subsequently for branched polyethylene using molecular fractions [48]. A detailed analysis of the crystallite morphologies underlying these superstructures in different temperature and molecular weight regions was undertaken in a series of electron microscopy studies of thin microtomed sections stained with chlorosulfonic acid and uranyl acetate, a method first proposed by Kaning [49]. Typical morphologies are shown in Fig. 8 for linear polyethylene. Roof-shaped and curved lamellae are observed for low and high undercoolings, respectively [50, 51]. It is clear that these

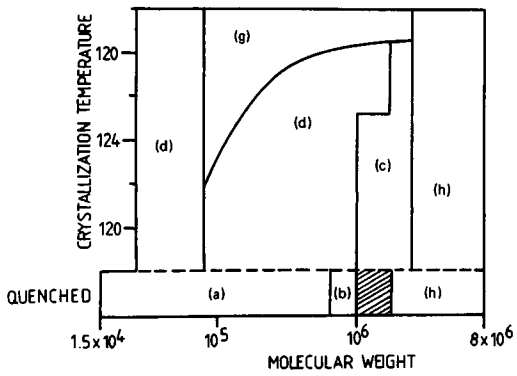

Figure 7. Schematic of the observed morphology in linear polyethylene as a function of molecular weight and crystallization conditions. The letters in parentheses refer to the morphologies: (a) spherulites consisting of curved lamellae; (b) spherulites consisting of twisted lamellae; (c) poorly developed spherulites; (d) large lamellar sheets; (g) lamellar sheets with multiple corrugations; (h) thick curved lamellae interspersed by thin lamellae [36].

features are identical to the ones described by Bassett on the basis of surface replica studies performed at about the same time. However, staining also revealed three important parameters, namely the thickness of the amorphous and crystalline regions as well as the molecular tilt with respect to the crystal surfaces. The images immediately suggest that the lamellar morphology and thickness of the (black) amorphous regions is related to the molecular trajectory, and this in turn is related to the molecular weight and undercooling. When the crystal tilt angle (not to be confused with the above molecular tilt) with respect to the electron beam is optimized for maximum contrast, the data can be quantified and the dependence of the crystal thickness d_c plotted as a function of molecular weight for the linear material (Fig. 9). These investigations thus revealed details about lamellar thickness as a function of molecular weight and crystallization temperature which were crucial for the understanding of crystallization kinetics and mechanical properties [52].

The electron micrographs also provided the information about the molecular tilt with respect to the lamellar normal in linear bulk material (as determined from the apex angle of the roof-shaped lamellae) and showed that the fold surfaces are predominantly $(\bar{1}01)$ in regime I, but $(\bar{2}01)$ and $(\bar{3}01)$ in regime II [53]. The results clearly demonstrated that the tilt angles increase with larger undercoolings because this alleviates the problem of dissipating the flux of chains emanating from the basal plane of the crystallites and that this phenomenon is related to the transition from regime I to regime II crystallization kinetics.

For branched co-polymers containing short branches at typical mole fractions of a few %, numerical analysis of electron micrographs and Fourier transformed small-angle X-ray scattering results provided the information required to formulate a new model of melting and crystallization for ethylene copolymers, which was shown to be quite different from the mechanism taking place in linear systems [54, 55]. In contrast to linear polyethylene, where lamellae continue to thicken at high temperatures, branched polyethylene shows a reversible change in long spacing related to the amorphous regions, while the crystallites retain their thickness, which is in fact related to the average distance between branches so that branches are located preferentially at the crystal surfaces [31, 52], thus preventing crystal thickening (Fig. 10).

The possibility that numerical values in stained thin sections may be falsified by beam damage or microtoming should

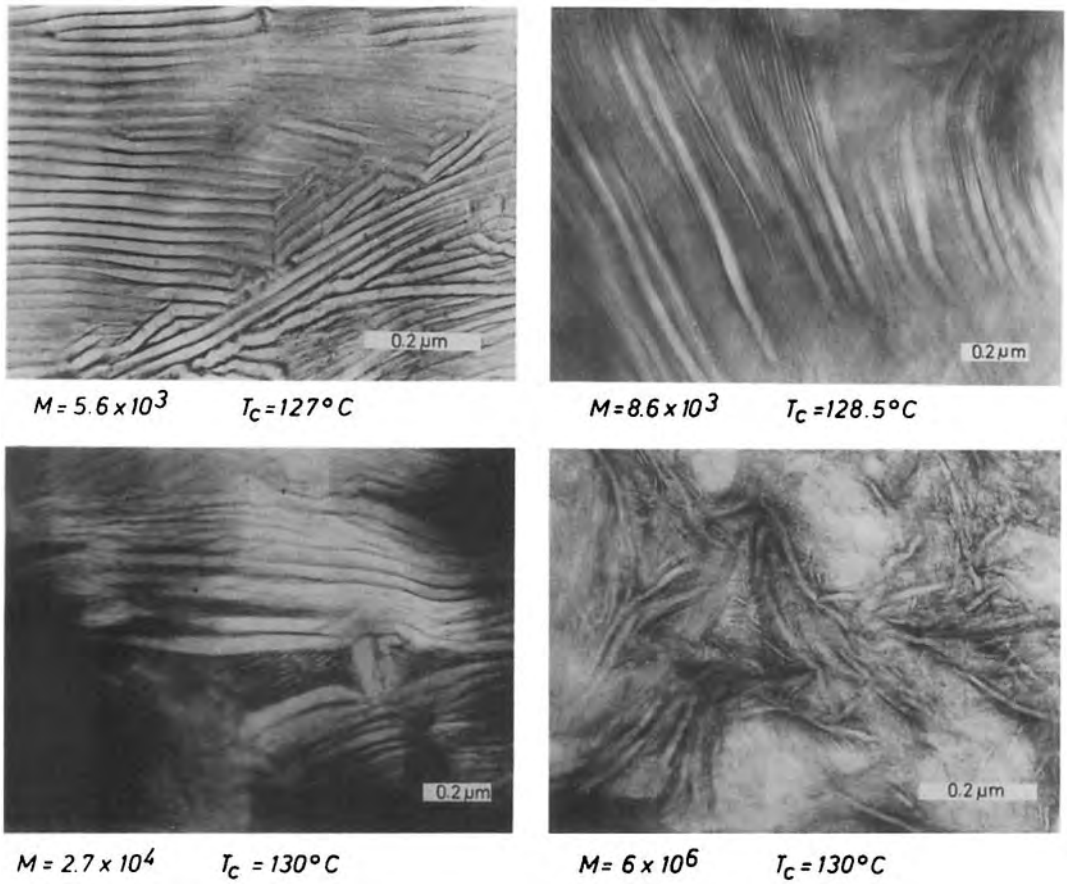

Figure 8. Lamellar morphology of linear high density polyethylene as a function of crystallization temperature and molecular weight [50, 52].

always be recognized and can be avoided by (1) proper attention to experimental procedures and (2) quantitative comparison with the results of X-ray small angle scattering [54] and Raman longitudinal acoustic mode measurements [56, 57] (Fig. 11).

In view of its enormous strength in providing detailed numerical information, it would be very short-sighted to reject quantitative analysis of electron micrographs because of difficulties (which can be overcome). Undoubtedly the insight into lamellar morphology provided by numerical electron microscopic investigations has also contributed to the understanding of polymer structure which has made the development of new materials with improved physical properties possible.

13.2.1.3 Defects in Bulk Polymers

Long before high resolution methods became generally useful in the investigation of polymers, electron microscopy played a crucial role in the characterization of polymer defects, which are of course related to the specific nature of the intermolecular and intramolecular

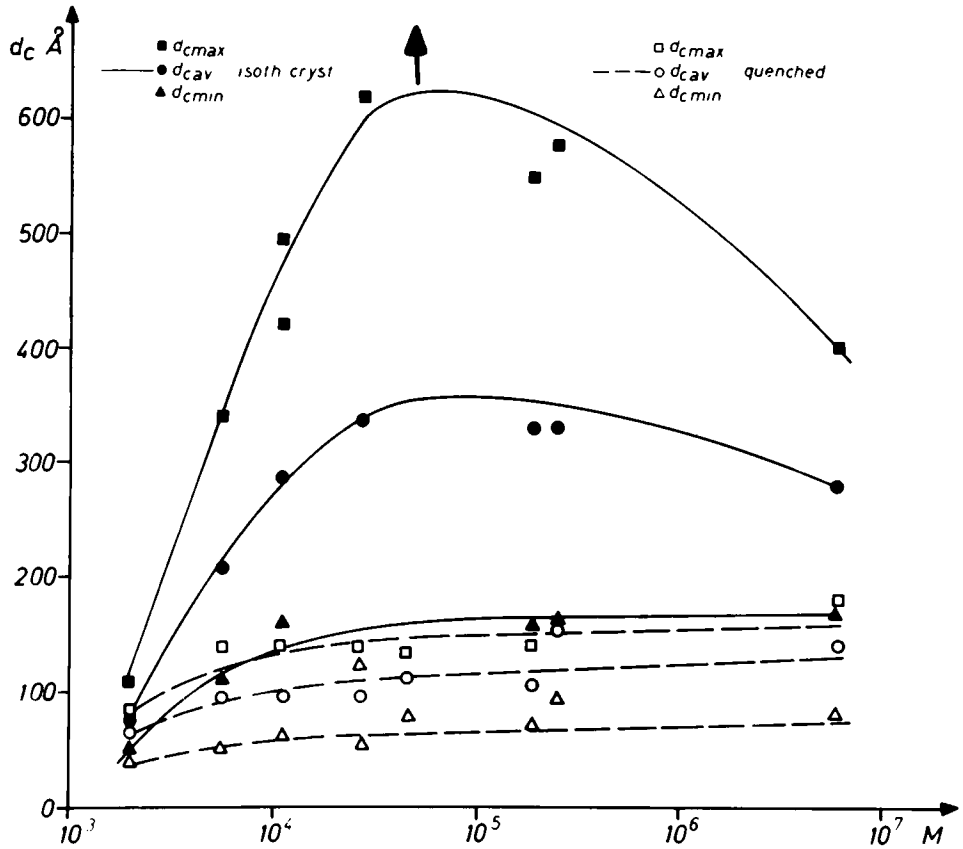

Figure 9. Dependence of crystal thickness on molecular weight [52].

bonds, local defects in bonding, chain branches, chain ends, etc. The analysis of such defects has been given impetus by the necessity to understand their effect on the mechanical, electrical, and optical properties as well as on the phase transitions and surface properties of polymers. In addition, the deliberate manipulation of defects offers the possibility of creating and controlling specific microstructures in ordered polymers [58]. Specific defects which have been identified by electron microscopy include elongated point defects, line defects, and grain boundaries.

Elongated point defects

Local translations and rotations of the polyethylene chain give rise to a family of single chain point defects [59].

Line defects

Line defects in polymers include dislocations (singularities in translational order), disclinations (singularities in orientational order), and dispirations (singularities in both translational and orientational order).

Screw dislocations, which have been associated with lamellar single crystal growth, have been identified in a careful

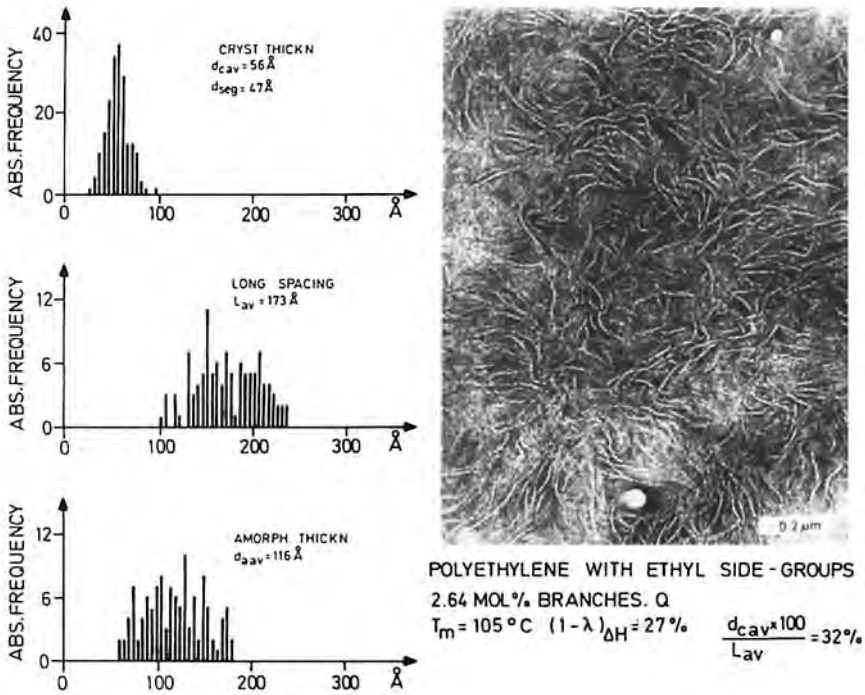

Figure 10. Polyethylene with ethyl side-groups: 2.64 mol% branches, $QT_m = 105°C$, $(1 - \lambda)_{\Delta H} = 27\%$; $(d_{cav} \times 100)/L_{av} = 32\%$ [52].

study as a four-fold twin in which lamellar sectors meet at the projected diagonals [60].

Edge dislocations in diacetylenes have been identified by etching experiments [61].

Aggregations of dislocation have been shown to create grain boundaries which can accommodate tilt or twist between domains [62].

The molecular organization of liquid crystalline polymers has been studied for $s = \frac{1}{2}$ disclinations [63] and for $s = 1$ disclinations [64] where s is the disclination strength.

Grain boundaries

Grain boundaries in extended chain crystalline polymers have been discussed extensively by Martin and Thomas [65]. In addition to these, specific defects related to copolymers are discussed in the following section.

13.2.2 Copolymers

When linear chains consist of different kinds of repeating units, A and B, they are called 'copolymers'; in this case either one or both of the components are amorphous. There are four extreme possible arrangements:

A–B–A–B–···	Alternating copolymer
A–A–A–A–B–B–B–A–A–A–A–	Ordered copolymer
···A–B–A–A–B–B–B–A–B–B–	Random copolymer
···–A–A–A–A–A–A–A–	Graft copolymers
	B B
	B B
	B B
	B B

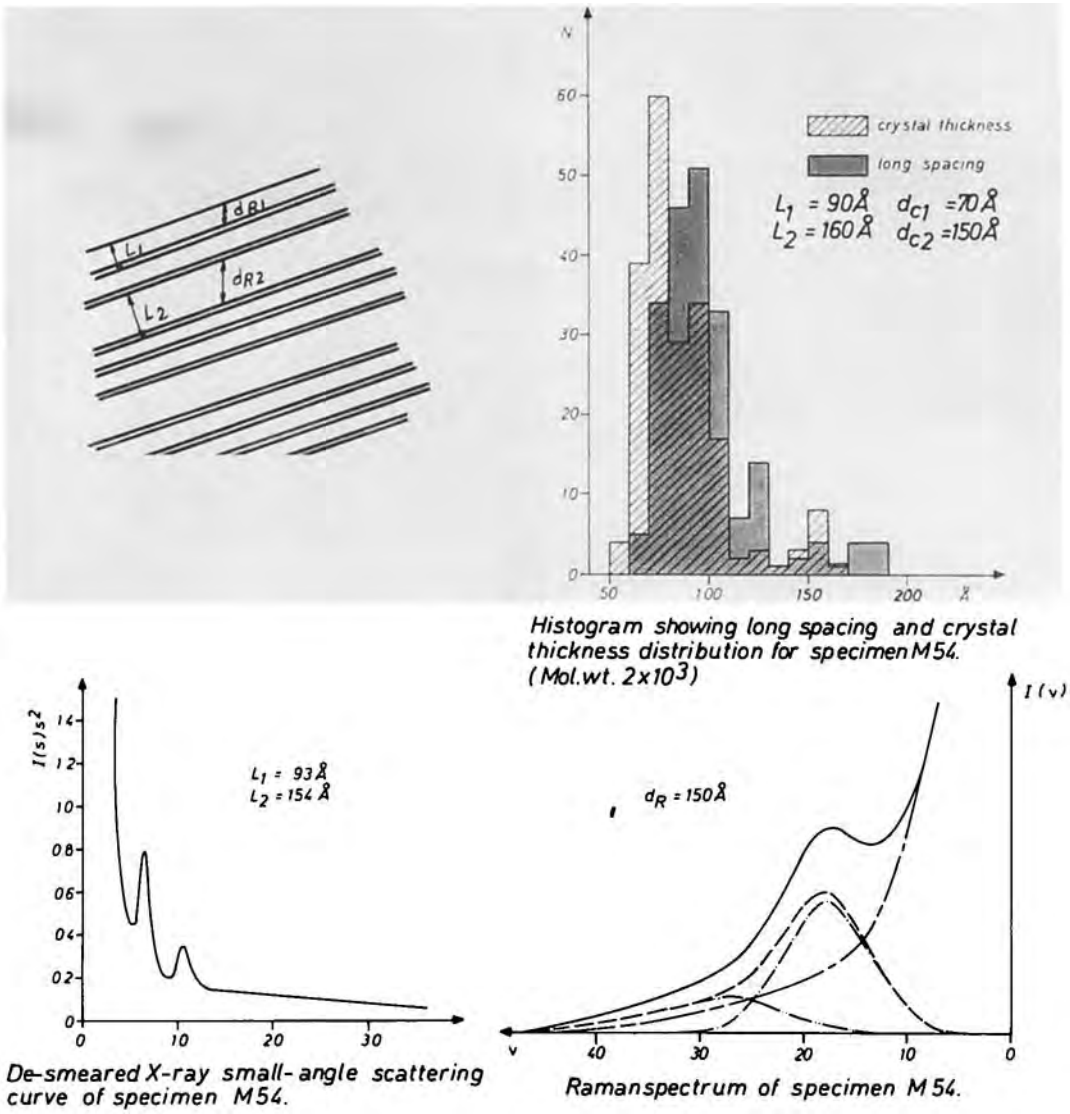

Figure 11. Comparison between Raman, Electronmicroscopy and small angle x-ray scattering for binodal distribution of lamella thickness and long spacing distribution in polyethylene. Molecular weight = 2×10^3 Da; $T_c = 117.3°C$ [57].

The different arrangements and types of copolymer unit give rise to very rich phase diagrams with an enormous range of superstructures, each of which gives rise to different physical properties. Here the emphasis usually lies on the optimization of mechanical properties, but it is quite feasible that specific optical or dielectric properties will be required. The chemistry and physical behavior of block copolymers have been reviewed in several comprehensive books [66, 67].

13.2.2.1 Equilibrium Morphologies

Theoretical considerations for the case of symmetric AB diblock copolymers consisting of two kinds of polymer A and B with the same degree of polymerization have been pioneered by Helfand [68] for the strong segregation limit and by Leibler for the weak segregation limit (WSL) [69]. For the WSL, Leibler has used the mean-field theory to explain the emergence of lamellar structures. Monte Carlo simulations on the ordered structures of bulk systems have been reported by Fried and Binder [70].

The complexity of the superstructures for more complicated systems makes electron microscopy a mandatory tool for their investigation and a basis for model calculations. Some possible staining agents are OsO_4 and RuO_4, depending on the components involved. Melts of AB diblock copolymers form phase-separated structures in which domains of one phase are separated from those of the other by an interfacial region. Early theories predicted three stable, ordered morphologies in both weak and strong segregation limits: alternating lamellae of A and B, hexagonally packed cylinders of A in matrix B, and spheres of A in matrix B [71].

Electron microscopic studies of star block copolymers identified a new 'equilibrium' microdomain morphology in styrene–isoprene copolymers, namely the ordered bicontinuous double-diamond (OBDD) [72]. The basic unit of the structure is a tetrahedral arrangement of short polystyrene rods (Fig. 12). Such units are interconnected on a cubic lattice with *Pn3m* space group symmetry. The resultant structure consists of two translationally displaced, mutually interwoven but

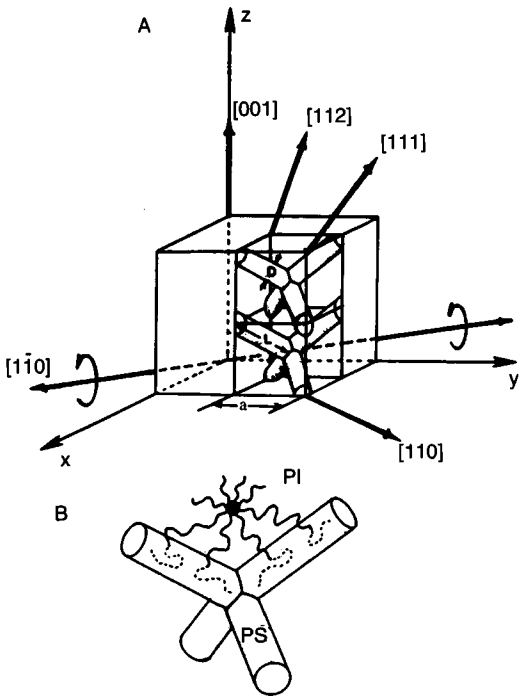

Figure 12. (a) Schematic of the OBDD structure showing the arrangement of the basic tetrahedral units. These interconnect to form two interwoven, but independent, diamond networks of polystyrene rods. (b) Schematic of the arrangement of the polystyrene and polyisoprene chains in the OBDD domain space [72].

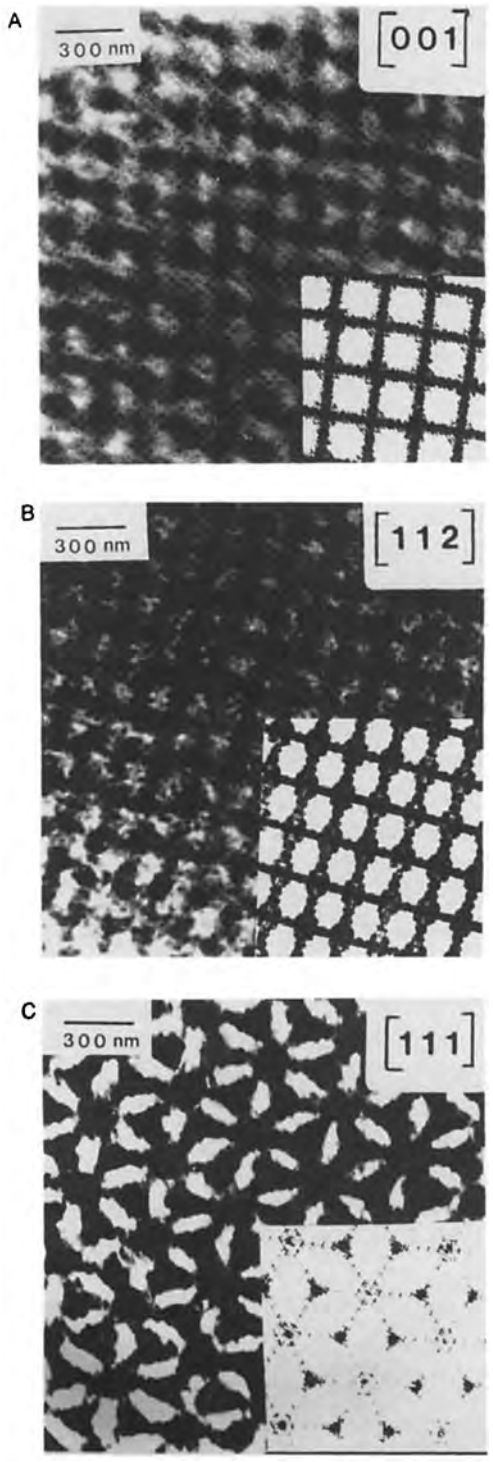
unconnected three-dimensional networks of polystyrene rods embedded in a polyisoprene matrix. By comparing computer-generated images with experimental images, it was shown that each of the separate polystyrene networks has the symmetry of a diamond cubic lattice (Fig. 13).

Recently, methods have been developed for calculating the free energy of bicontinuous morphologies in the strong segregation limit [73]. In the weak segregation regimes, a variety of new structures have been identified; the lamellar-catenoid [74, 75], hexagonally modulated lamellae, hexagonally packed lamellae [76], and the



double gyroid [77]. The analysis of such morphologies makes tilting series and a comparison with X-ray scattering mandatory, as the following example from Hadjuk et al. [77] indicates. Thin sections of a polystyrene–polyisoprene copolymer were microtomed at −100°C, stained with OsO_4, and examined in different projections in a 200 kV JEOL 200 CX electron microscope. Two prominent projections indicated a cubic and a hexagonal geometry. Selected regions of the images were then digitized, a two-dimensional Fourier transform performed, and the geometry in the images deduced as [100] (Fig. 14) and [111] projections of a cubic structure. Parallel to this, small angle X-ray experiments on the same sample revealed reflections at position ratios $\sqrt{3}:\sqrt{4}:\sqrt{7}:\sqrt{8}:\sqrt{10}:\sqrt{11}:\sqrt{12}:\sqrt{13}:\sqrt{15}:\sqrt{16}:\sqrt{19}$, consistent with an *Ia3d* space group. Subsequently, computer models of structures with space groups consistent with the observed reflection ratios and extinctions were simulated in both direct and reciprocal space from different projections and used to analyze the TEM images and diffraction patterns. The theoretical concepts behind the model structures are based on the creation of minimal surfaces. These are two-dimensional constructs embedded in three dimensions which possess zero mean curvature (ZMC) at all points on the surface, as proposed for bicontinuous fluids [78], or constant mean curvature (CMC), which minimize the area among all nearby surfaces produced by perturbations which

Figure 13. Images of styrene–isoprene copolymers showing the (a) [001], (b) [112], and (c) [111] projections, and the corresponding computer-generated images [72].

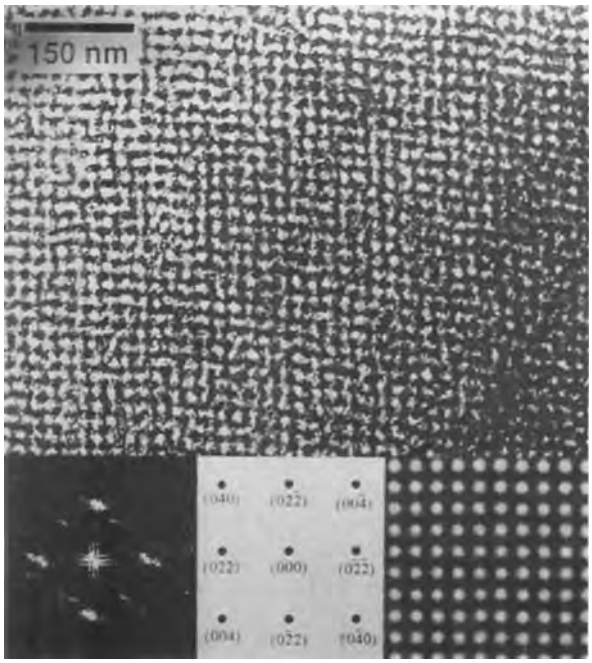


Figure 14. TEM micrograph of polystyrene–polyisoprene copolymer showing approximately four-fold symmetry corresponding to the [100] projection of the cubic structure. The insets show the image fast Fourier transform and indexed diffraction pattern. The inset on the right-hand side shows a simulated [100] projection of the constant-thickness gyroid structure [77].

preserve the volumes of regions on either side of the surface [79, 80]. The ordered bicontinuous double-diamond (space group *Pn3m*) and double gyroid (space group *Ia3d*) are examples of such structures. Finally, the model was viewed from the projections corresponding to the electron micrographs, and the Fourier transform calculated for comparison with the small angle X-ray scattering results. The results of the calculations for the gyroid structures are shown in Fig. 15.

In symmetric poly(A-block-B-block-C)triblock copolymers, electron microscopy has revealed a very rich phase diagram consisting of a multitude of new morphologies such as spheres and rings located at the surfaces of cylinders, multiple and single helical strands around cylinders (Fig. 16). In addition undulating sheets and cylinders (Fig. 17) embedded in a matrix of the major component [81–83] were characterized. An understanding of morphological features observed in these triblock copolymers is based on the following simplified considerations.

The free energy per chain (F_c/kT) in the strong segregation limit can be written as:

$$\frac{F_c}{kT} = \frac{F_c^{surf}}{kT} + \frac{F_c^{elastic}}{kT}$$

where F_c^{surf} is the surface free energy and $F_c^{elastic}$ is the elastic contribution

$$\frac{F_c^{surf}}{kT} = \gamma_{AB} \cdot \sum_{AB} + \gamma_{BC} \cdot \sum_{BC} + \gamma_{AC} \cdot \sum_{AC}$$

where $\sum_{xy}$ are the common contact areas of components x and y per chain experiencing a surface tension γ_{xy}

$$\frac{F_c^{elast}}{kT} = K_A\left(\frac{L_A^2}{N_A a_A^2}\right) + K_B\left(\frac{L_B^2}{N_B a_B^2}\right) + K_c\left(\frac{L_c^2}{N_c a_c^2}\right)$$

where N_A, N_B, and N_C are the number of

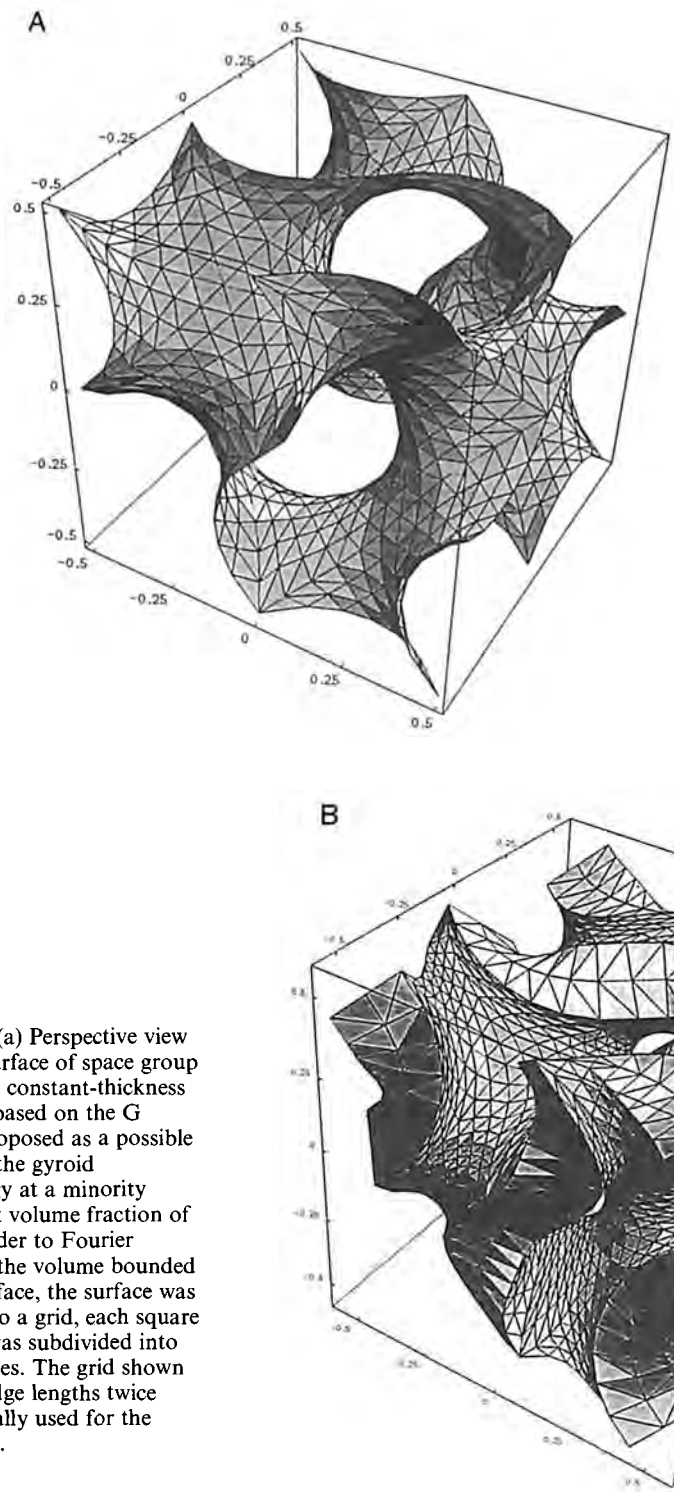

Figure 15. (a) Perspective view of the G surface of space group Ia^3d. (b) A constant-thickness structure, based on the G surface, proposed as a possible model for the gyroid morphology at a minority component volume fraction of 0.33. In order to Fourier transform the volume bounded by this surface, the surface was divided into a grid, each square of which was subdivided into two triangles. The grid shown here has edge lengths twice those actually used for the calculation.

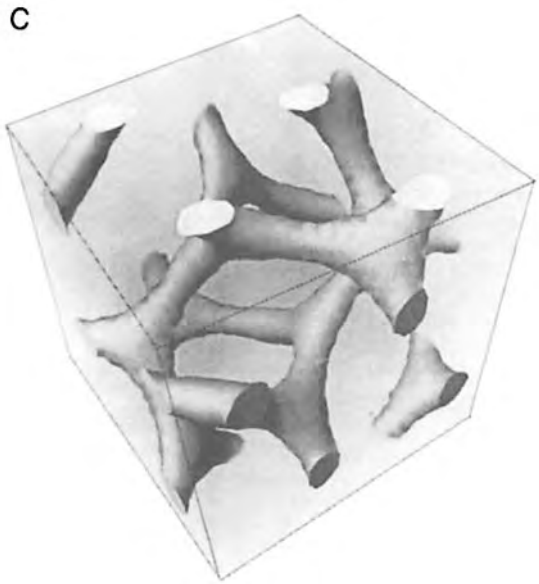

Figure 15. (c) The channel structure (minority component domains) of the constant-thickness model for the gyroid morphology [77].

monomer units of length a_A, a_B, and a_C, and L_A, L_B, L_C characterize a stretching of subchains A, B, and C, and K_A, K_B, and K_C are the force constants of the different subchains. L_A, L_B, L_C and the K values depend on the morphology of the system. The stability limit for different morphologies is obtained by minimization of the free energies. The calculations show that the morphologies which are observed by electron microscopy can be adequately predicted by theoretical arguments, and that morphological transitions can occur in ABC triblock copolymers by changing the thermodynamic balance even in the strong segregation limit. This offers an opportunity to tailor new mesoscopic microphase morphologies with specific physical properties by varying the degree of incompatibility between the components. Such ABC triblock copolymers are not only important because of the new microphase morphologies together with their associated unique mechanical properties, but also because of their potential as compatibilizers in polymer alloys [84].

13.2.2.2 Nonequilibrium Morphologies in Diblock Copolymers

Microphase separated equilibrium morphologies, such as spheres, cylinders, and lamellae are arranged within grain boundaries with very specific local arrangements (Fig. 18) [85]. The specific structure of the nonequilibrium boundaries has considerable impact on the physical properties such as elastic modulus and gas permeability, because these depend on the continuity of individual phases across the boundary. While considerably experimental [86] and theoretical [87–91] effort has been invested in the study of the equilibrium order–disorder transition and morphology versus composition phase diagrams, the grain boundary structure has only received attention more recently. In a series of articles grain boundary morphologies have been characterised in compositionally symmetric diblock copolymers forming lamellar morphologies (Fig. 19) [85].

Grain boundaries in three-dimensional crystalline materials such as metals and ceramics have five degrees of twist–tilt freedom [92, 93] of which only two, namely tilt and twist, are important for describing the grain boundaries in lamellar block copolymers, a system with only one-dimensional symmetry. The modeling approach is based on surfaces of constant mean curvature. The geometry of these interfaces was investigated by comparing experimental TEM images with ray tracing

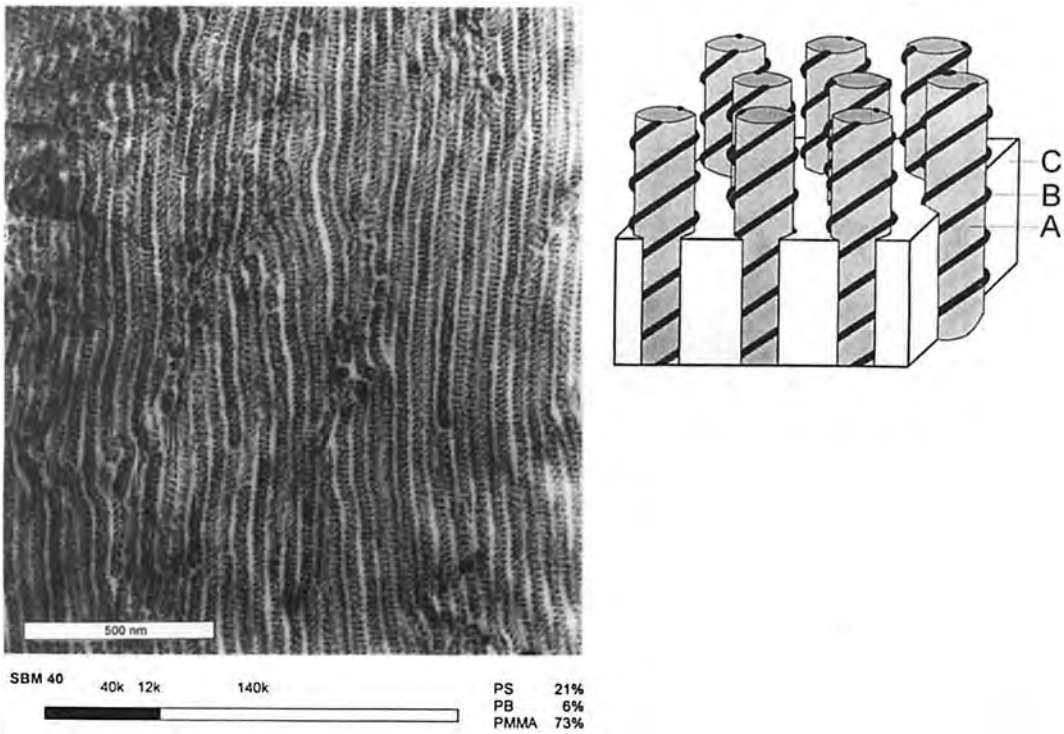

Figure 16. TEM micrograph of a triblock copolymer showing the twisted helices of polybutadiene (B) around polystyrene rods (A) in a polymethylmethacrylate matrix (C) for the compositions indicated [81].

computer simulations of the model surfaces as the projection direction was systematically varied. The two types of twist grain boundary which were observed by TEM were shown to have intermaterial dividing surfaces that approximate either Scherk's first surface or a section of a right helicoid (Figs 20 and 21) [94]. The helicoid section boundary was observed at low twist angles (<15°), while Scherk surface boundary morphologies, consisting of a doubly periodic array of saddle surfaces, was found over the entire twist range from 0° to 90° [85]. As the twist angle approaches zero degrees, the Scherk surface grain morphology transforms into a single screw dislocation which has an intermaterial dividing surface with the geometry of a single helicoid. TEM images showed the detailed core structure of this screw dislocation, and demonstrated that in lamellar diblock copolymers the screw dislocation core is nonsingular.

13.2.3 Blends

Polymer blends comprise a large class of materials in which different macromolecules are physically mixed, rather than chemically linked as in block copolymers. Generally, polymers do not mix homogeneously in solid solutions, but the phenomenon has been shown to occur in over 50 mixtures and has been investigated

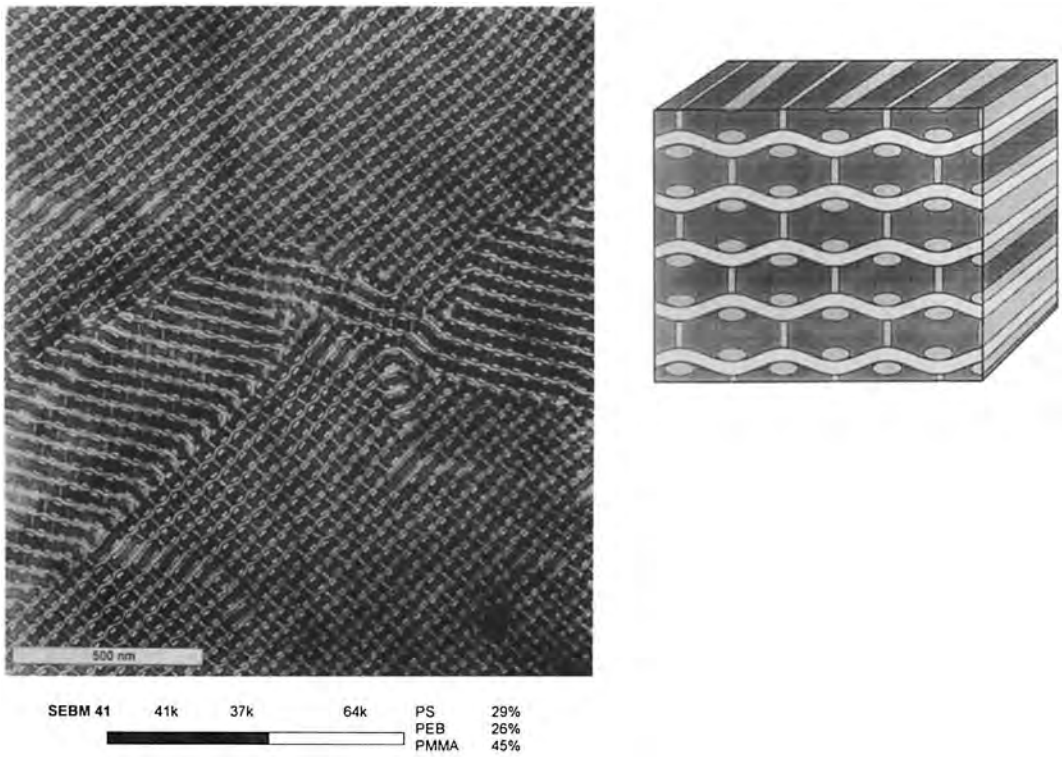

Figure 17. TEM micrograph of a triblock copolymer polystyrene–polyethylbutene–polymethylmethacrylate for the compositions indicated [82].

extensively both experimentally and theoretically [96]. Miscibility is generally limited to a certain temperature and one composition range; outside this range, the polymers phase segregate either by spinodal decomposition or by nucleation and growth.

When polymers form blends, they generally exhibit a lower critical solution temperature, as indicated in Fig. 22. The solid curves represent the cloud point (binodal) at which temperature and concentration the partial derivative of the Gibbs free energy G with respect to concentration is 0, that is $\partial G/\partial \Phi = 0$. The dotted curve encloses the spinodal region, where the transition from binodal to spinodal occurs and $\partial^2 G/\partial \Phi^2 = 0$. From the point of view of electron microscopy, the three regions are characterized by very different morphologies: (1) homogeneous outside the solid line; (2) spherical nuclei of varying sizes within a homogeneous matrix between the solid and dotted curves; and (3) a continuous, interconnected spinodal region of uniform size in a continuous matrix within the dotted region. Therefore, if the bulk samples can be quenched quickly enough from the appropriate regions, the phase diagram can be established by electron microscopy. This can be achieved in the case of long-chain polymers because the reorganization processes are sufficiently slow; however, the initial stages, which are very interesting theoretically, are generally inaccessible.

Figure 18. TEM micrograph showing the grain structure in a lamella forming poly(styrene-b-butadiene) diblock copolymer: PS 81 000 g mol^{-1}; PB 74 400 g mol^{-1} (designated SB 80/80). The inset shows a schematic illustration of the three-dimensional grain structure [85].

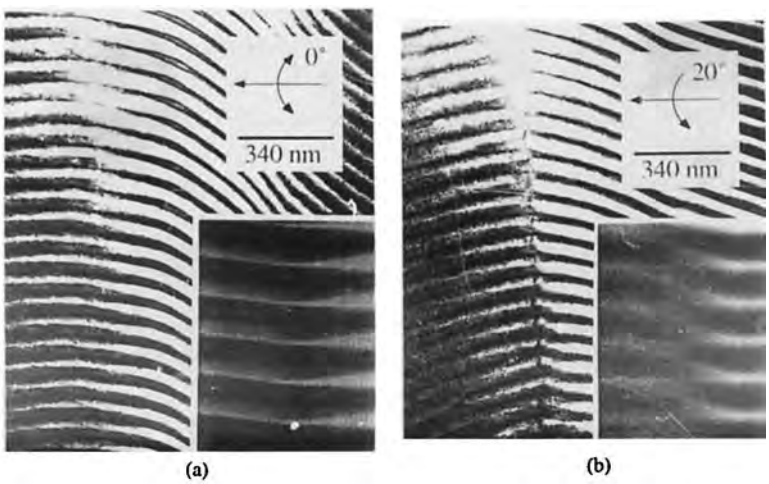

Figure 19. TEM tilt series of a helicoid section twist grain boundary (~10°) in SB 80/80. (a) The boundary and corresponding ray tracing computer simulation (inset) are viewed from a 0° tilt projection direction. (b) The specimen in the microscope and the corresponding computer simulation have been tilted by 20° about the axis shown. This tilting produces similar changes in the images of the specimen and the simulation [85].

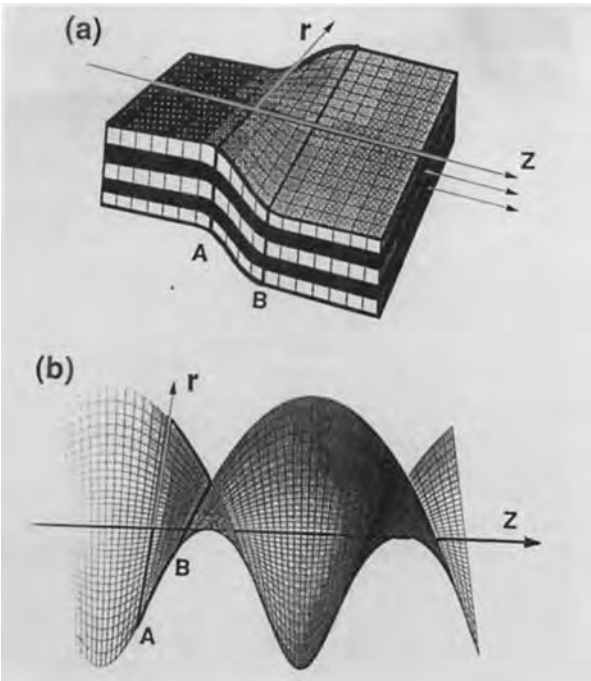

Figure 20. Helicoid section twist grain boundary morphology. (a) Lamellar material with a low angle twist grain boundary. The lamella undergo a slight 'ripple' in this boundary region which is concentrated between positions A and B. (b) The IMDS in the grain boundary region is modeled with the boldly outlined section of the right helicoid minimal surface, which is also delimited by A and B. The z axis of the helicoid, as on the mathematical surface (b), is repeated for each helicoid section of the stack of IMDSs in (a). (Computer graphic of right helicoid by J. T. Hoffman of GANG [85].)

The commercial advantage of polymer blends is due to their enormous versatility. With polymer blends in the two-phase region, a desired compromise between the properties of the two constituents may often be achieved. Typical examples include the improvement of stress-crack resistance, processability, friction, and wear resistance, as well as flame retardance. Alternatively, if one component is soluble, materials with specific pore-size distributions can be produced.

Theoretical aspects relating to the phase separation and critical behavior of polymer blends have been treated extensively in the literature [97–100]. From a theoretical point of view, the statistical mechanics of these complex fluids pose very exciting problems. The Ginsburg criterion affirms that the behavior of polymer blends becomes mean-field like in the long-chain limit [101–103]. Recently, there have been several new theoretical approaches which incorporate microscopic model features to account for chemical details: integral equation theories [104], cluster variational models [105], the lattice cluster approach [106], and the PRISM theory [107, 108].

Comparing theory with experiment is very difficult because an analytical treatment of the chemical microstructure is not possible and because the experiments can be performed over only a limited compositional and temperature range. The experimental methods of choice have generally been X-ray small angle scattering, neutron scattering, and light scattering [109, 110]. These methods have the advantage that an analysis of the scattered intensity enables important parameters such as the critical temperature to be determined, and the compositional fluctuations leading to the

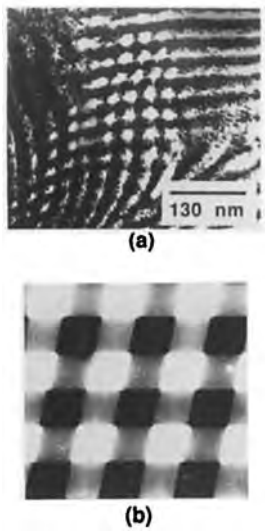

Figure 21. 80° Scherk twist boundary in SB 20/20. (a) TEM micrograph with a *z*-axis projection direction. (b) Corresponding ray tracing simulation. Three levels of intensity are present in both the TEM image and the simulation. Black regions result from the matching of PB lamella across the boundary, white regions result from the matching of PS lamella across the boundary, and gray regions result when PS and PB lamella come into contact and are separated by a Scherk saddle IMDS [85].

critical point can be detected. However, electron microscopy can play a useful role in determining the phase diagram. A typical spinodal region in tetramethyl polycarbonate/polystyrene obtained by permanganic etching of a bulk polymer surface [111] is shown in Fig. 23. In a more detailed analysis of polystyrene/polyvinylmethyl ether, the kinetics of phase segregation were studied [112, 113]. In the latter investigation, contrast was produced by mass loss of one component during exposure to the electron beam. The size d of phase-separated domains in the spinodal regions was shown to grow with time according to the relationship [113] (Fig. 24):

$$d \propto t^{\phi}$$

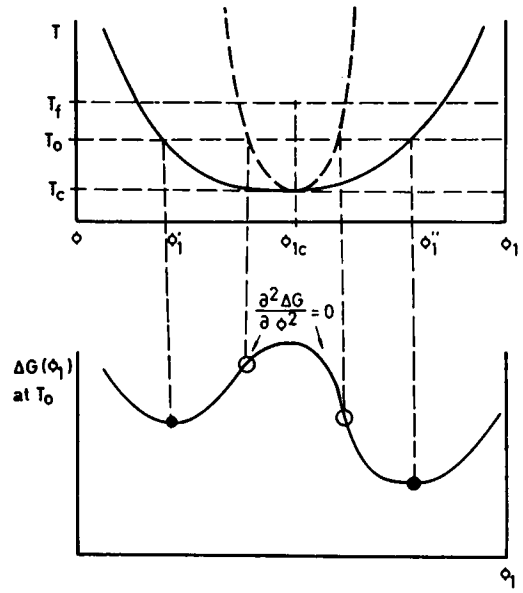

Figure 22. Phase diagram of a binary system with a lower critical solution temperature [113].

and ϕ was determined to be 1 in an intermediate region, corresponding to the theoretical expectation in that regime [114–119].

13.2.4 Fibers

The production of high strength fibers plays an essential role in polymer technology and their morphology has been studied extensively by electron microscopy. Many processing routes are possible: two important ones are gel spinning and self-assembly.

13.2.4.1 Conventional Polymers

Conventional flexible chain polymers are extended to highly extended fibers by gel spinning [120], hydrostatic extrusion [121],

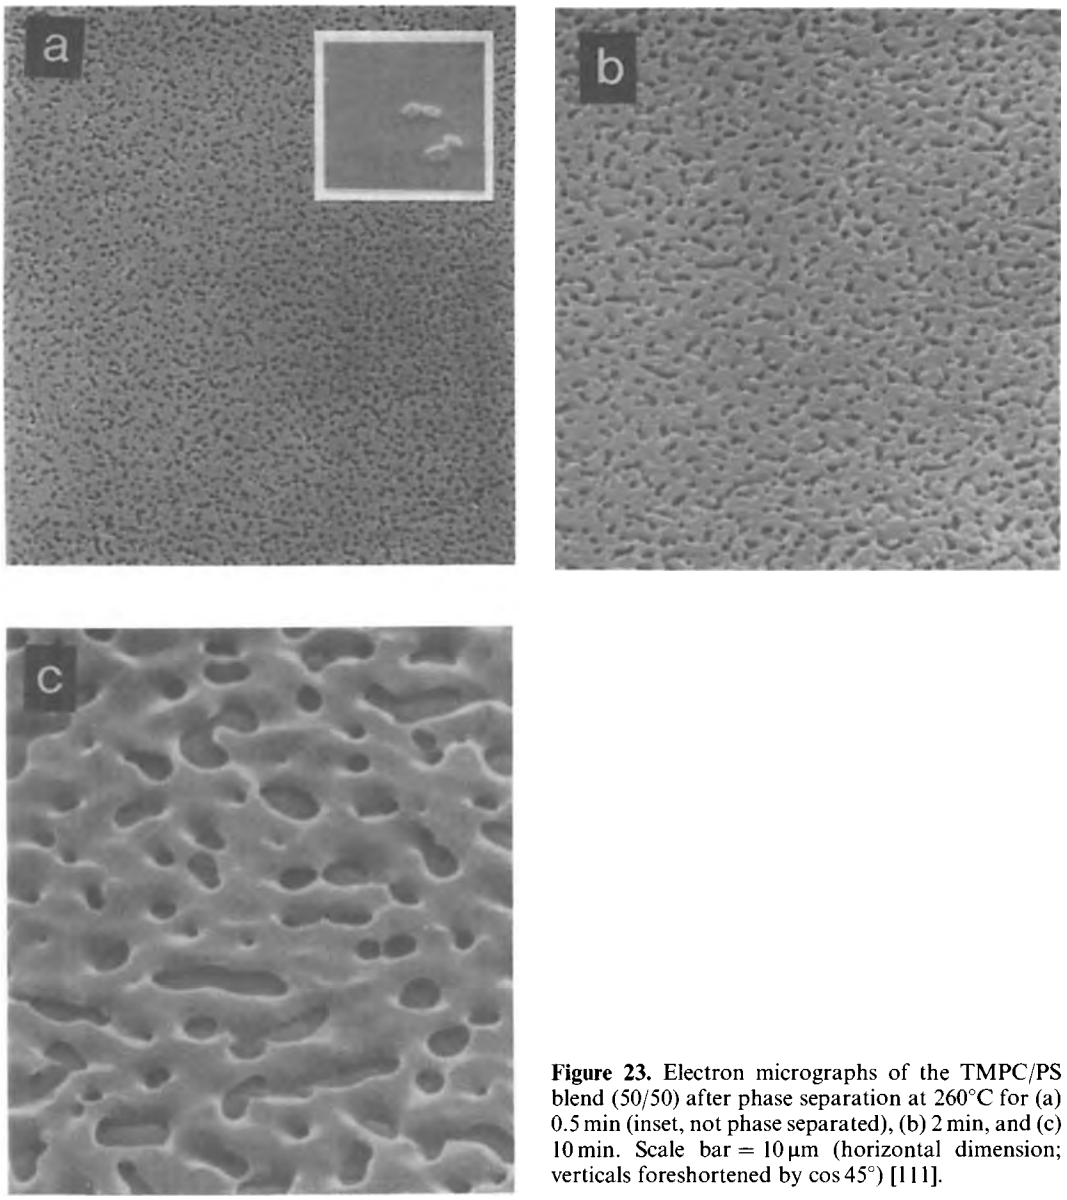

Figure 23. Electron micrographs of the TMPC/PS blend (50/50) after phase separation at 260°C for (a) 0.5 min (inset, not phase separated), (b) 2 min, and (c) 10 min. Scale bar = 10 μm (horizontal dimension; verticals foreshortened by cos 45°) [111].

die drawing [122], and superdrawing [123]. In addition to polyethylene, high modules fibers of polyacetal [124], polypropylene, polyamide hydrazides [124], and others are known.

Electron microscopic investigation of such fibers revealed deformed crystalline lamellae perpendicular to the draw direction, separated by highly drawn fibrils parallel to the draw direction in polyethylene [125]. In later work, details of the internal structure of such fibers were revealed by permanganic etching [126], using conventional transmission electron

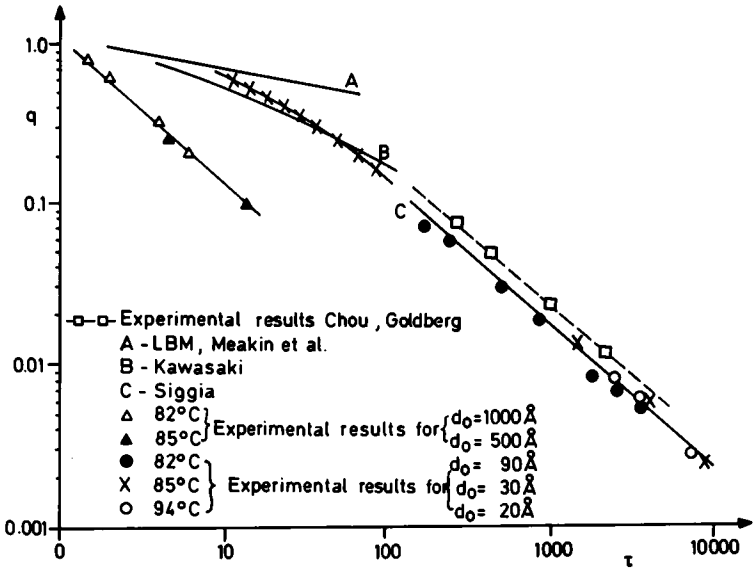

Figure 24. Inverse size of phase-separated regions versus time (dimensionless units) [113].

microscopy and by scanning transmission electron microscopy (STEM) [127]. It was found that deformation is initially accommodated by the inter lamellar regions, which cavitate and form microfibrils. With increased deformation, suitably oriented lamellar crystals deform by two chain-slip systems: {100}, ⟨001⟩; and {010}, ⟨001⟩. These *c*-axis shear processes (along the molecular axis) were further distinguished as fine slip or block shear (Fig. 25). When the block size is below a critical value, the blocks form highly oriented fibers with discrete microfibrils containing small block crystals and strain-induced fibrillar crystals (Fig. 26).

13.2.4.2 Liquid-Crystal Fibers

Stiff, rod-like molecules which exhibit nematic liquid crystalline behavior in the melt (thermotropic) or in solution (lyotropic) can be transformed into highly oriented extended chain structures by self-alignment. Thousands of liquid crystalline polymers are documented in the literature [128], the most important of which are:

- poly(*p*-phenyleneterephthalamide) produced by Du Pont under the tradename Kevlar;
- aromatic copolyesters produced by Hoechst-Celanese under the tradename "Vectra";
- a group of lyotropic, aromatic heterocyclic polymers which exhibit the highest fiber modulus yet observed [129, 130].

In a detailed study elucidating the structure–property relations of liquid crystalline polymer fibers, SEM revealed a microstructure composed of fibrillar units organized in a hierarchical structure (Fig. 27) [131]. The mechanical properties of these materials are related to the stress transfer between the individual structural units. It is generally accepted that full, three-dimensional crystallographic

registry is not necessary for efficient stress transfer [132].

13.2.5 Liquid-Crystalline Polymers

The fascinating physical properties induced by the self-ordering of large molecules with asymmetrical shapes (mesogens) is a well-known phenomenon [133, 134] and has been studied extensively in large monomeric molecules, which are generally synthesized with specific functionalized groups of atoms.

Liquid crystalline polymers are a comparatively new class of materials, which

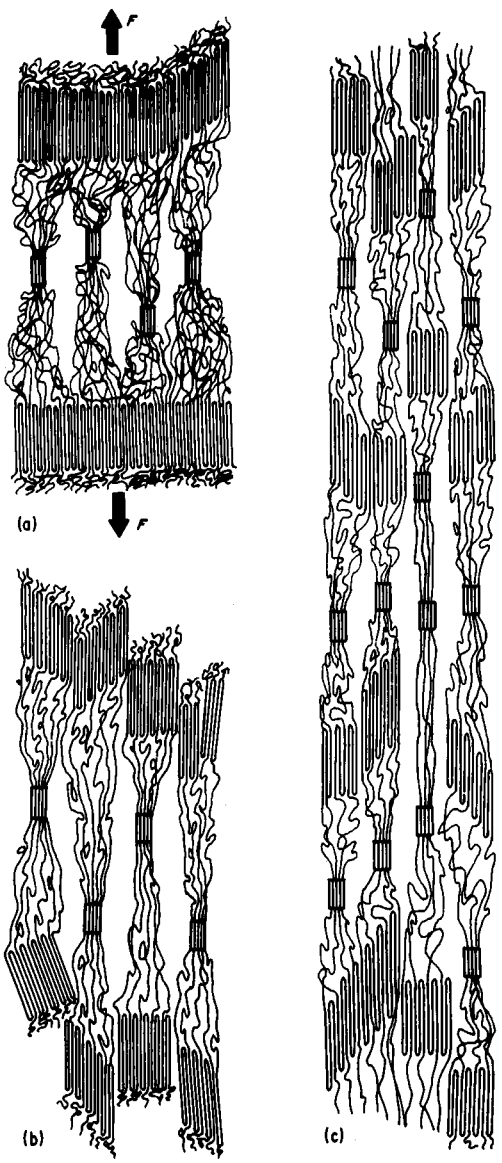

Figure 26. Ultrastructure of deformation: (a) strain in amorphous regions sufficient to induce crystallization in the fibers; (b) block slip resulting in break up of lamellae into large blocks; (c) fibrillar morphology with discrete microfibers containing some lamellar block crystals and strain induced fibrillar crystals [127].

combine the useful optical, electrical, and ferroelectric properties of liquid crystalline monomers with those of mechanical strength and considerably higher transition temperatures. In these materials the mesogens are generally attached to a polymer chain by alkane spacers, so that the materials retain their mobility and self-ordering characteristics without being too severely impeded by the tendency of the polymeric chain to form a Gaussian coil [1, 134, 135]. The thermodynamic properties of rod-like molecules were first treated by Flory [136] and the theory later refined by Saupe [137], while those of tilted layers and stacks of discs were discussed by McMillan [138].

Typical mesogenic geometries are shown in Fig. 28. The molecular shape and manner of attachment to the polymeric chain influence the nature of the mesophase, and the temperature interval in which it is formed, thus producing many useful materials (Fig. 29). In discussing their structural characteristics it is important to note that these materials possess only one- or two-dimensional quasi-long-range order, not three-dimensional long-range order as crystals do. Therefore they should be described by their pair correlation functions $g(2)$. The relationship between the pair correlations obtained for liquids, liquid crystals, and crystals is shown in Fig. 30a. The effect of the lattice statistics in layer structures on the structure factor $S(q)$ is shown in Fig. 30b. Although most structural investigations on liquid crystals have been performed using X-rays or neutrons, the structural information that can be obtained in reciprocal space is meager: Broad, oriented halos, in the wide angle range, loss of higher order small angle reflections due

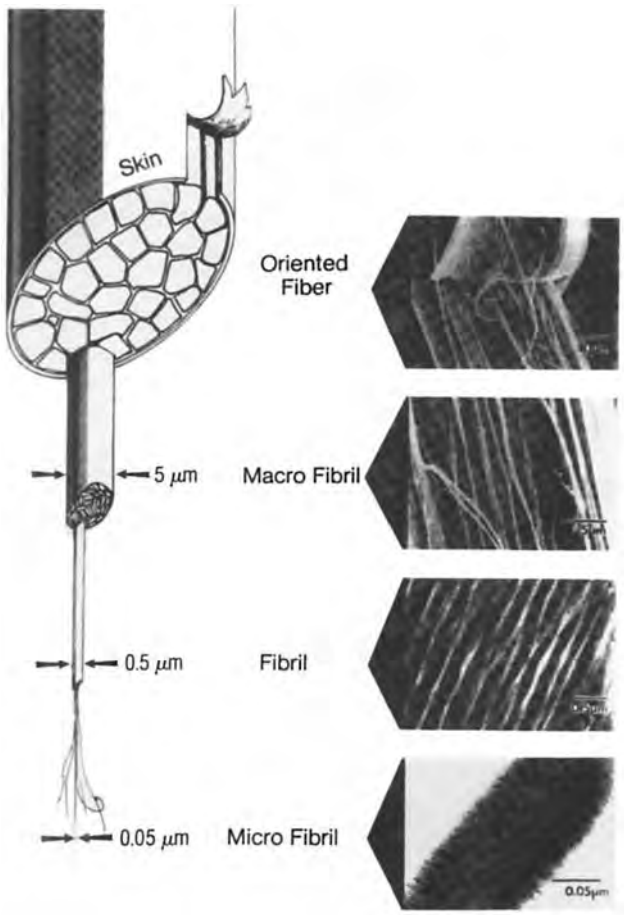

Figure 27. The long-chain polymer structural model shows the hierarchical, fibrillar texture of long-chain polymer materials in an artist's drawing (left) and in micrographs of oriented materials (right) [131].

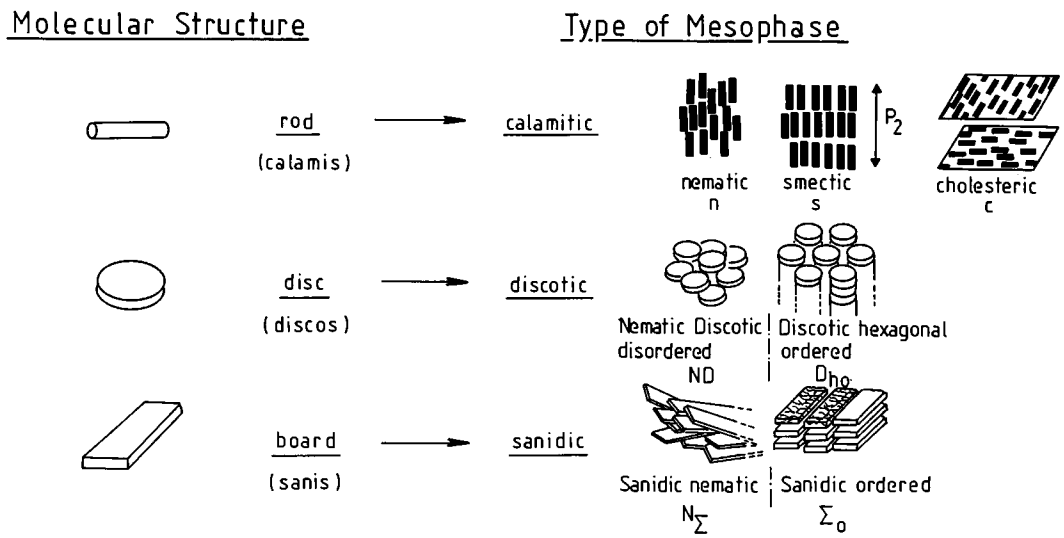

Figure 29. Effect of molecular shape on type of mesophase formation.

to the loss of short-range correlations, and loss of mixed reflections due to the lack of three-dimensional order. For this reason a real-space method such as electron microscopy is much more informative. The difficulty lies, as so often in electron microscopy, in finding a suitable method of sample preparation, image recording, and image interpretation, and in understanding the relation between the structure and the physical properties under investigation. As is usual for polymers, each material requires a special method of preparation and analysis. Therefore electron microscopic investigations on this fascinating class of materials are relatively limited. It is hoped that this chapter will stimulate such research.

Initial low resolution TEM investigations were concerned with the study of the

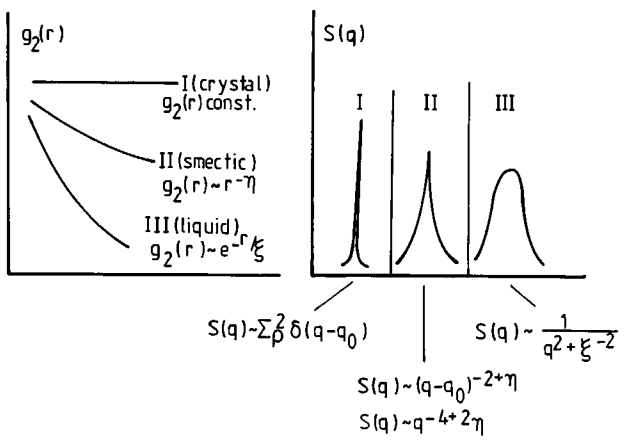

Figure 30. Order in smectic liquid crystals.

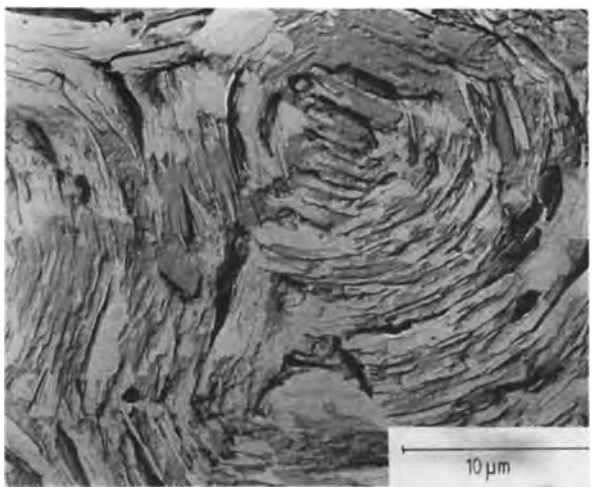

Figure 31. Image of $s = \pm 1$ disclination in ferroelectric chlorobiphenyl.

characteristic walls in thermotropic nematic copolyesters [139–141]. In a later paper on a similar system, two types of defects were observed: Néel bend walls, and $s = \pm\frac{1}{2}$ disclination lines [142]. Subsequently, other authors found $s = \pm 1$ disclination loops in a ferroelectric chlorobiphenyl [64] (Fig. 31) and parabolic focal conics in a semiflexible liquid crystalline polyester [143].

In order to interpret images of liquid crystalline polymers correctly some fundamental properties of liquid crystals need to be discussed. Liquid crystalline mesophases can be divided into four general classes, which are related directly to the shape of the mesogens. The defects are specific for these classes and are related to the elastic energy density of the system caused by bend, twist, and splay of the molecular layers.

Nematic Phase

The mesogens are arranged in such a way that their centers of mass display short-range order and their long axes, described by director $\bar{n}$, lie preferentially in one direction, producing long-range orientational order. Mesogens with twisted nematic phases are typically used as display devices. In the light microscope, the nematic phase displays typical defect structures [144] resulting from the three principal types of elastic distortion. The elastic constants K_{11}, K_{12}, and K_{33} correspond to splay, twist, and bend, respectively. The free energy density of the deformed system is given by [145]

$$F = \tfrac{1}{2}[K_{11}(\nabla \cdot n)^2 + K_{22}(n \cdot \nabla \times n)^2 + K_{33}(n \times \nabla \times n)^2]$$

The total energy of the system is:

$$E = \int F \, dr$$

Minimization yields a set of differential equations which describe the director field. If the director is confined to the xy plane,

$$n_x = \cos\phi, \; n_y = \sin\phi, \; n_z = 0$$

$$\phi = s\alpha + c$$

where $\alpha = \tan^{-1}(y/x)$, c is a constant, $s = \pm\frac{1}{2}, \pm 1, \pm\frac{3}{2}$, and $0 < c < \pi$ [146].

The director field for nematics according to this expression can be simulated and the corresponding structures in polymeric liquid crystals investigated by electron microscopy. The agreement between calculated and observed structures (for $s = \pm\frac{1}{2}$) was elegantly demonstrated thus by Thomas [63].

Smectic Mesophase

Rod-shaped mesogens are arranged in layers, so that the centers of mass now have quasi-long-range positional order. Within the layers their long axes are preferentially ordered in one direction. Mobility is possible about the long molecular axes and between layers. Frequently, benzoic acid phenylesters are used as mesogens. More recently, biphenyls and phenylcyclohexanes have been used. A comprehensive summary is given by Finkelmann [147]. Frequently, the mesogenic groups have been functionalized by dye-containing groups, by groups that undergo photoisomerizations, or chiral groups which induce tilt and destroy centrosymmetry [135]. Eleven types of smectic mesophase have been postulated; they differ in the order of the mesogens within the layers, ranging from smectic A (no order within layers, molecular long axis perpendicular to layers) via smectic C (no order within layers, molecular long axis tilted with respect to the layers), to various degrees of order within the layers (hexagonal, orthorhombic, cubic) with long axes either perpendicular or tilted with respect to the layers. The interest in layer structures lies in their ability to form sheets of highly directed functionalized groups by the application of an electric or magnetic field in the liquid-like mesophase. This may be smectic A for second-harmonic generation (the frequency of incoming laser light is doubled during transmission) [148, 149] or smectic C for ferroelectric applications (the direction of the dipole is reversed when the applied electric field is reversed) [150]. It is evident that structural defects play a major role in the applicability of such materials and that electron microscopy is an ideal tool to study them. As an example, consider the study of ferroelectric molecules for applications as display devices.

The elastic energy density in tilted smectic phases which are capable of giving a ferroelectric response is given by [146]

$$F = \frac{1}{2}\left\{\left(\frac{\partial\varphi}{\partial x}\right)^2 + \left(\frac{\partial\varphi}{\partial y}\right)^2 + \left[\left(\frac{\partial\varphi}{\partial z}\right) - q\right]^2\right\}$$

where the director C spirals around the C axis (perpendicular to the layers) such that:

$$\varphi = qz \quad \text{and} \quad q = \frac{2\pi}{p}$$

Minimization such that $\nabla^2\varphi = 0$ yields wedge dislocations along the z axis with

$$\varphi = s\tan^{-1} y$$

and twist dislocations along the y axis with

$$\varphi = s\tan^{-1}\left(\frac{z}{x}\right) + qz$$

where s is a constant which is ± 1 for smectic C meso phases.

These expressions were calculated analytically to give the director fields shown in Fig. 32. Comparing these with electron micrographs from suitably prepared samples shows the excellent agreement, and identifies the $s = \pm 1$ disclinations in Fig. 31 [64]. As well as the structural defects, a further parameter dictates the applicability of these molecules for display purposes,

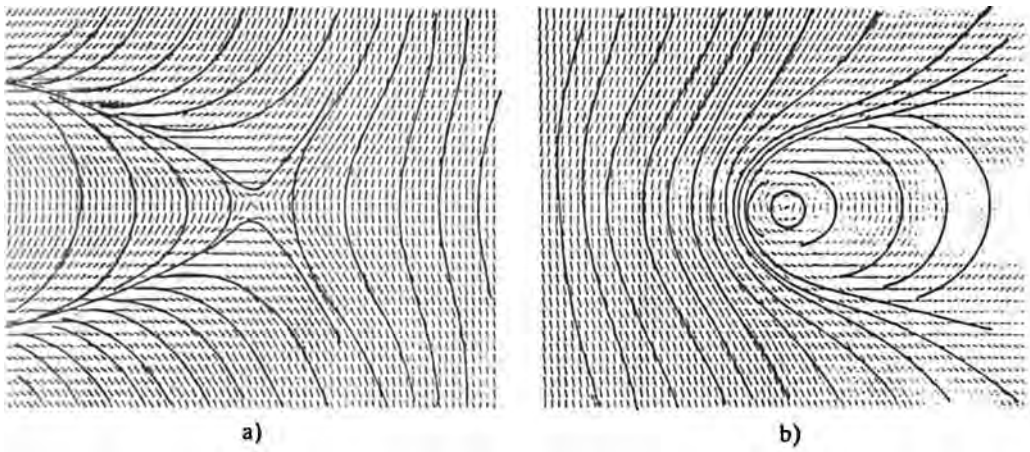

Figure 32. Calculated director field for $s = \pm 1$: (a) $s = 1$, $q = 0.1$; (b) $s = -1$, $q = 0.1$ [64].

namely their switching time. In this respect, the monomeric analogs are undoubtedly superior to the polymers. On the other hand, the polymers give stable, solid films at room temperature with highly directed dipoles.

In addition to these rather large-scale defects, it became clear that microscopic details regarding the layer structure were required for an understanding of the translational and orientational correlations in both smectic A and smectic C structures. Electron diffraction patterns indicated that the relevant features lie in the small angle region corresponding to 10–20 Å in real space. Therefore it is necessary that these spatial frequencies are transferred in the electron microscope for imaging. It was proposed that a rather unusual microscope transfer function χ must be used, in order to have $\sin \chi = 1$ in the appropriate range of spatial frequencies [151]. On the basis of these considerations, defects were revealed by high resolution electron microscopy and shown to play a decisive role in smectic systems. These defects are undulations and disclinations (Fig. 33) [152–154].

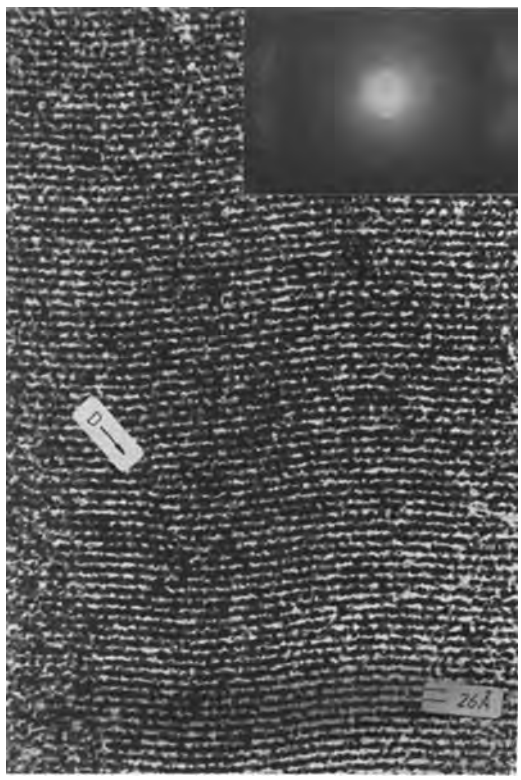

Figure 33. High resolution electron micrograph of a main chain/side group liquid crystalline polymalonate [153].

The observed undulations show that smectics do not conform to our usual notions of long-range order. In fact, long-range order is impossible in one dimension, as was shown by Landau and Peierls [155] because the mean square fluctuations $\langle u^2(r)\rangle$ are divergent:

$$\langle u^2(r)\rangle = (4\pi)^{-1}(BK)^{-\frac{1}{2}}kT\ln\left(\frac{q_{\max}L}{2\pi}\right)$$

where q is the scattering vector at which the maximum intensity is observed, T is the temperature, and B and K are the elastic constants for compression and curvature, respectively. The quasi-long-range order in smectic liquid crystals has been studied extensively by X-ray scattering in fundamental work by Als-Nielsen et al. [156]. From high resolution images more detailed information about the precise nature of this quasi-long-range translational order was obtained and related to the phenomena observed in the electron diffraction patterns [151–153]. The comparison revealed the expected sharp diffraction maxima, with only minimal diffuse scattering in the wings of the peaks. In addition, characteristic streaks on the diffraction maxima indicated the loss of long-range translational correlations in one direction. With the aid of high resolution images, the origin of the diffraction phenomena could be identified uniquely as small-amplitude (about 10 Å) undulations of long wavelength (several micrometers) [153, 157].

Discotic Mesophases

Discotic mesophases are formed from disc-shaped mesogens arranged in columns. The discs may be ordered or disordered within the columns, perpendicular or tilted with respect to the columns, and the columns may be arranged in a hexagonal, orthorhombic, or quadratic manner. Mobility is possible between the columns as well as within the columns (e.g. rotation of the discs). Typical examples are the triphenylene esters and ethers. The lattice statistics for these two-dimensional systems were derived by Selinger and Bruinsma [158] and one expects quasi-long-range order, experimentally indicated by δ functions for the diffraction peaks at each reciprocal lattice vector, surrounded by diffuse thermal scattering in the wings.

Such sharp, small angle maxima were indeed observed in an electron microscopic investigation on discotic polymers [159]. In addition, the high resolution images were evaluated by cross-correlation methods and the deviation vectors gave detailed information about the precise direction and size of deviations from perfect lattice positions [159, 160] (Fig. 34). In addition, the detailed structural analysis of monomeric analogs from electron diffraction patterns has given precise information about atomic positions; this is described in the chapter on electron crystallography (see Sec. 4.1.2 of this Chapter).

Sanidic Liquid Crystals

Sanidic, or 'board-like' liquid crystals are fully aromatic polymeric amides/esters/enamines with alkyl side-chains. These stiff molecules were originally synthesized in order to produce a high-tensile-strength material, but the material was found to be insoluble; to produce solubility and to reduce the melting temperature, flexible spacers, kinks, or side-groups were added to the polymer backbone. Both low level substituted polymers [161] and highly

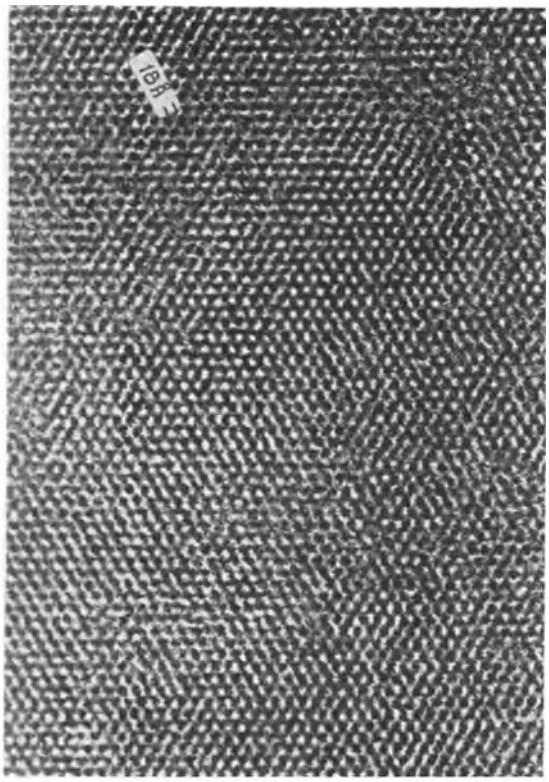

Figure 34. (a) Columns of discotic triphenylene molecules viewed from the top [159]. (b) Deviation vectors obtained by cross-correlation of discotic 'lattice' with perfect crystal [159].

substituted systems [162] were investigated by X-ray diffraction. Because of the appearance of two perpendicular rows of diffraction maxima, the board-like structure was proposed. The dramatic loss of tensile strength in these materials was not understood. In a detailed investigation by high resolution electron microscopy, the loss of mechanical strength could be related to the lack of coherence between small, rather poorly oriented domains (Fig. 35) [163]. Detailed structural analysis by electron diffraction of monomeric analogs revealed that the molecule cannot adopt a flat board-like conformation [164].

13.2.6 Organic Molecules with Functional Groups

A major aim in organic materials science is to design a molecular architecture that satisfies specific criteria with regard to the desired physical properties. In order to achieve this it is essential to know the molecular conformation and packing in the condensed state, as well as details regarding the superstructure and defects.

In recent years organic polymeric molecules have been synthesized in order to produce one of the following properties: ferroelectricity, photoconductivity, mechanical strength, or a second-order NLO effect. In order to achieve these properties, it is necessary to satisfy specific structural criteria as described in the following.

13.2.6.1 Ferroelectricity

Rod-shaped molecules must pack in such a way that their structure is

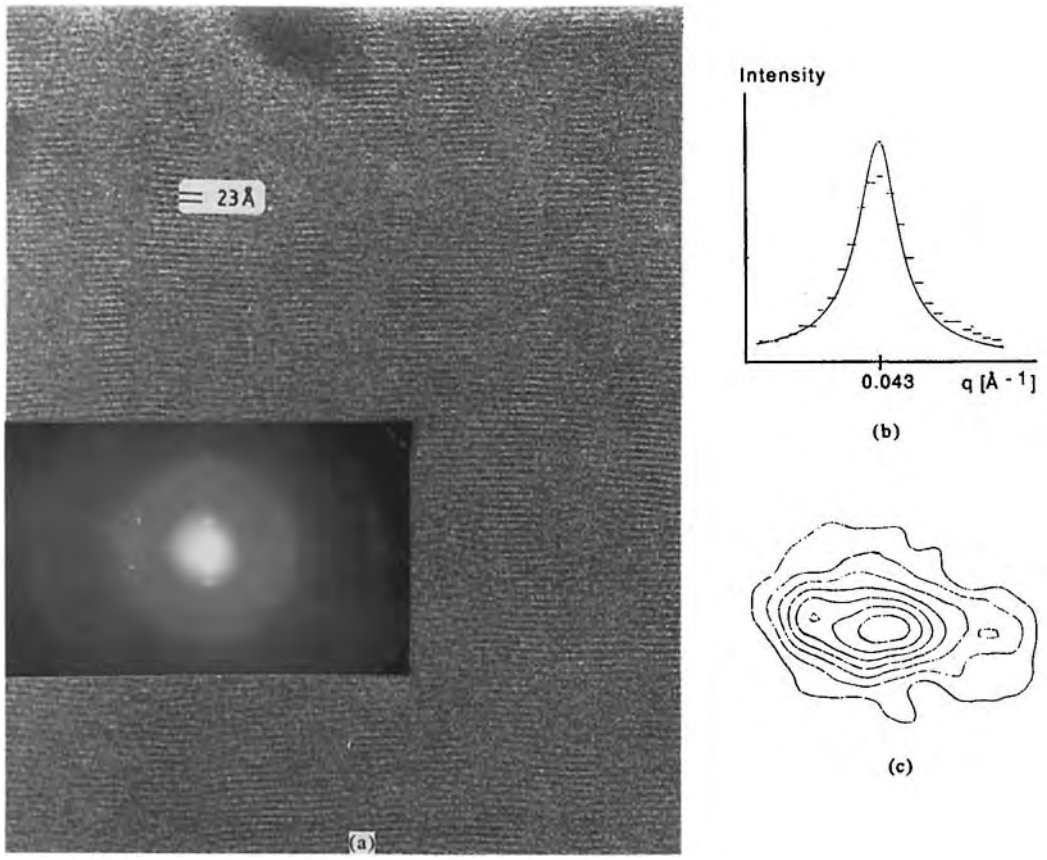

Figure 35. Line profile analysis of diffraction spots from poly(1,4-phenyleneterephthalamide) derivative: (a) micrograph and diffraction pattern; (b) intensity distribution (Lorentz fit); (c) spot-contour lines of second-order peak with satellites [163].

noncentrosymmetric and the dipoles μ are oriented so that there is a resultant polarization P in a direction which can be reversed on application of a field. The molecular dipole μ and the macroscopic polarization P are related by the formula:

$$P \propto \sum_i \langle \mu_i \rangle N_i$$

where N_i is the number density of dipoles. A ferroelectric effect can be induced if the molecule has a molecular subgroup with a suitably oriented dipole μ plus one or two chiral groups to induce molecular tilt and to prevent the formation of a centrosymmetric superstructure. The chiral group induces a helical superstructure which must first be eliminated by suitable alignment, thus giving rise to a tilted layer structure with a macroscopic polarization P.

Switching occurs if the molecules can be rotated collectively within the smectic layers by application of an electric field $\boldsymbol{E}$ [64]. In order to optimize the properties, it is clearly essential to understand the relationship between molecular conformation and dipole moment as well as the direction

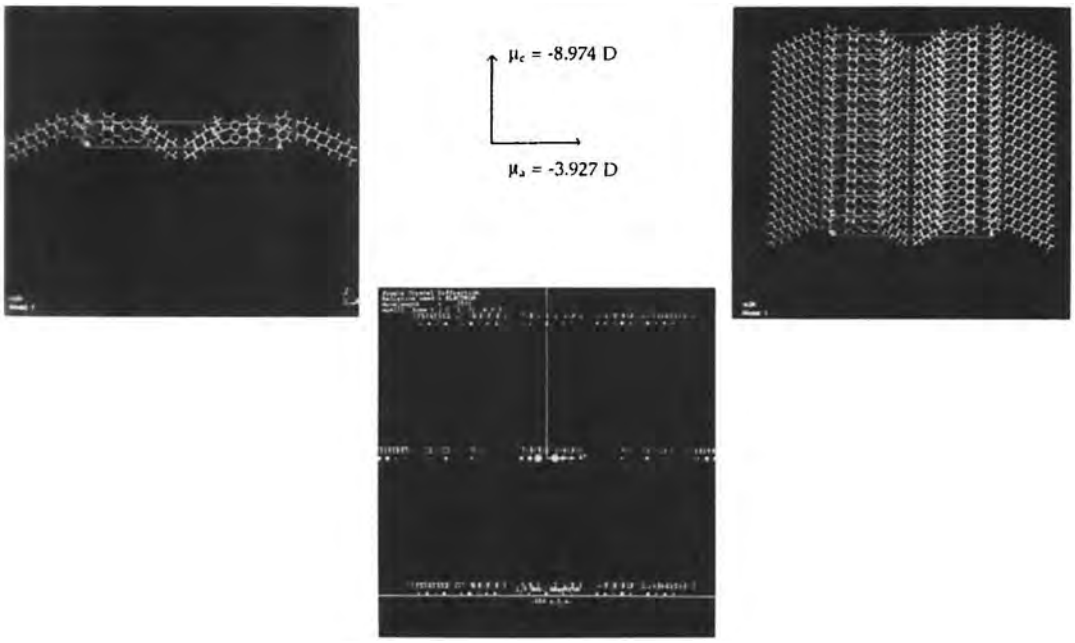

Figure 36. Unit cell, crystal, and diffraction pattern of a ferroelectric molecule, showing the direction of the resultant dipole [165].

of the dipole within the layers [165]. Typical molecules belonging to this category are biphenyl ester and thiadiazol compounds. In order to optimize the effect, the molecular dipole μ must have a large value perpendicular to the molecular layers. If molecules are to be synthesized with this aim in mind, their packing principles must be fully understood and the molecules oriented so as to produce the desired resultant polarizability P. It has been shown by electron diffraction combined with high resolution imaging that this information can be obtained from the monomeric analogs because these provide a sufficient number of reflections to perform structural analysis and derive the direction of the dipoles (Fig. 36). Although the polymers provide insufficient diffraction maxima for ab initio analysis, the relationship between intensities available from the polymer and those of the monomer can be established [165] and structural information about the polymer derived from the monomer.

13.2.6.2 Photoconductivity

Charge transfer, expressed in terms of the mobility of charge carriers, is possible perpendicular to thin organic films if, for example, suitable disc-shaped molecules are oriented in stacks perpendicular to the films [166]. In order to induce photoconducting properties, it is necessary to optimize the relationship between the molecular conformation, their mutual packing, as well as superstructural ordering. Typical examples are hexakis(heptyloxy)triphenylenes [159, 160]. The effective mobility m perpendicular to the layers is

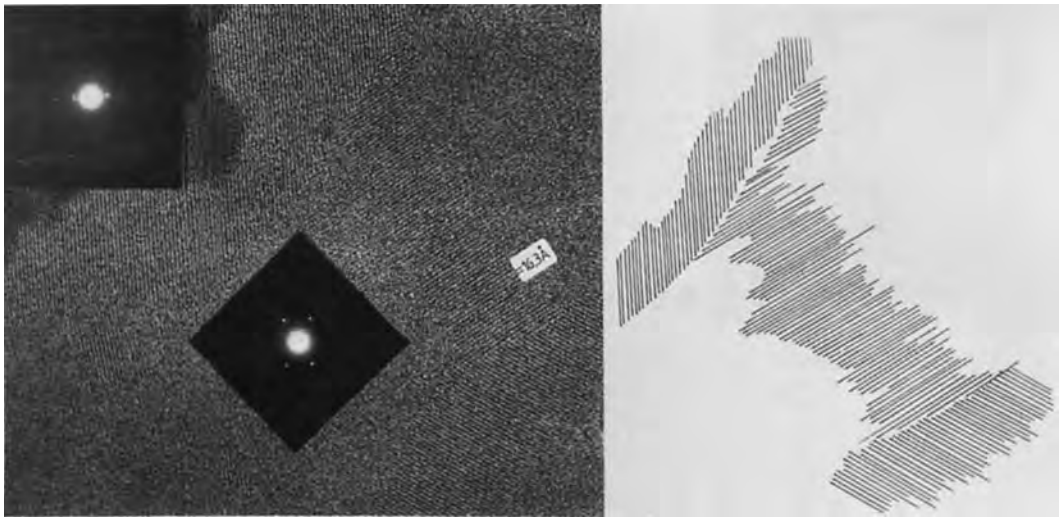

Figure 37. (Left) high resolution electron micrograph of crystalline triphenylene monomer with microdiffraction pattern in correct orientation. (Right) transparent overlay showing a grain boundary [159].

given by:

$$m = \frac{l^2}{t_T V}$$

where t_T is the transit time, l is the sample thickness, and V is the applied voltage across the sample. Transport occurs across the triphenylene cores and is affected by the distance between them, detailed structural parameters are required which can be obtained from electron diffraction data. In addition, information about superstructural parameters such as grain boundaries which act as local traps can be obtained from electron microscopic images.

From electron diffraction experiments combined with molecular modelling the structural space groups and molecular orientation were calculated. In the triphenylene ethers it was found that in the nonconducting crystalline phase, the cores of the ethers were arranged with orthorhombic symmetry and were tilted with respect to the layers [159], while those of the esters were arranged hexagonally and untilted [160]. In both cases the mutual stacking of the columns with respect to each other was such that a superstructure was created as well as numerous grain boundaries (Fig. 37). During the transition to the conducting discotic mesophase, molecular tilt vanishes, and all superstructure reflections are lost due to the onset of disc rotation while, however, retaining the average column positions and eliminating grain boundaries [165]. Crystal grain boundaries are eliminated in the discotic phase (Fig. 34a), so that charge transfer is not inhibited by local traps as in the crystalline phase.

13.2.6.3 Mechanical Strength

Sanidic, or board-like, molecules are fully aromatic polymeric amides or esters with alkyl side-chains. Such materials were expected to have good mechanical

properties because of the stiff polymeric backbone. In practice, the materials fell far short of expectation. The explanation was found to be related to details of molecular packing [163, 164]. The oriented regions were shown to be highly imperfect and of small dimensions. Using semiempirical quantum mechanical calculations (see Sec. 4.2.1 of this Chapter) the aliphatic chains at the terminal phenyl groups were shown to be rotated out of the plane containing the central phenyl group. The molecular conformation therefore deviates from the previously proposed board-like structure, because the aliphatic chains project out of the plane containing the phenylene core.

The molecular packing in the condensed phase was then determined by simulation of the electron diffraction patterns from the monomeric analogs in three different projections. The model structure obtained from electron diffraction (Fig. 38) immediately explains the previously puzzling observation that X-ray small angle scattering experiments always gave long spacing considerably below the extended chain length. This is due to the screw-like arrangement of the side-chains around the molecular backbone. The high resolution images indicated that the loss of mechanical strength arises because oriented regions are very small and poorly developed (Fig. 35).

13.2.6.4 Second-Harmonic Generation

The nonlinear optical properties of individual molecules are related to their transition moment β. In microscopic terms, the induced dipole moment μ in an electric field $\boldsymbol{E}$ is given by:

$$\mu_i = \mu_i^0 + \alpha_{ij}\boldsymbol{E} + \beta_{ijk}\boldsymbol{E}^2 + \gamma_{ijkl}\boldsymbol{E}^3 + \cdots$$

where μ_i^0 is the permanent dipole moment, α_{ij} is the molecular polarizability, β_{ijk} is the second-order hyperpolarizability, γ_{ijkl} is the third-order hyperpolarizability, and i, j, and k are the molecular axes.

The hyperpolarizability β_{ijk} of the molecule is related to the macroscopic second-order susceptibility χ_{IJK} of the crystal by the relationship:

$$\chi_{IJK}^{(2)}(-2\omega;\ \omega,\omega)$$

$$= \frac{1}{V} f_i^{(2\omega)}(\omega) f_j^{(2\omega)} f_k^{(2\omega)} \mathbf{R}\beta_{ijk}$$

where $f(\omega)$ are orientation distributions, $\mathbf{R}$ is the transformation matrix from molecular (i,j,k) to crystallographic (I,J,K) coordinates.

In a macroscopic experiment, the following parameters are determined:

$$\boldsymbol{P}_I = \chi_{IJ}^{(1)}\boldsymbol{E}_J + \chi_{IJK}^{(2)}\boldsymbol{E}_J\boldsymbol{E}_K + \chi_{IJKL}^{(3)}\boldsymbol{E}_J\boldsymbol{E}_K\boldsymbol{E}_L$$

where $\boldsymbol{P}_I$ is the polarization in the medium. Therefore, in order to obtain a second-order susceptibility χ_{IJK}, the structure must be noncentrosymmetric and the major component of the molecular transition moment β_{ijk} must be oriented in the desired macroscopic direction, namely in the plane of the oriented film. It is clear that a contribution can be made toward developing and synthesizing suitable materials with the desired properties only if the packing principles of the molecules (i.e. their conformation and orientation with respect to the macroscopic axes) are understood.

In an initial structural investigation on a dione, the direction of the molecule and its dipole in the unit cell were determined

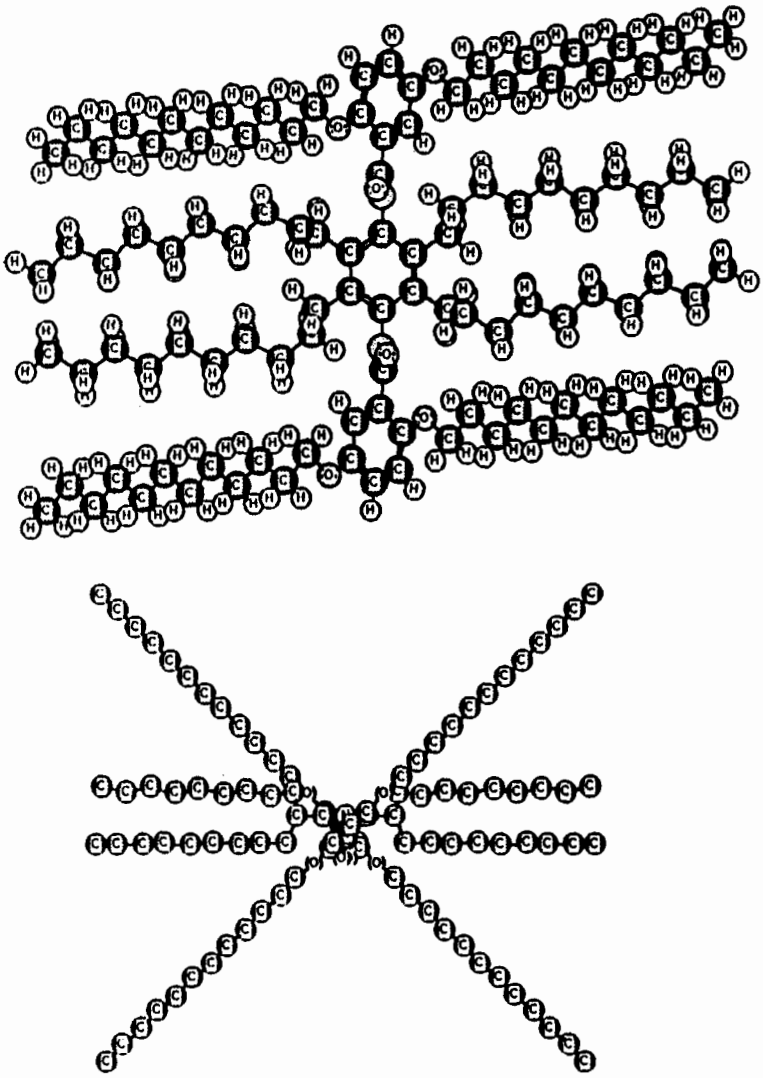

Figure 38. Molecular conformation of a substituted molecule in the crystalline phase from two different projections [164].

(Fig. 39) [149]. In a more detailed calculation, the conformation and orientation of the molecular head group were determined using both simulation methods and maximum entropy statistics [167]. The electron microscopic investigations indicated that the dione molecule in the required conformation has a good value of β but crystallizes in a centrosymmetric $P\bar{1}$ space group, thus destroying its ability to produce a second harmonic response. However, if the same head group is attached to an aliphatic side-chain, centrosymmetry is destroyed, but molecules in the unit cell are arranged so that most of the major components of β are mutually cancelled, leaving only a small resultant effect (Fig. 39). Finally, however, the molecular arrangement in Langumir Blodgett films avoid mutual cancellation and

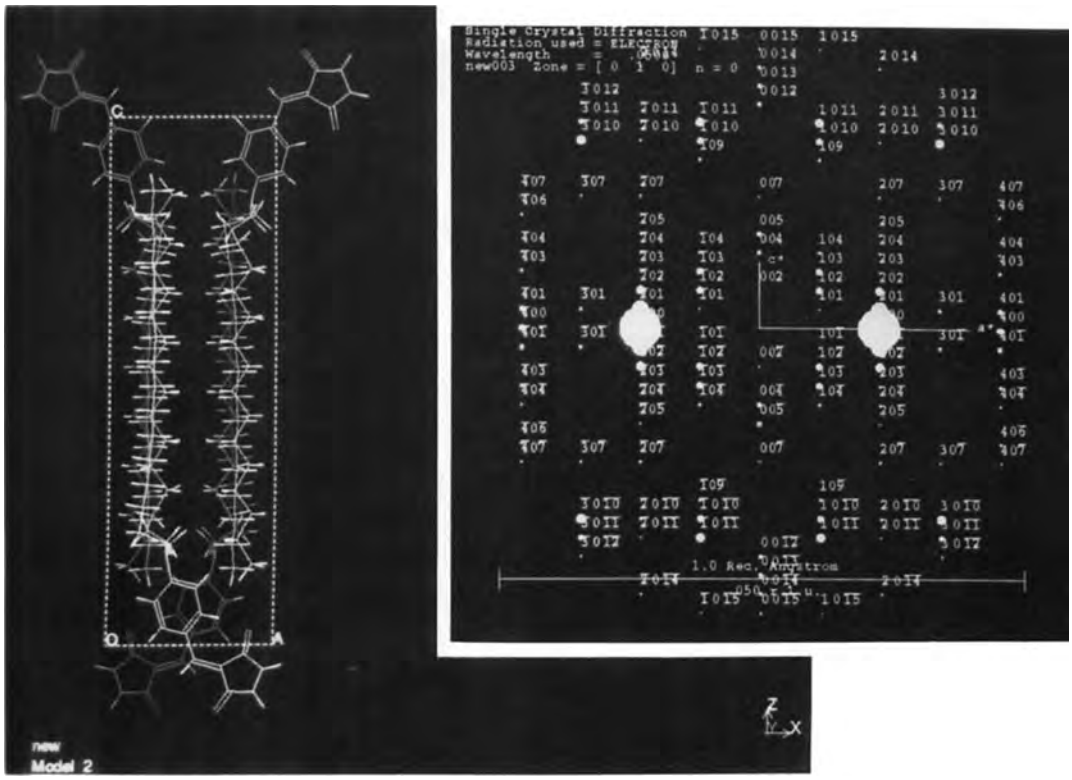

Figure 39. Orientation of a dione molecule in the unit cell, giving a resultant hyperpolarizability per unit cell of $\beta_c = 0.765 \times 10^{-30}$ e.s.u.

centrosymmetry, giving rise to the maximum value of χ, as expected when the molecular origins are understood [149, 168].

13.3 The Use of New Microscopy Methods to Study Polymers

13.3.1 Atomic Force Microscopy

Extensive use of atomic force microscopy (AFM) has been made in the study of polypropylene by Lotz et al. [169]. The situation for the investigations was particularly fortunate because the investigators had already performed detailed TEM investigations on this molecule and were thus able to use prior knowledge and experience as well as to being in a position to compare the results obtained with the two methods. From the TEM investigations of syndiotactic polypropylene the authors had already proposed a unit cell with $a = 14.5$, $b = 11.20$, and $c = 7.4$ Å and a space group *Ibca* [170] resulting from the presence of both right- and left-handed helices in strict alternation (Fig. 40). In addition, at lower crystallization temperatures, crystals having a unit cell with $a = 14.5$, $b = 5.6$, and $c = 7.4$ Å

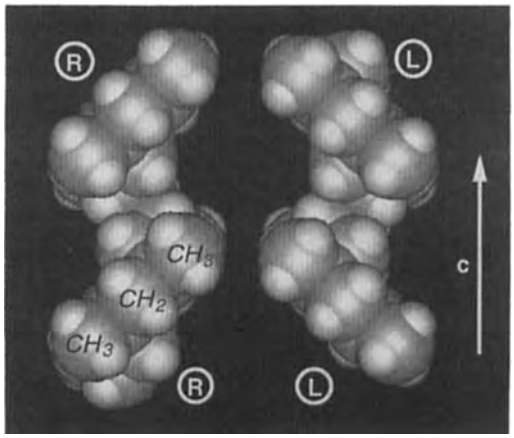

Figure 40. Computer-generated molecular models of right- and left-handed sPP helices in the $(t_2g_2)_2$ conformation, as seen along the crystallographic *a* axis (left- and right-hand sides of the figure, respectively). Note the prominent rows of CH_3, CH_2, and CH_3 groups at 45° to the chain-axis direction, which reveal unambiguously the helical handedness [175].

and a space group $C222_1$ are formed. In this case, the helices all have the same hand. In actual crystals, both packing schemes were found to coexist, where shifts of $b/4$ produced by 'mistakes' in the alternation of helical handedness in the *bc* planes were proposed. These cause streaking on $(hl0)$ reflections parallel to a^*. Summarizing these investigations, it can be said that they made a considerable contribution towards understanding the general principles of helical packing in polymeric molecules.

When applied to suitable polymers, AFM has reached methyl group resolution, as illustrated by the visualization of end groups and fold structures in crystals of linear and cyclic paraffins [171] of chain structure in thin films of PTFE [172, 173], poly(oxymethylene) [174], and isotactic polypropylene [170]. Therefore it was a particularly well-suited method to investigate the defects in helical packing on the *bc* planes of syndiotactic polypropylene [175]. In order to expose this face, a complicated series of preparative steps were necessary, which are described fully in the reference cited. In addition, AFM examination itself proved to be a challenge because of the softness of the polymer film and adhesion of the tip to the surface. AFM imaging in a liquid environment gave much improved resolution because a reduction of capillary forces made it possible to use imaging forces in the region of 10^{-10} N and below. It emerged that AFM recognition of the helical hand in synthetic polymers is more difficult than for larger double strands like DNA because the helices are not stabilized by intermolecular forces. The final results, shown in Fig. 41, confirm the striking regularity of the helical hand alternation with a crystal structure and symmetry consistent with the *Ibca* space group, after Fourier filtering of the unfiltered images. In a series of studies, the same authors examined the contact faces of epitaxially crystallized α- and γ-phase isotactic polypropylene [176].

13.3.2 Scanning Tunneling Microscopy

The structure of organic molecules and polymers at the surfaces of specific substrates has been investigated successfully by scanning tunneling microscopy (STM) [176, 177]. In order to achieve images, the material needs to be able to transport electrons from the emitter tip to a conductive support, either by electron tunneling for thin samples of about 50 Å, or by an additional conductive mechanism for thicker samples. Most successful

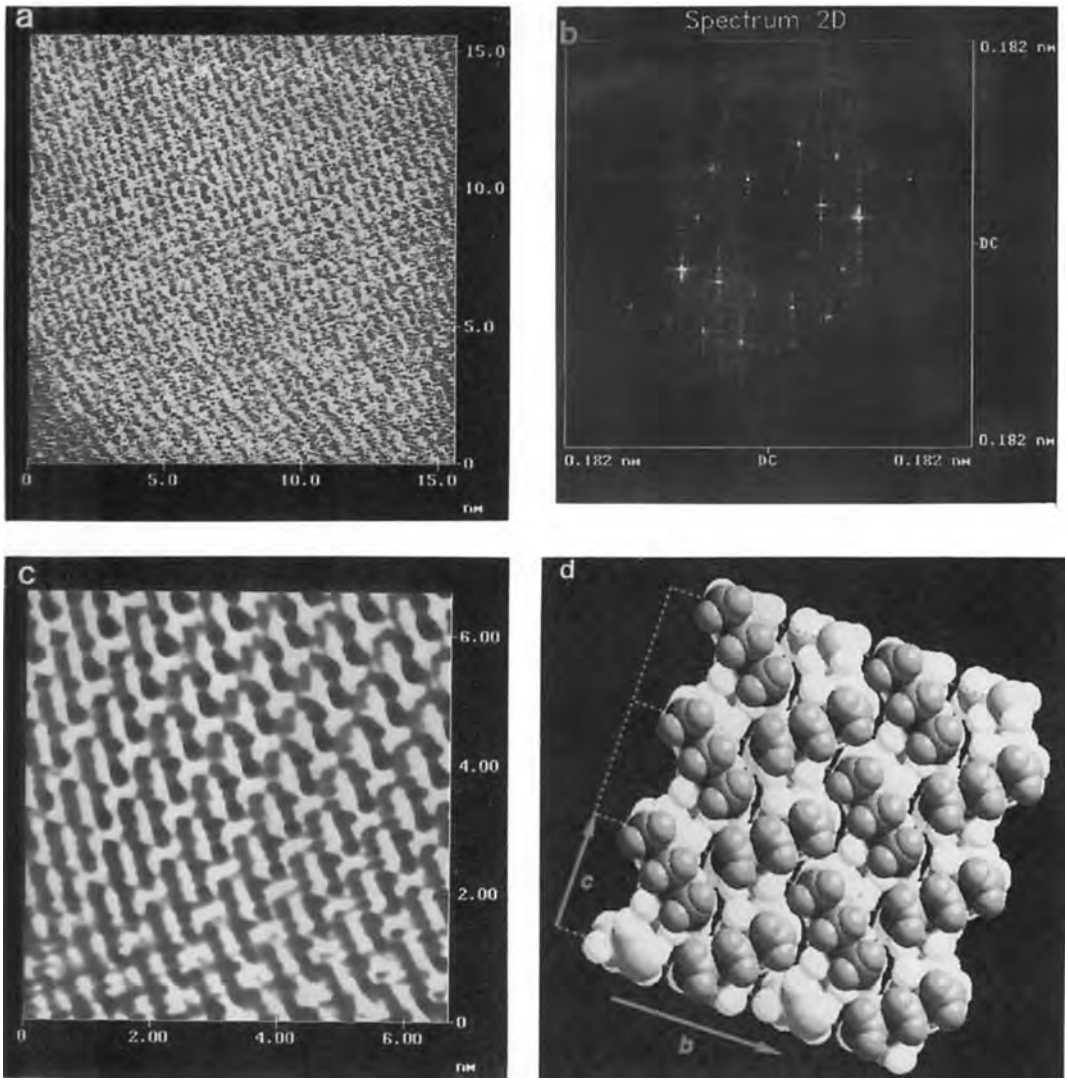

Figure 41. (a) High resolution AFM image of syndiotactic polypropylene, recorded in the liquid cell (force imaging, constant-height mode, no filter, scan rate 57 Hz or $8\,s^{-1}$). Orientation of chain axes is about 1 o'clock. (b) Power spectrum of the upper left part of the picture in (a). Periodicities along and normal to the chain axis direction are 0.72 and 1.1 nm, respectively. Note the appearance of more intensity peaks than in the electron diffraction pattern in Fig. 6, which is linked to the fact that the surface symmetry of sPP differs from its bulk one. (c) Fourier-filtered image of the upper part of (a) produced when selecting 20 pairs of spots in the power spectrum in (b). Note the better resolution of CH_3, CH_2, and CH_3 units oriented nearly normal to the scan direction. (d) Schematic representation of the AFM image in (c) using molecular modeling and shown in correct mutual orientation (cell III in Fig. 1, space group *Ibca*). The atomic van der Waals radii are depicted at 83% of their values to allow better visualization of the individual chains; the uppermost groups visualized in AFM are darkened [175].

investigations of organic molecules have been undertaken in the former situation. For a given tip, the contrast depends on the substrate, the structure and orientation of the absorbed molecules, and the applied bias [178, 179]. Several explanations for the change in measured current have been proposed: (1) changes in the electron density of states within the substrate or tip occur due to their electronic interaction with the absorbate (sample) [180]; and (2) changes in the tunneling barrier or resonant tunneling are caused by electronic levels close to the Fermi level of tip and substrate.

The imaging process can be described in terms of the transfer function

$$I(\boldsymbol{k}) = O(\boldsymbol{k})H(\boldsymbol{k}) + N(\boldsymbol{k})$$

where $I(\boldsymbol{k})$ is the Fourier transform of the image, $O(\boldsymbol{k})$ is the Fourier transform of the object, $H(\boldsymbol{k})$ is the Fourier transform of the transfer function, $\boldsymbol{k}$ is the scattering vector, and $N(\boldsymbol{k})$ is an additional noise term.

In TEM, $H(\boldsymbol{k})$ depends mainly on the spherical and chromatic aberration constants and the defocus value, while $N(\boldsymbol{k})$ depends on the recording device (photographic film or CCD camera). These parameters can be determined and the effect of $H(\boldsymbol{k})$ on the image can be calculated (see Sec. 4.1.2 of this Chapter). The corresponding parameters are not so well known for STM [180], but are certainly related to the geometry of the tip. For conductive surfaces with very small corrugation, the STM transfer function is given by [181]

$$H(\boldsymbol{k}) = \exp\left(\frac{-k^2}{k_0^2}\right)$$

where $k_0 = 4k/(r+s)$, r is the tip radius, s is the spacing between the tip and the sample, and k is the inverse decay length for tunneling [76].

For complex tip and sample geometries the imaging properties become highly nonlinear and harmonics with high amplitudes are created by the imaging process itself [178]. For this reason, analysis of the spatial frequencies in Fourier space can be very misleading. In addition to these geometrical considerations, the forces between the tip and the sample may deform the latter; these forces are approximately 10^{-10} N for organic samples, which is much lower than those for graphite, silver, or gold. With improved understanding of the contrast mechanisms, new insight into interfacial phenomena are to be expected.

In the following selected examples showing STM images of organic molecules, three different situations are distinguished: ultrathin adsorbate layers, organic conductors, and macromolecules.

Ultrathin Adsorbate Layers

For these studies on chemisorbed molecules under ultrahigh vacuum (UHV), small molecules were attached to reactive and atomically flat surfaces in UHV by chemisorption, thus immobilizing them [182]. In this way high resolution images were obtained from arrays of benzene coadsorbed with carbon monoxide on Rh(III) [183] (Fig. 42).

In experiments on *physisorbed molecules at interfaces*, the internal interface between two condensed media is imaged, one being a conducting solid and the other a gas, liquid, or soft solid. In such investigations the basal plane of highly oriented pyrolitic graphite [184] HOPG and MoS_2

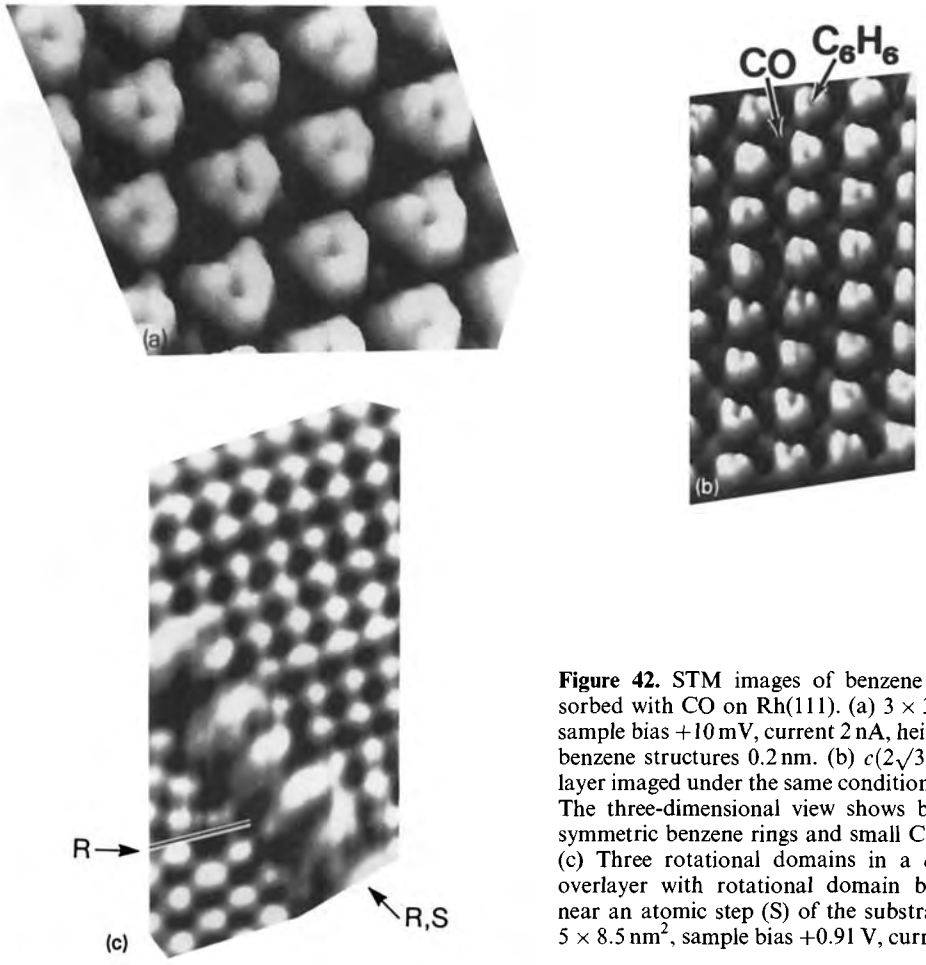

Figure 42. STM images of benzene (C_6H_6) coadsorbed with CO on Rh(111). (a) 3×3 overlayer [8]: sample bias +10 mV, current 2 nA, height of ring-like benzene structures 0.2 nm. (b) $c(2\sqrt{3} \times 4)$rect overlayer imaged under the same conditions as in (a) [17]. The three-dimensional view shows both three-fold symmetric benzene rings and small CO protrusions. (c) Three rotational domains in a $c(2\sqrt{3} \times 4)$rect overlayer with rotational domain boundaries (R) near an atomic step (S) of the substrate: image size $5 \times 8.5\,nm^2$, sample bias +0.91 V, current 2 nA [183].

MOPG [185] was used as substrate. Examples are shown in Fig. 43 [177].

High resolution molecular images at solid/fluid interfaces were thus obtained for two liquid crystals 4-n-octyl-4′-cyanobiphenyl and 4-(*trans*-4n-pentylcyclohexyl)benzonitrile on HOPG [186] and other liquid crystal/HOPG interfaces [187], as well as a homologous series of cyanobiphenyls [188]. The investigations showed that the molecular order at the interface is better than that in the bulk, and that the sample structure depends on the substrate (Fig. 44).

It has also been shown by STM that long-chain alkanes form highly ordered monolayers at the interface between organic solutions on HOPG [189–192].

Organic Conductors

Organic conductors which have been imaged by STM are tetrathiafulvalenetetracyanoquinodimethane [193], β-(BEDT-TTF)I_3 which becomes superconducting at low temperatures [194], organic charge-transfer complexes [195], and conducting polymers such as polyacetylene.

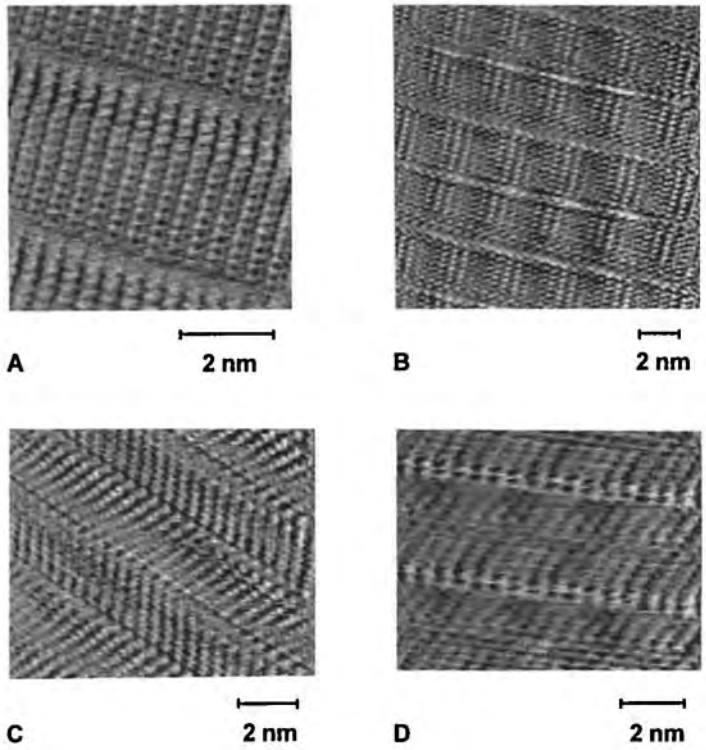

Figure 43. STM images of molecular monolayers adsorbed to the basal plane of graphite: (a) The alkane heptacosane ($C_{27}H_{56}$); (b) the fatty acid stearic acid ($C_{17}H_{35}COOH$); (c) the alcohol octadecanol ($C_{18}H_{37}OH$); (d) didodecylbenzene [$H_{25}C_{12}(C_6H_4)C_{12}H_{25}$]. The brightness is proportional to the current at quasi-constant height. The four cases show alkyl chains perpendicular to ((a) and (b)) and tilted ((c) and (d)) relative to the lamella boundaries (first and second row), as well as chain packings commensurate ((a) and (c)) and noncommensurate ((b) and (d)) with the substrate lattice (first and second column) [177].

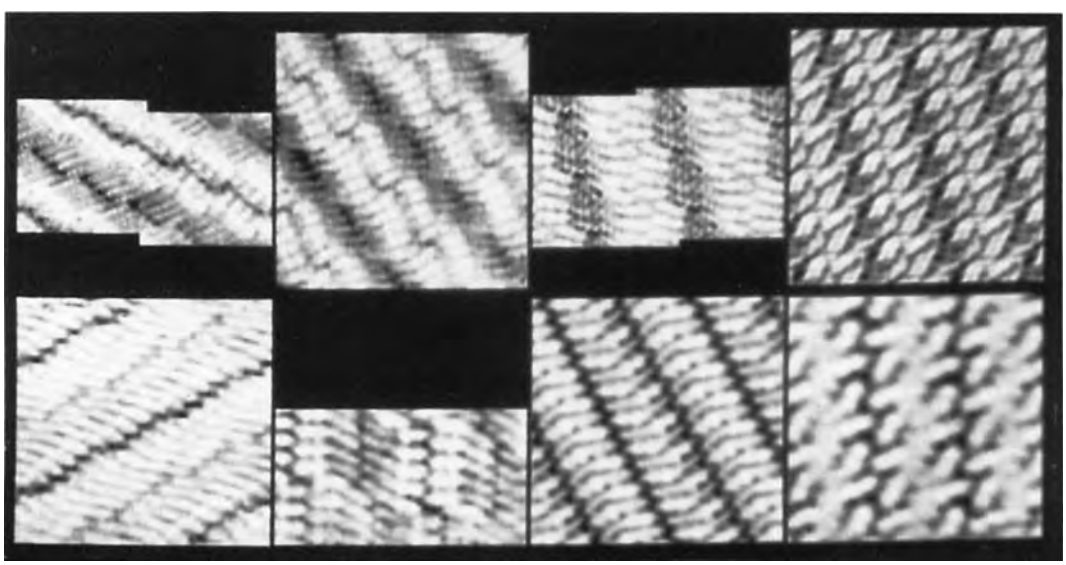

Figure 44. STM images of four alkylated cyanobiphenyls (6CB through 12CB) with 6, 8, 10, and 12 carbon atoms in the alkyl side-chain. The top row displays the images on MoS_2 and the bottom row images on graphite [188].

Macromolecules

Synthetic macromolecules produce STM images which show, at best, molecular resolution. The reason for this is the fact that they are less well ordered than their monomeric analogs and resolution may be adversely affected by chain ends, side groups, etc. The situation is most favorable for stiff macromolecules [196] and polyglutamate [197]. In the case of large biopolymers such as DNA, which are stabilized by intermolecular forces, good images can be obtained which clearly show the right-handed helical structure [198]. Another class of biopolymers giving extremely good STM images are membrane proteins [199].

13.3.3 Electron Spectroscopic Imaging and Electron Energy-Loss Spectroscopy

The simultaneous imaging of the crystalline and amorphous areas of semicrystalline polymers is possible without a staining agent by using electron spectroscopic imaging (ESI) in an energy filtering electron microscope (EFTEM). The method has been applied successfully to obtain structural information about polyethylene [200, 201], block copolymers such as poly(styrene-b-methylphenylsiloxane) [202] and polystyrene-block-poly(2-vinylpyridene) [203], using the Zeiss EM 902 at 80 kV for imaging and the Zeiss EM 912 W operated at 120 kV to obtain electron energy loss spectra. The inelastic interactions of the primary beam with inner shell electrons of the sample give rise to distinct energy losses, the magnitudes of which are characteristic for each element. Conventional electron energy-loss spectrometers contain an electromagnetic prism, a slit diaphragm for energy selection and an electron detector to measure intensity. The local resolution is limited to about 500 Å. Calibration is difficult because of the remanence of magnetic fields. In contrast, in the electron energy-loss spectrometer of the prism–mirror–prism type [204] the spectrum is scanned by varying the accelerating voltage and the electron optical system remains fixed, so that fine calibration of the magnetic prism is unnecessary. By use of a slit diaphragm in the energy dispersive plane, 'monochromatic' electrons can be selected for image formation. The potential advantages of ESI were demonstrated in an investigation of the morphology of polyethylene fibers crystallized from stirred xylene solutions. While it was clear from early conventional TEM studies that the resulting 'shish-kebab' structures consisted of a central core with chain-folded lamellae attached to the central backbone, details relating to the microstructure of the core still remained to be elucidated (Fig. 45). Using stepwise solvent exchange followed by low-temperature embedding in Lowicryl HM20, the polyethylene crystalline gel was changed to the solid state without morphological deformation and excellent high contrast images obtained (Fig. 46) [203]. The contrast arises from the higher density of carbon atoms in the crystalline areas compared with the Lowicryl matrix.

Electron energy-loss spectroscopy (EELS) is particularly well adapted for investigating block copolymers if staining is difficult or undesirable. A good example which shows the improvement in contrast

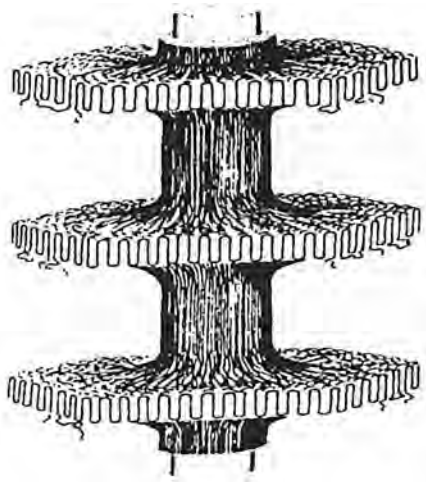

Figure 45. Schematic 'shish-kebab' structure of polymer fibers.

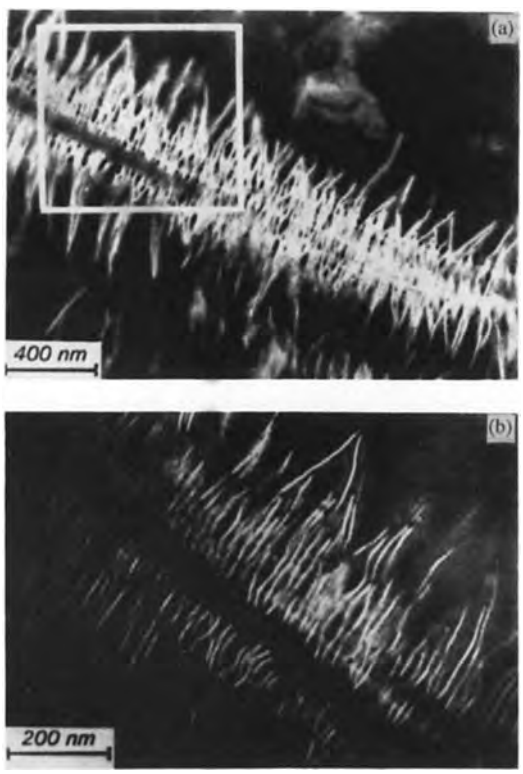

Figure 46. (a) High-contrast ESI image of nonisothermally crystallized polyethylene shish-kebab; (b) detailed view of the marked area from (a) showing the polyethylene backbone.

is a polystyrene-block-poly(1-methyl-2-vinylpyridium iodine) copolymer, and the iodine-specific image with $\Delta E = 206\,eV$ (Fig. 47). This iodine-specific energy loss peak was found to be particularly useful as there was only slight overlap with other peaks, while other and stronger iodine-specific loss peaks were found to be adjacent to nitrogen or carbon loss peaks [205].

13.3.4 Low Voltage High Resolution Scanning Electron Microscopy

Most polymers are nonconducting, so that in conventional SEM operation charging effects necessitate coating samples with a 200–300 Å metal film, thus obscuring fine structural details. At conventional accelerating voltages (≈30 keV) the beam/sample interaction volume in carbonaceous materials is about 10 μm in diameter. Under these conditions, secondary (inelastically scattered) electrons emerge from a shallower, more localized region than the (elastically) backscattered electrons, and therefore provide better image resolution. The secondary image resolution so obtained is effectively equal to the diameter of the incident electron probe, which in turn depends on the brightness of the electron source and the accelerating conditions. Thus the highest resolution which can be obtained for organic samples with a conventional scanning electron microscope (LaB_6 tip at ~30 keV) has been about 50 Å. With a field emission gun and a low voltage (~1–2 keV), the beam can be focused to about 25 Å and even to <10 Å at higher energies (>10 keV).

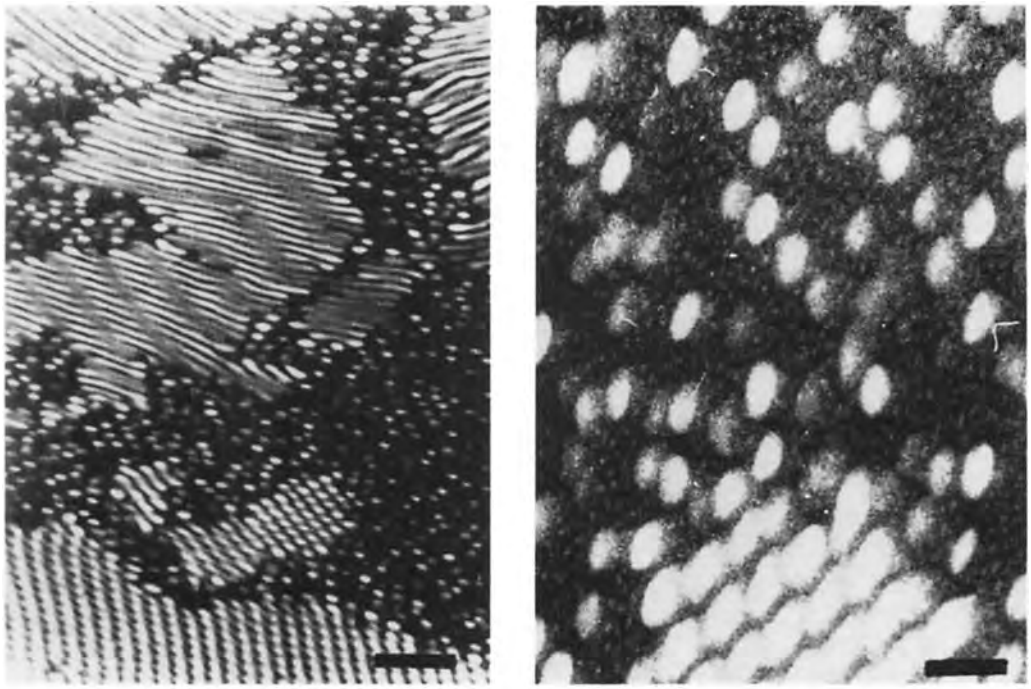

Figure 47. Ultrathin section of a polystyrene-block-poly(1-methyl-2-vinylpyridinium iodide) film from *N*,*N*-dimethylformamide at 50°C. Iodine-specific image (energy loss compensation $\Delta E = 206\,\text{eV}$); scale bar (a) 400 nm, (b) 100 nm [205].

The situation for carbonaceous materials has been recently reviewed [206]. The secondary electrons escape from a depth of about 200 Å, regardless of incident beam energy. Therefore, the only way to improve resolution is to use an accelerating voltage so low that the interaction teardrop dimensions are less than the 200 Å escape depth. The resolution is decreased, but charging is eliminated. When the secondary electrons escape depth is of the same order as the incident electron penetration depth, the build-up of surface electron charge is eliminated. At a given accelerating beam energy, usually called $E2$, the sum of the secondary and backscattered electrons equals that of the incident beam and it is possible to obtain images without a conductive surface coating. The value of $E2$ was found to be in the range 0.9–1.5 keV for different polymers [207, 208]. Because polymers have different $E2$ values, secondary electron imaging compositional contrast can be obtained from copolymers, which also give rise to surface topography.

In practice, charging is not completely eliminated even when working at the crossover voltage, because local variations always occur [206]. Another practical difficulty arises because often samples can be imaged uncoated at TV rates on the cathode ray tube (CRT), but an image cannot be collected because the slower scan rates required to record an image increase charging. There are two possible solutions:

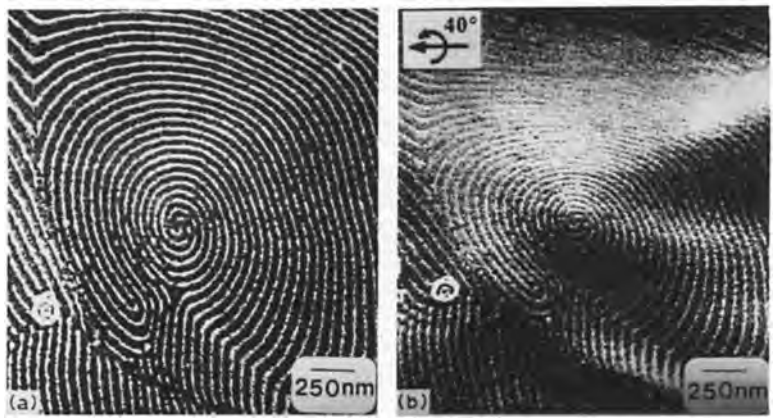

Figure 48. Low-voltage, high-resolution SEM images of an OsO_4-stained PS-PB lamellar diblock copolymer: (a) incident beam approximately parallel to the regional surface normal, giving maximum contrast; (b) the upper region of the micrograph shows a loss of contrast and change in apparent lamellar spacing due to the 40° sample tilt. (From Thomas [205].)

(1) a frame-grabber can be used to take the digital output of the CRT and integrate several images taken at fast scan speeds; and (2) new coating technologies, such as dual ion beam sputter coaters, enable extremely thin continuous conductive coatings of about 10 Å to be applied [209]. Many technical aspects regarding the reduction of contamination and improvement of resolution as well as contrast mechanisms are discussed in the article by Thomas [205], from which Fig. 48, showing a polystyrene–polybutadiene diblock copolymer, is reproduced.

13.4 Electron Crystallography

Electron crystallography is known to pose so many difficulties that its success in solving structures in the most difficult samples of all, namely beam sensitive organic materials, seems very surprising. Undoubtedly, benefit has been obtained from the enormous development in X-ray methods [210], but the technique is still far from reaching the resolution and almost routine application common in X-ray structure analysis and refinement. Unfortunately, many long-chain polymers form only microscopically small crystals, which are quite unsuitable for X-ray analysis, and so electron diffraction is the only possible route to structure determination. The technique has the enormous advantage that selected area diffraction produces single-crystal diffraction patterns which can be obtained in different projections with the aid of a goniometer stage or by using epitaxial orientation. A list of the diffraction structure analyses made of linear chains up to 1993 is given in Table 1 [211–242]. In the older papers, either only the unit cell constants were determined, or a crystal structure which had already been determined by X-ray analysis was confirmed. However, both statistical methods and computational facilities have improved considerably, so that ab initio structure determinations from electron diffraction data are now possible. These methods are described in more detail below. After some experimental information, the discussion is divided into three additional subsections:

- Experimental procedure.
- Simulation of electron diffraction patterns and high resolution images.

Table 1. Quantitative electron diffraction structure analyses of linear polymers (from Dorset [211])

Polymer	Data	*R*	Phasing technique
Two-dimensional determinations			
Poly(tetrafluoroethylene) (oligomer) [211]	*hk*0	0.11	Theoretical model
Poly(diacetylene) [212]	0*kl*	0.12	Patterson map and chain rotation
trans-Poly(acetylene) [213]	0*kl*	0.09	Chain rotation
Poly(ethylene sulfide) [214, 215, 216]	*hk*0	0.33 (0.19 when corrected)	Conformational refinement
α-Poly(3,3-bis-chloromethyl oxacyclobutane) [217]	*hk*0	0.25	Conformational refinement, previous model

13.4.1 Experimental Procedures

13.4.1.1 Sample Preparation

The following methods of sample preparation can be used:

- Growth of single crystals from solution.
- Epitaxial growth on a suitable host crystal [243].
- Application of shear forces, either by spin coating or rubbing.
- Orientation in a liquid crystalline phase by electric or magnetic fields [149].
- Orientation in mono- or multilayers by the Langmuir–Blodgett method [244, 245].

13.4.1.2 Electron Diffraction and High Resolution Imaging

Electron diffraction patterns must be obtained in several projections by a tilting series, using the goniometer stage. Experimentally this step is very demanding. The beam dose has to be reduced to a minimum and, at the same time, the tilting axis carefully aligned in order to obtain diffraction patterns from suitable zones. In some aromatic samples, as many as nine different projections can be obtained [246].

From these experiments the unit cell and space group are determined. Alternatively, a suitable preparation technique may be used to obtain the desired orientation. In order to check whether forbidden reflections are occurring, it is desirable to compare data with a simple X-ray powder pattern. Using the series of electron diffraction patterns (and, if possible, the X-ray powder pattern) the basic zones must be established and consistent indexing achieved in all zones [246, 247].

High resolution images are obtained by phase contrast imaging using cryogenic and low-dose facilities. It is convenient if the phase contrast transfer function can be controlled by transferring the image via a video camera to a computer with fast Fourier transform capabilities [159, 167].

13.4.1.3 Quantitative Analysis of Electron Diffraction Patterns and High Resolution Images

The quantitative analysis of electron diffraction patterns represents a crucial and difficult step. At this stage the space group is known and undesirable symmetry-forbidden reflections are deleted. At present the most convenient analysis of the intensities is performed by using a CCD camera and transferring the data to a PC where it can be analyzed using the ELD software package [248]. Undoubtedly, if CCD cameras with a large dynamic range could be used for on-line analysis of diffraction patterns, this would be of great benefit in electron crystallography. A possible method of analyzing the images and confirming the plane groups in the appropriate projection is available in the CRISP software [249]. Structure factor magnitudes from the electron diffraction patterns are determined in the usual way. The high resolution images are digitized by a CCD camera and transferred to a PC via a frame-grabber. The diffraction pattern of the image is calculated by a fast Fourier

transform routine and the amplitudes and phases determined as in older programs developed at the MRC Laboratory in Cambridge [250]. From this information CRISP finds and imposes the correct symmetry of the crystal and the image is thus restored. These images can then be compared with those obtained from the model structures, as described below.

13.4.2 Simulation of Electron Diffraction Patterns and High Resolution Images

13.4.2.1 Molecular Conformation

To begin simulation, the molecular conformation has to be calculated. This is now standard practice in theoretical chemistry and many degrees of accuracy can be attained, ranging from force field calculations via semiempirical quantum mechanical methods to the ab initio methods. In view of the fact that the molecular conformation as calculated for the gas phase is not identical to the one adopted in the crystal field, the most accurate ab initio methods need not be used. Instead, most of the calculations can be performed using the semiempirical methods incorporated in MOPAC 6.0. The approximations used in semiempirical quantum mechanical calculations are well known [252–254]. All semiempirical quantum mechanical methods use the formalism of ab initio methods (linear combination of atomic orbitals (LCAO) self-consistent field (SCF) approach). The methods differ only with respect to the type of approximations used (e.g. complete neglect of differential overlap (CNDO), modified intermediate neglect of differential overlap (MINDO), modified neglect of differential overlap (MNDO), extended Hückel approach). Other models differ only in the parametrization (MNDO, Austin model (AMI), parametric method 3 (PM3)). The method has been used to obtain the structure of monomeric analogs of the discotic triphenylene ethers and esters [159, 160] as well as the sanidic aromatic polymeric amides [164, 165] discussed in Sec. 13.2.5.

Most molecules have several local energy minima. The conformation which is closest to the one which gives good agreement between simulated and experimental diffraction pattern is chosen to initiate the analysis. See, for example, the cyanobianthryl molecule, which was analyzed in order to determine its suitability for non-linear optical applications [246, 251] (Fig. 49).

13.4.2.2 Simulation of Diffraction Patterns

The unit cell and possible space groups are calculated from a series of experimental diffraction patterns obtained in different projections. Generally, several space groups can be postulated initially, on the basis of the observed extinctions. This number can be reduced when the symmetry requirements of the molecule are taken into account. For simulation, the MOPAC calculated molecule can be placed into the unit cell using CERIUS such that the required symmetries of the molecule and the cell are satisfied and agree with the observed extinctions and symmetry. As the molecule is adjusted, the changing diffraction pattern is immediately displayed; a first qualitative agreement and a good value of the density can usually be

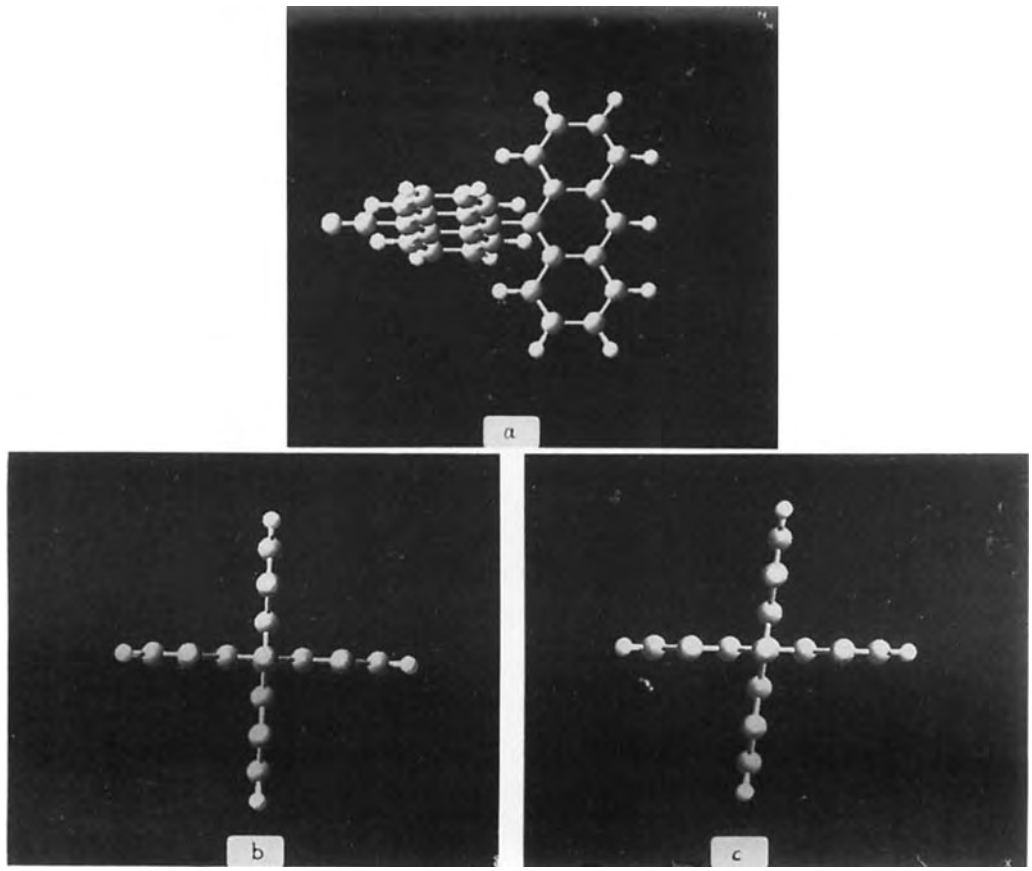

Figure 49. Conformation of CNBA molecule: (a) showing the angle between anthracene moieties; (b) in the gas phase; (c) in the crystalline phase [246, 251].

achieved within reasonable time. At this stage, the packing energy is usually positive and a number of nonallowed close contacts observed. These require adjustment of distances in the Z matrix to satisfy specific criteria involving the packing of aliphatic chains or known bond angles from molecular fragments. Subsequently, the CRYSTAL PACKER is used to ensure that the packing energy of the crystal is negative and that nonallowed contacts are eliminated while retaining the correct symmetry. The potential energy of the crystal is written as the superposition of various two-body, three-body, and four-body interactions:

$$E = E_{\mathrm{VdW}} + E_{\mathrm{Coul}} + E_{\mathrm{hb}} + E_{\mathrm{tors}}$$

The van der Waals term E_{VdW} is treated using the Lennard–Jones functional term and will, of course, represent the major contribution in organic crystals. The Ewald summation technique is used to treat the Coulomb energy E_{Coul} [255]. The energy of the hydrogen bonds E_{hb} is treated with the CHARM-like potential.

A Dreiding force-field is used for the calculation of subrotation interactions E_{tors} [256]. Finally, the R factor, which relates the observed and calculated intensities by the relationship

$$R = \frac{\sum_{hkl} ||F_0| - |F_c||}{\sum_{hkl} |F_0|}$$

has to be calculated. For electron diffraction, the values commonly achieved in X-ray diffraction cannot be reached; a reasonable value, if all the above criteria are satisfied, lies in the range 0.1–0.3. Examples of successful simulations of organic monomeric analog crystals based on these considerations are the dione head group [247], the triphenylene ether [159], and the cyanobianthryl [246] (Fig. 50). Further examples are polybutene (Fig. 51) [257], several polysaccharides [258], and chitosan [259].

It is pertinent to ask the question why simulation methods are proving to be successful with organic molecules, despite the difficulties associated with beam damage, as well as dynamical and secondary scattering effects. It seems that there are a number of contributing factors. The unit cell is not too large by biological standards ($\sim$1000–2000 Å^3), containing only a few hundred atoms. Of these, many are covalently linked, with well-defined bond lengths. Furthermore, parts of the molecule frequently have very stiff, well-defined fragments. In addition, aliphatic chains often adopt a close-packed arrangement similar to that in alkanes, so that the attached functional groups are forced to fit into available spaces by molecular subrotations, while keeping allowed intra- and intermolecular bond distances and retaining the symmetry observed in the electron diffraction patterns.

13.4.2.3 Simulation of Images

The images can be simulated using the atomic coordinates from the model structures obtained by electron diffraction simulations. The CERIUS HRTEM mode simulates dynamical diffraction patterns and real-space images using the multislice method [260]. The expression for the two-dimensional image intensity distribution $I(x, y)$ is given by:

$$I(x,y) = |q(x,y)|^2 \cdot \left[\frac{J_1(\pi u_0 r)}{\pi\tau}\right]^2 \times |F \exp\{i\chi\}|^2$$

where $[J_1(\pi u_0 r)]/\pi r$ is the first-order Bessel function representing scattering from a spherical atom with coordinates x, y at a distance r in real space, q is the transmission function and $|F \exp\{i\chi\}|$ is the Fourier transform of the transfer function χ where

$$\chi_{ph} = \frac{2\pi}{\lambda}\left(\Delta f \frac{\boldsymbol{k}^2}{2} - C_s \frac{\boldsymbol{k}^4}{4}\right)$$

$\boldsymbol{k}$ is the scattering vector, C_s is the spherical aberration, Δf is the defocus, and λ is the electron wavelength.

In practice, for organic samples the required transfer function χ is carefully determined beforehand and adjusted in an adjacent area before the area of interest is moved into the beam and immediately photographed.

Examples of successful structure determinations using a combination of electron diffraction, high resolution imaging, and molecular modeling are the liquid

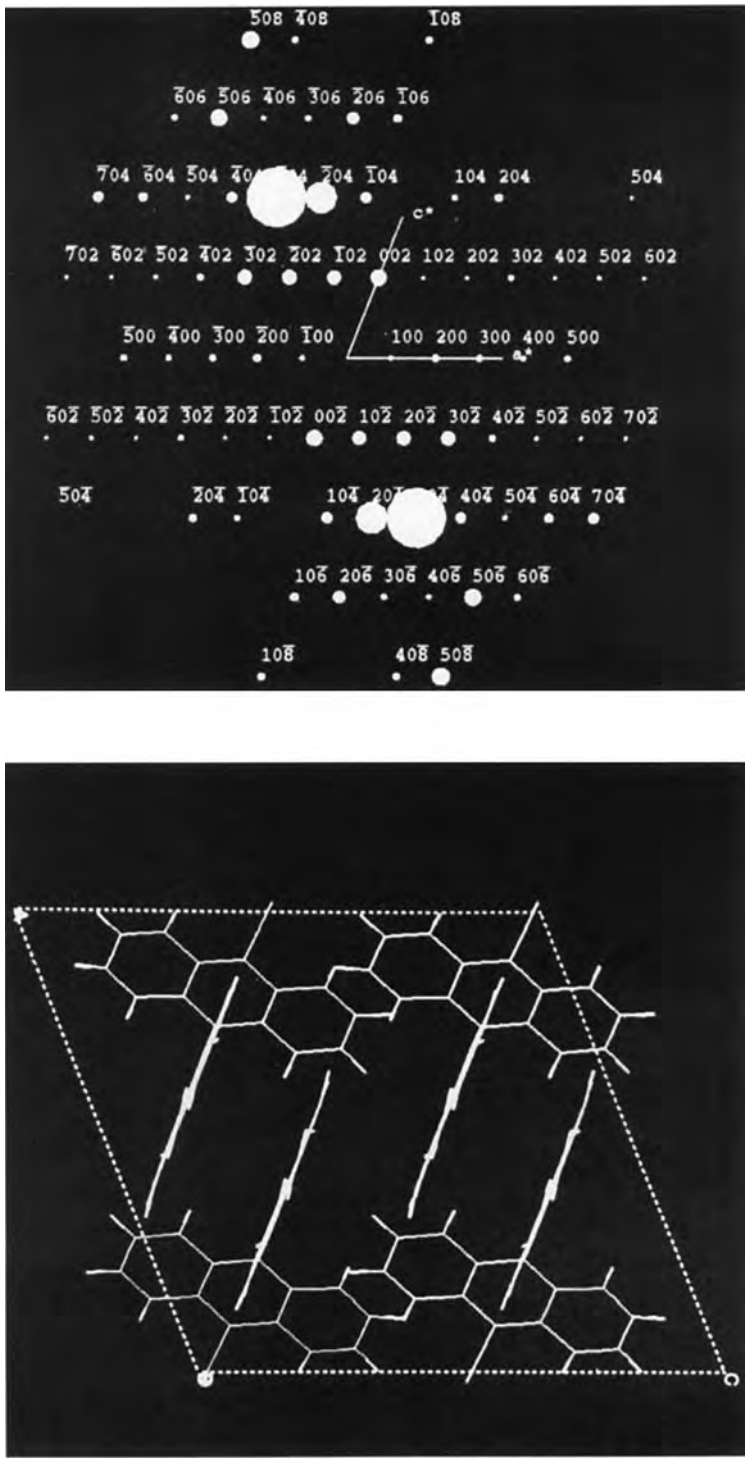

Figure 50. Model and its diffraction pattern of cyanobianthryl obtained by simulation of experimental diffraction patterns [251].

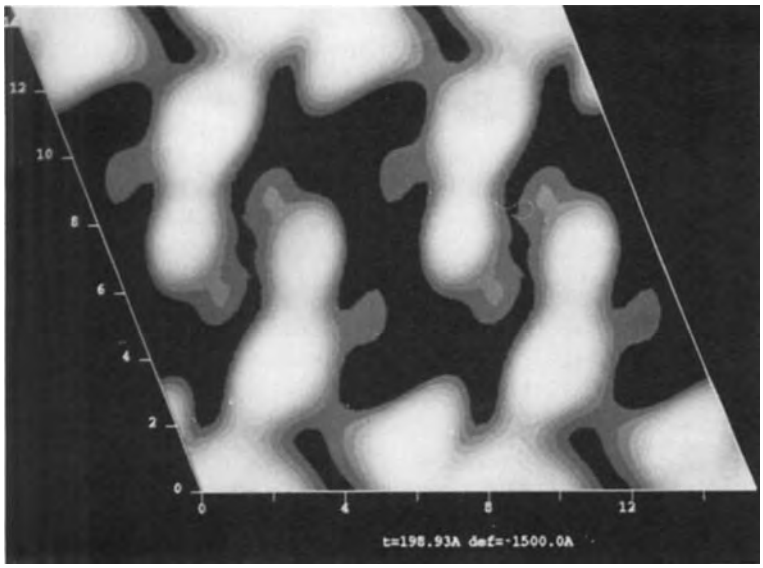

Figure 50 Continued

crystalline polymers and their monomeric analogs [159, 160, 164, 167, 168], as well as several linear polysaccharides [224, 225, 236, 244].

13.4.3 Direct Methods

For several years direct methods have been used successfully for the analysis of organic crystals from electron diffraction data [261–267]. In the case of large macromolecules, electron diffraction structure factor magnitudes have been used together with crystallographic phases determined from high resolution images in order to visualize the unit cell contents [268] using appropriate methods of averaging statistically noisy images [269] to improve their interpretability. However, in the case of organic polymer crystals with small molecules and small unit cells the direct phasing methods can be used for ab initio structure determination at very high resolution because electron diffraction patterns can be obtained with a resolution down to about 1 Å. Initially, normalized structural factor magnitudes $|E_h|$ are calculated using electron scattering factors F_h

$$E_h^2 = \frac{|F_h|^2}{\epsilon \sum_{i=1}^{N} f_i^2}$$

where f_i is the atomic scattering factor for atom i, and ϵ is a multiplicity factor which accounts for translational symmetry elements.

In direct methods the probability is calculated that certain combinations of crystallographic phases ϕ_h will have a specific value ψ (0 or π in centrosymmetric crystals) [270, 271]

$$\psi = \Phi_{h_1} + \Phi_{h_2} + \Phi_{h_3} + \cdots$$

subject to the constraint

$$\sum_i h_i \equiv 0$$

where h_i are the Miller indices of several reflections, based on normalized structure

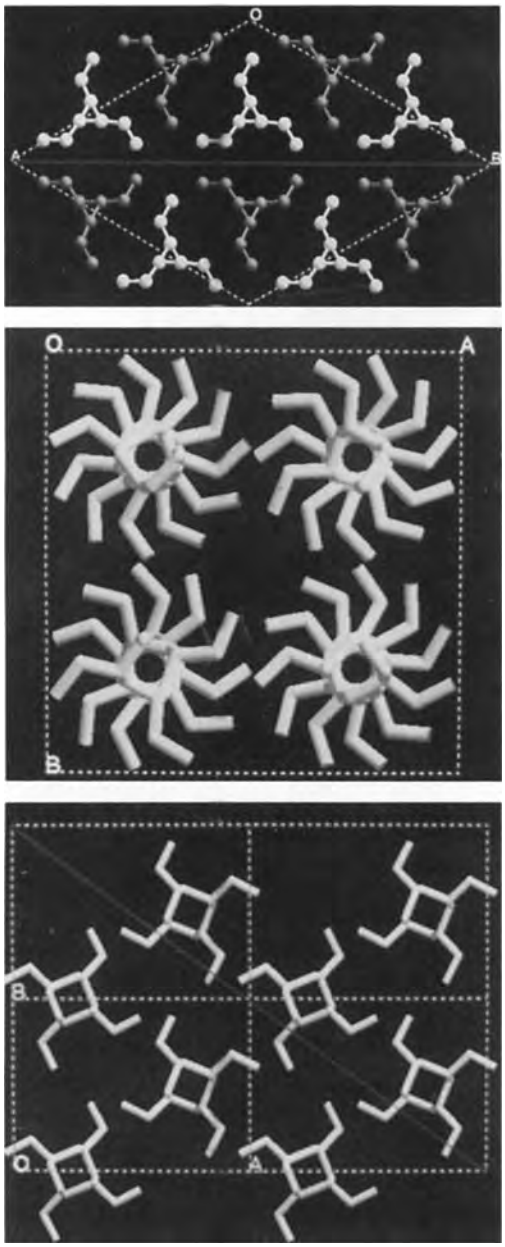

Figure 51. (Top) computer-generated molecular model of PBu: form I and I′ unit cell; (*ab*) plane; View along chain axis showing 3_1 helices in trigonal packing. Note the layered structure with interdigitated antichiral helices. (Middle and bottom) computer-generated molecular model of PBu: form III unit cell; (100) projection showing the 4_1 helices in projection (orthorhombic packing) [257].

factor magnitudes. Initially, a subset of highly probable phases is chosen and combined with a small number of additional individual phases to give a consistent set of simultaneous equations. The process is repeated with different combinations of reflections. Often a consistent set of phased structure factors can be found and some features of the molecular packing in the unit cell determined from the potential map obtained by Fourier transformation [272]. The intensity values can be improved when the effects of dynamical scattering and crystal bend deformation are considered [273, 274].

In principle, the phases obtained from the Fourier transform of high resolution images can be used to obtain some of the phases from the low resolution diffraction maxima for the initial subset [275], but they may be misleading if the symmetry of the object is not retained fully during the imaging process, so that it is better to attempt an ab initio determination.

Once an initial crystal structure has been found, the valence parameters (bond lengths and angles) can be optimized using various different techniques.

Difference Synthesis

Given the potential map derived from the phased structure factors ϕ_c, a difference synthesis,

$$\phi_0 - \phi_c = \frac{1}{V}\sum\sum\sum \Delta F_{hkl}(-2\pi i r \cdot s)$$

can be calculated, where $\Delta F = (F_0 - F_c)$, the difference between observed and calculated structure factors [276].

Least-Squares Fit of Parameters

In this approach the atomic positions, thermal parameters, etc., are adjusted to

give best agreement between the calculated and experimental data. In practice, the multisolution phase determining programs MULTAN and RANTAN have proved effective for phase extension [277], on the condition that the subset phases are known from other experiments. The program QTAN was applied to the electron diffraction problem with more success [279, 280]. In this procedure the most likely phase solution is sought in the most negative value of NQEST [279] based on negative quartet invariants. The results of direct phase determination for the polymers polyethylene, poly(e-caprolactone), and poly(1-butene) are shown in Fig. 52 [277]. The projection of polybutene (Fig. 53) shows excellent agreement with the structure obtained by simulation (Fig. 51).

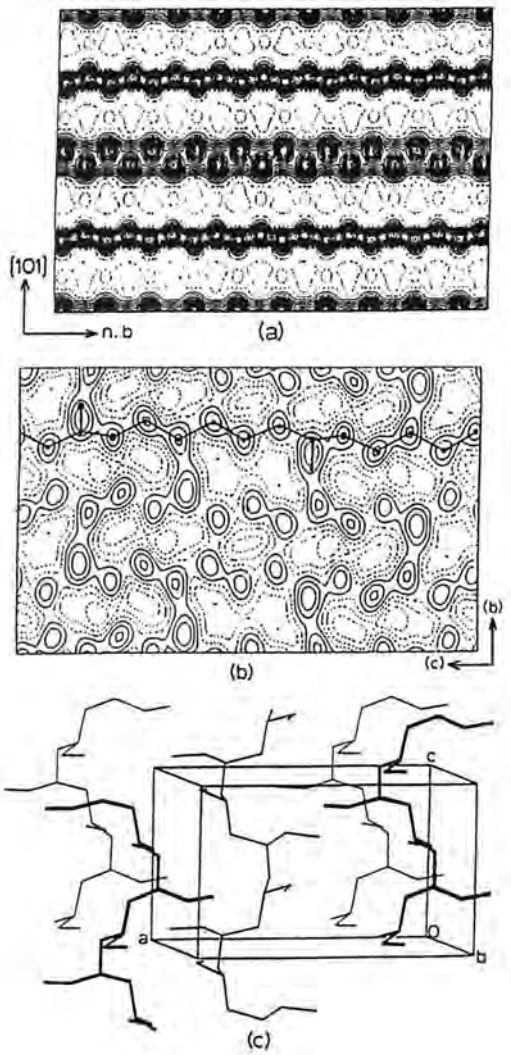

Figure 52. Results of direct phase determination for three polymers: (a) polyethylene; (b) poly(ε-caprolactone); (c) poly(1-butene) [278].

13.4.4 The Maximum Entropy Phasing Method

Direct methods of crystal structure determination impose rather stringent requirements on the data set:

- A data resolution of 1.1–1.2 Å.
- A nearly complete sampling of reciprocal space to this resolution.
- A reasonably accurate set of intensity measurements devoid of large systematic errors.

The third criterion may be particularly troublesome because of secondary and dynamic scattering. The maximum entropy approach is not so constrained with respect to data quality and has been used successfully to solve the structure of two monomeric analogs containing the chromophores for second-harmonic generation [246, 247] and the structures of some small organic molecules [281, 282]. The procedure is summarized below.

In direct methods, probability limit theorems are used to estimate the joint probability distribution of suitably chosen structure factors; the substitution of the

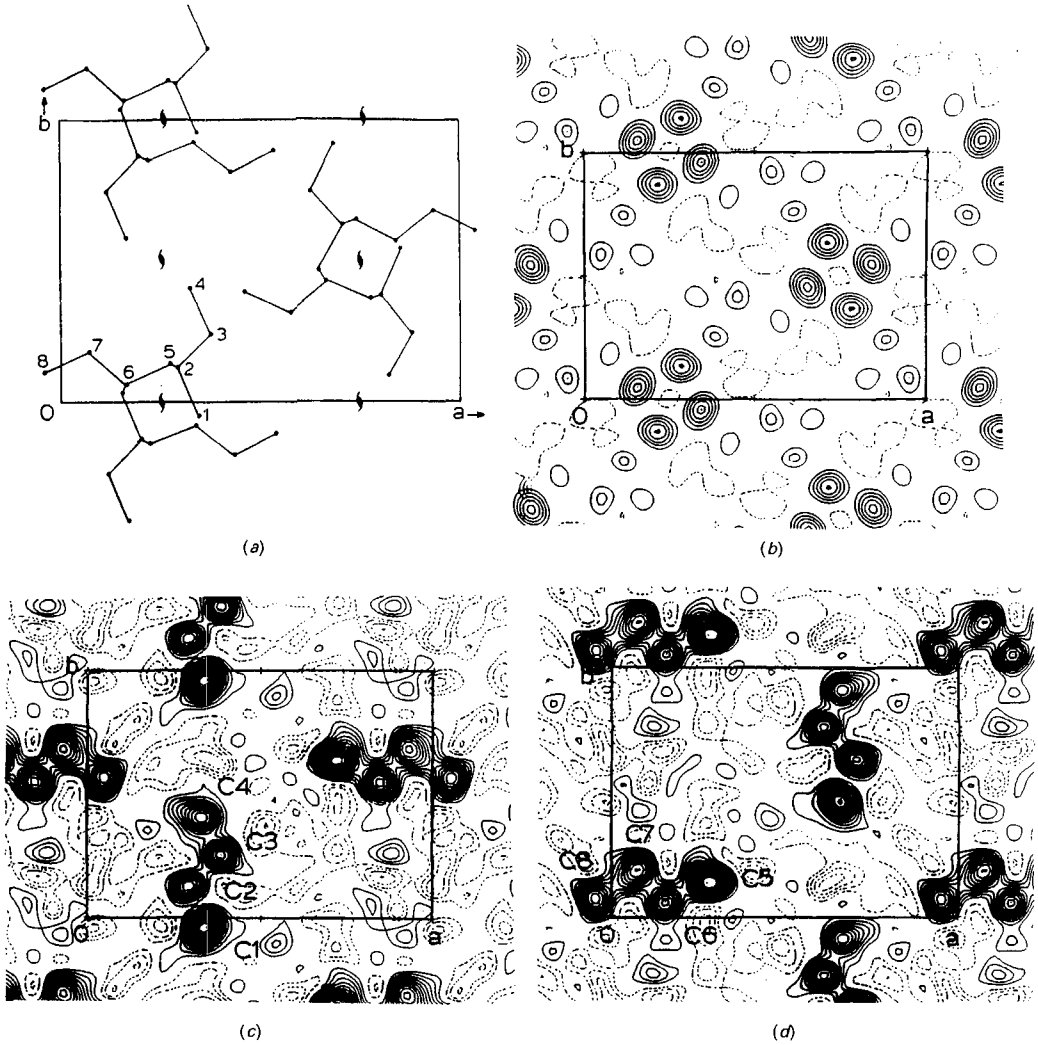

Figure 53. (a) Molecular packing in the projection along c, showing the pseudo-four-fold symmetry. (b) Electrostatic potential in the projection along c. (c) Electrostatic potential in the section $z = 0.12$. (d) Electrostatic potential in the section $z = 0.35$ (indicating that density persists somewhat beyond the $z \pm 0.25$ required by the pseudo-4_1 symmetry operation) [278].

observed structure factor into these distributions yields conditional joint distributions for the phases, indicating that certain combinations of phase values are more probable than others once the amplitudes are known. However, the traditional procedure involving the Gram–Charlier or Edgeworth series [283, 284], or related expressions [285], is not used in the maximum entropy approach. Instead, the saddlepoint method [286] is invoked. This is equivalent to requiring the distribution of random atomic positions to be updated whenever phase assumptions are made, so as to retain maximum entropy under the constraints embodied in these assumptions. This approach to the phase problem leads naturally to a general multisolution strategy of structure determination [287–289] in which the space of hypothetical

phase sets is explored in a hierarchical fashion by building a phasing tree. Each trial phase set is represented as a node on the tree, and is ranked according to the log-likelihood gain (LLG), or the Bayesian score, associated with it. This, in turn, measures how well a trial phase choice predicts the pattern of observed, unphased intensities via the process of maximum entropy extrapolation. The growth of the phasing tree is guided and controlled throughout by this heuristic function.

For the purposes of ab initio phasing from electron diffraction, the method is implemented as follows [289, 290]:

(1) The unique intensities are normalized using MITHRILL [291, 292] to give unitary structure factors $|U_h^{obs}|$ and their standard deviations σ_h by using electron scattering factors and imposing a suitable isotropic temperature factor.

(2) An origin is defined by fixing phases of suitable reflections using the MICE software with a second neighbor search procedure [293, 294]. These phased reflections form a basis set $\{\boldsymbol{h}\}$. The remaining reflections comprise a disjoint set $\{\boldsymbol{k}\}$ $(\boldsymbol{h} \cap \boldsymbol{k} = \phi)$.

(3) These phased reflections are used in an entropy-maximization procedure using an exponential modeling scheme [289] to procedure an initial maximum entropy atom distribution $q(x, y)$. In this way node 1 of a phasing tree is generated.

(4) At this stage, maximum entropy extrapolation from the Fourier transform of $x(x, y)$ is weak. Therefore further reflections $(h \in k)$ are added on the basis of (a) strong intensity and (b) optimal enlargement of the basis set. This gives rise to a series of phase choices, each of which is represented as a node on the second level of the phasing tree. Each node is subjected to constrained entropy maximization and an LLG is calculated for each one. A Rice-type likelihood function is used to rank the models [287–289].

(5) The LLGs are analyzed for phase indications and only those consistent with *t*-test results [293] are kept. Further reflections are permuted and a new level of nodes generated. The ME distributions associated with the various nodes are not electron potential maps in the traditional sense; instead, centroid maps are produced [289] using a Sim-type filter [294].

The method has been successful with electron diffraction data sets for perchlorocoronene [295] and a variety of organic and inorganic molecules [296]. Examples of a successful application of the method to two organic molecules with functional groups, which had also been analyzed using the simulation method, are the dione head group [247] and cyanobianthryl [246, 251] (Fig. 54). The *ac* projection shown in Fig. 54 demonstrates the excellent agreement with the results of the simulation shown in Fig. 50.

13.5 High Resolution Transmission Electron Microscopy

High resolution imaging of polymeric materials presents a number of specimen-specific problems. However, in the past 10 years there have been some critical improvements in modern microscopes and computer technology which have led to a dramatic increase in high resolution TEM investigations of polymers.

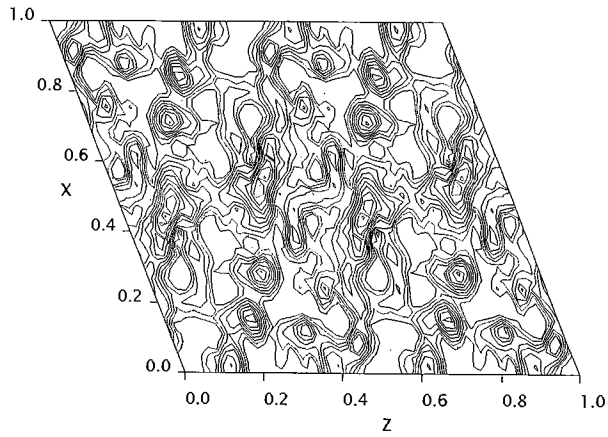

Figure 54. Maximum entropy calculated potential map of 10-cyano-9,9′-bianthryl from electron diffraction data in the [010] projection [246].

The theoretical and experimental conditions required for high resolution imaging are well known [297, 298]. This section is therefore devoted to technical problems concerning organic molecules and their solution (Sec. 5.1 of this Chapter) and the direct impact of such investigations on the understanding of polymer structures (Sec. 5.2 of this Chapter).

13.5.1 Specimen-Specific Problems

13.5.1.1 Radiation Damage

The most serious problem limiting the quality of high resolution images from polymers is beam sensitivity. Radiation damage in polymers during electron-beam exposure is a well-known problem which was first analyzed about 30 years ago [299, 300]. The effect depends on details of the interaction between the electrons and the molecule, which are temperature dependent. In some samples free radicals are formed which move along the polymer chain and finally cause cross-linking (increasing the molecular weight). Alternatively, high energy electrons can cause degradation of the molecule (decreasing the molecular weight). Beam damage is characterized by a quantity called the 'critical end-point dose' J_C and is obtained from the loss of intensity I of a Bragg reflection as a function of dose:

$$I = I_d \exp\left(\frac{-J}{J_C}\right) + I_b$$

A related quantity is J_e, the incident electron dose required to destroy crystallinity in the sample. Typical values at room temperature are 600 electrons nm^{-2} for an aliphatic polymer such as polyethylene and 144 000 electrons nm^{-2} for an aromatic polymer such as poly(paraphenylene benzobisthiadiazole). Therefore the experimental situation is considerably more favorable in the latter case.

Experimentally, it is often necessary to use low-dose and cryogenic methods. These have the disadvantage that a sample position is imaged which is adjacent to the one used for focusing and may therefore require different imaging conditions. In addition, the resolution attainable in good cryogenic holders is only about 5–10 Å.

13.5.1.2 Choice of Microscope Transfer Function

In polymeric samples the features that one wants to image may lie between 2 and 30 Å. Because of beam sensitivity, the correct transfer function cannot be found experimentally by defocusing but has to be calculated beforehand [151, 154, 167]. It is well known that the phase contrast function is given by $\sin \chi$, where

$$\chi(\boldsymbol{k}) = \frac{2\pi}{\lambda}\left[-\frac{1}{4}C_s\boldsymbol{k}^4 + \frac{1}{2}\Delta f\boldsymbol{k}^2\right]$$

λ is the electron wavelength, C_s is the spherical aberration, $\boldsymbol{k}$ is the scattering vector, and Δf is the defocus value.

This function oscillates strongly when the contrast function is manipulated to give a maximum in the small angle region, transferring higher spatial frequencies with positive and negative contrast. Since the image intensity $I(x_1, x_2)$ is given by a convolution $(*)$ of the Fourier transform of the transmission function with the Fourier transform of the transfer function, it is essential to know the transfer function for image interpretation, since in the weak phase approximation:

$$I(x_1, x_2) = 1 + 2\sigma\Phi\varphi(x_1, x_2) * F[\sin \chi(k)]$$

where

$$\sigma = \frac{\pi}{\lambda_0 E}$$

with λ_0 being the electron wavelength, E the acceleration potential, and $\phi(x_1, y_1)$ the projection of the mean inner potential of the object [260]. Therefore quantitative analysis of the image is essential in order to establish its relation to the object.

13.5.1.3 The Damping Function

In view of the 'unusual' transfer functions which are often used in polymer microscopy, the effect of the damping functions $D_1(\boldsymbol{k})$, $D_2(\boldsymbol{k}, \Delta f)$, and $D_3(\boldsymbol{k}, M)$ on the transfer function T must also be considered:

$$T = \exp[i\lambda(\boldsymbol{k}\Delta f)]\, D_1(\boldsymbol{k})\, D_2(\boldsymbol{k}, \Delta f) \times D_3(\boldsymbol{k}, M)\, A_1(\boldsymbol{k})$$

where M is the magnification, D_1 is the damping envelope due to defocus spread, D_2 is the damping envelope due to beam divergence, D_3 is the damping due to the film response, and A_1 is the aperture function [301].

From these equations, the defocus, the maximum defocus spread, and the limiting semi-angle of illumination for any microscope can be determined; these quantities are required to image specific features in the polymer [154, 301, 302]. In practice, the electron dose may be too high at the required magnification.

13.5.1.4 Image Simulation

Polymer microscopists have mainly been using commercially available program packages such as MACTEMPAS (Lawrence Berkeley Laboratory) and CERIUS (Molecular Simulations, Inc.), which all use the multislice approach of Cowley and Moodie [303]. The effect of the contrast transfer function and dynamical scattering on the image are taken into account; therefore, both quantities need to be known quite accurately. In addition, the atomic positions are required. If these are available from an X-ray structure

analysis it is relatively simple to calculate the image for various thicknesses. However, frequently in polymer science, especially in the case of new, innovative materials, these are not available and one of the methods described in Sec. 13.4 must be applied.

A possible way of proceeding is as follows. The microscope transfer function is monitored by a computer with fast Fourier transform capabilities attached to the electron microscope via a suitable CCD camera. On the basis of the electron diffraction pattern from the sample, a decision is made as to which spatial frequencies are to be transferred, and the appropriate phase contrast transfer function chosen [153, 154, 159, 164].

In order to interpret the images, the atomic coordinates are required. If the crystals are too small for X-ray structure analysis and refinement, these parameters must be determined from electron diffraction [159, 163–165, 215–246]. A series of electron diffraction patterns showing different projections is required. Using these, a model structure is proposed, which eventually has to satisfy all the following criteria: (1) all intensities from all projections must give a good agreement with experiment; (2) the calculated density must agree with experiment; (3) the packing energy must be negative; and (4) there must be no nonallowed bond distances or bond angles; (5) possible hydrogen bond patterns must be considered. As indicated in Sec. 4.2 of this Chapter this step is extremely demanding.

The coordinates of all the atoms in the unit cell can be obtained from the model processed in the HRTEM mode of a suitable modelling program to calculate the image convoluted by the correct transfer function and taking account of the sample thickness. High resolution images and their calculated models can thus be obtained and compared with one another. As slow-scan CCD cameras with increased resolution and at lower cost become available, they will undoubtedly play an increasingly important role in high resolution imaging of polymers, because the correct transfer function can be found very quickly from the Fourier Transform of the image.

As an alternative to TEM, STM and AFM will play an increasingly important role in high resolution imaging, as discussed in appropriate preceding sections of this Chapter. However, their limitations should also be kept in mind: (a) it is very difficult to obtain the same high quality images from polymers as those which have been achieved for monomers; and (b) the substrate controls the molecular packing, which is expected to be different from that in crystals, thin films, or bulk material.

13.5.2 Experimental High Resolution Images of Polymers and their Monomeric Analogs

The first high resolution images of poly (p-phenylene terephthalamide) fibers [304] clearly showed the lateral packing and intermolecular registry between PPTA molecules and confirmed their extended chain structure. The size and shape of crystalline domains in PPTA as well as their relative orientations were analyzed and compared with the results of X-ray diffraction experiments [305].

When image restoration methods became generally available, a whole series

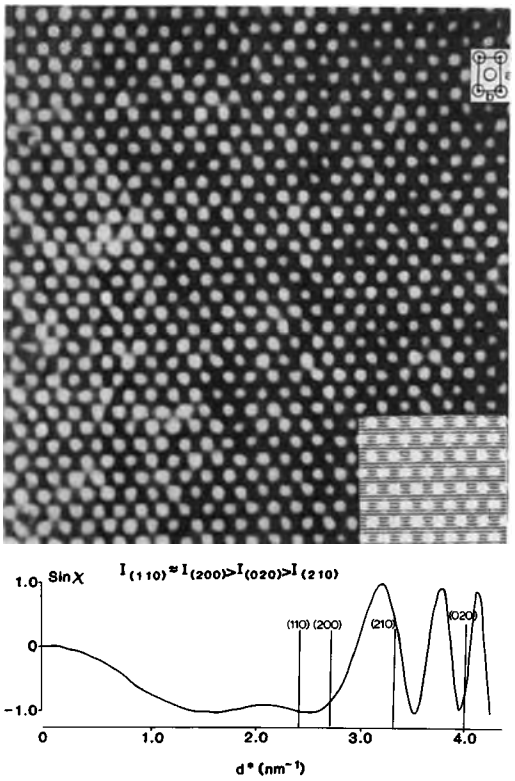

Figure 55. High resolution, low dose image of a monolamellar *n*-paraffin (n-$C_{44}H_{90}$) crystal obtained with a cryoelectron microscope. The image was averaged by correlation techniques. The inset shows a multislice *n*-beam dynamical calculation carried out for the known crystal structure and instrumental conditions used to obtain the micrograph [310].

of polymers were investigated using high resolution TEM methods: isotactic polystyrene [306], polydiacetylene [307], polytetrafluoroethylene [308], poly(phenylene sulfide) [309], and single crystals of alkanes [310] (Fig. 55), polyethylene [311, 312], and polyparaxylylene [313]. Lattice images from poly(paraphenylene benzobisthiazole) and poly(paraphenylene benzobisoxazole) showed specific defects within crystals, and indicated local bending of molecules within compressive failure zones [314].

These observations were used to develop a classification scheme for grain boundary defects in extended-chain polymers [314]. In syndiotactic polystyrene, antiphase boundaries, due to local variations in the crystallographic packing of the helical sPS chains, were revealed [315]. An investigation of polyimides provided evidence for dislocation-mediated splay distortions of lamellae [316]. Lattice images have also been obtained from biopolymers such as cellulose [317, 318] and bacterially synthesized poly(ester)poly(hydroxybutyrate) [319].

From high resolution images of low molar mass organic molecules, such as paraffins [17] and Langmuir–Blodgett films of phthalocyanines [244, 245], it has been possible to characterize the packing of molecular chains and the defects at grain boundaries. In particular, it was possible to characterize the high concentration of defects and misorientation in thin monolayer films. Subsequently, the structure of lipid systems exhibiting lamellar textures were studied and crystal boundaries and local fluctuations of lamellar orientation investigated [320].

The defects in a series of polymeric liquid crystals with highly functionalized mesogenic groups, and their monomeric analogs, were analyzed using cross-correlation methods and their crystal structures analyzed and refined [159, 160]. Recently, a series of such molecules was imaged using high resolution TEM [165, 167, 168, 246], and their atomic positions were determined by simulation of diffraction patterns and maximum entropy crystallographic methods [167, 168, 246]. Using these atomic positions, the images were calculated and compared with the high resolution TEM images [163, 164, 167, 168] (Fig. 56).

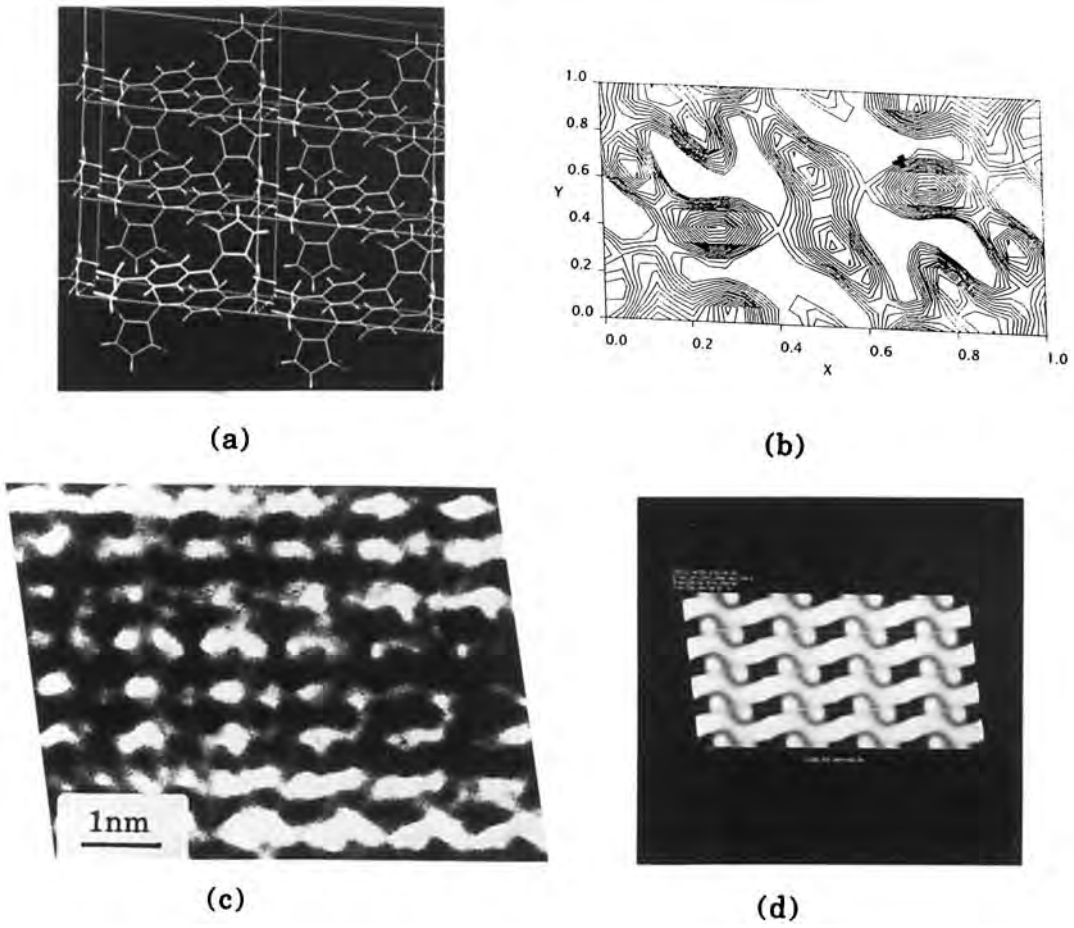

Figure 56. Comparison between the model structure (a), potential map (b), high resolution image (c), and simulated image (d) [247].

Figure 56 shows the dione molecule which was investigated for possible NLO applications. A series of images at different defocus and thickness values is shown in Fig. 57.

From this long list of fairly recent successful high resolution imaging in polymers and their monomeric analogs, it is apparent that the method, as well as the interpretation of images and defects, is becoming increasingly sophisticated.

13.6 Summary

As indicated in the Introduction, electron microscopy and diffraction have played a major role in the investigation of polymers. Some typical applications have been summarized in this Chapter. In writing this article, a possible route could have been to produce a long list of successful investigations on a wide variety of different polymers. However, this would have detracted

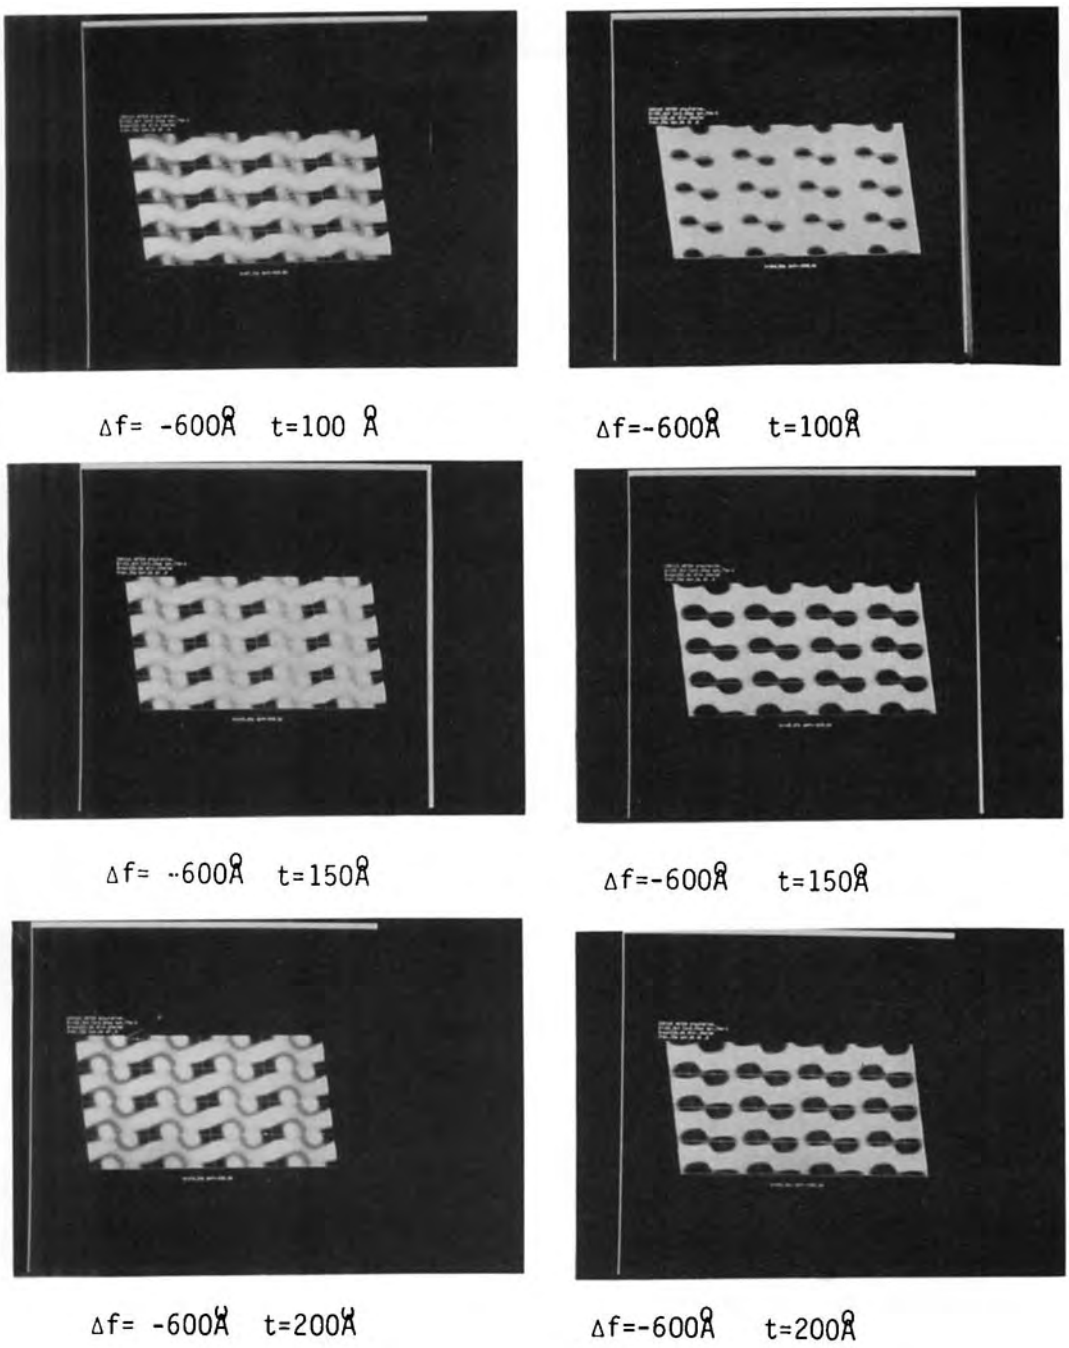

Figure 57. Simulated images obtained from model structures for different defocus (Δf) and thickness (t) values.

from some very exciting new developments currently taking place. Sophisticated methods of analyzing defects have been developed and detailed information can be obtained at atomic level, even from organic samples, by using a combination of electron crystallography and high resolution imaging or by applying one of the new near-field methods. It has been indicated why this information is needed to produce specific physical properties and the kind of molecular architecture which is required. It has also been shown that the difficulties associated with electron crystallography and the interpretation of the high resolution images from organic samples can be overcome. Frequently the situation arises that theoretical papers overemphasize the problems associated with the interpretation of diffraction patterns and images, so that experimentalists are discouraged from even attempting to use the technique. Hopefully the present Chapter will encourage more experimentalists in the polymer field to continue their struggle against the, admittedly awesome, difficulties and, if necessary, to collaborate with a suitable theoretician if the results are difficult to interpret.

Acknowledgements

I am extremely grateful for the immediate and generous response of my colleagues, who supplied figures and reprints of their recent publications.

14 Nuclear Materials

14.1 Introductory Remarks on Handling Nuclear Materials

14.1.1 Overview

Optical and electron optical methods are used in research for characterizing all types of nuclear materials, although the problems treated vary widely. Before irradiation, material properties have to be correlated with the microstructure as the necessary basis from which after in-pile service property changes due to the histories of irradiation, stress, temperature, and corrosion can be established, and improved materials can be developed. The high standards for reliability and safety in the nuclear industry require a detailed characterization of all materials before they are used in nuclear reactors. The methods are different in the analysis of radioactive particles on filters or in biological tissue (see Sec. 14.5 of this Chapter).

Necessary background information on reactor technology and nuclear fuel cycle can be found in *Ullmann's Encyclopedia of Industrial Chemistry* [1]. Structural materials, nuclear fuels and materials for waste disposal, are treated by Frost [2].

From a practical point of view, nuclear materials have to be classified according to their degree of radioactivity. This has to be quantified along three lines:

(i) Out-of-pile by the rate of nuclear decay, measured in becquerels (Bq) ($1\,\mathrm{Bq} = 1\,\mathrm{s}^{-1}$) (formerly expressed in curies (Ci), $1\,\mathrm{Ci} = 3.7 \times 10^{10}\,\mathrm{Bq}$), with the emission of γ quanta, α and β particles, and in-pile by the rate of nuclear fission with the emission of energetic fission fragments, neutrons, and γ quanta.

(ii) By the energies of the various particles absorbed in biological tissue or in solids. The absorbed energy is defined by the gray ($1\,\mathrm{Gy} = 1\,\mathrm{J\,kg}^{-1} = 100\,\mathrm{rad}$).

(iii) Depending on the type of radiation and the type of biological tissue the absorbed energy dose (gray, Gy) has to be multiplied with a factor f to arrive at the biological effects. Formerly these were qualified by the *r*adiation *e*quivalent dose for *m*an (rem). Now the official unit is the sievert (Sv), and $1\,\mathrm{Sv} = 100\,\mathrm{rem}$.

The general rules for the safe handling of radionuclides have been established by the International Atomic Energy Agency (IAEA) in Vienna [3], apart from national law. A useful collection of rules and data on health physics, safety, and control

measures in handling transuranium elements has been given by Vaane [4]. Further details on these and other aspects of handling radioactive materials are treated in the IAEA *Safety Series* [5].

Because of the possible health hazards in work with radioactive materials, as with other toxic or otherwise dangerous materials, special permission is required, and has to be supervised by a qualified authority. Based on local and national laws, this authority usually defines the degree of protection and the quantity and type of radioactive material allowed for handling and storage in a given type of installation.

There are roughly three types of protective installations for radioactive materials, to which the optical and electron optical instrumentation has to be adapted:

(a) Irradiated nuclear fuel elements and the fuel rods can only be remotely dismantled, inspected, cut and analyzed in α/γ cells. These are heavily shielded concrete cells which contain air-tight α boxes equipped for the introduction of manipulators for handling equipment and materials.
(b) Structural alloys (not in previous contact with nuclear fuels) in general contain isotopes which are γ activated by the neutron flux in the reactor core. Hence, ordinary sized specimens of such irradiated structural core materials can be manipulated in simpler γ concrete cells or behind lead shielding provided their surface is not α contaminated.
(c) Materials containing purely α-emitting heavy isotopes, such as ^{235}U and ^{239}Pu, under all circumstances have to be stored in air-tight containers and manipulated in air-tight glove boxes. If the α material contains isotopes emitting hard γ rays, for example certain plutonium, americium, and curium isotopes, the glove box has to be shielded as well.

In general, the procedure to prepare and to analyze radioactive specimens by advanced analytical techniques is as follows. The heavily shielded α/γ or γ concrete cells are used for cutting smaller parts and raw specimens from highly radioactive fuel rods and from irradiated structural materials. Some of this material may be submitted to further testing in these cells. Eventually, depending on specimen size, the final preparation and microscopic analysis can be done under conditions which require less severe or even very little γ shielding.

14.1.2 Technical Solutions for Optical and Electron Microscopes

Here the methods for analyzing highly α/γ-active specimens are mainly outlined. The analysis of irradiated γ-active structural alloys without α contamination is correspondingly simpler. The examination of highly α/γ-radioactive samples by microscopy is complicated by two factors:

(i) Total α-containment is required at every stage of specimen preparation, handling, transfer, and observation to prevent possible α contamination of the environment and of the operator.
(ii) Adequate γ protection of the operator is essential to minimize personal exposure to γ radiation from the samples.

14.1.2.1 Optical Microscopy

For the analysis of the cross-sections of fuel rods and of macroscopic samples from reactor core materials (steels, nickel-base alloys, Zircaloy, etc.), remotely operated optical microscopes are attached to the α/γ and γ hot cells.

For the analysis of nonirradiated, plutonium-containing fuel materials (ceramic pellets or alloys) the optical microscope is enclosed wholly or partly in an air-tight α box. The specimens have to be transferred from the preparation box without breaking the air-tight containments by a special technique (double-lid air locks or welded plastic bags) into the α box of the microscope.

In both of the above situations all conventional techniques of optical microscopy can be applied up to 1000× magnification, as outlined in Secs. 14.2 and 14.3 of this Chapter.

14.1.2.2 Transmission Electron Microscopy

Due to the small size of transmission electron microscopy (TEM) specimens, and with the shielding of the specimen chamber by the microscope column and by the coils of the objective lens, the operator is totally protected against γ radiation from the specimen. Also, the final stage of specimen thinning poses little problems for radiation protection as long as the specimens are neutron-irradiated materials (alloys or ceramics) free of α emitters. These near to normal conditions are, however, drastically changed if irradiated nuclear fuels or nonirradiated alloys and ceramics containing plutonium and higher actinides are to be analyzed by TEM (see Sec. 14.3 of this Chapter).

In the following, a transmission electron microscope for work with highly α/γ-active specimens at the European Institute for Transuranium Elements, Karlsruhe, is described. It is a basically standard 200 keV Hitachi H700 HST with a scanning attachment for scanning transmission and secondary electron imaging and a Tracor Northern TN 5500 Energy Dispersive X-ray Analysis and image-processing system. The modifications made in order to meet the requirements for operation with radioactive and α-contaminated materials are as follows:

(i) Filters (glass fibre, 20 $m^3 h^{-1}$ capacity) were fitted in the rough vacuum lines between the rotary pumps and the microscope to prevent any aerosol release from the vacuum system. This necessitated replacing the original pumps with pumps of a higher pumping speed (1370 $l\,min^{-1}$). The fore vacuum pumps exhaust into a waste gas system which is continually monitored for $\alpha/\beta/\gamma$ radiation levels.

(ii) A self-contained recirculating cooling water circuit was attached to the microscope.

(iii) The side entry goniometer stage was rebuilt with minor internal modifications to make it α tight, but this involved no changes in the design or principle of operation. No additional restriction is placed on the range of specimen movement or tilting.

(iv) The microscope is linked to a three-stage glove box chain for the changing and handling of specimens. This system is shown in Fig. 1. A three-stage chain was chosen so as to minimize the

Figure 1. The Hitachi H700 HST transmission electron microscope linked to a three-stage glove box system for the handling of radioactive and α-contaminated specimens. Samples are introduced into glove box 1 through the transfer device at A, and loaded into the specimen holder at B, where just the tip of the holder projects into the contaminated glove box. Glove box 2 is for transfer and specimen holder storage. Glove box 3 links directly to the microscope through a double door and bellows arrangement.

possible transfer of contamination to the microscope column, since the column must be opened at regular intervals for servicing and cleaning.

The as-prepared specimens are introduced into box 1 through a specimen transfer chamber (A), which is compatible with flanges on the specimen preparation glove boxes. In this glove box they are loaded into the microscope specimen holder under a stereo microscope, which is also equipped with a camera. Only the very tip of the holder projects into box 1 through an airlock arrangement (B), which is the only connection between glove box 1 and the next box, and is closed when no holder is in position. The system is shown in detail in Fig. 2.

Box 2 serves as a transfer box, and also as storage for the various different microscope specimen holders. It is connected by a simple lifting door to box 3.

Glove box 3 can be opened to the electron microscope goniometer stage using a double door and bellows arrangement as shown in Fig. 3. This double door is opened for specimen changing, but

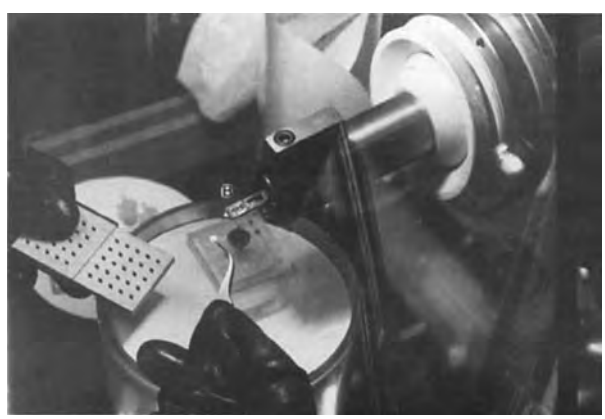

Figure 2. The tip of the specimen holder projects into glove box 1 through a small aperture at position B, which can be sealed with a ball valve when not in use. This system is designed to minimize the transfer of α contamination to the microscope column. Specimens, either on a grid or as 3 mm disk thinned at the center, are loaded with tweezers into the holder under a stereo microscope mounted above the glove box.

Figure 3. The microscope goniometer stage (3) is linked to the glove box system via a La Calhène double door (1) and a bellows (2). This double door is detached, as shown, when the microscope is in use, but attached and the inner component opened for access to the goniometer stage.

closed and decoupled from the microscope column during observation. This decoupling is essential since vibration transfer from the recirculating nitrogen atmosphere of the glove boxes strongly affects the image resolution.

The glove boxes are equipped with automatic alarms for loss of underpressure, fire, and flooding, and with operator hand/foot alarms for accidents. The laboratory air and the glove box nitrogen recirculating system are continuously monitored for contamination.

Operations such as plate changing, filament replacement, or aperture renewal are performed in the normal way, but with careful monitoring at each stage for possible contamination. In over 10 years of daily operation with radioactive materials no significant levels of contamination have ever been detected in the microscope column. The major exposure risk is during the specimen loading and transfer operations. Here it has been found by experience that the total operator dose is smaller when the operations are performed directly, but very rapidly, using gloves and tweezers rather than when they are carried out indirectly, but slowly, using manipulators and a shielded glove box. In the second case there is a much higher risk of specimen damage necessitating repeated preparation work. During specimen loading the operator is protected by wearing a lead jacket, and the radiation dose is monitored with finger dosimeters. A typical specimen change operation takes about 15 min.

In transmission mode the attainable image resolution is limited in the first instance by the nonideal nature of the specimens rather than the microscope performance, but a routine resolution of better than 0.1 nm is obtained, with a demonstrated capability of 0.2 nm. In secondary electron mode a surface resolution of better than 5.0 nm is achieved.

14.1.2.3 Scanning Electron Microscopy

A JEOL JEM 35C Scanning Electron Microscope is being used at the European Institute for Transuranium Elements for the examination of α/γ-active samples, including full cross-sections of irradiated plutonium-containing fuels. In this case the approach to the problems introduced by the active nature of the samples was quite different—the column of the microscope was totally separated from the

electronics and control console, and mounted complete with pumps inside a heavily shielded cell. The system is illustrated in Fig. 4.

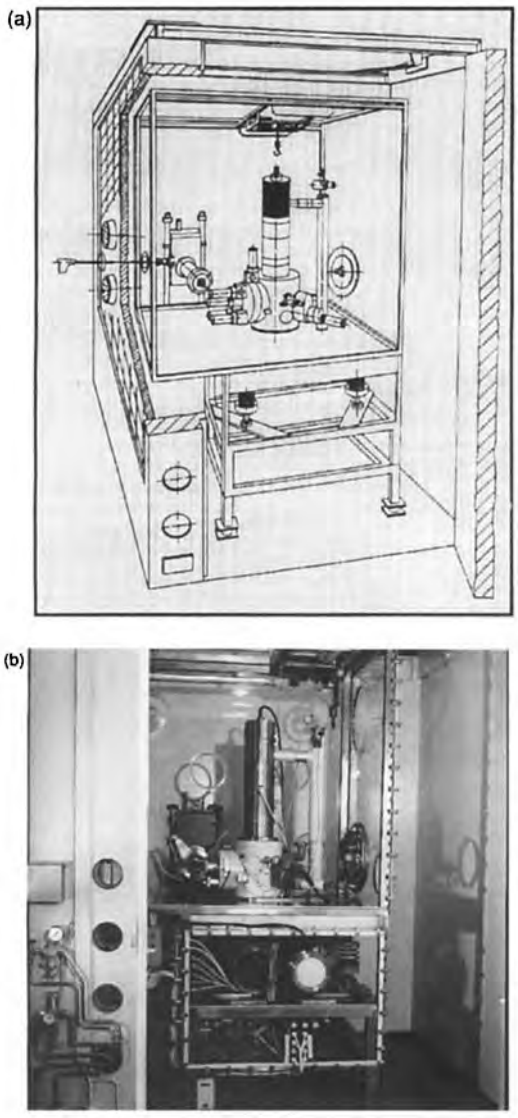

Figure 4. (a) Schematic view of the detached column and pumping system used to contain the JEOL JEM 35C Scanning Electron Microscope inside a glove box and a heavily shielded lead cell with one wall movable. (b) The JEM 35C microscope was installed before the closure of the glove box. The system was then moved into the lead cell [6].

The microscope column and specimen chamber are mounted inside a large fully sealed N_2 atmosphere glove box for α containment, which is surrounded on either side by movable 15 cm thick steel walls and at the front by a 15 cm thick lead brick wall for γ shielding. The front wall contains two windows for visual inspection of the upper part of the box, and manipulators for specimen handling. The steel walls can be swung aside to provide operator access to the glove box for servicing operations. The maximum permissible γ activity of the sample is 2 Ci.

The high-vacuum pumps are mounted inside the cell and are backed through filters by rotary pumps outside. A titanium ion-getter pump is used for the electron gun, and a turbomolecular pump for the specimen chamber.

A shielded secondary electron detector has been installed, and to compensate for the losses in signal involved a high-brightness LaB_6 electron gun has been used.

All the movements of the goniometer stage are driven by micromotors controlled by potentiometric transducers.

Samples are prepared by fractography and are not decontaminated. When necessary they can be coated using a remote-controlled sputtering chamber.

A resolution of 5.0 nm can be routinely achieved, but for large irradiated fuel samples this is reduced by the specimen activity.

For routine applications of scanning electron microscopy (SEM) to γ-active samples free of α contamination a much simpler installation can be used. The microscope column and pumps are freely accessible and only shielding between the specimen chamber and operator is required. Samples must, however, be

decontaminated in a shielded cell before observation to prevent contamination of the microscope from loose active particles.

14.2 Structural Materials (Alloys)

14.2.1 Introduction

The principal microscopic method applied to the characterization and further development of technological alloys for use in nuclear reactors is TEM in combination with metallography, and SEM in combination with mechanical testing for the analysis of fracture surfaces as well as for further surface studies. In most cases the relation between microstructure and the properties of the alloy before service has to be compared with this relation after in-pile service. This means that the methods of investigation must provide quantitative results. Therefore, in Sec. 14.2.2 of this Chapter an outline of several aspects particular to the quantitative analysis of irradiated alloys mainly by SEM and TEM is first given.

Next, in Secs. 14.2.3–14.2.6 of this Chapter, six types of alloys are discussed as they are used in the most common applications in nuclear technology. These are:

- low alloyed steels for reactor pressure vessels (RPVs) and components of the primary coolant circuit;
- ferritic and austenitic steels for piping systems;
- high corrosion-resistant and high-strength nickel-base alloys (e.g., for steam generator tubing);
- zirconium-based alloys for cladding in light-water reactors (LWRs) and hafnium;
- cladding and wrapper materials for fast breeder reactor (FBR) fuel elements; and
- first wall and blanket structures in fusion devices.

For most of these alloys the main characteristics which have to be analyzed by microscopic methods are condensed in the relevant sections in the form of four tables:

(1) composition (specifications),
(2) thermomechanical treatment,
(3) main applications and in-service conditions, and
(4) examination procedures before and after service,

with short descriptions of the relevant structural properties and some details illustrated by micrographs.

14.2.1.1 Microscopy of Irradiated Alloys

The quantitative aspects of the various methods of microscopy are treated in Vols. 1 and 2 of this Handbook. Hence, only some aspects of metallography and examples of quantitative TEM and SEM particular to irradiated alloys in general are given before the six groups of alloys are treated.

Metallography

The metallography of irradiated structural alloys (steels) is based on the wide experience gained with the nonirradiated reference materials. However, a few particulars in the metallography of irradiated alloys

should be mentioned:

- In the hot cells and glove boxes the use of dangerous solutions containing, for example, critical concentrations of perchloric and picric acid is to be avoided for safety reasons.
- When comparing the surface attack by a given etching solution between the irradiated alloy and its nonirradiated reference state the irradiated alloy is often attacked faster. Hence the time of attack should be shorter for the irradiated material to reach the same degree of attack as for the reference material.
- Under neutron irradiation, alloys containing boride precipitates show a special effect due to the nuclear reaction $^{10}B(n, \alpha)^{7}Li$. The high-energy α particle and the heavier lithium recoil atom emitted from the location of the boron atom are slowed down in the adjacent matrix, producing additional lattice damage (Frenkel pairs and clusters). If the irradiation temperature is not too high, that is, below $0.5T_m$, this damage does not anneal out under irradiation and can be made visible by etching. If the borides are mainly precipitated at grain boundaries these become decorated by a double line with the grain boundary in between. The distance of each line from the grain boundary indicates the range of the emitted particles, as shown in Fig. 5.
- Neutron irradiation of the natural isotopes of iron, cobalt, and nickel involves (n, γ) reactions. Amongst these, the decay of the ^{60}Co nuclei is accompanied by especially hard γ radiation (>3 MeV), with a half-life of 5.25 years. Following the different nuclear properties of the iron and nickel natural isotopes, a neutron-irradiated austenitic 16CrNi12 steel gets a three times higher γ dose rate than an equivalent amount of martensitic 10–12% Cr steel after the same neutron dose.

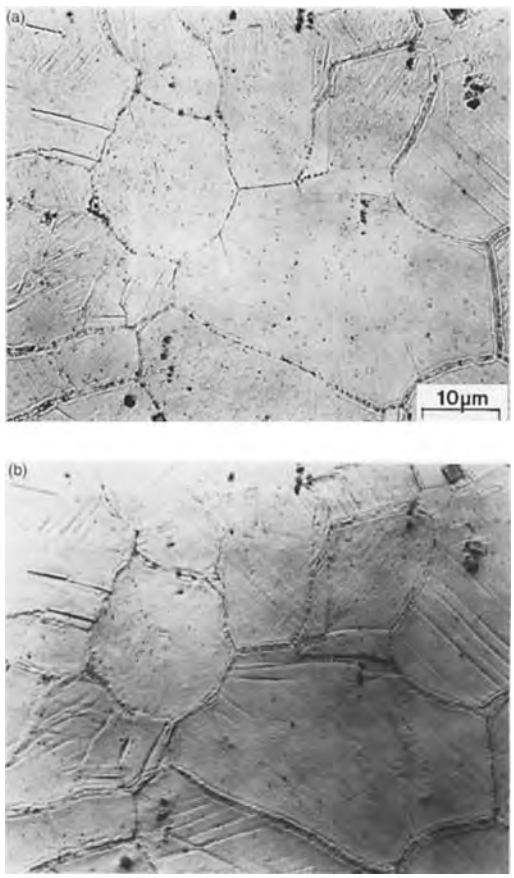

Figure 5. The recoil zones of the $^{10}B(n,\alpha)^{7}Li$ reaction along the grain boundaries in DIN 1.4970 steel (X10 Cr Ni Mo Ti B 15 15)revealed by sensitive etching. Irradiation dose 2 dpa, 100 appm He. (a) Standard optical micrograph. (b) As (a) but with interference microscopy.

In addition to the etching methods mentioned below for the individual alloys and purposes in Tables 1–3, a universal etching solution for irradiated steels is given in Table 4 which can be used for both martensitic and austenitic materials.

Quantitative Fractography by Scanning Electron Microscopy

Irradiation embrittlement of reactor materials is an important phenomenon. It can be analyzed by comparing the mechanical properties and microstructure of the irradiated alloy with reference material submitted to the same thermal history as the irradiated alloy. Mechanical testing of the irradiated material is performed in remotely handled hot cells. Following

Table 2. Materials specification and heat treatment sequences

	NiMoCr type	MnMoNi type	Cr, CrMo type

3. Austenitic, 16CrNi12	160 s	
4. Welding seams between martensitic and austenitic steels	80–160 s	

[a] Solution: 10 g of $AlCl_3$, 30 ml of HCl, 15 ml of HNO_3, 100 ml of H_2O.

tensile testing, notch impact tests, or creep tests and macroscopic evaluation of the specimen geometry, fractured parts are decontaminated and fixed on the SEM specimen holder. Loose particles are removed by a brief ultrasonic cleaning to avoid the loss of precipitates located in the fracture surface. According to the type of load, fracture is classified as follows:

(1) Fracture after mechanical load:
  (a) spontaneous fracture (ductile or brittle);
  (b) fatigue fracture.
(2) Corrosion-induced cracks and fracture.
(3) Thermally induced cracks and fracture.
(4) As (3) and irradiation induced cracks and fracture.

Fracture cannot be observed directly, hence the process of material separation has to be deduced from the fracture pattern. It is of crucial importance to recognize fracture initiators as well as to determine the deformability of the matrix or the residual fracture. Each type of fracture is characterized by a number of features which allow conclusions with regard to the load, the medium, and the state of the material before fracturing. These are:

(a) mechanical data (e.g., yield stress, tensile strength, fracture stress and strain, neck diameter);
(b) ductile/brittle proportions of the fracture surface (SEM);
(c) fracture roughness observed from metallography of a cut section or by confocal laser scanning microscopy of the fracture surface;
(d) dimple structure and statistics by ECD (equivalent circle diameter);
(e) precipitates in the dimples (SEM plus EDX or WDX); and
(f) dislocation structure and precipitate distribution in the starting material (TEM plus EDX).

Basically, the effects of neutron irradiation are expected to possibly produce:

(1) changes of the dislocation distribution, for example due to the effects of Frenkel defects, defct agglomerates and subgrain formation;
(2) changes in precipitate sizes, compositions, and density; and
(3) formation of helium bubbles and/or voids.

To recognize and characterize irradiation-induced effects, a quantitative evaluation of the fracture surface has to be carried out by comparing a suitable selection of items (a) to (f) between the irradiated material and the reference material.

In this context the applications of EDX and WDX to irradiated alloys meet certain limitations. Due to the neutron activation

of certain alloy constituents, especially nickel and iron, the γ activity of the specimen due to the spontaneous radioactive decay interferes with the excitation of the characteristic X rays by the electron beam of the scanning electron microscope. In the small Si(Li) counting crystal the hard γ radiation generates a number of interfering pulses, resulting in an excessive counting rate and high dead times. Hence the background is increased considerably and the measuring time accordingly. In an unirradiated specimen of the low-alloyed constructional steel 22 NiMoCr 3 7 (DIN 1.6751) the nickel content of about 1% (detection limit $\geqslant 0.1\%$) is clearly visible in the spectrum after a measuring time of 1 min. In a slightly irradiated specimen (fluence ~ 0.5 mSv) a measuring time of at least 5 min is required to detect a nickel peak above the background.

Other interferences are caused by nuclides such as ^{55}Fe, which emits a γ quantum of 5.95 keV located exactly on the manganese peak. This means the manganese content for iron alloys cannot be determined unambiguously. Of course this spectrum is also generated without the exciting SEM electron beam. Therefore, this low-energy γ radiation can be used to calibrate the EDX detector, and the resolution of the manganese peak generated by an ^{55}Fe test emitter can be checked.

In highly activated materials K capture and β radiation contribute to the background, and EDX is no longer suitable. In this case WDX is more useful as the analytical radiation is deflected by the spectrometer prism and, hence, the detector does not directly see the irradiated specimen. Thus, a better peak to background ratio is achieved, and the resolution is improved. However, the spectra are recorded in wavelength steps, and several crystals have to be used to cover the necessary range of wavelengths; the method is thus time-consuming.

Most of the literature on quantitative fracture analysis [8–12] deals with the evaluation of the fracture roughness or dimple structures in ductile fracture. To characterize the change of the material ductility it is useful to compare the dimple size distribution. In this case the form of an ECD can be applied, and varying dimple diameters can be evaluated statistically. If inclusions or precipitates still exist inside the dimples and can be analyzed by means of WDX or EDX, information can be deduced with respect to cavity initiation. Fracture initiation may be changed by neutron irradiation if the microstructure and its precipitation behavior are affected.

As far as martensitic 12% Cr steel is concerned, this phenomenon has been observed after in-pile creep. Neutron irradiation was found to result in a shorter time to fracture and a hardening of the alloy as compared to reference creep tests without irradiation [13].

On the basis of the statistics of the dimple structure and the analysis of the inclusions and precipitates, it is concluded that in-pile conditions mainly cause the formation of large dimples. These are the dimples generated around inclusions (MnS, Al_2O_3) or primary carbides (NbC). The other precipitates ($M_{23}C_6$) along the martensite laths were coarser, but their influence on dimple formation in fracture was much smaller than in the unirradiated alloy.

The effect on the ductility of the alloy is derived from the dimple depth. This can be obtained from metallographic

cross-sections. Another possibility of evaluating surface structures or roughness consists in the application of confocal laser scanning microscopy. By recording level lines a three-dimensional image of the surface can be set up and evaluated quantitatively (xy resolution 0.2 μm and z resolution 0.4 μm) [14].

Martensitic 10–12% Cr steel (1.4914) irradiated at $T \geqslant 400°C$ shows ductile fracture up to high neutron doses $\geqslant 65$ dpa. Compared to the unirradiated alloy, irradiation decreased the upper shelf of impact tests and the surface area of the ductile fracture showed the reduced dimple depth (Fig. 6). The coarsening of

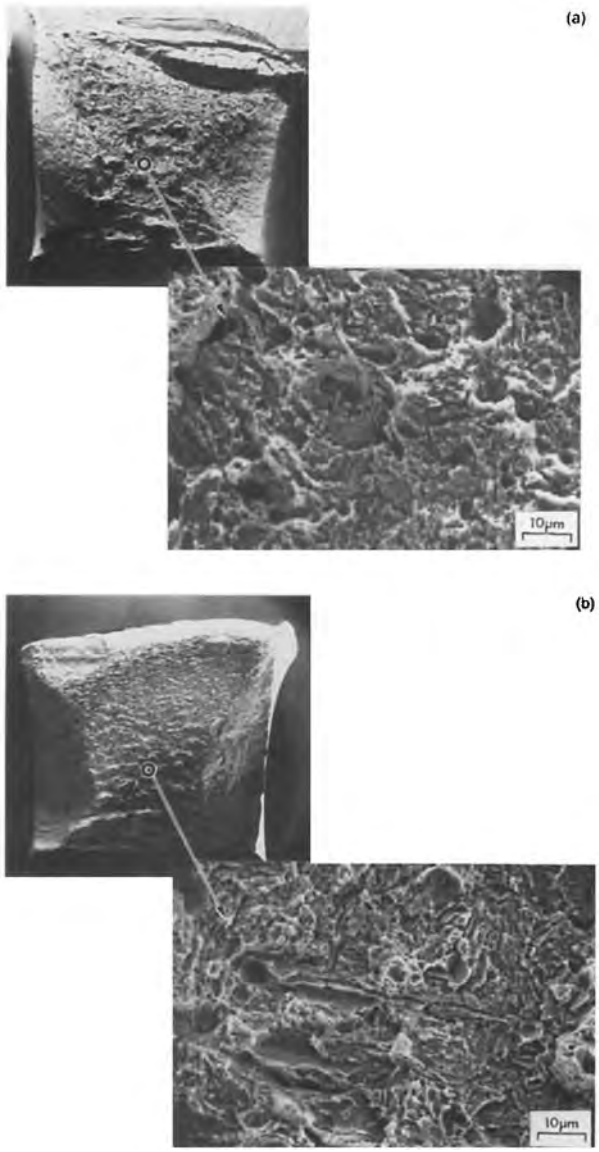

Figure 6. Notch bar tests of martensitic 10–12% Cr steel (DIN 1.4914). (a) Ductile fracture of an unirradiated sample tested at −30°C. (b) Ductile fracture of an irradiated sample tested at +60°C.

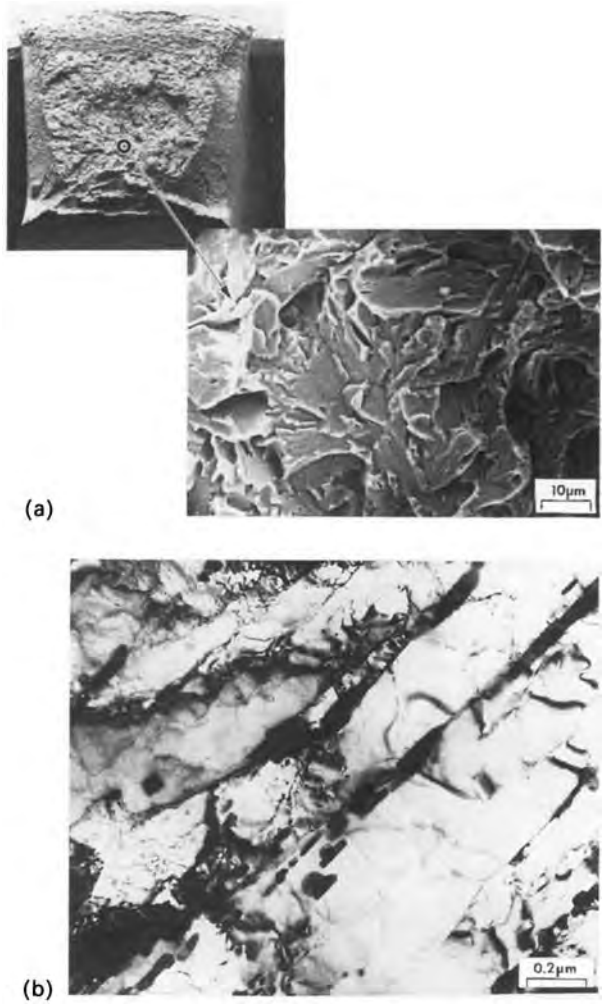

Figure 7. Cleavage fracture of a nonirradiated sample (same material as Fig. 6) with $FATT_{50}$. (a) SEM image of the fracture surface after testing at $T = -60°C$. (b) Microstructure of the martensitic 10–12% Cr steel before the test as produced by quenching and annealing for 30 min at 1075°C and subsequently for 2 h at 700°C.

the precipitates along the lath boundaries after irradiation caused a flattening of this fracture surface. Depending on irradiation, the martensitic cleavage changes too. Figure 7 shows the fracture surface and the microstructure of the lath in the non-irradiated state. After irradiation (Fig. 8), a further separation occurred along the lath boundaries, but the crack runs transcrystallinely through the material (Fig. 8a). The matrix is strengthened by coherent, finely dispersed, irradiation-induced precipitates (Fig. 9). The DBTT (ductile to brittle transition temperature) is shifted from −60°C for the nonirradiated material to +20°C with the irradiated one [15].

Quantitative Transmission Electron Microscopy of Fast Reactor Alloys

Fast reactor materials show some typical forms of lattice defects. The rate of displacement of lattice atoms due to the collisions with neutrons of a high flux of

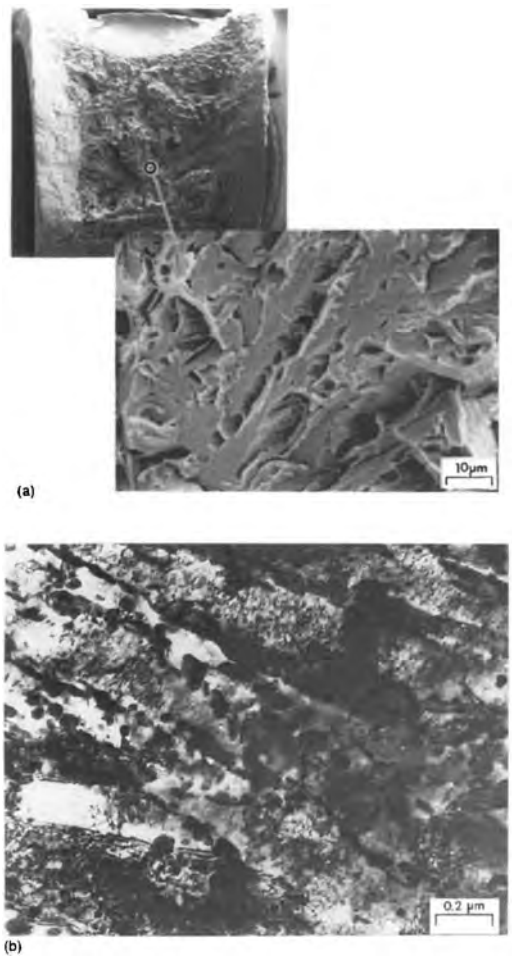

Figure 8. Cleavage fracture of a martensitic 10–12% Cr steel sample (same material as in Fig. 7) after irradiation to a neutron dose corresponding to 74.5–100 dpa. (a) SEM image of the fracture surface with $FATT_{50}$ at a test temperature of +20°C. (b) Martensitic microstructure of the specimen in (a). Note the dense rows of carbides and the presence of several voids.

the order of $10^{15}\,cm^{-2}\,s^{-1}$ results in a high production rate of Frenkel pairs. Some 0.1% of these defects form stable aggregates, vacancies condense into voids, interstitials precipitate in dislocation loops, and second-phase particles may dissolve or new precipitate not normally observed may be generated. By nuclear reactions with the alloy constituents, helium and hydrogen can be formed under certain conditions. The concentrations of these defects have to be controlled because they strongly affect the dimensional stability of the reactor core components and their mechanical properties.

Helium Bubbles. In steels containing boride precipitates the $^{10}B(n,\alpha)^{7}Li$ reaction leads to helium concentrations in the matrix and at grain boundaries from which bubbles are precipitated. Figure 10 shows bubble formation by this effect in the matrix and in a grain boundary of the austenitic steel DIN 1.4970 (Fe–15Cr–15Ni–Ti).

Void Swelling. Void swelling is quantified by measuring the void size distribution, that is, the void concentrations in the various size classes. The visibility of the voids, typically with diameters between 5 and 150 nm, is best in a lattice orientation for kinematic diffraction conditions when large diffraction contrast is absent. A slight underfocus gives the facetted voids a dark rim, and this improves the visibility. A size class is best determined by comparison with a tuneable equisized diaphragm coupled to a multi-class counter. At small void sizes it is important to remain in focus as near as possible to observe the correct size. The automatic measurement by image-processing methods mostly fails due to the strongly varying contrast conditions.

Voids may be nucleated at existing defect clusters (helium atoms and nuclei of second-phase particles). Figure 11 shows facetted voids, part of which have grown together with NbC precipitates.

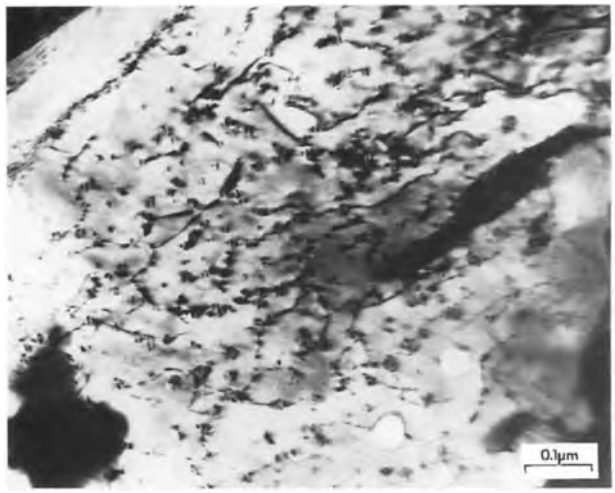

Figure 9. TEM image of the matrix of the sample of Fig. 8. The irradiation has hardened the matrix by producing fine and coherent precipitates.

For the determination of the volume concentration of the voids the foil thickness has to be measured. Here different methods have to be used, especially at the beginning of the study of a new material as long as the operator is not acquainted with the typical aspects of this material:

(i) analysis of stereo pairs of features localized on the upper and lower specimen surface such as dislocation ends or dirt spots;
(ii) the extinction fringe method;
(iii) the use of a contamination cone produced by a steady highly focused electron beam in a 45° tilt position and measuring the distance between the upper and lower parts in the −45° position; and
(iv) by convergent beam diffractometry [16, 17].

Yet, contamination methods usually lead to somewhat larger thickness values

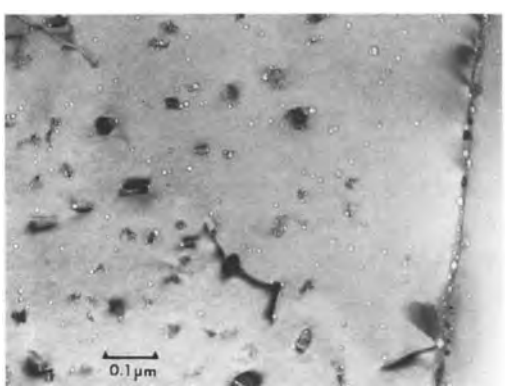

Figure 10. Helium bubbles formed at and in the vicinity of grain boundaries due to nearby boride precipitates in the austinitis steel DIN 1.4970 irradiated at 640°C to a dose of 5 dpa.

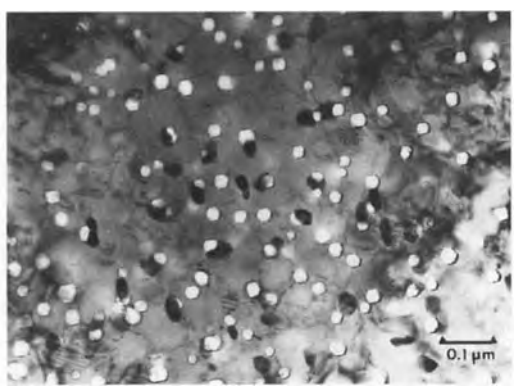

Figure 11. Co-precipitation of voids and NbC in a DIN 1.4981 steel irradiated at 465°C to a dose of 65 dpa.

of the foil than diffraction contrast-controlled methods. All these methods are quite laborious and time-consuming, and an experienced operator is able to estimate the thickness of a specimen of a well-known material to a degree of accuracy which is nearly comparable to the methods mentioned above. In addition, comparison of the TEM analysis with the macroscopically determined density of the material provides a control of the measurements.

Dislocation Loops. In contrast to the void analysis, the determination of the nature and volume concentrations of dislocation loops is more difficult. The visibility of the loops is best under two beam diffraction conditions with $\boldsymbol{gb} \neq 0$. For the distinction between interstitial and vacancy loops the loop size effect caused by the change from inside to outside contrast is used when operating under $+\boldsymbol{g}$ and $-\boldsymbol{g}$ conditions. The size of the loop image is larger (outside contrast) if the value of the product $(\boldsymbol{gb})\boldsymbol{s}$ is positive. Interstitial and vacancy loops have different signs of $\boldsymbol{b}$ according to the FS/RH convention [18].

Figure 12 gives an example of possible interactions between voids, dislocations, and dislocation loops. The loops show in part stacking fault contrast.

Irradiation-Induced Precipitates. On the one hand, the displacements of atoms by collision with fast neutrons and with knock-on atoms on the average increase the mobility of the lattice atoms. Thus, thermodynamic and chemical equilibria are attained in a shorter time. On the other hand, the strongly increased concentrations of lattice vacancies and interstitials give rise to precipitation mechanisms not observed without the strong dynamic irradiation effects. Hence, both the dissolution of precipitates and the formation of new precipitates can be observed.

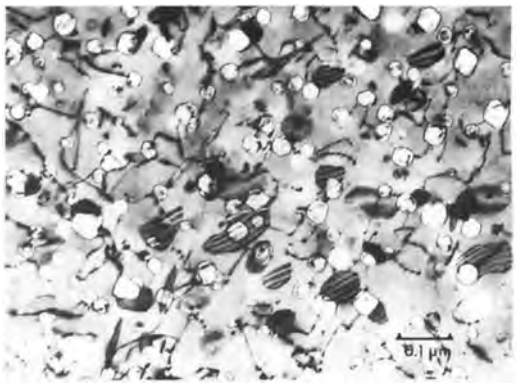

Figure 12. Formation of voids and loops in a titanium-stabilized steel (DIN 1.4970) (cladding material), irradiated at 465°C to a dose of 30 dpa.

An example of a precipitate which is only formed under irradiation is given in Fig. 13 [19]. In an austenitic titanium-stabilized steel (DIN 1.4970), irradiated under a neutron flux of $2 \times 10^{15}\,\mathrm{cm^{-2}\,s^{-1}}$ to a fluence of $48\,\mathrm{dpa_{NRT}}$, the completely coherent γ'-phase Ni_3Si is barely visible under bright field conditions (Fig. 13a). The diffraction pattern (Fig. 13b) shows weak reflections between the normal face-centered cubic (f.c.c.) matrix spots, indicating a phase with the same lattice parameter as the matrix but of ordered primitive Bravais type instead of the f.c.c. matrix. The dark field image (Fig. 13c) obtained by using one of the superstructure reflections readily shows the faint images of the precipitates [19]. In general, these precipitates are found only in nickel-rich steels.

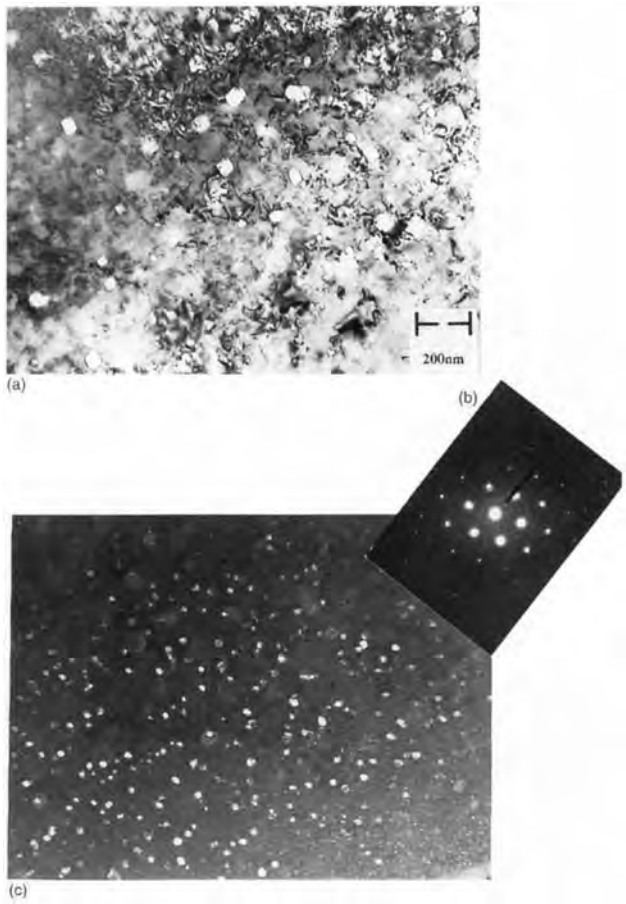

Figure 13. γ' precipitates of type Ni_3Si in a titanium-stabilized steel (DIN 1.4970) after irradiation with fast neutrons at 480°C. (a) The bright field image shows only faint evidence of the precipitates. (b) Diffraction pattern. (c) The dark field image with the superstructure reflection marked in (b) reveals the high concentration of these precipitates.

14.2.2 Reactor Pressure Vessels and Other Main Components of the Primary Circuit

14.2.2.1 Fine-Grained Structural Steels

In general, two different material concepts are employed for the components of the pressurized wall of the primary circuit of LWRs:

(a) All components of the primary circuit (RPV, main coolant line, pump, steam generator) are made of low-alloy ferritic steels. Component surfaces in contact with the primary coolant have a weld-deposited or a rolled cladding.

(b) Low-alloy ferritic steels are used for the large components (RPV, steam generator, pressurizer) in addition to their use for corrosion-resistant cladding. Smaller components, for example the main coolant piping, main coolant pumps, and gate valves, are made of austenitic stainless steel as the structural material.

This section will describe the fine-grained low-alloy ferritic steels used in both concepts [20–25]. The austenitic stainless materials will be described in Sec. 14.2.3.

The steels used are mostly of the nickel–molybdenum–chromium type (22 NiMoCr 3 7) or the manganese–molybdenum–nickel type (20 MnMoNi 5 5), in the USA and Europe, and the chromium–molybdenum type in Russian (originally Soviet) designs.

All steels exhibit a high fracture toughness over the entire service temperature range. The nominal chemical composition of the most important materials is given in Table 1 (for more detailed information the reader is referred to *Ullman's Encyclopedia of Industrial Chemistry* [1]). The specifications and heat treatment procedures of the materials are described in Table 2. The applications, service conditions, problem areas, and targets of characterizations are surveyed in Tables 3 and 5.

14.2.2.2 Characterization and Evaluation of the As-Fabricated State

As can be deduced from Table 5, the purpose of a microscopic examination is focused on various targets, as described below.

Microstructural Properties

Specified values of microstructural properties, for example the size and number density of nonmetallic inclusions, segregations, grain size, and hardness, are checked.

The impurity characteristics, among others, affect the ductility, the fracture toughness, and the anisotropic behavior of the material. In addition, the inclusions, which are elongated according to the material flow during deformation, are often accompanied by microsegregations arranged along the striations, and may cause problems after welding or service due to delayed hydrogen cracking after welding [28, 29] or to lamellar tearing, where cracking occurs in steps along the lamellas enriched with inclusions with lower ductility. To avoid problems, the amount of impurities is restricted. In addition, the risk of lamellar tearing has been reduced by modifications of the design of welds.

Grain Structure

An example of the quenched and tempered base material of 20 MnMoNi 5 5 is shown in Fig. 14. The bainitic structure reflects the quenching and tempering treatment (time at temperature, and cooling rate), and is of important influence with respect to the mechanical properties of the material.

Heat-Affected Zone

The quenched and tempered microstructure of the base material is influenced by heat due to welding. Depending on the distance to the fusion line and the parameters applied during welding, the microstructure of a heat-affected zone (HAZ) can be divided into separate characteristic zones (Fig. 15), starting from the unaffected base material, to the fine-grained zone, and to the coarse-grained zone adjacent to the fusion line and the weld metal. The coarse-grained zone itself is subdivided into an alternating sequence of zones, which are affected by the thermal heat influence of following weld layers, frequently characterized by carbide decorations at the austenite grain boundaries (Troostit seams) and zones which are only superheated by one individual weld pass

Table 5. Survey of procedures for the examination and sample preparation of low-alloyed ferritic steels.

Target	Light microscopy	Scanning electron microscopy	Transmission electron microscopy
As-fabricated condition	Impurities (sulfides, oxides) Cracks/flaws formed during fabrication Grain size Grain structure HAZ characterization, segregations, hardness Stress relief cracks in HAZ (tangential sections!)	Appearance of ductile (dimples) and brittle fracture portions (trans- or intergranular) Irregularities (e.g., flaws) or inclusions of impurities) Structure and composition of contaminants on the surface	Details of the microstructure with respect to dislocation arrangement and density Crystal structure, chemical composition of the matrix (microsegregations, concentration profiles) Morphology and chemical composition of carbides (precipitates)
During/after operation	Verification of nondestructive testing indications	Appearance of the ductile and brittle fracture proportions of irradiation test samples (increasing to amount of inter-granular fracture) Characterization of cracks caused by the operation	Temperature- or irradiation-induced changes in the microstructure with respect to the formation of precipitates/segregates, the carbide structure, or dislocation structures Formation of dislocation networks caused by low cycle fatigue
Sample preparation	Standard metallographic grinding and polishing procedure Etchant for microsections: 3 vol.% HNO_3 in ethanol Etchant for macrosections: 10 vol.% HNO_3 in ethanol	SEM: no special procedures needed On fracture surfaces or surfaces covered with oxides the scales may be removed by the endox 214 method [27]: Cathodic polarization of the surface of interest in an aqueous solution of about 5 wt.% HCN (!), 50 wt.% NaOH and organics) $J \sim 200\,\mathrm{mA\,cm^{-2}}$	*Matrix* Standard preparation of TEM thin foil samples by: – Mechanical cutting of about 0.3 mm sections with low deformation rate by diamond or abrasive (SiC) cutting tools – Mechanical thinning by smooth stepwise (2 µm/step) abrasive grinding down to 0.1 mm thickness – Punching of standard disks with 2–3 mm diameter – Jet stream polishing until an about 50–100 µm diameter hole appears in the center of the disk *Polishing agents* I: 90 vol.% acetic acid 10 vol.% perchloric acid Temperature: 12–15°C, $U = 20$–$30\,\mathrm{V}$ II: 90 vol.% methanol 10 vol.% perchloric acid Temperature: −30°C, $U = 30$–$40\,\mathrm{V}$

			Precipitates Standard metallographic preparation Deep etching about 1 min with 98 vol.% methanol, 1.8 vol.% HNO_3, 0.2 vol.% HCl, 40 g picric acid, extraction of the precipitates with a standard replica technique
Optical instruments used	Standard optical microscopes for metallography, air or immersion oil optics, microhardness tester HV0.1 to HV10	Standard SEM with energy dispersive and/or wavelength dispersive (light elements) electron beam analysis system	Analytical TEM with energy dispersive and/or electron energy loss analyzer system, scanning transmission mode (STEM) for X-ray mapping and electron beam analysis system
Magnification range	10:1–1000:1	20:1–5000:1	30 000:1–1 000 000:1

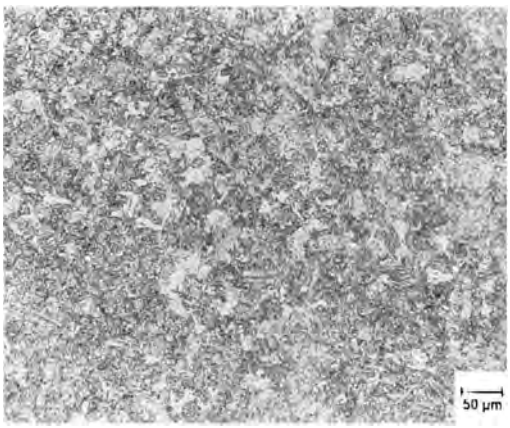

Figure 14. Quenched and tempered microstructure of the steel 20 MnMoNi 5 5.

(e.g. final pass), and therefore reveal a microstructure with a clearly visible primary austenite grain structure formed during superheating, subdivided by lamellar secondary ferrite grains formed during cooling. The uniformity of properties across the weld is checked by hardness profiles (generally Vickers) in macro- (e.g., HV10) or microsections (e.g., HV0.2), and care is taken not to exceed certain limiting values in order to avoid zones with lower ductility and fracture toughness.

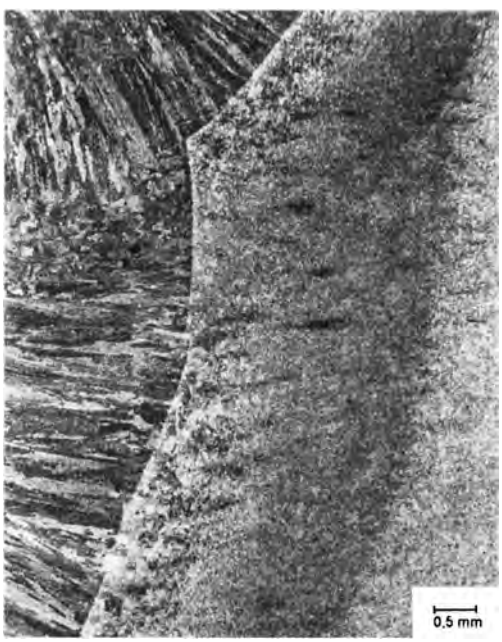

Figure 15. Heat-affected zone of a submerged arc weld of the steel 22 NiMoCr 3 7.

Zones of the HAZ or the weld metal of ferritic steels with high hardness or high residual tensile stresses may also force hydrogen migration. The recombination of atomic hydrogen to the molecular form may cause the formation of hydrogen-induced cracks after quenching or welding (cold cracking). In the HAZ the cracks appear intergranular with respect to the austenite grain boundaries. In the fine-grained base metal, the orientation is often perpendicular to the direction of welding. To reduce the risk of cracking, restrictions on the ingress of hydrogen (drying of electrodes, powders for submerged are welding), the formation of sensitive zones (restricted hardness and grain size), and hydrogen effusion by soaking heat treatments are applied.

During welding, the carbides in the HAZ are dissolved by superheating and precipitated again during cooling. Therefore, an analysis of the morphology and the chemical composition of the carbides, using the extraction replica technique in addition to analytical TEM, not only provides information on the chemical composition of the material, but also on the local thermal treatment of the material (Fig. 16) [30].

The coarse-grained zone of the HAZ is also of importance with respect to the formation of stress relief cracks (SRCs) during the stress relief annealing heat treatment of the weld (Fig. 17). The cracks

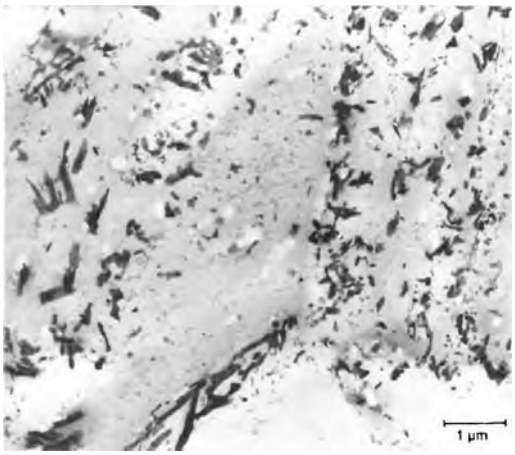

Figure 16. TEM extraction replica of carbides in the coarse-grained zone of an HAZ in 22 NiMoCr 3 7 after stress relief heat treatment. The coarse carbides correspond to M_3C (M = Fe, Mn, Cr), and the fine needles to MC (M = Fe, Mo, Cr, Mn, etc.).

occur intergranularly at the grain boundaries of the austenite grains and are caused by the superposition of creep strain (decrease in dislocation density, relief of residual stresses) with precipitation (carbides) and segregation (sulfur, phosphorus, residual elements) processes, and the existence of coarse austenite grains, which in addition restrict the local creep ductility [23, 29].

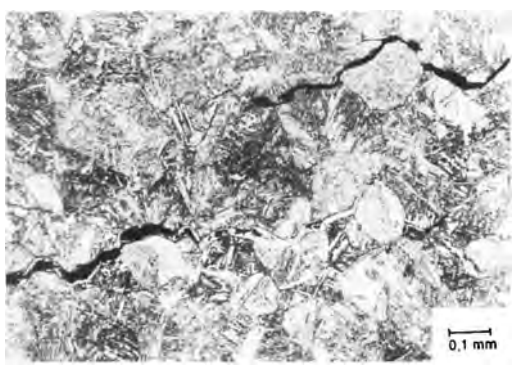

Figure 17. Stress relief cracks in the coarse-grained zone in an HAZ of 22 NiMoCr 3 7 (field metallographic replica technique).

The steel 20 MnMoNi 5 5 is less susceptible to SRCs than 22 NiMoCr 3 7. In both steels, the risk of SRCs is drastically lowered by restrictions on the chemical composition and the welding procedure (heat input, preheat, interpass temperatures) in order to avoid the formation of coarse austenite grains.

14.2.2.3 Characterization and Evaluation During and After Service

Corrosion

As the components are entirely covered by an austenitic stainless steel cladding the materials in general are not affected by corrosion during service. Specific corrosion phenomena of ferritic and austenitic steels are described in more detail in Sec. 14.2.3 of this Chapter.

Low Cycle Fatigue

Many components are operating under conditions resulting in restrictions on the operating lifetime (e.g., thermal stratifications during restricted numbers of start-up or shut-down cycles) caused by low cycle fatigue.

The fatigue straining causes the formation of characteristic dislocation structures (Fig. 18). Their quantitative characterization, for example by TEM, allows the estimation of the residual lifetime of a component [31].

Irradiation-Induced Changes in Properties

During operation under neutron irradiation (and long times at elevated temperature), the material properties may be affected by a shift of the transition temperature regime of the brittle to ductile

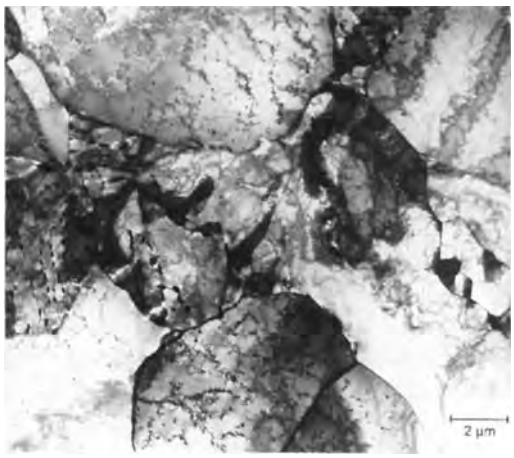

Figure 18. Onset of the formation of dislocation networks at the beginning of low cycle fatigue straining of 20 MnMoNi 5 5 steel (TEM image of a thin foil sample).

fracture behavior to higher temperatures and a decrease of the ductile fracture toughness [26, 32, 33]. As this ageing effect is of importance to the integrity of components, the effect of irradiation is monitored intensively by irradiation programmes for postirradiation mechanical and fracture-mechanical testing.

Recent results have shown that the ageing of the steels caused by neutron irradiation is accompanied by hardening due to the formation of very small and numerous precipitates with diameters between 1 and 10 nm enriched in copper, vanadium, manganese, nickel, and other elements [34, 35]. Because of the characteristics of these precipitates, their examination requires the use of high-resolution TEM and scanning TEM (STEM) techniques, in order to gain additional information on the state of ageing of reactor components.

Thermally Induced Changes in Properties

As most of the components of the primary system operate for a very long time at elevated temperatures, changes in material behavior may be caused by thermal ageing, due to age-hardening processes (nitrogen migration, precipitation, and segregation processes).

The thermal changes in the materials are minimized by the use of deoxidized steels with a low content of degrading impurity elements and adapted tempering and stress relief annealing heat treatments. Laboratory ageing studies [36] and material testing of replaced components after long-term service have shown the low sensitivity of the steels to thermally induced loss of ductility or a shift in transition temperature without affecting component integrity.

14.2.3 Piping

14.2.3.1 Ferritic and Austenitic Steels for Piping Systems

Several ferritic or austenitic stainless steels are in use as materials for pipes, fittings, valves, and pump casings in nuclear and non-nuclear systems (Table 6). For austenitic stainless steel in LWRs, there are generally two types, the unstabilized stainless steels and the stabilized stainless steels. Details on the specifications of commonly used materials and the heat treatment conditions are listed in Table 7. The impact of the use of the individual steels depends on the type of reactor and the system of application (Table 8).

14.2.3.2 Characterization and Evaluation of the As-Fabricated State

The aims of microscopic examination of the different steels, as listed in Table 8,

generally differ for ferritic and austenitic stainless steels.

Ferritic Steels

The as-fabricated condition of the steels are examined with respect to the following.

Microstructural Properties. Specified values of microstructural properties, for example the size and number density of nonmetallic inclusions, segregations, grain size, and hardness similar to the pressure vessel steels described in Sec. 14.2.2.2 of this Chapter, are checked.

Grain Structure. Depending on the heat treatment condition of the steel, for example as listed in Table 7, the microstructure is either quenched and tempered or normalized (Fig. 19).

Due to its influence on strength, ductility, and weldability, the ferritic grain size is restricted [37] to low values (e.g., finer than No. 6). In certain cases of quenched and tempered or HAZ microstructure, the ferritic grains appear as fine bainitic lamellas, and are not easily detectable according to the standardized procedures for grain size measurements. Instead, the former austenite grains are often considered (if clearly apparent) or the bainitic structure is quantified with the line intercept procedures given in the standard procedures for grain size evaluations [38, 39].

Heat-Affected Zone. For the influence of welding on the microstructure and the targets of evaluations, refer to Sec. 14.2.2.2 of this Chapter. In addition to the microstructure, the macroscopic geometry of weld connections of piping is important, in order to avoid local increases in stress intensity due to misfits, local reductions of the wall thickness, or the geometry of the root layer.

Table 8. Applications, service conditions, problem areas, and targets of characterizations

	Ferritic steels	Austenitic steels
Reactor type	PWR, PHWR, BWR, RPV internals, structural parts of fuel elements	
Main use	Main steam line, feed water line, lines for auxiliary systems with large diameters (>DN 100) in secondary systems (e.g., 15 MnNi 6 3, 15 NiCuMoNb 5, 15 Mo 3) auxiliary and monitoring lines with small diameters (e.g., St 35.8, 15 Mo 3, 15 NiCuMoNb 5)	Nuclear auxiliary systems with diameters from DN25 up to DN400, US designs preferentially use unstabilized stainless steels (SSs) European designs use stabilized SSs
Material properties	High strength/ductility at ambient and elevated temperatures Excellent weldability, uniform properties in the base metal, HAZ, and weld metal Excellent failure detection with nondestructive test (NDT) methods (ultrasonic, X-ray, magnetic particle test)	High ductility even at low temperatures, no ductile/brittle fracture transition Excellent weldability, no preheat and post-weld heat treatment required Good failure detection with NDT methods (X-ray, ultrasonic, penetrant test)
Operational conditions		
Operational temperatures (K)	$\leqslant 623$	$\leqslant 623$
Coolant	Feed water PWR, PHWR: low oxygen due to hydrazine or phosphate chemistry BWR: $O_2 < 200$ ppb, depending on the water chemistry	PWR, PHWR and BWR primary coolant as given in Table 3, and coolant conditions as applied for ferritic steels
Coolant pressure (bar)	refer to Table 3	refer to Table 3
Maximum neutron fluence	Not relevant	$\leqslant \sim 10^{22}\,cm^{-2}$

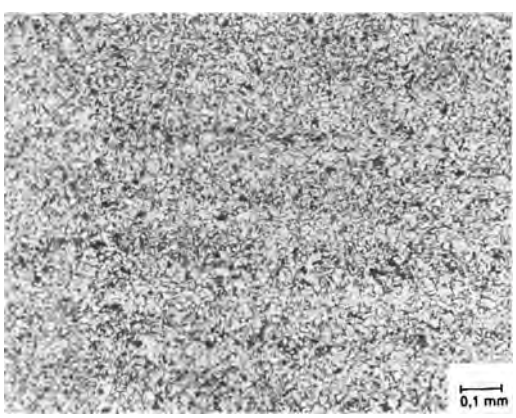

Figure 19. Microstructure of the steel 15 Mo 3 in the normalized condition.

Austenitic Steels

Microstructural Properties. Specified values of microstructural properties, for example the size and number density of nonmetallic inclusions, segregations, precipitates, grain boundaries, and hardness are checked.

The austenitic steels contain sulfidic inclusions and exogenous and endogenous oxidic inclusions. In titanium-stabilized steels, the amount of endogenous oxides is markedly higher due to the affinity of titanium for oxygen, nitrogen and other impurity elements. All stabilized steels may in addition contain coarse carbides or

carbonitrides. The content of sulfidic inclusions is of importance with respect to the corrosion resistance of the material and the weldability. The amount of oxides is of minor influence on the mechanical properties and the weldability of very ductile material, but affects the surface quality and is the cause of frequently detected positive penetrant test indications in machined surfaces or weld edges. Deviations in the hot forming routine (forging with high deformation rates at low temperatures) may cause the formation of numerous small cracks along the stringers of inclusions (Fig. 20).

Because of their excellent ductility, the austenitic stainless steels are susceptible to strain hardening caused by cold deformation after the final solution heat treatment by, for example, machining. As a small amount of cold deformation may accelerate the precipitation of carbides during service at elevated temperatures (>200°C), the strain hardening of weld edges, and also of base material in contact with a corrosive agent, may be restricted to a certain maximum hardness (e.g., 300–350 HV).

A higher degree of cold deformation may cause the formation of martensitic structures with poor corrosion and stress corrosion cracking resistance.

Grain Structure. Except from the δ–γ transition at high temperatures, as will be described below, the austenitic steels are not affected by phase transformations during cooling to ambient temperatures (the formation of martensitic structures in the considered range of chemical composition may occur to a minor extent only at very low temperatures, for instance by cooling with liquid nitrogen). The grain structure results entirely from the hot and/or cold deformation sequence and the recrystallization during the intermediate and final (solution) heat treatments. If the forging results in locally low deformations or the heat treatment sequences (especially the final solution heat treatment) do not allow for complete recrystallization, a mixed grain structure with alternating zones with recrystallized and non-recrystallized zones may result (Fig. 21). As in the non-recrystallized zone, the

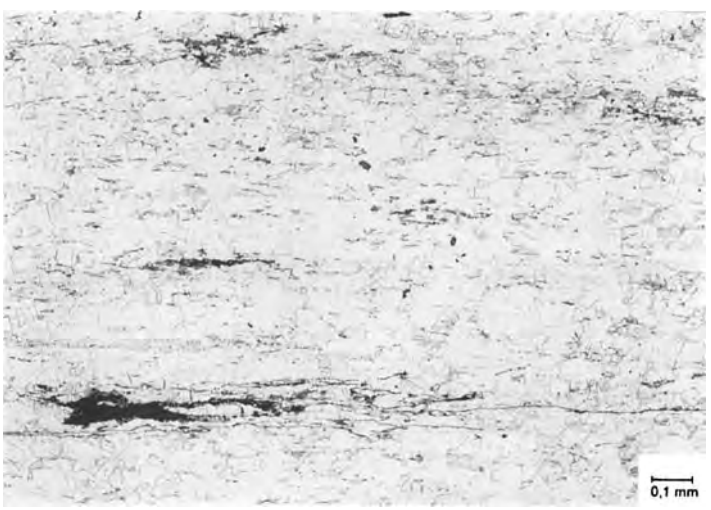

Figure 20. Bands of nonmetallic inclusions (titanium rich oxides and carbonitrides) in the stabilized austenitic stainless steel X6 CrNiTi 18 10. Cracks formed during forging can be seen.

Figure 21. Partially recrystallized microstructure in a forging of stabilized austenitic stainless steel 1.4550.

grain structure is difficult to develop by metallographic etching, and may be considered as having coarse-grained zones, which may restrict the weldability and the resolution of ultrasonic testing. For further investigations, either TEM of thin foil samples or reweld testing as described below may be performed. The reweld test shows in addition to the evaluation of the δ ferrite content the behavior of the non-recrystallized zones during welding, because of the risk of the formation of a coarse-grained HAZs due to critical deformation rates.

Welding and Heat-Affected Zones. During the solidification of molten base or weld metal, the risk of the formation of hot cracks due to the segregation of impurities at the dendritic interface is much higher if the solidification takes place in the f.c.c. γ phase (austenite). Therefore, the chemical composition of the materials is specified within a range where the solidification will occur in the body-centered cubic (b.c.c.) δ ferrite phase followed by a solid–solid transformation to the γ phase. Depending on the cooling rate during welding or the thermomechanical treatment during the fabrication of the semi-finished product, a certain amount of δ ferrite phase may remain in the microstructure. The total amount of possible δ ferrite content is specified to range from 2 vol.% up to about 12 vol.%; at higher concentrations, care must be taken to prevent large networks of δ ferrite in welds because of the risk of low-temperature brittle behavior, corrosion attack of the ferritic phase or the ferrite/austenite interphase, and long-term embrittlement during service at elevated temperatures caused by the formation of the σ phase [40].

The amount of δ ferrite may be evaluated by several methods:

- calculation by means of the chemical composition and the formulas and diagrams given by Schaeffler [41] or DeLong [42];
- electromagnetic measurement of the ferromagnetic δ phase by the Förster— or Fischer—probe; and
- metallographic evaluation (Murakami etchant, Table 9) of the amount of δ

Table 9. Survey of procedures for the microscopic examination and sample preparation of ferritic and austenitic stainless steels

Target or characterization	Light microscopy	Scanning electron microscopy	Transmission electron microscopy
As-fabricated condition	*All materials* Impurities Cracks/flaws formed during fabrication Grain size Grain structure, recrystallization HAZ characterization Weld geometry, hardness *Austenitic steels* Grain size, deformation structures Hardness of machined surfaces δ ferrite content in base metal and HAZ Carbide precipitation in HAZ Hot cracks, by liquations in HAZ	*All materials* Irregularities (e.g., flaws, or inclusions of impurities) in fracture of samples for mechanical testing Structure and composition of contaminants on the surface	*Ferritic steels* Crystal structure and chemical composition of the matrix (microsegregations, concentration profiles) Morphology and chemical composition of carbides (precipitates) *Austenitic steels* Dislocation structures (incomplete recrystallization during hot forming) Chromium-rich carbides on grain boundaries and formation of chromium-depleted zones (sensitization against IGA, IGSCC)

ferrite phase by comparison with standard series or image analysis.

An experimental estimation of the potential of a material to form δ ferrite may be performed by a local welding of the material under standardized conditions [20] (e.g., remelting of the zone of interest with tungsten inert gas (TIG) welding, ~20 V, ~160 A, ~200 mm min^{-1}) followed by a metallographic or field-metallographic examination or by magnetic measurements.

The remelt test is also used to check the susceptibility of a material to form hot cracks ('liquations') in the HAZs during welding.

This mode of failure during fabrication occurs most frequently in niobium-stabilized stainless steels because the excess niobium, which is not ligated to carbon, is able to form eutectic intermetallics with the matrix [43] (Fig. 22). The risk for the formation of cracks is higher in coarse-grained base materials or HAZ structures (influence of welding), and may be minimized by restrictions on the grain size of the base material (<No. 4), the chemical composition, and the heat input during welding.

Figure 22. Reheat cracks in the HAZ of a weld in a coarse-grained austenitic stainless steel 1.4550 (field metallographic replica technique).

14.2.3.3 Characterization and Evaluation During and After Service

Ferritic Steels

Corrosion. During operation at elevated service temperatures in water with a low oxygen content, the ferritic materials will form a dense layer of oxides (magnetite), which protects the surface from further corrosive attack. At lower temperatures (e.g., during outages) water with a high oxygen content is able to penetrate the shielding oxide layer, resulting in a mould corrosion attack with a low penetration depth and a porous, pustular oxide. During service, a repassivation of the moulded zones will take place, if the oxygen level in the water decreases again to a low level.

In the case of components that operate in contact with the coolant water, the hardness of the materials, especially of the HAZs, should not exceed the limit value of about 350 HV10 [44] in order to avoid failure by hydrogen-induced stress corrosion cracking, which often appears as intergranular cracking of the austenite grain boundaries in the coarse-grained zone of an HAZ (Fig. 23). In direct contact with water containing high oxygen levels (e.g., during commissioning or after outage), the steels, as most of the low-alloyed ferritic steels, may be attacked by environmental assisted cracking (EAC; here strain-induced cracking). The cracks are formed due to the concentration of strain at zones with higher stress intensity (e.g., notches, geometric mismatches) or locally lower yield strength (Fig. 24) [45–47] in the weld metal or the HAZ and in very minor amount in the base materials.

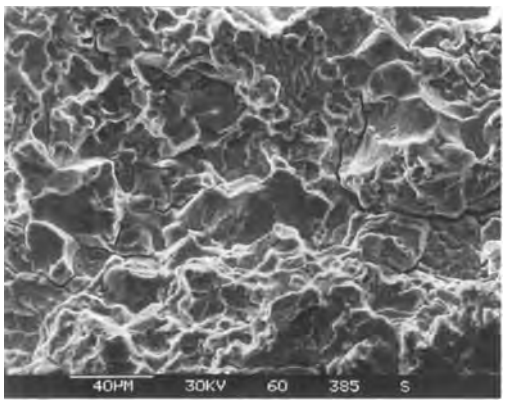

Figure 23. Intergranular and transgranular brittle crack facets due to hydrogen induced cracking in an HAZ of a ferritic steel (15 Mo 3). Crack surface examined by SEM.

Low Cycle Fatigue. Cracks formed due to low or high cycle fatigue mostly occur in combination with EAC, and the mechanical effects are barely detected by fractograph due to secondary corrosive attack. The examination of changes in the microstructure may reveal more information (see Sec. 14.2.2).

Irradiation- and Temperature-Induced Changes in Properties. In general these are not relevant for LWR piping (see Sec. 14.2.2).

Figure 24. Environmentally assisted (strain-induced) cracking in the repair weld and HAZ of a quenched and tempered ferritic tube weld (material 15 NiCuMoNb 5).

Austenitic Steels

The austenitic steels as described in Table 6 are sensitive to contaminants containing high concentrations of chlorides in aqueous solution in the temperature range between about 50 and 150°C, which will cause pitting corrosion or, under the influence of operational or residual stresses, transgranular stress corrosion cracking (TGSCC (Fig. 25) [48]). To avoid failures, strict restrictions on the use of chlorine-containing lubricants and cleaning agents, or other chlorine sources (e.g., sealings containing asbestos) are required. The higher level of oxygen (about 150–200 ppb) and free radicals (e.g., from H_2O_2) in the coolant of boiling water

Figure 25. TRSCC caused by local contamination with chloride-containing impurities in a tube of the austenitic stainless steel 1.4550.

reactors may cause intergranular stress corrosion cracking (IGSCC) in pipe systems which draw high-temperature water from the reactor. This mode of failure is well known to occur in unstabilized stainless steels [49, 50]. Since 1993, some cases have become apparent in titanium-stabilized austenitic steels (1.4541) as well [51, 52].

The cracking occurs mostly in the coarse-grained HAZ of welds and in the weld metal (Fig. 26). TEM examinations of extraction replica show that the cracks mostly follow a path close to the fusion line, where the grain boundaries are decorated with chromium-rich carbides in addition to the carbides resulting from the stabilization (TiC) (Fig. 27). In order to avoid the risk of cracking, restrictions on chemical composition ($C \leqslant 0.04$ wt.%, $Ti/C \geqslant 8$) are required, and care should be taken to machining and welding processes during fabrication (cold deformation of weld edges, heat input during welding). As the austenitic steels have a higher coefficient of thermal expansion, the risk of the introduction of high residual tensile stresses due to welding may be reduced by using special welding techniques (e.g., reduction of welding volume, narrow gap welding) or post-weld thermal or mechanical treatments.

14.2.4 Materials for Steam Generator Tubing and High Strength Components

14.2.4.1 Survey of Alloys and Data

The nickel-base alloys Inconel 600 and 690 and the high nickel and chromium alloyed

stainless steel Incoloy 800 exhibit excellent uniform and localized corrosion resistance in various environments, and are therefore used for heat exchanger tubes in PWR and PHWR steam generators [53, 54].

The nickel base alloys Inconel X-750 and 718 are used in precipitation hardened condition for components that require high yield strength and high resistance against thermally or irradiation-induced relaxation [55, 56].

The chemical composition ranges of the alloys typical for nuclear application are listed in Table 10 and a brief description of material specifications and typical heat treatment sequences is given in Table 11.

The fields of applications, and service conditions are given in Tables 12 and 13. The procedures for examination are closely related to those of austenitic stainless steels (see Sec. 14.2.3). Specific targets for characterization and procedures for examination are given in Table 13.

14.2.4.2 Characterization and Evaluation in the As-Fabricated State

The microstructure of the materials corresponds very closely to that of the austenitic stainless steels described in Sec. 14.2.3 of this Chapter, and many of the targets for examination are very similar.

Microstructural Properties

The specified values for the microstructural properties, such as the size and number density of inclusions, segregations, grain size, and hardness, is checked.

Most of the targets correspond to those of the austenitic steels. Depending on the carbon content, the materials may contain various large inclusions of carbonitrides (Fig. 28) affecting the surface quality.

Hardness testing is of use to check for the effectiveness of the heat treatment sequence for age hardening. The hardness may reach values up to 500 HV. The resistance of the materials to IGSCC is very sensitive to the heat treatment procedure.

As comparable hardness levels may be achieved by differing heat treatment sequences, care must be taken not to use the hardness as the single criterium to qualify the final product.

Grain Structure and Precipitates

The grain structure of the materials in general corresponds to the recrystallized condition. The ranges for the grain sizes are specified with respect to the intended application. In nuclear applications, for the sake of resistance against IGSCC and low-temperature strength, the grain size is specified to fine values (<No. 4 according to ASTM E 112), whereas high-temperature applications require a coarser grain structure (>No. 3 acc. to ASTM E 112) with respect to increased creep strength.

Depending on the amount of the alloying elements titanium, niobium, and aluminum, all alloys, especially the age hardenable ones, are able to precipitate intermetallic phases in blocky or needle-like incoherent morphology ($Ni_3(Al,Ti)$, or $Ni_3(Al,Nb)$), during heat treatments in the range of 600–800°C, often forming a dense decoration along the grain boundaries (Fig. 29). Titanium or niobium carbides, as well as chromium rich carbides, may also occur in a comparable morphology.

The precipitation of chromium-rich carbides may be accompanied by the formation of chromium-depleted zones along the

grain boundaries, affecting the susceptibility to IGSCC [57–59] (Fig. 30).

The age-hardening effect is caused by the formation of semicoherent platelets of γ' ($Ni_3(Ti,Al)$) or γ'' ($Ni_3(Nb,Al)$) in the grains. Depending on the heat treatment sequence, the platelets occur in monomodal or heteromodal size distributions (Fig. 31), and a γ'/γ''-depleted zone may be apparent parallel to the decorated grain

boundaries. A cold deformation prior to the age-hardening treatment may result in an inhomogeneous distribution of the precipitates due to the formation of decorations on slip bands and dislocations.

Welding, Rolling, and Annealing

The alloys are more susceptible to the formation of hot cracks during solidification, compared to the austenitic stainless steels. Nevertheless, the weldability is sufficient to perform high-quality seal or repair welds. In age-hardened materials, the microstructure and strength in the weld and HAZ may be changed completely, resulting in poor strength and corrosion resistance in addition to high-tensile residual stresses. Tensile residual stresses

Figure 29. Deep etched structure of the γ' phase at the grain boundary and in the grains of Inconel X-750. Electrolytic etching by orthophosphoric acid (SEM image).

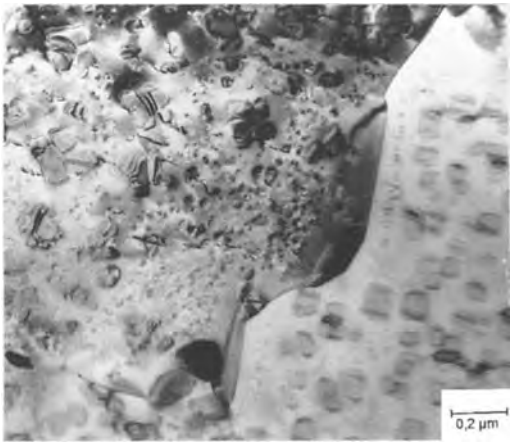

Figure 31. Hardening by semicoherent precipitates in a bimodal size distribution caused by a two-step age-hardening treatment of Inconel X-750 (TEM image of a thin foil sample).

may also promote the formation of IGSCC, and cold deformation processes (e.g., rolling in the manufacture of steam generator tubes from tube sheet) must be applied with qualifications and care.

All materials, especially those with high nickel contents, are sensitive to contaminants containing sulfur (e.g., lubricants) during annealing above temperatures of about 400°C, necessitating a thorough cleaning prior to heat treatments or service.

14.2.4.3 Characterization During and After Service

Corrosion

The alloys Inconel 600 and X-750 are sensitive to primary waterside IGSCC under the influence of tensile stresses (service and residual stresses!), and to the formation of a sensitive microstructure caused by segregation of impurities (e.g., phosphorus and sulfur), and/or the precipitation of chromium-rich carbides (chromium-depleted zones!) at the grain boundaries [53, 59–61] during long-term service (low-temperature sensitization, LTS). Additional thermal treatments may reduce the risk of LTS significantly [62, 63]. The alloys Inconel 800 and 690 under optimal conditions have, from practical experience, proven to be insensitive to LTS [53].

The alloy Inconel 718 is generally used in fuel element structural components where short operational periods reduce the risk of IGSCC. Steam generator tubes may suffer from the so-called phosphate wastage zones caused by the enrichment of degrading slurry in the lower zone of the secondary side of the steam generator [64].

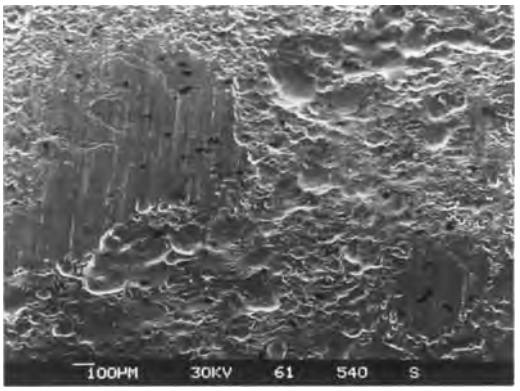

Figure 32. Wastage corrosion attack at the outer surface of a steam generator heat exchanger tube of the austenitic stainless steel Incoloy 800 (SEM image).

The corrosion attack occurs uniformly and may even cause local perforations (Fig. 32).

Fatigue

The age-hardened alloys used for mechanical components (e.g., springs) may fail by high cycle fatigue cracking. The fatigue cracks in coarse-grained materials often exhibit a transgranular fracture with fatigue striations within an intergranular structure (Fig. 33).

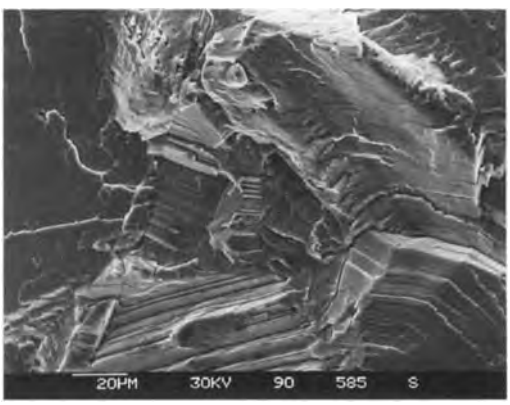

Figure 33. Fatigue crack in a spring of Inconel X-750 (SEM image of the crack surface).

14.2.5 Zirconium-Based Cladding Materials and Hafnium

14.2.5.1 Zirconium-Based Alloys and Hafnium

Zirconium-based alloys as given in Table 14 have been used for fuel claddings and structural parts of fuel elements since the beginnings of nuclear power production, and have proven their efficiency and reliability in many hundreds of thousands of fuel rods. Hafnium has practically the same metallic properties as zirconium but opposite nuclear ones, that is, a high cross-section for absorbing neutrons. Therefore, hafnium is separated from zirconium during the raffination process and used for the fabrication of control rods. The zirconium alloys are usually fabricated from two or three times vacuum remolten ingots of sponge zirconium [66] together with recycled material and the alloying elements tin, iron, chromium, nickel, and niobium. The ingots are hot forged or rolled, extruded, and cold pilgered or cold rolled to their final dimensions in several steps, followed by stress relief or recrystallization treatments (Table 15).

Zirconium (and hafnium) and its alloys are characterized by a phase

Table 14. Chemical composition of hafnium, zirconium, Zircaloy 2 and 4, and Zr-2,5Nb

Chemical composition (wt.%)[a]	Sn	Fe	Cr	Ni	Nb	O	Others

transformation from the high temperature b.c.c. β structure above about 1000°C, with an $\alpha + \beta$ two-phase interval between ~1000 and ~850°C and the transformation to the hexagonal close-packed (h.c.p.) α-zirconium phase field below this temperature. Because of the anisotropic deformation behavior of α-zirconium, all α-phase materials possess a texture specific for the semifinished products [67–69], and behave anisotropically.

Applications, service conditions, problem areas, and targets of characterization are given in Tables 16 to 18. Because of the general tendency to increase burn-up of the nuclear fuel, more recently the study of the waterside corrosion of Zircaloy claddings has led to the application of SEM and TEM to analyze the oxide scales and the intermetallic precipitates of the cladding material at the end of operation in commercial PWRs, BWRs, and HWRs, see Table 18.

14.2.5.2 Characterization of the As-Fabricated State of Zirconium-Based Alloys

The various alloys in Table 14, in principle, behave similarly, with respect to the metallurgical treatments. Nevertheless, the individual materials possess characteristic differences important for their applications.

Inclusions and Hardness

Depending on the fabrication process and due to the high solubility of nitrogen and oxygen in zirconium, the zirconium alloys are specified to possess very low levels of nonmetallic inclusions. In general these appear as elongated silicon- and zirconium-rich carbides and silicides with lengths in the range 0.5–5 µm [70]. Hardness is affected by grain size and shape, dislocation density, texture, and chemical composition as a consequence of the history of thermal treatment. Thus, with respect to the special problems of interest, hardness measurements have to be performed and analyzed with care, taking account of the type of alloy and its thermal history.

Grain Size and Structure

Due to the high total deformation which has to be applied during fabrication of tubing and sheet, the grain size in the final product is small. In the recrystallized condition, zirconium, zirconium alloys, and hafnium consist of a homogeneous equiaxed grain structure which is easily detectable by optical microscopy with polarized light (Fig. 34). The structure of zirconium–niobium alloys is more complex and may contain, besides the h.c.p. α phase and depending on the thermomechanical history, one or several niobium-containing phases as the β, β', or ω phases [71].

Depending on the required strength, the alloys may be used in the cold-worked and stress-relieved state, or in a partly recrystallized state [72]. According to the deformation and degree of recrystallization applied during the final production steps the grains are more or less elongated in the direction of deformation and may have irregular shapes. Based on the fabrication parameters and the final dimensions the grain size ranges from about Nos. 8–10 (ASTM E-112) for sheet material or tubing with thick walls ($\geq$2 mm) up to Nos. 15–16 for highly cold worked materials. The

method for measuring grain sizes must be carefully chosen because the evaluation by means of standard series given in the standard procedures (e.g., ASTM E-112) may result in considerable deviation when applied with polarized light [73] (Table 17). In stress relieved and partly recrystallized microstructures the evaluation of the grain size requires at least the averaging of three directions (rolling, transverse, and normal directions). For simplicity the grain size is measured frequently following a standardized laboratory heat treatment which results in a recrystallized microstructure. Nevertheless, the deformed microstructure may reveal information on the degree of deformation or the degree of recrystallization if image analysis is applied (Fig. 35).

Hydrides

Hafnium, as well as zirconium and its alloys, exhibit a high affinity for hydrogen. The solubility of hydrogen in the zirconium matrix is a function of temperature, and ranges from very low values at room temperature to about 150 ppm at 350°C [74]. If the hydrogen concentration exceeds the solubility limit, hydrides with compositions between ZrH and ZrH_2 are formed. At lower concentrations at first the f.c.c. δ hydrides ZrH_x ($1.4 \leqslant x \leqslant 1.6$) are formed. With increasing concentration these transform into the tetragonal ϵ-ZrH_{2-x} [75].

With the formation of hydride precipitates the alloy exhibits a ductile to brittle transition in fracture toughness. The transition temperature increases with increasing hydrogen concentration from room temperature to about 200–300°C.

In the absence of stress the hydrides precipitate on lattice planes nearly parallel to the (0001) basal planes [76], and the hydride precipitates reflect the texture. If tensile stresses exist, resulting either from service conditions or from fabrication, the hydrides precipitate perpendicular to the tensile stress axis with a tendency to migrate to locations with stress or temperature gradients (Fig. 36) [77]. The consequence is the formation of high local hydrogen concentrations with brittle behavior. Together with (residual) stresses the locally hydrided zones may form cracks (delayed hydrogen cracking, DHC), for example after cold deformation or welding. The zirconium–niobium alloys with higher strength are more sensitive to DHC compared to the Zircaloys and the unalloyed metal [78]. To minimize the risk of DHC during fabrication the hydrogen concentrations are restricted to low values (zirconium and Zircaloys $\leqslant$ 20 ppm, Zr2.5Nb $\leqslant$ 5 ppm). The influence of the orientation of the platelet-shaped hydride precipitates on the ductility is assessed by determining the orientation distribution of the platelets on metallographic sections by image analysis (F_N number).

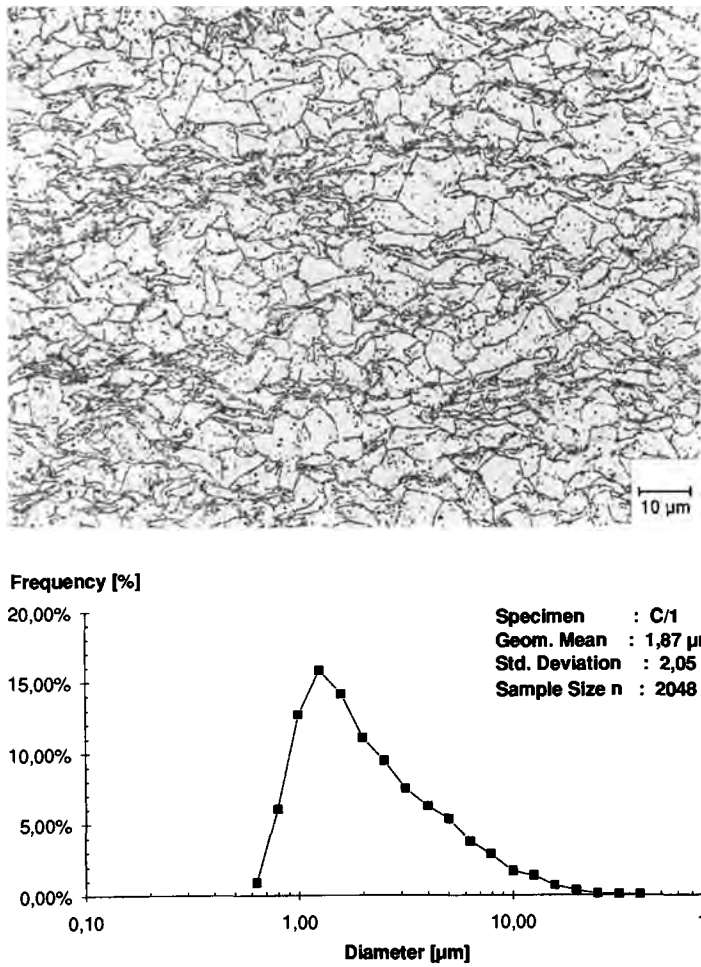

Figure 35. Nonsymmetric grain size frequency plot of a 10% cold-worked Zircaloy 4 sample (optical microscopy of an anodized section).

Recrystallization

Depending on the type of alloy, the materials recrystallize after cold work by annealing for several hours in the temperature range 450–650°C. Deformations of about 10% may produce coarse grains by critical recrystallization. Very high deformations and high annealing temperatures may initiate secondary recrystallization with the formation of very large individual grains [73]. The degree of recrystallization depends sensitively on the final annealing temperature [68] and on texture, and affects the behavior under irradiation in the matrix. Therefore, the ratio between recrystallized grains (low dislocation density) and only-recovered grains (high dislocation density) is determined by TEM (Fig. 37).

Second-Phase Particles (Intermetallics)

The alloying elements iron, chromium, nickel, and niobium are soluble in the high temperature β-zirconium phase. During transformation to the α phase these elements form intermetallic precipitates

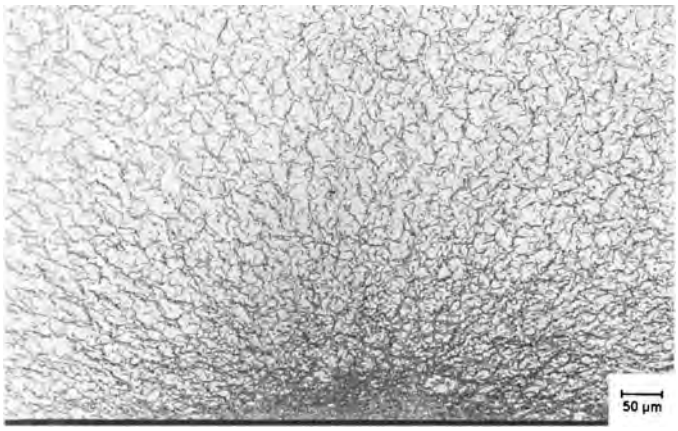

Figure 36. Enrichment of hydride precipitates due to local cold deformation in Zircaloy 4 (optical micrograph).

(Table 17) [79–81]. In Zircaloys the rate of cooling through the $(\beta + \alpha)$ two-phase field determines the density of their nuclei, and further annealing in the high α-phase field their growth [82, 83]. The size distribution of the intermetallic precipitates governs the corrosion behavior during service [84]. The optimized size distribution depends on the water chemistry of the reactor, and must be adjusted individually by modified fabrication routes. Hence the measurement of the size distribution and number density of the precipitates is an essential means for the prediction of the corrosion behavior of fuel rod cladding and fuel element components in service. The sizes of the precipitates occur most frequently in the range 10 nm up to nearly 0.1 µm, with particle densities in the range 1–2 particles per square micrometer of examined area (number density), equivalent to approximately 6–10 particles per cubic micrometer. Individual particles may attain diameters up to 5 µm. The majority of the particles have the structure of the Laves phase $Zr(Fe,Cr)_2$ with ratio $Fe:Cr \approx 2:1$, with a small portion of the precipitates with higher iron content depending on the exact alloy composition. The quality control routines are performed by TEM or SEM [85] (see Sec. 14.2.5.3).

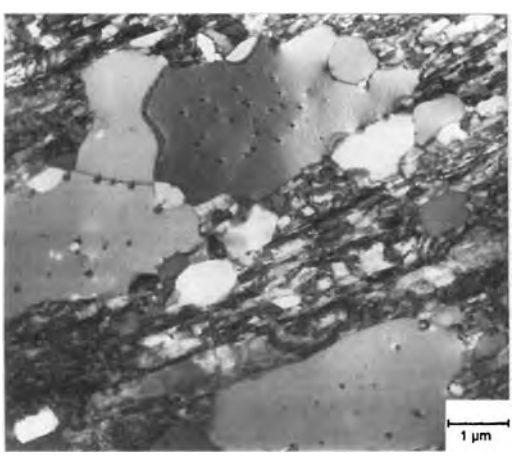

Figure 37. Partially recrystallized microstructure of Zircaloy 4 (TEM image of a thin foil sample).

Welding

Zirconium and its alloys possess an excellent weldability with TIG, laser and electron beam methods (Fig. 38). The affinity of zirconium for oxygen and nitrogen requires very pure protective (argon) atmospheres during welding. Insufficient gas purity results in the formation of tarnish colors by the solvation of oxygen or nitrogen, and may markedly increase

Figure 38. TIG weld on a longitudinal welded tube of Zircaloy 4.

the hardness in the weld metal and the HAZ. This reduces fracture toughness and corrosion resistance, provokes residual stresses, and increases the risk for cracks by DHC after welding.

The melting interval of zirconium alloys is around 1800–1900°C. At these temperatures the elements tin, iron, chromium, and nickel have relatively high vapor pressures, and during welding this is sufficient to reduce their concentrations in the molten alloy. Thus the composition of the welded metal should be compared with that of the base alloy by electron probe microanalysis.

The large range of melting temperatures of the zirconium alloys in combination with surface impurities may cause the formation of hot cracks in the HAZ of the weldings. These appear as intergranular cracks on the β-grain boundaries of Zr2.5Nb. Low-melting phases on the crack surface may be detected by electron probe microanalysis (Fig. 39).

14.2.5.3 Characterization After Service and Irradiation Damage

In addition to the effects of stresses and temperature during reactor operation the fast neutron flux induces changes in the microstructure of the alloy which affect its mechanical properties and corrosion resistance. The most important targets for microscopic examination after service are as follows, Table 18.

Hydrides

During reactor operation the surface of the components of the fuel elements is very slowly oxidized. The oxygen is released by the dissociation of the coolant water. Depending on the coolant chemistry (high or low oxygen concentrations) a certain portion of hydrogen (between 5 and 15%) is picked up by the alloy [86]. During in-pile life the hydrogen concentration in zirconium and Zircaloys may reach local concentrations up to 2000 ppm at special positions due to stress concentration, or temperature gradients.

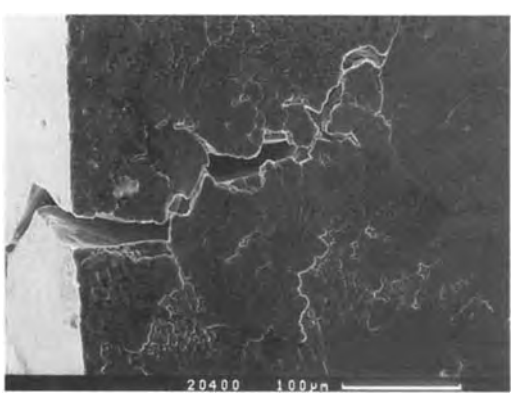

Figure 39. Reheat crack in the HAZ of a Zircaloy 4 weld caused by local impurities (SEM image of the near-weld surface of a section).

Dislocation Structures

After an incubation fluence the vacancy–interstitial pairs (Frenkel pairs) produced by the fast neutron flux at temperatures below 450°C precipitate and form dislocation loops on $\{10\bar{1}0\}$ planes [87–90] (a-type dislocations). The diameter of these loops depends on the irradiation temperature, and they start to become visible by TEM at a fluence $\Phi \sim 10^{19}\,\mathrm{cm}^{-2}$ for $T = 300°\mathrm{C}$ and $E > 1\,\mathrm{MeV}$ as black dots with about 10 nm diameter. Their density increases with the fluence, and seems to saturate at a fast flux of $10^{20}\,\mathrm{cm}^{-2}$. The regular arrangement of the dislocation loops causes a wavy deformation of the thin foil TEM specimens, and appears as a sequence of bright and dark striations ('corduroy' contrast) [91] (Fig. 40).

Depending on texture, the formation of dislocation loops causes irradiation-induced growth of the material. Growth is usually positive along directions normal

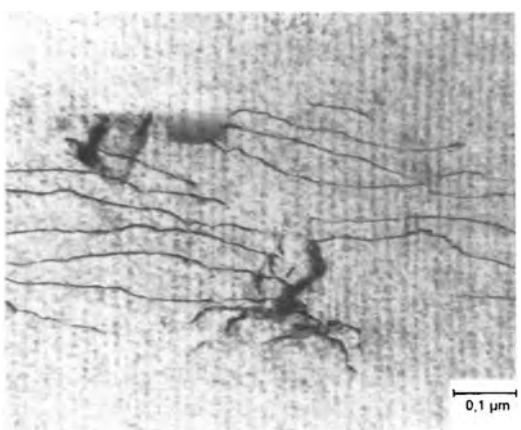

Figure 40. Bands of $\{10\bar{1}0\}$ dislocation loops (black dots, 'corduroy' contrast) in Zircaloy 4 irradiated at 300°C to a fast fluence ($E > 0.8\,\mathrm{MeV}$) of $1.1 \times 10^{22}\,\mathrm{cm}^{-2}$ (TEM image of a thin foil sample).

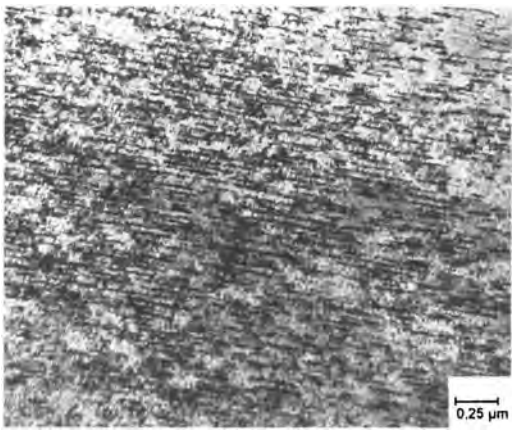

Figure 41. c-component dislocations (black striations) formed by irradiation of Zircaloy 4 at 300°C to a high fluence ($E > 0.8\,\mathrm{MeV}$) of $1.1 \times 10^{22}\,\mathrm{cm}^{-2}$ (TEM image of a thin foil sample).

to $\{11\bar{2}0\}$ and $\{10\bar{1}0\}$ planes and negative normal to (0001) basal planes [92]. This results in a growth in the axial direction of the rod for which the (0001) texture factor (fraction of [0001] poles oriented in axial direction) is very low. At fluences above $3.5 \times 10^{21}\,\mathrm{cm}^{-2}$ ($E > 0.90\,\mathrm{MeV}$) and temperatures ~300°C, new dislocations with Burgers vectors containing a c component are formed in addition to the a-type loops in recrystallized grains [88, 93] (Fig. 41). As a consequence of the formation of c-component dislocations and their increase in density, the rate of irradiation-induced dimensional changes increases after a preceding saturation of the growth [88, 94, 95].

Precipitates (Intermetallics)

Neutron irradiation changes the structure, the chemical composition, the size, and the density of the intermetallic precipitates in Zircaloy [88, 96–98]. Zircaloy 4 contains precipitates of zirconium with iron and of zirconium with iron and chromium. In

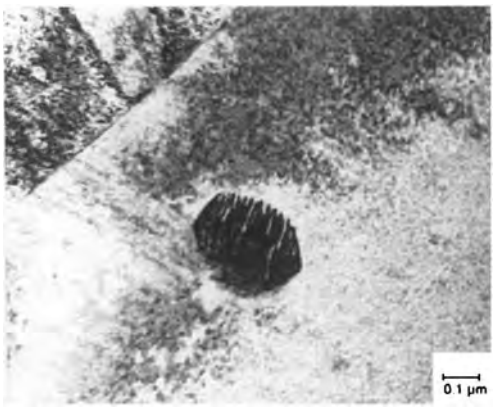

Figure 42. Partial dissolution of a zirconium–iron intermetallic Zr_3Feprecipitate in Zircaloy4 due to irradiation at 300°C to a high fluence ($E > 0.8$ MeV) of 1.7×10^{22} cm^{-2} (TEM image of a thin foil sample).

particular, one observes:

(1) During irradiation in the temperature range 290–310°C the iron goes into solid solution in the matrix, and the precipitates may form lamellas (zirconium–iron type) (Fig. 42), or become amorphous (zirconium–iron–chromium type) and dissolve completely at higher neutron doses.

(2) The density of intermetallic precipitates of the zirconium–iron–chromium type remains approximately constant, but three effects occur [99]:
   (a) The initial composition of the precipitates with ratio Fe:Cr ≈ 7:3 transforms into a spectrum of different compositions ranging from Fe:Cr = 1:0 to Fe:Cr = 0:1, with the majority of intermetallic precipitates in the range 1:9 < Fe:Cr < 4:6.
   (b) Within individual precipitates a radial variation in composition can be found, most frequently with an iron-rich core, as in the example of Fig. 43, with the associated electron dispersive X-ray (EDX) analysis showing the variation of the ratio iron : chromium beween large precipitate, amorphous zone, and small precipitate.
   (c) The original crystalline populations of precipitates transforms to an increasingly amorphous state, an exception to this being the iron-rich precipitates, which remain crystalline. Particles can be found with a crystalline iron-rich core and an amorphous iron-depleted rim. An example of this is shown in Fig. 43 along with the associated diffraction patterns.

At temperatures of 370°C the zirconium–iron–chromium-type intermetallics do not change much. The Fe:Cr ratio remains stable, and some growth may occur. As the precipitates could govern the corrosion behavior of the alloy, depending on the service temperature, a change in the corrosion rate may occur during service up to high fluences, especially under BWR conditions [100].

On cross-sectional specimens of the cladding wall the transition zone between the oxide and the metal matrix can be investigated. Of particular interest is the variation in the type and distribution of the intermetallic precipitates as a function of distance into the metal from the oxide–metal interface.

Electron Microscopy and the Study of Corrosion

Zirconium-based alloys possess relatively good corrosion resistance in water and steam up to 400°C under operating

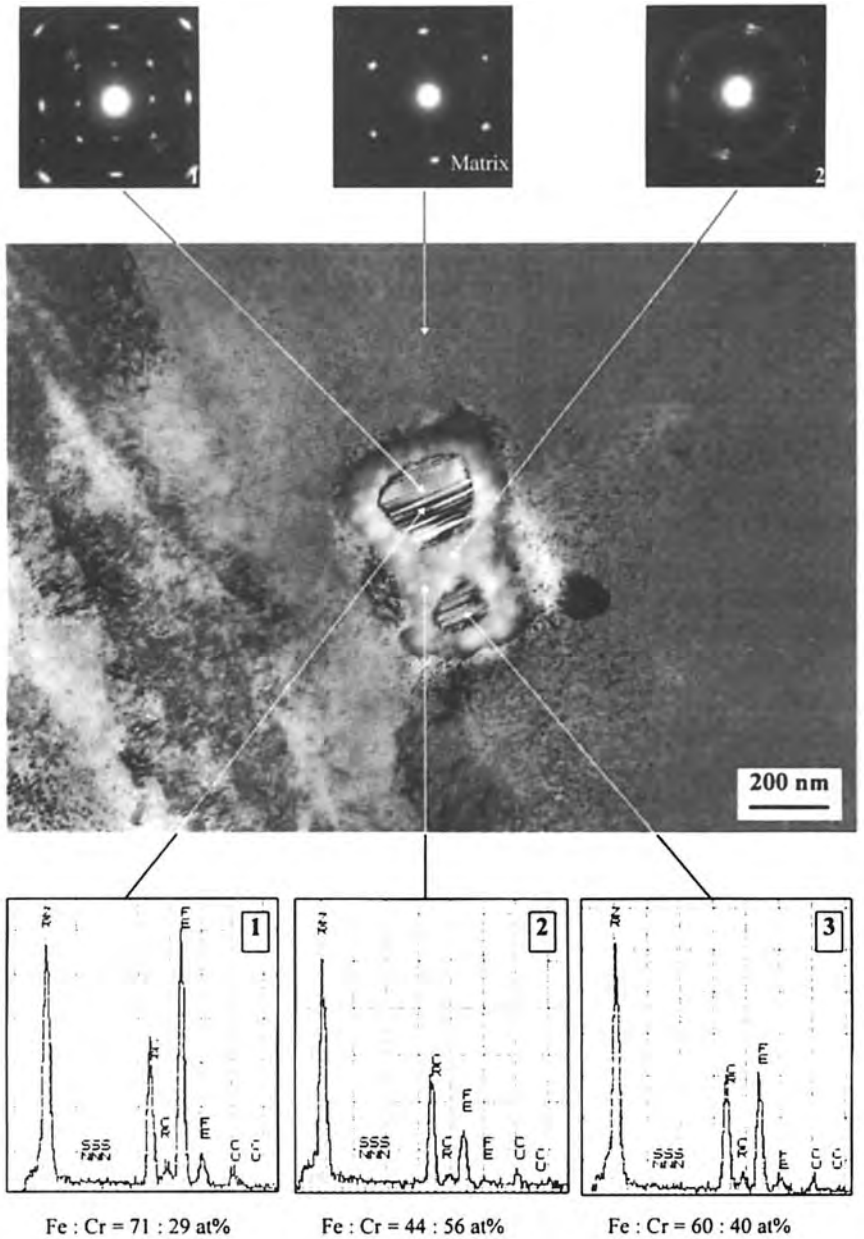

Figure 43. TEM micrograph of two closely spaced $Zr_2(Fe,Cr)$ precipitates in Zircaloy 4 of a cladding section near the cool end of a fuel rod (about 320°C) after four reactor cycles. Note the amorphous zone around the crystalline precipitates as indicated by the selected area diffraction patterns. The lines of Fe and Cr in the local EDX spectra show that Fe is lost from the precipitates and diffuses from the amorphous zone into the α-Zr matrix.

conditions in PWRs, BWRs, and HWRs (see Tables 3 and 16). Nevertheless, with the development of high burn-up fuels and increasing in-pile operating times, corrosion becomes a lifetime-limiting factor for the fuel rods. There is a very abundant literature on the corrosion of zirconium-based alloys (a recent discussion of the state of the art and the related problems with still many open questions in this field has been published by the IAEA [101]). During uniform post-transition corrosion of Zircaloy 4 and Zr2.5Nb the oxide forms a relatively thin (about 2–3 μm) oxide layer, called 'barrier layer', which adheres firmly to the alloy but is periodically replaced and determines the rate of corrosion. Hence, among other fields of parameters, research has concentrated primarily on the analysis of this barrier layer in order to understand the factors which govern the corrosion mechanism. By dissolving the alloy substrate of fuel claddings after irradiation, the morphology and structure of the in-pile grown oxide scale can be analyzed by SEM and TEM [102]. However, it appears that also the detailed structure of the alloy phase close to the oxide–metal interface has to be taken into consideration in order to understand the effects of alloy composition on the post-transition corrosion rate in PWRs [103].

The preparation of TEM specimens as transverse sections across the oxide–metal interface of irradiated cladding material has been performed by grinding and ion etching [104]. Because of the stress gradients existing across the oxide–metal interface in the irradiated bulk material, cracks usually develop in the oxide phase of the TEM specimens parallel to the oxide–metal interface during thinning. This makes successful thinning difficult and impedes the interpretation of the structures.

14.2.6 Structural Materials for Fast Breeder Reactors and Fusion Devices

14.2.6.1 Material Selection and Operating Conditions for Cladding and Wrapper Materials of Fast Breeder Reactor Fuel Elements

The FBRs of today have in common the choice of liquid sodium as the cooling medium with core inlet and outlet temperatures ranging typically from 380 to 560°C. This determines the temperature range of operation for core structural materials such as cladding materials for fuel pins and wrappers of fuel bundles from about 380°C up to 620°C and 580°C, respectively. In exceptional cases hotspot temperatures up to 680°C are to be expected in cladding materials. Hence, corrosion resistance and high-temperature mechanical properties, especially the time-dependent creep rupture strength data and structural stability, are of primary importance for a first material selection.

High-temperature resisting austenitic stainless steels of the type 18CrNi13 (AISI 316) and modifications were the first choice for cladding materials in many FBR projects. Also, high nickel-bearing, precipitation-hardened austenitic alloys of type PE 16 and Inconel 706 and nickel-based alloys such as Inconel 625 have been used. Today, after more than 20 years experience under very high neutron fluences of up to 130 dpa, the

titanium-stabilized austenitic stainless steels of Type 15CrNi15 (DIN 1.4970) in modified version (AIM 1) and the high-nickel austenitic alloy PE 16 are the most promising choices for cladding materials. They should achieve a target burn-up of 15–20% and a displacement dose of 150–200 dpa [105]. Limitations can possibly be expected from irradiation-induced swelling and creep in the austenitic steels at high neutron doses, which lead to unacceptable dimensional changes of fuel elements and to strong ductility losses of the PE 16 alloy.

For wrapper materials with a lower maximum operational temperature, the group of 9–12% CrMoV(Nb) steels has been selected because these alloys possess adequate strength, are sufficiently corrosion-resistant, exhibit low swelling under irradiation, and show no serious embrittlement problems under irradiation [106]. Experience with austenitic stainless steels of types AISI 304 and 316 and other alloys were less encouraging because of strong swelling and coupled irradiation creep.

Table 19 gives typical compositions of cladding and wrapper materials for FBRs, and in Table 20 the optimum thermomechanical treatments for three candidate materials are compiled.

14.2.6.2 Materials for First-Wall and Blanket Structures in Fusion Devices

The first wall of the next fusion device, ITER, and a future DEMO reactor, will be the component with the highest neutron wall loading and—together with the divertor—also have the highest thermal loading. Therefore, the primary selection criteria are favorable thermophysical properties, adequate mechanical and corrosion properties, high radiation resistance, and a low radiation-induced activation. In addition, the tritium pick-up and permeation are of importance. In Table 21, typical operational conditions for the first wall and the divertor of the ITER and a general outlook for the expected loading conditions of a future DEMO reactor are summarized [107]. The first wall is exposed to plasma particles, electromagnetic radiation, and high-energy 14 MeV neutrons. The plasma–wall interaction leads to surface effects such as physical and chemical sputtering and a high thermal wall loading, which is—in combination with the pulsed mode of operation—a major source of thermal fatigue. In addition, plasma disruptions can lead to surface heat loadings which can even exceed 50 MJ m^{-2} in time steps of less than milliseconds. In order to prevent melting and evaporation of the metallic structural materials, protection of the first wall by beryllium, carbon, or tungsten (for the divertor) is foreseen.

The neutron wall loading is characterized by the high energy of the neutrons (14 MeV). Whereas the calculated defect rate of displacements induced by elastic interaction between neutrons and lattice atoms is well in the range of values known from fission reactors, the rate of inelastic reactions increases strongly with the increasing neutron energy. This could have drastic consequences on radiation effects such as helium and hydrogen embrittlement, which are induced by the formation of hydrogen and helium through (n, p) and (n, α) transmutation reactions. Also, the radiation-induced activation is increased by the 14 MeV neutrons.

Table 19. Typical chemical compositions of cladding and wrapper materials for FBRs

Table 20. Recommended typical thermomechanical pretreatment for selected cladding and wrapper materials

Materials group	Type of pretreatment
Austenitic stainless steels Type X 10 CrNiMoTi B 15 15 (DIN 1.4970 mod., AIM 1)	Solution heat treatment (1100–1150°C/10 min) + cold working (20–25%)
Precipitation strengthened alloys Type nimonic PE 16	Solution heat treatment (1075–1100°C/5 min) + ageing (700–720°C/16 h)
Martensitic steels Type X 18 CrMoVNb 12 1 (DIN 1.4914, FV 448)	Austenitization annealing (1050–1075°C/30 min/air) + tempering (740–760°C/1 h/air)

For the ITER project, where only a limited level of radiation damage will be accumulated, the main concerns about material degradations under 14 MeV neutrons are the radiation hardening induced by defect clusters and precipitates at the lower end of the operational temperature range, and the in situ thermal fatigue under irradiation. For the future DEMO reactors, where the operational temperatures and the accumulated neutron damage will be much higher, it is expected that the effects of helium embrittlement, the swelling, and the irradiation creep will play the dominant roles in determining the material behavior [108, 109].

For the ITER project the austenitic stainless steel 316LN has been selected as a candidate structural material, mainly because of the very well established database and the low neutron exposure to be expected. For the long-term aim of a DEMO reactor the European Fusion Technology Programme has included the class of 9–12% CrMoV(Nb) conventional ferritic–martensitic steels, the 8–10% CrWVTa low-activation ferritic–martensitic steels as alternatives, the class of vanadium-based vanadium–chromium–titanium alloys and ceramic composite materials of the type SiC/SiC. Typical compositions of all the alloys are given in Table 22 [110].

Table 21. Typical loading conditions of the first wall and divertor components in the ITER [107]

14.2.6.3 Special Simulation Techniques to Study Radiation Damage

With the development of materials for FBRs and fusion devices, so-called simulation techniques to study different aspects of radiation damage were introduced. Electron irradiation—partially performed in HVEMs—are essentially applied to study the in-situ development of different microstructural components such as dislocations, defect clusters, precipitates, and other properties as indicated in Table 23. Heavy ion irradiation is—for example—extensively used to study high-fluence phenomena such as void formation, precipitate stability, and resolution, as well as ordering/disordering effects. The specific advantage of light ion irradiation is its relatively large penetration depth so that

combined mechanical loadings and irradiation can be applied in in situ tests. This has made the goal of cyclotron irradiation in two-beam constellations very attractive, especially in the field of fusion materials research. All these simulation experiments have the advantage that the control of irradiation conditions such as temperature, flux and fluence, and other parameters is more precise than in very complicated in situ reactor irradiation. Of course, some uncertainties have to be taken into account when the results of such simulation studies have to be transferred to the real situation in a reactor system. To mention only few among many points of concern: the different energy transfer to the lattice during a primary knock-on event, the additional effect of implanted ions on the material, and the performance of experiments in different damage rate regimes. But in general the results of such studies have essentially contributed to the development of materials.

Special problems arise when intensive and quantitative microstructural investigations by TEM have to be performed on samples irradiated with ions. In Fig. 44 the problem is manifested for the case of heavy ion irradiation. Dependent on the energy of the projectile, the radiation damage and implantation profiles are very narrow and at different depths. Dependent on the depth of the damaged zone the preparation of samples for TEM investigations have to be made according to a scheme shown in Fig. 45. For low-energy particles the damaged zone is near the surface, so that an electrolytic back-thinning normally leads to a good sample for TEM. For higher energies when the maximum damage zone is placed far in the bulk of a sample, a selective depth preparation by mechanical, electrolytic, or ion beam thinning techniques has to be adapted, before a back-thinning can again be applied (lower process row in Fig. 45). The problem here is to control the material removal to an accuracy of less than 0.25 μm. For the case of mechanical material take-off by vibratory polishing, this process is controlled by weight-loss measurements and/or by microhardness indentations. Two examples for such investigations in austenitic steels are shown in Figs. 46 and 47, where a direct recrystallization of material under heavy ion irradiation in competition with void formation and sweeping of grain boundaries is being observed by TEM.

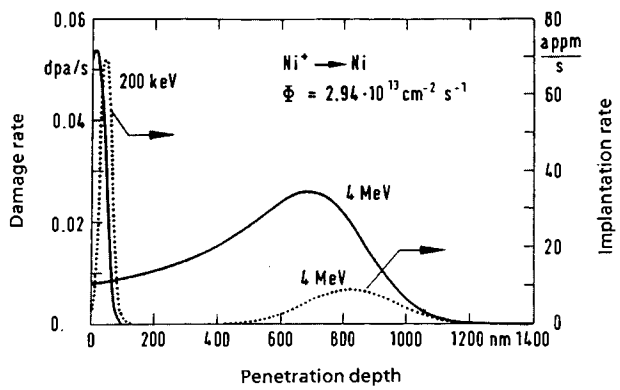

Figure 44. Damage rate and implantation profile in iron under irradiation by nickel ions.

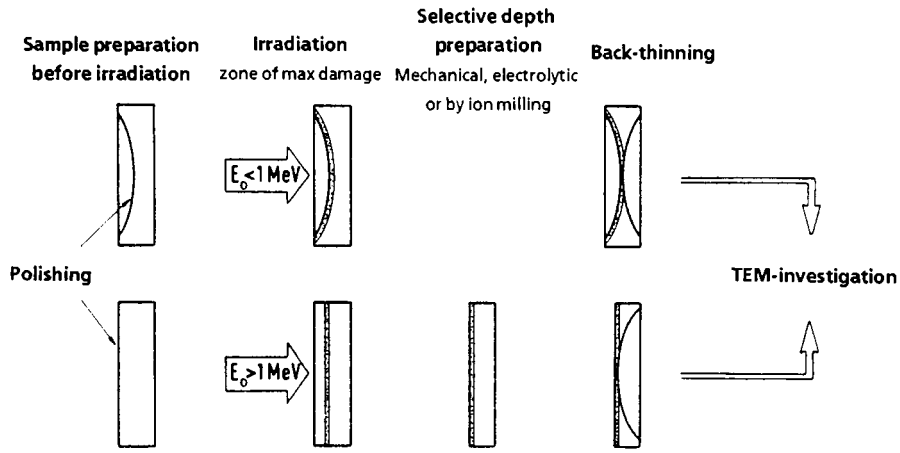

Figure 45. Steps in sample preparation for targets irradiated with low ($E < 1$ MeV) or high energy ions.

A more effective but experimentally very difficult method is to try a cross-sectional preparation of samples so that the whole penetration depth of ion-implanted specimen can be made visible. A method which has recently been developed to investigate the problem of radiation damage and helium bubble formation in ceramic materials for fusion applications is shown in Fig. 48. This method has been used for SiC material irradiated with 200 keV helium ions. After forming a sandwich of several SiC platelets, two of them are implanted with helium, and a transversal cut is polished by inert gas (argon) ions. The thin sections of irradiated samples clearly show in a cross-sectional view the damaged zone with the formation of black dot damage (Fig. 49).

In summary, the simulation irradiation together with a highly developed TEM technique allow the optimum information to be gained about the development of radiation damage that is dependent on dose, temperature, penetration depth, and other irradiation parameters. Very different problems associated with the radiation damage phenomena can be investigated in this way.

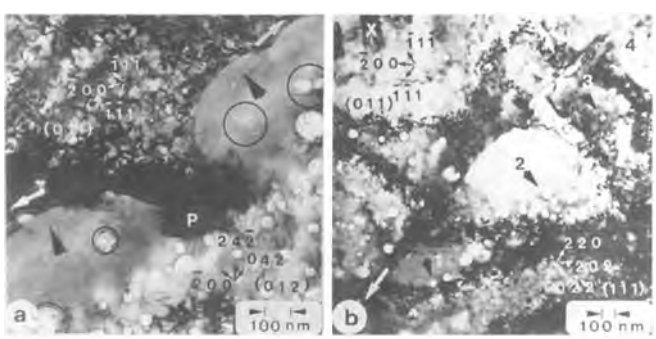

Figure 46. Typical features at the initial grain boundaries in an austenitic stainless steel (DIN 1.4970) during irradiation with 46 MeV nickel ions. Arrows mark the position of the grain boundaries, arrowheads show the direction of migration, and deeply etched voids are encircled.

14.3 Nuclear Fuels

14.3.1 Background

The nuclear fuels of today's electricity-producing nuclear power stations are ceramics, compounds of uranium and or plutonium, most commonly the dioxides UO_2 and $(U,Pu)O_2$, the latter material usually being called MOX (mixed oxide). Most of this discussion will therefore be on UO_2 and MOX, although other fuels are or were also used. In the 1970s, so-called advanced fuels for reactors operating with fast neutrons were widely studied. These were carbides, nitrides and carbo-nitrides of uranium and plutonium. Examples of other fuels are ThO_2-based ceramics, metallic fuels, or metal–ceramic composites called cermets, coated particles—small fuel spheres coated with layers of carbon or SiC for high-temperature gas-cooled reactors, and the silicides U_3Si and U_3Si_2, mainly used in small research reactors. These latter fuels will not be treated here since they are not widely used.

The fuel materials discussed here are ceramics with high melting points, for

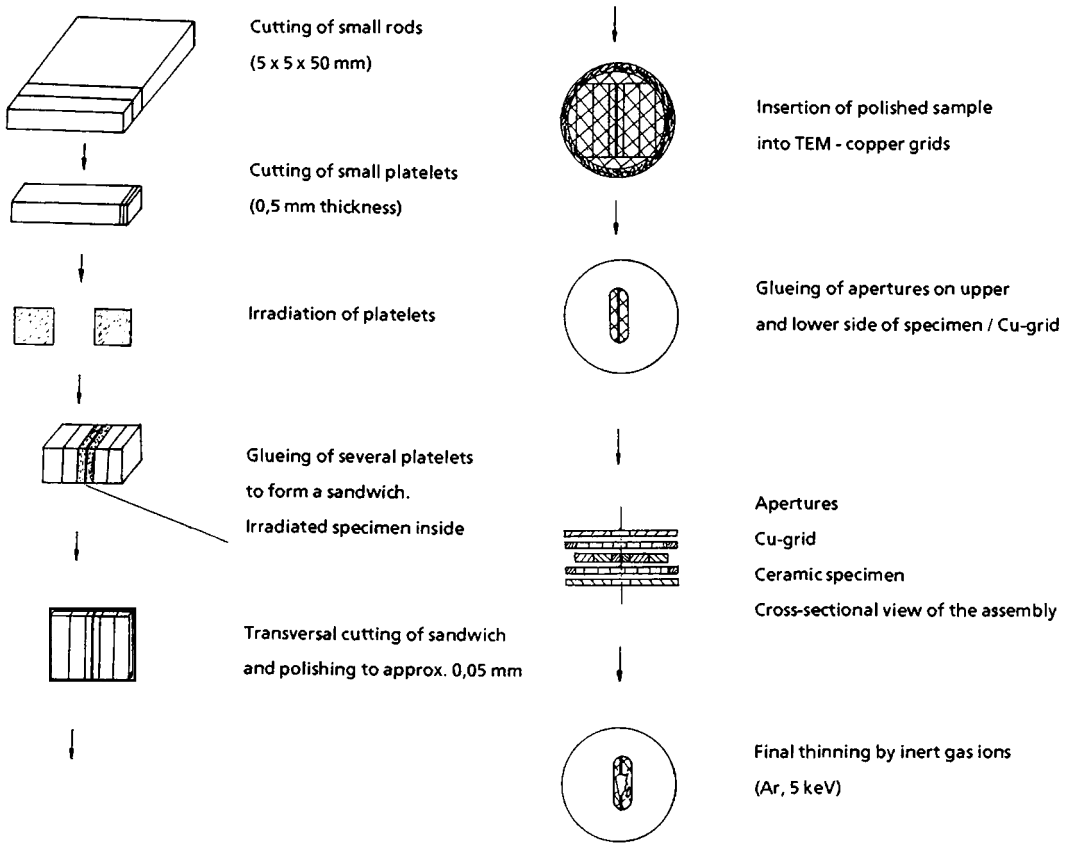

Figure 48. Cross-sectional preparation of ceramic materials for TEM investigation with a new sandwich technique.

example UO_2 (3150 K), UN (3035 K), and PuN (2843 K). The dioxides UO_2 and $(U,Pu)O_2$ have the fluorite structure, while the monocarbides and mononitrides have the rock salt structure. All these materials can be nonstoichiometric, are brittle, and have densities of $\sim 11\,g\,cm^{-3}$ (MO_2) or $\sim 14\,g\,cm^{-3}$ (MC, MN).

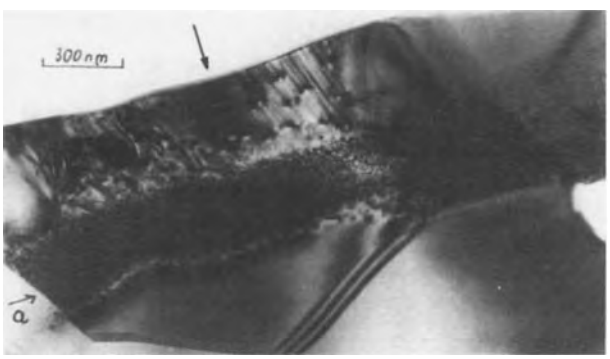

Figure 49. Cross-sectional view of SiC after helium implantation at 800°C (3×10^{21} ions m^{-2}, $E_{He} = 200$ keV). The zone of maximum radiation damage (~300 μm width) is indicated (a).

The ceramic fuel is most commonly used as sintered pellets which are stacked in metal tubes or sheaths called the clad. For water-cooled and -moderated reactors, the clad is a zirconium alloy (see Tables 14 to 18). The fuel pellets have a diameter of about 10 mm, the clad has typically a wall thickness of 0.72 mm, and the fuel rods, for LWRs, have typically a length of 4 m. The operating conditions are summarized in Table 16.

Due to the low thermal conductivity of oxide fuels, radial temperature gradients are formed during operation. Typical fuel central temperatures of LWRs are ~1200°C. Water reactors can also use heavy water for neutron economy and effective moderation of the neutrons. The most widely used type is the CANDU reactor (for *Can*adian *D*euterium *U*ranium). CANDU reactors have thicker and shorter fuel rods, and therefore the central temperatures are higher.

Reactors operating with fast (energetic) neutrons have fuels with a high plutonium content, typically 20%; the fuel rods are much thinner, typically 5.5 mm in diameter. Cooling is done with liquid metals, typically sodium. Other features are high neutron flux, high achievable burn-up, and high operating temperatures, since the high neutron energies lead to small cross-sections and enable a high power density to be obtained. Therefore, the center of the small fuel pellets gets very hot if oxides are used as fuel; temperatures above 2000°C can be reached in the center, whereas the surface of the pellet is held at about 600°C, due to the action of the coolant. Therefore, very large temperature gradients exist (up to $10^4\,K\,cm^{-1}$). If advanced fuels (MC, MN or M(C,N), where M = U + Pu) are used, these gradients are much smaller because of the much higher thermal conductivity λ of these nonoxide fuels (typical values of λ at 1000°C are $3\,W\,m^{-1}\,K^{-1}$ for MO_2 and $18–20\,W\,m^{-1}\,K^{-1}$ for MC and MN). In the fast reactor fuel, up to 20% of the metal atoms (U and Pu) can be fissioned, thus producing 40% of foreign atoms, relative to the metal sublattice. These fission products grow in as impurities at a rate of some $30\,ppm\,day^{-1}$. About 30 different elements are formed as fission products, ranging from germanium ($Z = 32$) to dysprosium ($Z = 66$)—and many of these change their chemical behavior during reactor operation due to nuclear reactions and radioactive decay. During the operating time in the reactor, radiation causes each atom in the fuel to be displaced up to and above 10^4 times. Such extreme working conditions do not exist during the operation of other, non-nuclear ceramics. A useful relation as a guideline for nuclear fuel utilization is 1 at.% burn-up of the metal atoms = 9375 MWd/tM (M = heavy metals, U + Pu). The present burn-up of LWRs is about 40 000 M Wd/t M, equivalent to the fission of ~4 at.% of uranium and plutonium.

14.3.2 Problems Treated by Optical Microscopy and Scanning Electron Microscopy

Microscopic techniques are vital to obtain oxide fuel capable of sustaining the above extreme conditions. Conventional optical microscopy and SEM are used to characterize the starting powders before pressing green pellets. The as-sintered pellets have also to be characterized with these two techniques to determine grain size and

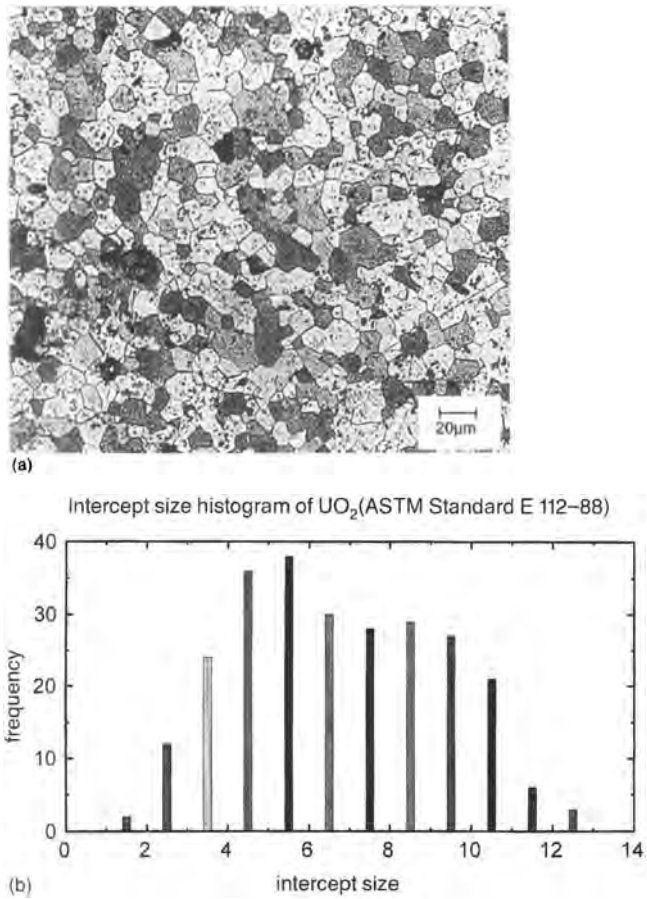

Figure 50. (a) Optical micrograph of an etched as-sintered UO_2 pellet. (b) Intercept size histogram of the same pellet (ASTM Standard E 112-88).

porosity. Figure 50 shows an optical micrograph of as-sintered UO_2, together with an intercept size histogram, applying the standard ASTM E 112-88 test method lineal intercept procedure on a 500 mm test pattern. The grain size was determined to be $9.7 \pm 1.0\,\mu m$ based on three independent intercept counts. Knowledge of the grain size is important to predict the irradiation behavior, since the grain size determines, beyond all else, the creep behavior, the release of fission rare gases, and the amount of such gases which can be accommodated at grain boundaries.

A further important result from optical microscopy and SEM is the pore size distribution. During the irradiation, the fuel matrix swells and the fission product rare gases (krypton and xenon) precipitate into bubbles. At the same time, irradiation-induced densification causes sintering pores to shrink. Figure 51 shows an unstable product. Shrinking proceeds very fast, faster than swelling, causing unwanted free volume in the fuel rod. Actually, this elimination of very fine-sized pores caused technological problems with cladding collapses in operating reactors some 20 years ago.

This densification, due to a kind of sputtering process by fission spike–pore interactions with partial escape of the

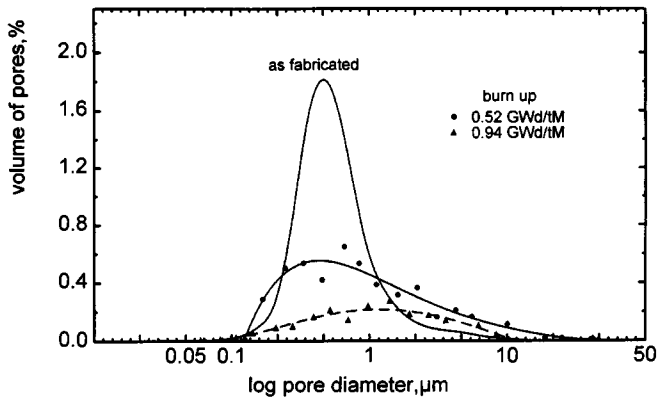

Figure 51. Effect of reactor irradiation on porosity in an unstable sintered UO_2 fuel type [113].

vacancies created in this way to grain boundaries, is less effective for bigger pores, as is obvious from Fig. 52. Two types of pellets are shown, one having a monomodal pore distribution peaked around a pore diameter of ~2.5 μm. It shows a very good dimensional stability: densification and swelling cancel one another up to a high burn-up. The second fuel with a bimodal pore size distribution shows a more pronounced swelling since the big pores do not shrink and the volume of pores usable to compensate swelling is smaller. This demonstrates the need for careful fabrication and exact microscopic investigation of the as-produced fuels.

This example of characterization and quality control shows the specific difficulty of microstructural analysis of nuclear fuels. Whereas UO_2 can be handled in controlled laboratories but without shielding, hence with normal microscope techniques, any plutonium-containing material must remain and be analyzed in a dust-tight glove box. The reactor-irradiated material has to be investigated in hot cells; see Sec. 14.1 of this Chapter. Figure 53 shows the interplay between optical microscopy in the hot cells, and the local analyses by replica electron microscopy (REM), TEM, and SEM. The gross structural changes such as cracking and pore migration in the thermal gradient to form long (columnar) grains in highly rated oxides can be deduced from optical microscopy. Finer details of the microstructure necessitate REM, TEM, and SEM techniques.

Before giving further examples of progress achieved with electron microscopy techniques on high burn-up UO_2 fuel, some very recent progress will be mentioned, obtained with high-resolution transmission electron microscopy (HRTEM) and with atomic force microscopy (AFM). Figure 54a shows the original HRTEM micrograph of a thin UO_2 specimen with lattice plane resolution. An area is shown containing a dislocation line. This is the first direct observation of a dislocation line in UO_2 obtained in February 1995 by Wang and Matzke [111] with the HRTEM instrument of the University of Albuquerque, New Mexico. Figure 54b shows the Fourier transform of Fig. 54a, Fig. 54c shows the filtered Fourier transform pattern with two of the 111 spots and Fig. 54d, finally, shows the dislocation line clearly in the inverse Fourier transform of Fig. 54c. Another

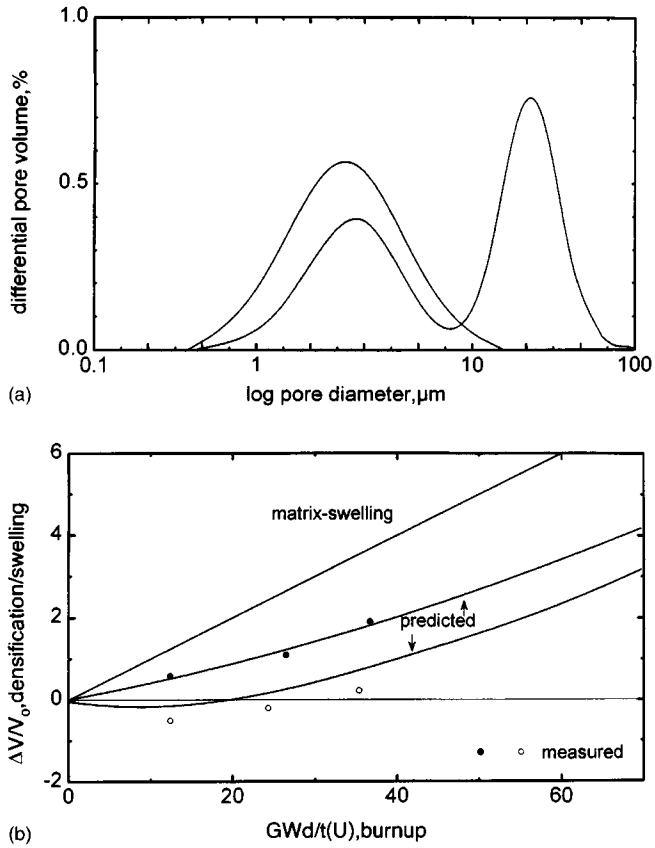

Figure 52. (a) Initial pore size distribution of two types of UO_2 pellets: 1, monomodal pores (95.7% TD); 2, bimodal pores (94.5% TD). (b) Dimensional behavior during irradiation [114].

recent advance [112] was obtained by investigating UO_2 by AFM. Small faceted voids with {111} faces could be seen in the nonirradiated material, thus giving a good 'background' to fully understand high-resolution results on the microstructure of irradiated UO_2.

14.3.3 Specimen Preparation and Electron Microscopy of Irradiated Fuel Samples

There are three techniques which have been developed for studying irradiated fuels by TEM, and these are illustrated in Fig. 53, which is a composite figure showing the combination of optical microscopy with TEM, REM and SEM on the same LWR irradiated fuel cross-section. All of the TEM methods require an initial stage of preparation within the hot cells. The methods used can be summarized as follows.

14.3.3.1 The Replica Technique

In this method a plastic film (Triafol) is used to make a replica of a polished and lightly etched fuel cross-section using remotely controlled techniques within the hot cells. The plastic replica is

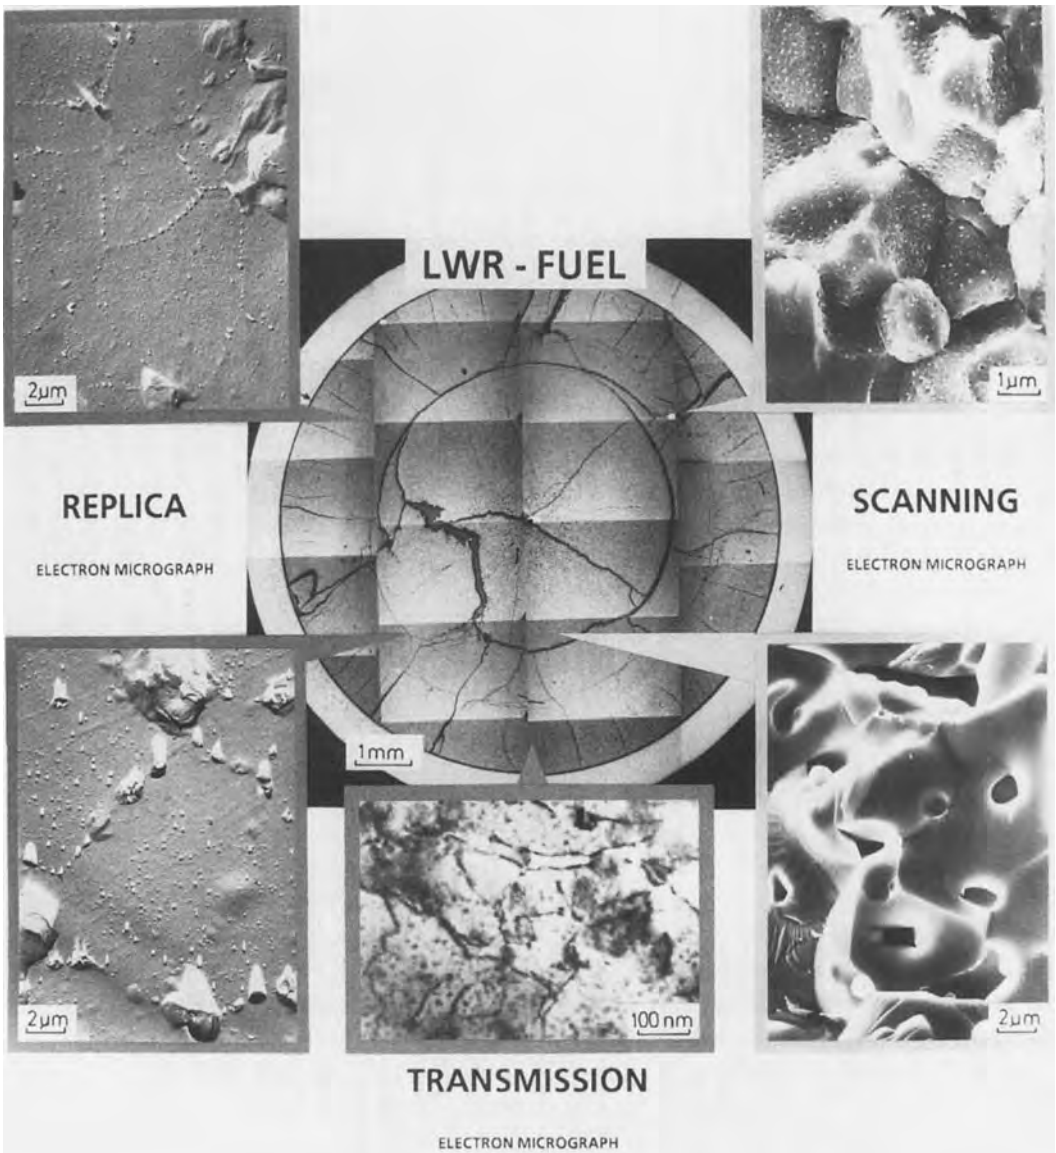

Figure 53. Cross-section of a UO_2 rod irradiated to 45 GWd/tM and subsequently transient tested at a linear rating of 41 kW m^{-1}. At the positions indicated by arrows in the central cross-section (optical microscopy), local examinations with REM, SEM and TEM were performed [115].

decontaminated using a series of ultrasonic baths, and a germanium-shadowed carbon positive replica is then prepared from this plastic film. The residual activity of the carbon replicas is usually so low that they can be handled in the open laboratory.

The information which can be obtained from a subsequent TEM analysis of the replicas encompasses inter- and

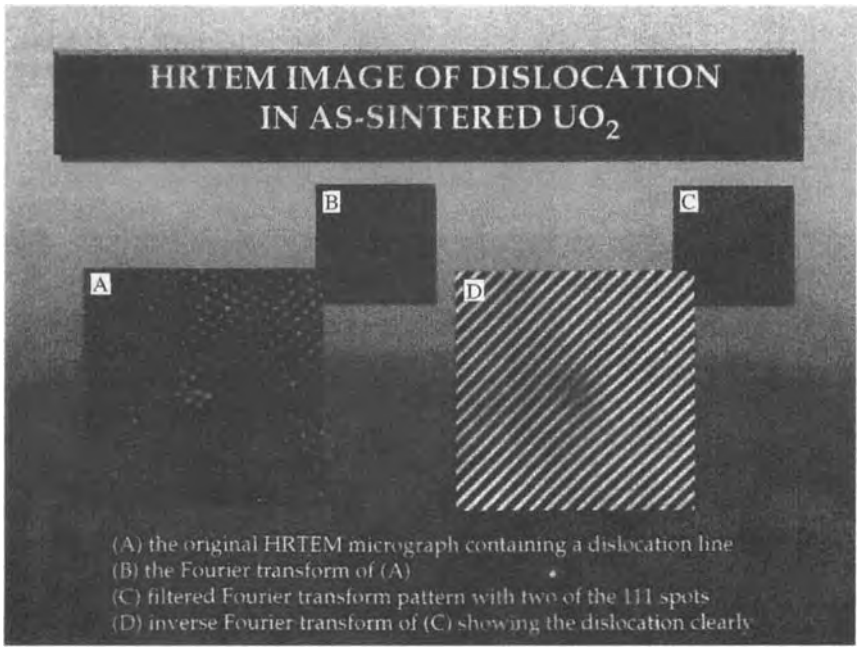

Figure 54. HRTEM of UO_2 showing lattice image resolution and a dislocation line [111].

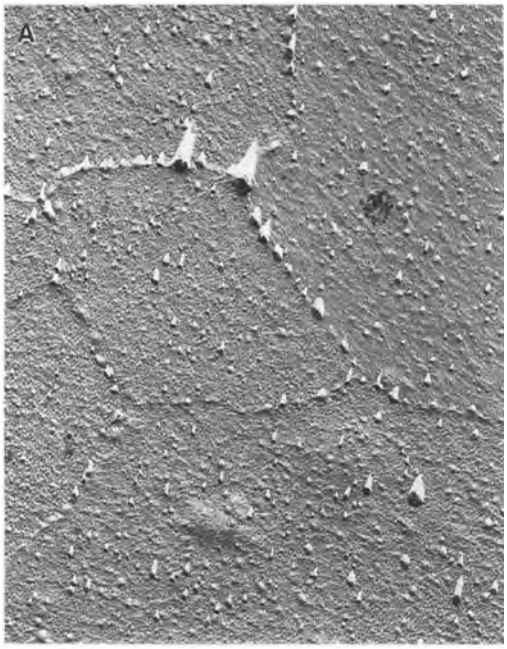
intragranular porosity and fission gas bubbles, grain boundaries, fuel cracks, and other structural features down to a resolution limit of about 30 nm. The technique has the advantage that the replicas can be decontaminated, making handling easy, and can show the structure over a very large area. Thus the full diameter of a fuel cross-section can be analyzed with a small number of replica samples, and information, for example on fission gas bubble distributions, can be obtained easily with very high radial positional accuracy. The disadvantage of the method is that features below the 30 nm resolution limit and the internal microstructure are not revealed.

The use of this method can be illustrated by the pair of replica electron micrographs in Fig. 55 taken from close to the periphery and towards the center of an irradiated LWR UO_2 fuel pin. The peripheral micrograph shows decoration of the grain boundaries by small fission gas bubbles. The central micrograph shows the development of an intragranular bubble population and high grain boundary porosity, which can be separated into grain edge porosity and grain face bubbles as demonstrated by the scanning electron micrograph of Fig. 56 of a corresponding fracture surface close to the fuel center.

Fission gas bubble size distributions and densities can be calculated from the replica images and used to construct radial fission-gas swelling profiles for the fuel cross-sections [117, 118].

14.3.3.2 Direct Transmission Microscopy of Thinned Fuel Pieces

In this method small pieces of fuel are thinned either electrolytically or by ion beam etching, and mounted directly in



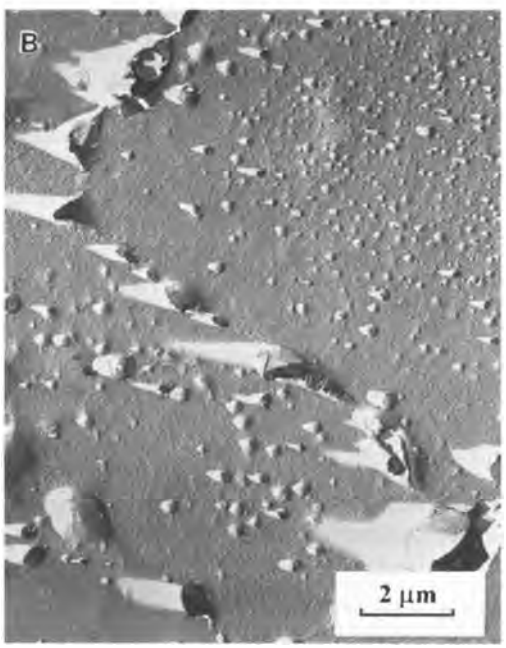


Figure 55. Replica electron micrographs taken from (A) close to the periphery and (B) towards the centre of an irradiated LWR UO_2 fuel pin. The peripheral micrograph shows decoration of the grain boundaries by small fission gas bubbles. The central micrograph shows the development of intragranular fission gas bubbles, and high grain boundary porosity.

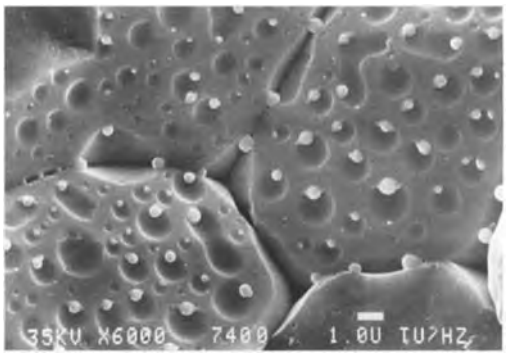

Figure 56. Scanning electron micrograph of a fractured surface of an ex-reactor LWR UO_2 fuel pellet, recorded close to the fuel centre, showing very high grain boundary porosity and a high density of spherical precipitates of the metallic fission products.

the microscope. This technique has the advantage that high-resolution analysis of the microstructure can be made, revealing, for example, very small fission gas bubbles (<10 nm), solid fission product precipitates and the dislocation or lattice defect damage structures. The disadvantage is that only very small areas can be surveyed and the positional accuracy is usually not very high.

Because the fuel cross-sections are usually heavily cracked after irradiation, it is normally not possible to cut a standard 3 mm diameter disc for the specimen preparation. A method has been developed where the fuel is separated into small irregular pieces defined by the original crack structure of the cross section, and these pieces are thinned for transmission. The pieces are typically about 2 mm in size and 0.3 mm thick. This technique has the

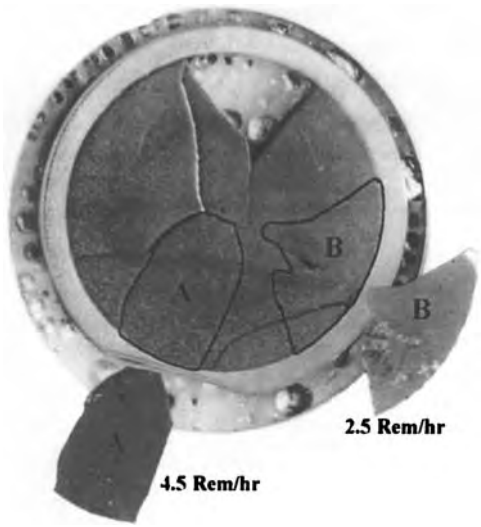

Figure 57. Small pieces of an irradiated LWR fuel cross-section which have been extracted and are of sufficiently low activity to be electropolished and examined directly by TEM. The activities of the pieces are indicated. The small pieces are about 300 μm thick, and the diameter of the fuel cross-section is about 9 mm. The curved surfaces where the pieces were in contact with the cladding permit the radial positions of the areas examined to be determined with high precision.

advantage that by referring the shape of the pieces back to optical micrographs of the full polished fuel cross section better radial positional accuracy can be obtained for the areas examined. An example of this is shown in Fig. 57. The work of separating the small pieces of fuel is performed remotely in the hot cells, but the single pieces usually have a sufficiently low β–γ activity for them to be handled with care in unshielded glove boxes.

Figure 58 shows the lead-shielded glove box which is used for the electropolishing of highly β–γ fuel samples for TEM. Biological shielding is provided by a 5 cm thick lead shield, and all operations are performed remotely using manipulators. The rear lead wall can be wheeled back if necessary to provide direct access with gloves to the box.

The right-hand compartment of the box contains a remotely driven double-jet electropolishing cell, and waste electrolyte can be drained off into a special shielded container beneath the box. The left-hand compartment of the glove box is kept clean from electrolyte and rinsing solutions, and is used for the dry handling of the samples—mounted in the Teflon holders prior to polishing and subsequent manipulations following polishing. A shielded transfer chamber attaches to this part of the cell, and this is compatible with the specimen entry port on the electron microscope glove box chain.

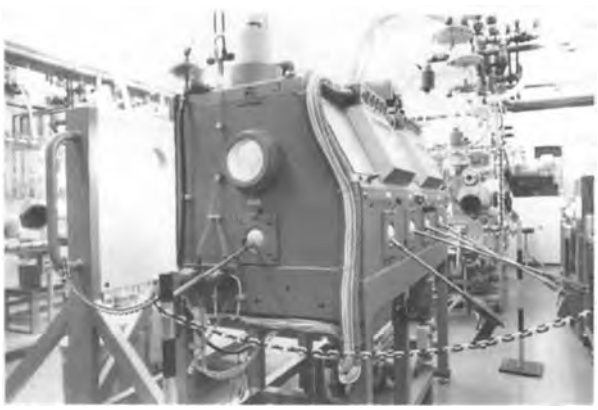

Figure 58. The lead shielded glove box used in the laboratory for the remote electropolishing of highly β–γ active samples, such as irradiated fuel.

The small fuel pieces are thinned for TEM by electrolytic polishing in a remotely operated Unithin double-jet cell mounted inside a lead cell equipped with manipulators. As the electrolyte, either Lenoir's solution or 20% phosphoric acid/80% methanol is suitable, though the latter is preferable for safety reasons inside a glove box, at a polishing potential of 20–25 V. After perforation the specimen surfaces are usually cleaned for a short time (<30 min) by argon ion etching. This preparation method is suitable for plutonium-containing oxide fuels and advanced carbide or nitrides [115, 119].

One of the main applications of TEM in the study of irradiated fuels is to investigate the behavior of the fission products as a function of the burn-up of the fuel or during a power transient, simulating a reactor incident or accident. During the steady state irradiation of an LWR UO_2 fuel, most of the fission products, both gaseous (xenon, krypton, and caesium) and solid (molybdenum, palladium, technetium, ruthenium, etc.) remain in solution in the fuel matrix, or precipitate out into very small bubbles or solid precipitates (<10 nm diameter) which can undergo fission-spike induced re-solution. Figure 59 is an example of a transmission electron micrograph of a UO_2 peripheral fuel sample with a burn-up of 4.5% FIMA, in which a very high density of small fission gas bubbles with an average diameter of 8 nm and a very narrow size distribution can be seen. The fission gas bubbles are associated with a population of precipitates of the solid fission products with approximately the same density and size distribution.

Figure 60 shows an equivalent area of fuel with similar steady-state irradiation history, but following a power transient for a period of 24 hours. Here very large fission gas bubbles and precipitates can be seen to have formed, with diameters up to 0.2 μm, leading to significant local swelling of the fuel. The precipitates are large enough to be analyzed by EDX in the microscope.

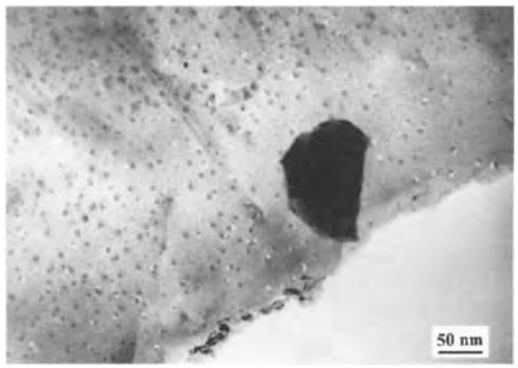

Figure 59. Transmission electron micrograph of the periphery of an irradiated UO_2 fuel sample, showing the presence of a very high density of small fission gas bubbles linked to small precipitates of the metallic fission products.

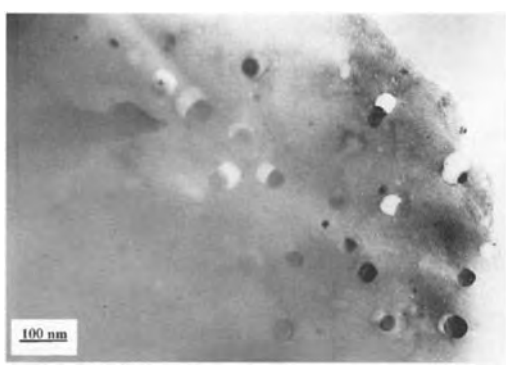

Figure 60. Transmission electron micrograph of an area of irradiated UO_2 fuel equivalent to that shown in Fig. 59, but following a power transient over a period of 24 hours.

14.3.3.3 Fuel Powder Samples

A third method of examining fuels by TEM is to use a powder sample produced either by crushing a small piece of fuel extracted from a chosen radial position on a polished cross-section, or by microdrilling into a cross-section and extracting the powder. This method has the advantage of low specimen activity, but relatively poor positional accuracy. The microdrilling must be performed within the hot cells, but small pieces can be crushed within a glove box in a standard agate pestle and mortar.

Small pieces of the fuel in the resulting powder are often thin enough for transmission. This method has the advantages of small specimen mass, thus low activity, and relatively good positional accuracy. The use of this powder method can be illustrated by TEM examinations made of the rim regions of high burn-up UO_2 fuel.

Figure 61 shows a transmission electron micrograph of a small fuel particle extracted from the rim zone of a fuel where the local burn-up is very high, in which the very small subgrain size can be seen. The inset diffraction pattern taken from the full area of the micrograph demonstrates the small difference in orientations (<5°) between the individual subgrains, which are free of dislocations or fission gas bubbles.

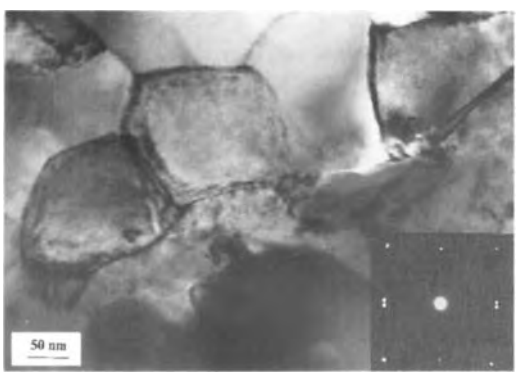

Figure 61. Transmission electron micrograph of a small fuel particle from the rim zone of a high-burn LWR UO_2 fuel pellet, showing the development of a fine subgrain structure. The inset diffraction pattern shows the small difference in orientation between the individual subgrains (<5°), [116].

14.4 Materials for Waste Disposal

For safe, long-term storage, high-level waste (HLW) originating from the reprocessing of spent nuclear fuels of electricity generating nuclear power stations is solidified in a stable matrix with high durability. Per tonne of typical reactor fuel, 300 litres of HLW are obtained in liquid form (acid solution, 2 N). This HLW is highly radioactive. The above 300 litres of HLW has a total β–γ activity of 530 000 Ci and an α activity of 2800 Ci (1 Ci = 3.7×10^{10} disintegrations per second, or 3.7×10^{10} Bq).

Today's technology of waste solidification is vitrification. Tailor-made borosilicate glasses are used, optimized for a number of properties allowing acceptability in a large-scale fabrication unit in shielded hot cells operated with remote control. These properties include viscosity of the molten glass, melting temperature, corrosion rates between molten glass and furnace and/or container, and minimization of evaporative losses during fabrication (e.g., for caesium and ruthenium). Simultaneously, acceptable glass properties have to be achieved: These include resistance against crystallization, ease of

Table 24. Composition of the (simulated) nuclear waste glass GP 98/12 (wt.%)

Material	Content (wt.%)
SiO_2	48.3
B_2O_3	10.7
Al_2O_3	2.3
Na_2O	14.9
MgO	1.8
CaO	3.5
TiO_2	4.0
Fe_2O_3	0.3
HLW[a]	14.2

[a] Contains fission products, corrosion products, and actinides (0.3 wt.% of uranium), 14.2 wt.% of HLW corresponds to ~6 mol.% because of the high molecular weight of actinide and fission product oxides. The added fission product oxides vary slightly between different glasses and are, typically: BaO, CeO_2, Cs_2O, Eu_2O_3, Gd_2O_3, La_2O_3, Nd_2O_3, MnO_2 (for Tc), MoO_2, PdO, Pr_2O_3, Rb_2O, Rh_2O_3, RuO_2, Sm_2O_3, SrO, TeO_2, Y_2O_3, and ZrO_2.

incorporating the different elements of the waste (Table 24), resistance against water attack (leaching) and against radiation. Table 24 shows, as a typical example, the composition of the German waste glass GP 98/12. This glass is a 'simulated' product, that is, the added fission products are not radioactive; the main content of the (simulated) HLW (fission product oxides, actinide oxides, and corrosion products from the reprocessing plant) are also given. Typical properties of these tailor-made, HLW-containing borosilicate glasses are: density, $\sim 2.8\,g/cm^3$; mean thermal expansion coefficient, $8 \times 10^{-6}\,K^{-1}$; thermal conductivity at 300 K, $1.1\,W\,K^{-1}\,m^{-1}$; viscosity at 1372 K, 10–20 Pa s; transformation temperature, 770–810 K; Young's modulus, $E = 83$ GPa; fracture toughness, $K_{Ic} \sim 0.95\,MPa\,m^{1/2}$ [120].

To solidify special waste streams, ceramics are studied. The basic idea originated from the fact that many natural rocks and minerals are known to accept elements of the HLW, both fission products and actinides, and to retain these elements over a long time period in a wide range of geological and geochemical environments. Typical ceramics studied as waste matrices are summarized in Table 25.

Optical microscopy, SEM, and TEM have all been extensively used to study the waste matrices. For instance, the noble metals in the HLW (palladium, ruthenium, technetium, and rhodium) form solid precipitates in the waste glass visible in the optical microscope. Or, during storage and due to accumulation of radiation damage (mainly α decay), helium bubbles can be formed, and the ceramics can be damaged to the extent that long-range periodicity of the lattice

Table 25. Some waste ceramics for actinide or HLW incorporation

SYNROC	A synthetic rock composed of (predominantly) 3–4 phases simulating minerals: perovskite $CaTiO_3$, Ba-hollandite $BaAl_2Si_2O_8$, zirconolite $CaZrTi_2O_7$ and rutile TiO_2, together with, for example, 10 wt.% of added calcined HLW
Supercalcine	Produced by adding about 50% of SiO_2, Al_2O_3, and SrO to the HLW solution. The reacted calcined product contains crystalline phases of the apatite, fluorite, scheelite, pollucite, and spinel structure
$CaZrTi_2O_7$	Zirconolite, monoclinic
$Gd_2Ti_2O_7$	Pyrochlore structure, cubic
$Ca_2Nd_8(SiO4)_6O_2$	Apatite structure, hexagonal
$ZrSiO_4$	Zircon, tetragonal
$CaTiSiO_5$	Sphene
Monazite	Mixture of orthophosphates, e.g. $(Ce,La)PO_4$

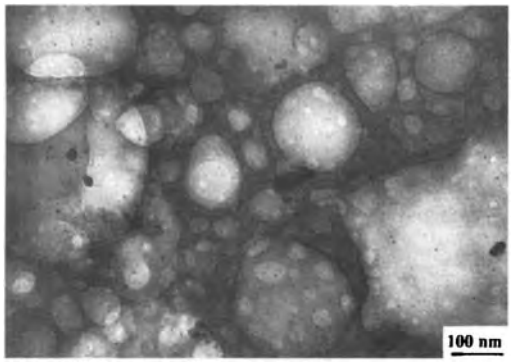

Figure 62. TEM image showing pore and bubble formation in a foil of the waste glass GP98/12 ion implanted with 4×10^{16} Xe^+ ions cm^{-2} of 225 keV energy, [121].

gets lost, that is, the materials become radiation-induced amorphous, or metamict. In glasses, radiolysis can produce free Na^+ ions and molecular oxygen, thus causing the formation of oxygen bubbles. These phenomena were studied with TEM, in the case of the ceramics in combination with electron diffraction. Figures 62–64 give typical examples.

Figure 62 shows pores/bubbles produced in the waste glass GP98/12 by ion implantation with 4×10^{16} Xe^+ ions cm^{-2} of 225 keV energy. A high density of small bubbles (5–50 nm) and a population of much larger features, resembling bubbles or pores with largely irregular shape and up to 400 nm diameter, are seen as radiation effects. The TEM results for the population of small bubbles could be shown to be in excellent agreement with parallel small-angle X-ray scattering (SAXS) results [121].

Figure 63 shows radiation damage in three potential waste matrices, $Ca_2Nd_8(SiO_4)_6O_2$, $Gd_2Ti_2O_7$, and $CaZrTi_2O_7$, containing the short-lived α emitter ^{244}Cm, to produce the α-decay

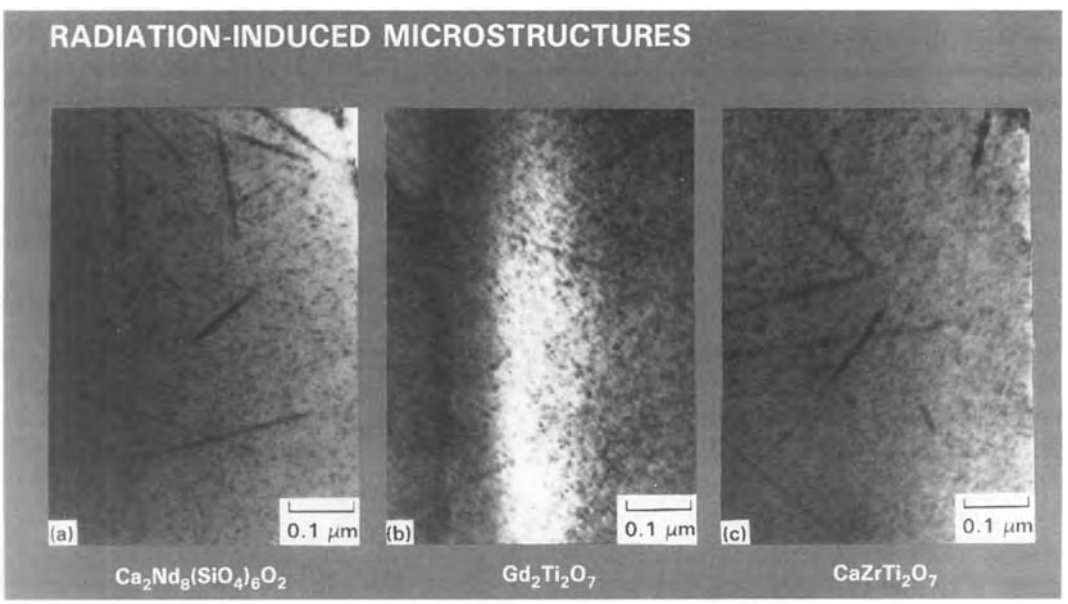

Figure 63. TEM image showing microstructural changes in three potential ceramic waste matrices of Table 25. The ceramics contained the short-lived actinide ^{244}Cm and experienced 3.6×10^{18} to 3.9×10^{18} α-decay events per cubic centimeter [122].

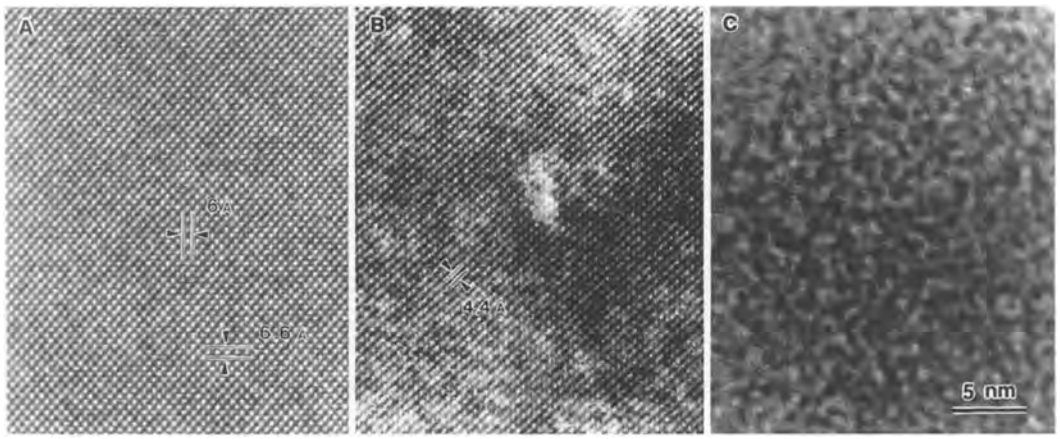

Figure 64. HRTEM image of zircon $ZrSiO_4$ before and after irradiation with 1.5 MeV Xe^+ ions. (a) Unimplanted [010] zone. (b) Same zone implanted with 1×10^{12} ions cm^{-2}. (c) Same zone implanted with the critical dose for amorphisization (2×10^{14} ions cm^{-2}). The fringes marked in (a) and (b) with 6.6, 6, and 4.4 Å show the lattice spacings for (100) (001) and (001) planes, respectively [123].

damage expected in an HLW matrix after a few 10^3 years of storage in a much shorter time period of a few years. The as-produced materials showed no specific microstructural features. Following 3.6–3.9×10^{18} α-decay events per cubic centimeter, which corresponds to 20–30% of the critical dose for amorphisization, small individual defects (~2.5–5.0 nm diameter) are seen. These defects are interpreted as amorphous, and result from the highly disordered track produced by the ^{240}Pu recoil daughter nucleus emitted with an energy of ~100 keV in the α decay of ^{244}Cm. Also seen are 'fission tracks', that is, the tracks of ~100 MeV fission products originating from the spontaneous fission of ^{244}Cm. The contribution of these tracks to swelling and amorphisization was estimated to be ~2–3% [122].

Figure 64, finally, shows damage effects in a further possible waste ceramic, that is, zircon $ZrSiO_4$. Lattice image resolution is achieved in high-resolution TEM. Damage was produced with 1.5 MeV Xe^+ ions. At small dose levels, regions with slightly mottled contrast or regions in which lattice fringes are absent are found (Fig. 64b). These regions are comparable in size to displacement cascades, indicating direct amorphization within the displacement cascades. At higher doses, complete amorphisization is observed [123].

In the above cited, and in many other publications, damage ingrowth was followed as a function of dose with TEM, HRTEM, and electron diffraction, such that a large database exists on critical doses for amorphization of different potential waste ceramics.

14.5 Electron Microscopy of Radioactive Aerosols and Particles and the Assessment of Toxicological Hazards

The release of radioactive materials into the environment, whether intentionally as a consequence of the use of nuclear weapons

or accidentally as the result of nuclear reactor accidents, represents a major area for concern. This release occurs most frequently in the form of an aerosol of small particles into the atmosphere, which can be biologically incorporated directly into the lungs, or indirectly following settlement by contact or through the food chain.

Electron microscopy plays an important role in the characterization of such aerosols and in the examination of the effects on cell tissues following incorporation. Two major areas of application can be identified:

(1) SEM is used primarily in the characterization of the aerosol particle shape and size distributions. These distributions govern how far the contamination spreads from the original source and the rate at which the particles settle.
(2) TEM is used to investigate the biological effects following incorporation of the radioactive particles.

These applications are illustrated by the following examples:

(1) The formation of radioactive aerosols under accident conditions has been investigated using simulation tests of glove box fires in which plutonium and uranium oxides have been replaced by cerium and europium oxides. The smoke produced was sampled by drawing air through filters at different distances from the fire, and particle size distributions constructed for each filter. An example of the aerosol formation is shown in the scanning electron micrograph of Fig. 65. Such micrographs also enable the interaction between soot and particles to be investigated, and permits an assessment of possible techniques for enhancing particle agglomeration [124].

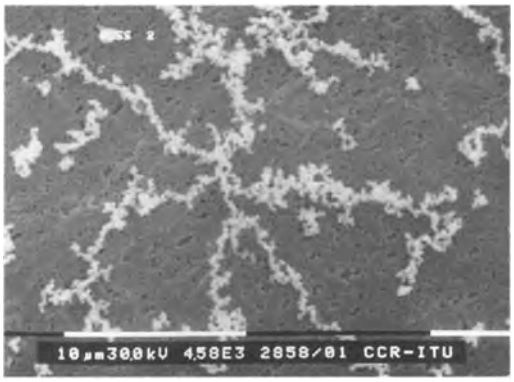

Figure 65. A scanning electron micrograph showing agglomerated soot particles on a filter, following an experimental ultrasonic precipitation test on smoke.

(2) Figure 66 shows a scanning electron micrograph of spherical $(Pu,U)O_2$

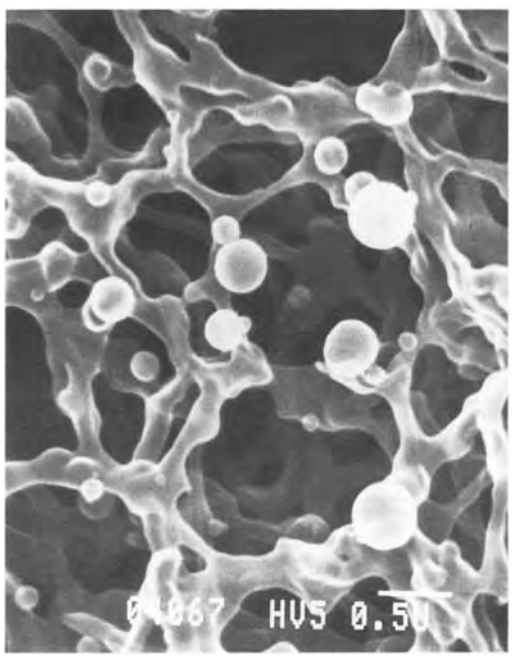

Figure 66. Scanning electron micrograph of spherical $(Pu,U)O_2$ particles deposited on a filter from aqueous suspension. With such micrographs the size distribution can be characterized prior to use in toxicological experiments on living tissues.

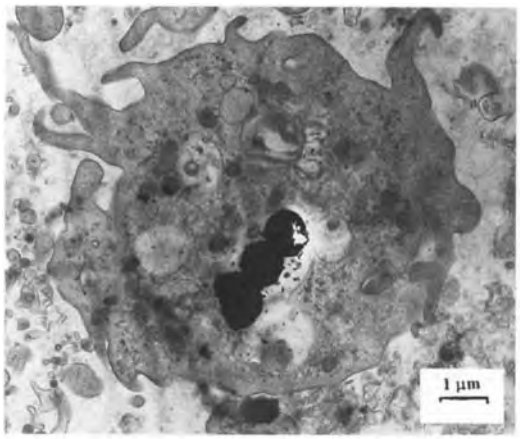

Figure 67. Transmission electron micrograph of a macrophage cell incorporating three of the $(PuU)O_2$ particles after 3 hours of incubation.

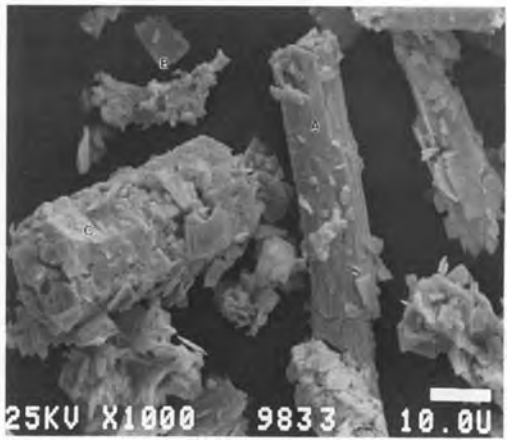

Figure 68. Scanning electron micrograph of a powder sample taken from a 'vagabond' find of radioactive materials, showing three distinct components, which could be identified by a combination of EDX analysis and electron diffraction in the transmission electron microscope. Two forms of PuO_2 were present, rod-shaped particles as indicated at A and platelets as shown at B. The third component, C, rod-like particles with a characteristic hexagonal cross-section, was identified as U_3O_8.

particles deposited on to a filter from aqueous suspension. These particles were subsequently incorporated by intratracheal injection into rats to assess the damage to the lung tissues caused by the α activity [125, 126].

The transmission electron microscope was used to follow the development of the toxicological effects of plutonium on the lung tissue. Figure 67 shows a stained section of tissue following 3 days of exposure, in which an incorporated aggregate of three of the $(Pu,U)O_2$ particles is visible. The development of the damage was studied as a function of time over a period from 1 hour to 200 days incorporation.

(3) SEM is being used to investigate the occurrence and nature of so-called 'hot spots', which are particles of very localized intense activity found in the ground following nuclear incidents such as the Chernobyl reactor accident. This is becoming an important aspect in the field of nuclear safeguards.

(4) Characterization of samples of illegal 'vagabond' radioactive materials. Very recently, electron microscopy has started to play an important role in the examination and characterization of illegal quantities of plutonium- and uranium-bearing materials which have appeared on the black market, with the objective of identifying the sources from which they have come.

The initial 'isotopic fingerprint' of the material is determined by mass spectrometry. The samples, which are usually in the form of powders, are then analyzed in the scanning electron microscope to determine whether they are homogeneous, or consist of different components. TEM is used for a structural determination using electron diffraction, and to examine the microstructure and grain size, which provide information on the original methods of production.

An example of such a 'vagabond' sample, containing a mixture of plutonium and

uranium oxides, is shown in the scanning electron micrograph of Fig. 68. This apparently homogeneous fine powder was shown in the scanning electron microscope to consist of three quite distinct components—platelets and two different types of rod-shaped particles—which could be separated and shown to have different isotopic compositions.

15 Magnetic Microscopy

15.1 Introduction: Observables and Methods

Below a critical temperature, the so-called Curie temperature, the elementary magnetic dipoles of magnetic materials (ferromagnetic or ferrimagnetic substances) are spontaneously ordered on a microscopic scale. This ordering can be determined, for example, by neutron diffraction techniques. Magnetic microscopy does not cover this aspect. It focuses on an intermediate, mesoscopic regime. In a volume of nanometer dimensions, many thousands of elementary dipoles are present, and micromagnetism only registers their average value, the magnetic moment density or *magnetization*. Mathematically, we have to deal with a classical vector field, the magnetization or magnetic polarization $\boldsymbol{J}(\boldsymbol{r})$.

A property of all regular magnetic materials is that the absolute value of this magnetization vector is a function of temperature alone. It is constant throughout a (chemically uniform) sample and is even largely independent of applied magnetic fields. We can therefore write $\boldsymbol{J}(\boldsymbol{r}) = J_s \boldsymbol{m}(\boldsymbol{r})$ with $\boldsymbol{m}^2 = 1$. The task of magnetic microscopy is to determine the unit vector field $\boldsymbol{m}(\boldsymbol{r})$ in the whole sample.

The magnetic microstructure $\boldsymbol{m}(\boldsymbol{r})$ is influenced by many parameters. In most materials it can easily be modified by an external field (soft magnetic materials). But it can also be pinned by lattice defects and surface imperfections, leading to hard magnetic materials and magnetic storage media. The shape of a sample is always an important parameter. In magnetic materials it is impossible to cut a sample into small pieces in order to look for the magnetic microstructure inside. The magnetization distribution would, in general, be strongly modified by the cutting process.

Unfortunately, there are virtually no microscopical techniques available to observe the interior magnetic structure of bulk samples. The methods that will be discussed in the following are either restricted to surface observations or to observations on thin films. This difficulty is partially compensated by the availability of a well-established theory called micromagnetism. The theory, which was introduced by Landau and Lifshitz in 1936 [1], is a continuum theory which derives the optimum vector field $\boldsymbol{m}(\boldsymbol{r})$ from a nonlinear and nonlocal energy functional. The external field, crystal anisotropy effects, exchange and dipolar interactions, and lattice strains contribute to the total free energy. The details cannot

be elaborated on within the scope of this contribution. It is sufficient to emphasize that due to the mentioned difficulties in experimental observation, the theoretical analysis of microscopical observations is a necessary part in successful magnetic microstructural research.

The available experimental methods in magnetic microscopy can be classified by examining the basic field equation connecting the magnetization field $\boldsymbol{J}(\boldsymbol{r})$ with the magnetic field $\boldsymbol{H}(\boldsymbol{r})$ and the magnetic flux density $\boldsymbol{B}(\boldsymbol{r})$

$$\boldsymbol{B}(\boldsymbol{r}) = \mu_0 \boldsymbol{H}(\boldsymbol{r}) + \boldsymbol{J}(\boldsymbol{r}) \tag{1}$$

which, based on the Maxwell equation $\operatorname{div} \boldsymbol{B} = 0$, leads to

$$\mu_0 \operatorname{div} \boldsymbol{H}(\boldsymbol{r}) = -\operatorname{div} \boldsymbol{J}(\boldsymbol{r}) \tag{2}$$

The magnetic field $\boldsymbol{H} = \boldsymbol{H}_{\text{ext}} + \boldsymbol{H}_{\text{d}}$ comprises any external applied field $\boldsymbol{H}_{\text{ext}}$, and also the magnetization-generated, so-called stray or demagnetizing field $\boldsymbol{H}_{\text{d}}$, which arises due to the 'charges' or poles on the right hand side of Eq. (2). The divergence of the external field is usually zero within the sample so that the field on the left hand side of Eq. (2) is just the stray field $\boldsymbol{H}_{\text{d}}$.

Figure 1 demonstrates two classical examples of magnetic microstructures, one of which does not generate a stray field, which the other does. Both possibilities are observed in nature, depending on the anisotropy properties of the material. Note that the continuous vector field $\boldsymbol{m}(\boldsymbol{r})$ of micromagnetism has been replaced in these drawings by discrete blocks or 'domains'. The formation of such domains is a well-known experimental fact. It can be justified from the mentioned theory of micromagnetism. With sufficient resolution it is possible to see that these domains

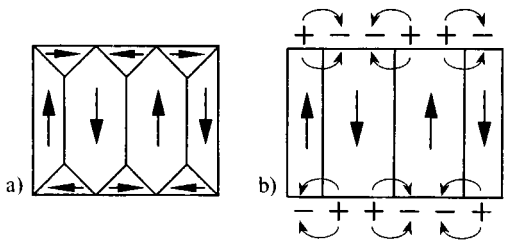

Figure 1. (a, b) Cross sections through two simplified magnetic patterns in a ferromagnetic body. For the case of the open structure (b), the magnetic charges or poles are indicated by + and − signs. The stray field extends from the positive to the negative charges, as in the corresponding electrostatic case.

are not really discrete. They are in fact connected by *Bloch walls* which form continuous transitions between the domains on the 10–1000-nm scale.

All three of the vector fields in Eq. (1) can be responsible for contrast in magnetic microscopy. Light interacts directly with the magnetization field $\boldsymbol{J}(\boldsymbol{r})$ via magnetooptical effects. Optical polarization microscopy therefore offers direct access to the magnetic microstructure. Essentially the same is true for electron polarization methods in which polarization-dependent electron scattering is analyzed, with the additional advantage of an enhanced resolution potential.

Conventional, unpolarized electrons are deflected by the $\boldsymbol{B}$-field in and around a sample. This is equivalent to a phase shift of the electron waves. Various electron microscopical imaging and scanning techniques are based on this effect.

The stray field $\boldsymbol{H}_{\text{d}}$ above a sample can be depicted by decoration with magnetic particles, leading to classical *Bitter* patterns, the method with which magnetic domains were visualized for the first time at the beginning of the 1930s [2–4]. A modern technique that is also basically sensitive to the stray field is magnetic

force microscopy, a scanning force technique using a magnetic tip. A disadvantage of the stray-field-sensitive methods is that the magnetization field determines the stray field in Eq. (2), but this relation cannot be inverted. For example, the idealized structure in Fig. 1a does not generate a stray field and hence the magnetization field cannot be inferred from any method that only scans the stray field.

There are further methods based on other effects such as the elastic deformation ('magnetostriction'), often connected with the magnetic microstructure, or effects in the inner electron shells which are somehow coupled to the magnetization vector and which can be sensed by X-ray or electron scattering methods. In practice, these new or exotic methods do not play a big role in magnetic microstructural research.

In the following we will focus on three important fields of research, which are each naturally connected with one important technique. The three fields are:

1. The investigation of magnetization *processes* in all kinds of magnetic materials. The dynamic capability and the compatibility with arbitrary applied fields of the *magnetooptic methods* make them ideally suited for this application. The available resolution (down to a few tenths of a micrometer) is fully sufficient in virtually all applications of this kind.
2. The study of *micromagnetic* details, either in thin films or at the surface of bulk materials. The enhanced resolution of various *electron microscopy* methods can be favorably used in this field.
3. Patterns in magnetic and magnetooptic *recording media* are increasingly investigated by *magnetic force microscopy*. Excellent resolution can be achieved and is needed in this application. The danger of interactions between the magnetic tip and the sample is less important because written patterns are magnetically rather hard. Also, the fact that force microscopy is primarily sensitive to the stray field becomes an advantage as the information is (at least in conventional recording) read out exactly using this field.

15.2 Magnetization Processes and Optical Microscopy

15.2.1 The Principles of Magnetooptical Imaging

The standard method of imaging magnetic domains in the optical microscope is based on a 'gyroelectric' effect which is known as the Faraday effect in transmission and as the magnetooptical Kerr effect in reflection. The electrical vector of the illuminating light interacts with the magnetization vector in a cross product fashion in the same symmetry as in the Lorentz force.

Let $\boldsymbol{E}$ be the electrical vector of an illuminating plane light wave anywhere in the sample. Then at this point a secondary amplitude

$$\boldsymbol{D}_{\mathrm{mo}} \approx Q(\boldsymbol{m} \times \boldsymbol{E}) \tag{3}$$

is generated, where Q is a (small) complex material parameter. As only transverse electromagnetic waves can exist in free space, the magnetooptic response of Eq. (3) has to be projected onto the plane perpendicular to the propagation direction of the light wave used in observation. It

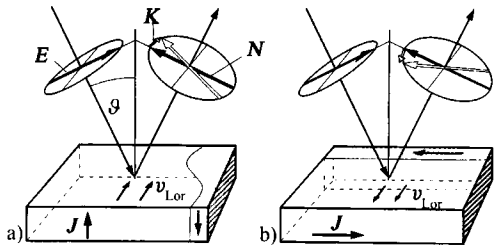

Figure 2. Schematic diagrams of (a) the polar and (b) the longitudinal Kerr effect. The interaction of the incident light ***E***-vector with the magnetization ***J*** generates the 'Lorentz velocity' v_{Lor} [parallel to the dielectric displacement $\boldsymbol{D}_{mo}$ in Eq. (3)]. This leads to a rotation of the ***E***-vector in reflection.

was shown by Wenzel et al. [5] that this simple recipe describes for small Q all possible cases: transmission, reflection, all directions of the magnetization, and even magnetic diffraction by nonuniform magnetization fields. Examples are shown in Fig. 2 for the cases of the polar and the longitudinal Kerr effect. Oblique illumination is necessary for the latter case in order to achieve a nonvanishing reaction, which consists of a small rotation of the plane of polarization of the light, changing its sign with the sign of the magnetization vector.

The magnetooptical response can be made visible in polarization microscopes as they are used in metallography or mineralogy. A high intensity light source of a limited spectral range, high quality polarizers, and the possibility to use a restricted, offset illumination aperture are important. Details of the contrast mechanism, the possible background intensities and the best modes of operation can be found in Kranz and Hubert [6]. As the effect is weak, polarization effects from imperfect surfaces and defects can easily obscure the magnetic image. The contrast can be enhanced by the application of dielectric anti-reflection coatings [6]. The most powerful option, however, is the implementation of digital difference techniques [7] which subtract a digitally stored reference image from the actual incoming image, thus getting rid of most of the disturbing background. This method is illustrated in Fig. 3. The reference image can either be a saturated image taken in a large applied field or the average of moving domain pictures taken in alternating fields of sufficient amplitude.

It is instructive to take a look at the contrast mechanism for the last-mentioned case of a digital difference image. Let φm_x be the (real part of the) magnetooptic rotation angle caused by the magnetization component m_x, and let β be the analyzer angle counted from the position of extinction (Fig. 4). Then the intensity passing through the analyzer is $\sim \sin^2(\beta - \varphi m_x)$. Assuming the reference

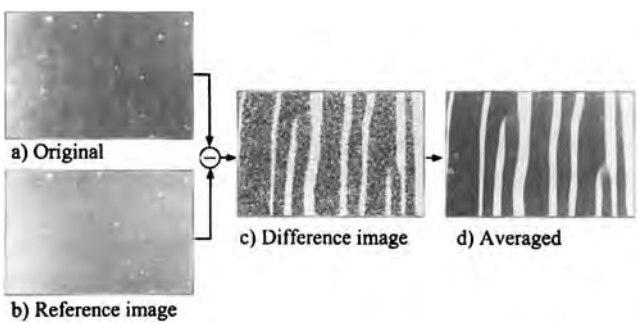

Figure 3. Illustration of the digital difference technique. In (a) the original, the domains on a Permalloy film are barely visible. Digital subtracting (b) the saturated reference image leads to (c) the difference image, which, after averaging several frames, results in (d) a clear and low noise picture.

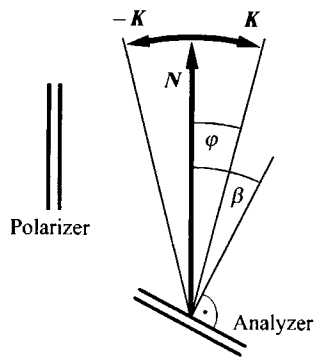

Figure 4. The principle of magnetooptic contrast formation. The regularly reflected amplitude N of the polarized light is modified by a small magnetization-dependent magnetooptical amplitude K, leading to rotation of the polarization plane by a (small) angle φ. This rotation is made visible by an analyzer which is offset by a larger angle β. If K differs from N in phase, the rotation is connected with some ellipticity. In this case the phase should first be adjusted by an additional compensator.

image is formed at $m_x = 0$, we obtain for the difference signal

$$S = I_0 + I_1[\sin^2(\beta - \varphi m_x) - \sin^2(\beta)]$$
$$\approx I_0 + 2I_1\beta\varphi m_x \qquad (4)$$

where I_0 is a chosen bias level and I_1 is the regularly reflected light intensity. The approximation is based on φ, $\beta \ll 1$ and $\varphi \ll \beta$.

We note a number of important properties:

1. The signal is *linear* in the magnetization component m_x observed, a property not often found in microscopy.
2. The intensity of the signal can be tuned by adjusting the analyzer angle β over a wide range to adjust to the sensitivity of the detector.
3. Assuming shot noise as the basic noise mechanism, the noise should be proportional to the square root of $I_1 \sin^2(\beta) \approx I_1\beta^2$. The signal-to-noise ratio is then proportional to $K = \varphi\sqrt{I_1}$, which is the magnetooptical amplitude shown in Fig. 4. The noise content of an image is therefore not influenced by changing the analyzer angle β, as long as it stays large compared to the magnetooptical rotation φ and small compared to unity.
4. If the magnetooptic signal K contains an imaginary part relative to the regularly reflected light amplitude N, an adjustable phase compensator should be inserted to convert the magnetooptical signal into a detectable rotation.

With different microscope settings, different magnetization components can be observed separately. This is best achieved by adjusting the illumination diaphragm inside the full aperture of the microscope. A central aperture, corresponding to perpendicular incidence, only detects the polar magnetization component. Choosing two different off-center positions of the diaphragm, corresponding to two orthogonal planes of incidence, both in-plane components of the magnetization vector can be detected. Such 'quantitative' procedures are discussed in the literature [8–10]. Possible interference between different effects should always be considered. Reliable results require some kind of contrast calibration.

The magnetooptic Kerr effect is not sensitive to the reflecting surface alone. The signal is formed by linear superposition of contributions from various depths, weighed in phase and sign by the amplitude penetration function of the incident and the secondary emitted light, as explored in detail in Traeger et al. [11]. Choosing different phase conditions, the depth sensitivity characteristics can even

be adapted according to the specific aims of the experiment [12].

15.2.2 Magnetization Processes in Thin Film Elements

Many applications such as magnetic sensor or memory devices are based on magnetic thin film elements. Their magnetization process can be quite complex, but still less involved than the processes in extended, bulk magnetic materials in which far-reaching and local interactions act together, forming complex three-dimensional domain structures. Thin film elements do not hide much in the third, i.e., the thickness dimension, and the whole sample can be observed at the same time. The behavior of such elements is demonstrated for two examples.

The first thin film element has a circular shape and actually consists of many exchange-coupled sublayers which act, however, as a homogeneous, nearly isotropic, soft magnetic film. The demagnetized state in such circles can consist of a simple concentric pattern (Fig. 5a), but also of much more complex states depending on the history of the applied field. Figure 5b–f demonstrates how the simple pattern in (a) is converted into a concentric two-domain pattern (f) via a sequence of applied fields which lead to the formation of a domain wall (b) and the interaction of this wall with the sample edge (c–d). More details on these samples can be found in Hubert and Rührig [13].

In the second example the magnetization process of an elongate rectangular Permalloy ($Fe_{81}Ni_{19}$) element is studied. Such elements display a near-saturation high-remanence state if their aspect ratio is larger than about 6:1 [14]. This does not mean, however, that they are completely saturated. Both ends always carry a kind of closure pattern which avoids strong magnetic charges and replaces them by a more distributed charge pattern. A quantitative evaluation of such a closure pattern is shown in Fig. 6.

On applying an external field opposite to the remanent magnetization, the closure patterns expand from both ends until they meet in the middle. If the two closure configurations happen to be oppositely magnetized in their transverse components,

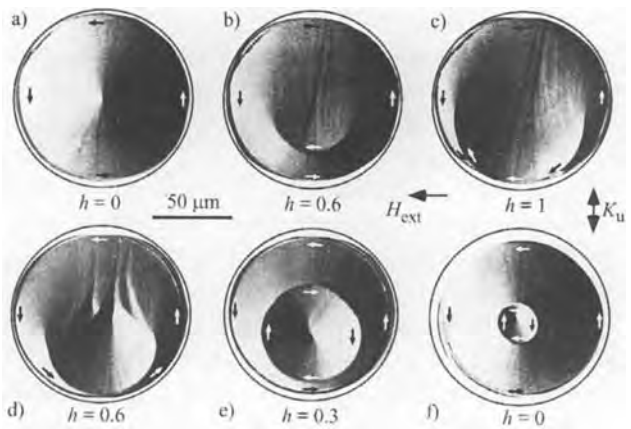

Figure 5. Magnetization process in a soft, magnetic, circular disk. (a) The simple concentric state spontaneously forms (b) a domain wall in an applied field, which, when touching the sample edge (c), leads to (d, e) an irreversible domain rearrangement ending in (f) a metastable concentric two-domain state. The external field is given by h, the reduced field relative to the theoretically derived saturation field for the inner part of the disk.

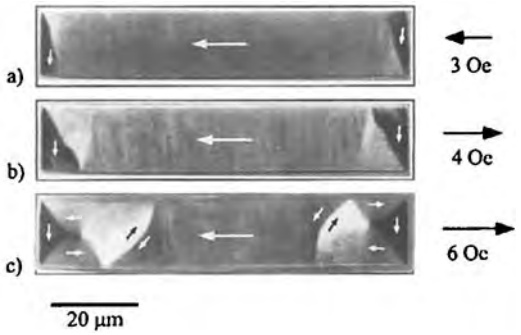

Figure 6. Closure patterns in a rectangular element in a high-remanence state. The sample consists of a single layer of Permalloy of 17-nm thickness. Depending on the strength and sign of the longitudinal field, the domains at the sample ends shrink and expand, while the central part of the element stays saturated. (1 Oe $\approx$ 80 A m^{-1}.)

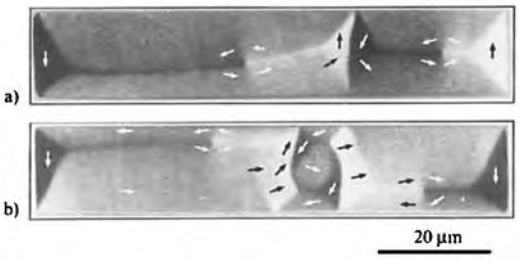

Figure 7. Zero-field result of a collision of expanded closure patterns: two cases. The variant (a) develops when the edge closure domains are magnetized in opposite directions. The complex pattern (b) is only found as a metastable structure when the two end domains are oriented along the same direction. A quantitative analysis leads to the inserted magnetization direction arrows. Sample as in Fig. 6.

they can form a domain pattern after their collision which is related to the well-known cross tie pattern and which is shown in Fig. 7a. Alternatively (Fig. 7b), an awkward metastable residual pattern is formed in the middle [15] which can barely be understood other than by quantitative experimental evaluation.

In a field parallel to the remanent magnetization in the center part, the closure pattern shrinks, but it remains stable up to remarkably high field values, as shown in Fig. 8. The complete disappearance of the closure pattern cannot be directly observed with optical means. It can be derived from experiments, however. If a high field does not destroy the pattern completely, the residual domains act as

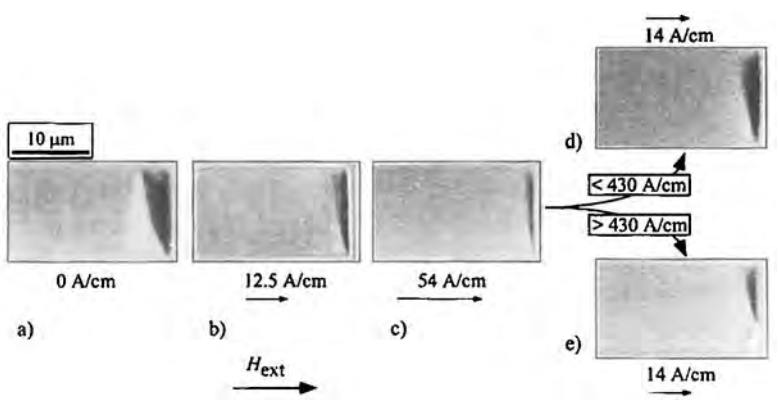

Figure 8. High field behavior of closure patterns in rectangular elements. The last residual domains in higher fields than in (c) cannot be seen with optical means. Their presence can only be inferred from the behavior of the domains when the field is reduced again. Up to a field of 430 A cm^{-1} a pattern as in (d) is observed which corresponds to (b). Beyond this threshold a new symmetric pattern as in (e) is formed, which is only converted back into the lower energy asymmetric configuration at negative fields. Sample as in Fig. 6.

nuclei, and closure patterns of the same type will reappear after reducing the field. If, on the other hand, the field was high enough to annihilate the closure structure, a newly formed, almost symmetrical closure pattern forms. Experiments based on this criterion revealed that residual domains persist in fields that are several times as large as needed to make the domains invisible. This behavior of residual domains is quite typical in ferromagnets and leads to important consequences in hard magnetic materials. To achieve the highest coercivity, many such materials have to be magnetized first in very high pulse fields of many thousand kiloamps per meter.

15.2.3 Domains and Magnetization Processes in Bulk Crystals

Oxidic magnetic materials such as ferrites or garnets are transparent to visible light or at least to infrared radiation. In these materials the internal magnetic structure can in principle be investigated. A good example is given in Fig. 9 [16]. Here the highly complex surface structure made visible by the Bitter pattern technique is shown to be formed on top of a smooth internal structure which becomes visible by infrared transmission microscopy. This mechanism is called domain *branching*; it occurs if the easy direction in the bulk of a sample is incompatible with the surface orientation and tries to reconcile a low energy, simple domain pattern in the volume with a finely divided surface pattern [17].

An interesting feature of these branched domain patterns in uniaxial crystals led to a widely accepted application. On increasing the thickness of such a crystal, the internal complexity increases continuously, leading to wider and wider internal domains. The surface domain width, however, stays constant [18], independent of the crystal thickness. This is determined by an equilibrium between the wall energy and the demagnetizing energy. From its measurement the wall energy can be conveniently determined [19].

Metallic materials do not offer the opportunity to look inside or through bulk crystals (except with expensive and at the same time quite limited techniques

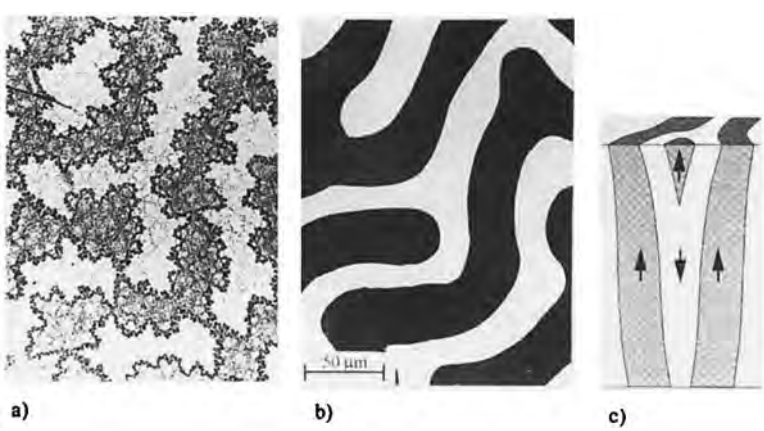

Figure 9. Domains of a hexaferrite crystal plate (a) on the surface and (b) in infrared transmission. The qualitative interpretation (c) indicates how wide internal domains can coexist with fine surface domains. (Courtesy of R. Szymczak, Warsaw.)

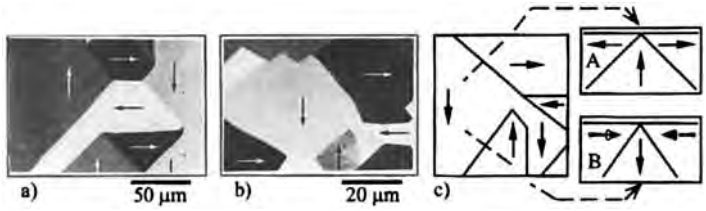

Figure 10. Domains on a (100)-oriented silicon iron crystal. The simple domains in (a) are found on stress-free crystals. Slight mechanical stresses may favor the perpendicular easy direction and lead to the appearance of V-lines as in (b). Their internal structure is indicated in (c) by a schematic top view and two cross sections.

such as X-ray topography [20, 21] and neutron topography [22, 23]). Some theoretical 'insight' is necessary to understand what is going on under the easily observable surface. Examples of observations and interpretations are shown in Fig. 10.

The possible domain directions in such crystals are determined by the preferred crystal directions which are the ⟨100⟩ directions in iron. Most of the observed domain walls offer a natural interpretation of two such domains separated in a stray-field-free manner. Such walls can immediately be recognized by their well-defined and straight orientation (Fig. 10a). Different-looking domain walls appear if, induced for example by mechanical stress, the additional easy directions perpendicular to the surface are favored. The 'domain walls' visible under such conditions are actually intersection lines of two internal domain walls which meet at the surface. These lines are called V-lines. They are explained in the cross sections of Fig. 10c.

External fields can also lead to the formation of internal domains and to a complete rearrangement of the domain structure if the field is applied along a hard direction. This is illustrated in Fig. 11 for a transformer steel material, i.e., a (110)-oriented silicon iron crystal. A field is applied parallel to the [111] direction rather than along the easy [001] axis. The complex domain patterns formed in this magnetization process demonstrate the extra magnetization losses that occur if a transformer material is activated along a disfavored axis. In the highest fields,

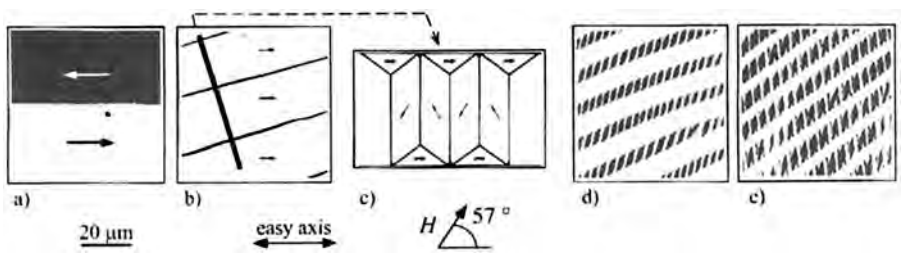

Figure 11. Domain rearrangement processes on a (110)-oriented SiFe transformer steel crystal in increasing applied fields along the hard direction [111]. The simple, field-free state (a) is only shown for reference. The model in (c) shows a cross section through the first field-induced pattern (b) which occurs at about two thirds of saturation. The internal structures of the later, heavily branched structures (d, e) have never been explored in detail.

complex surface patterns are formed which are related to the branched patterns of uniaxial crystals (see Fig. 9).

15.3 Micromagnetics and High Resolution Electron Methods

15.3.1 Optical Investigation of Micromagnetic Details

Exploring the details of domain walls and their substructures contributes to the fundamental understanding of magnetic materials. Important technical properties are directly linked to domain wall processes. The high permeability of soft magnetic materials, which can easily exceed 10^5 times the permeability of air, is a consequence of the ease of displacing domain walls in undisturbed crystal lattices. On the other hand, modern hard magnetic materials rely on the high energy and narrow width of their domain walls. (A high wall energy makes nucleation of new domains difficult, a narrow wall width favors an effective pinning of walls by lattice defects.)

The fastest and most economical access to magnetic microstructures is always optical microscopy, if it is applicable. The introduction of digital image processing opened this field to optical methods which had been unsuitable except for transparent oxide crystals. Figure 12 shows the beautiful substructures of domain walls visible without any special techniques in garnet crystals. No resolution problem appears to exist in the case of these very wide walls. The characteristics of the various wall types agree with theoretical predictions based on the anisotropy and magnetostriction material data.

Substructures of opposite wall chirality, as visible in Fig. 12, can only be indirectly inferred in metallic samples. However, a special asymmetric surface structure of domain walls becomes visible in soft magnetic materials. The polar magnetization direction in the interior gives way to a surface vortex which closes most of the magnetic flux. Observations and their interpretation are shown in Fig. 13. The slight tilting of some wall segments is a

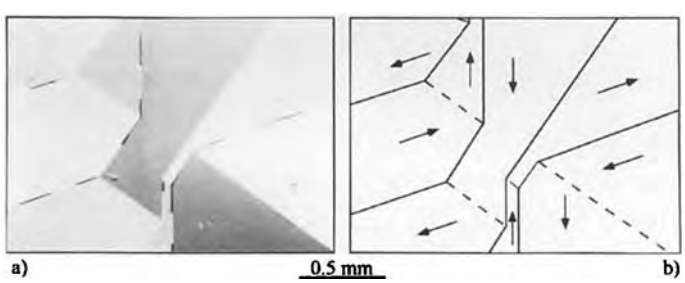

Figure 12. Domains and walls on a (110)-oriented garnet crystal observed by the Faraday effect. Mostly the domain walls contribute to the contrast. Note that both 180° walls and 109° walls are widened and often subdivided into segments of opposite polarity, while 71° walls [dashed in (b)] appear narrow, uniform, and somewhat diffuse. The domains are also visible due to a slightly nonperpendicular illumination. The domains structure is explained in (b), based on the ⟨111⟩ easy directions of the magnetic garnet.

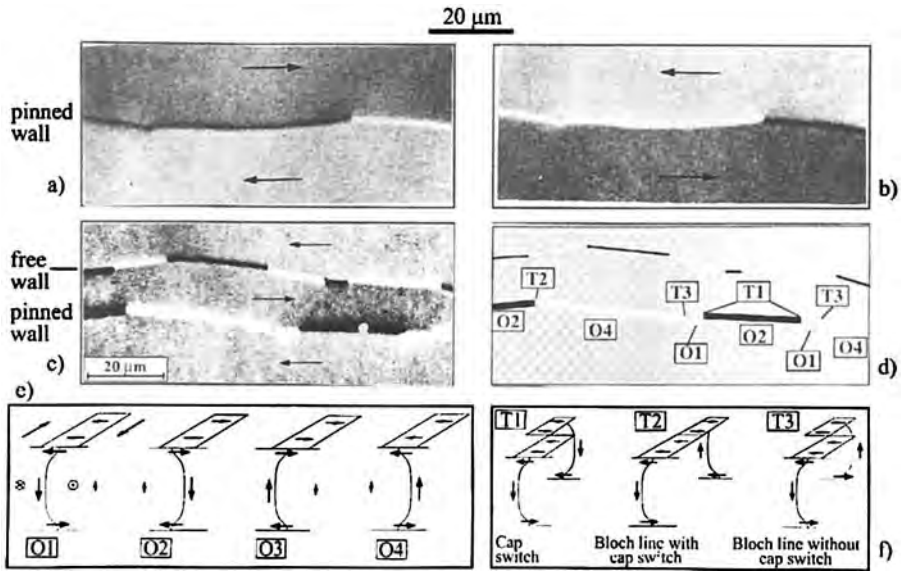

Figure 13. Different wall states compatible with a baked-in wall pattern in a nearly magnetostriction-free metallic glass of 30-µm thickness. Variants of the pinned wall, which are both compatible with the baked-in anisotropy pattern, are shown in (a, b). An additional 'free wall' with an arbitrary internal structure appears in (c). The internal structure of the pinned wall in (c) is indicated in (d–f), listing all possible wall orientations and wall transitions.

consequence of the vertical flux, indicating domain walls of opposite chirality. Some of the transitions are not connected with a kink. They represent mere 'cap switches', a change in the orientation of the surface vortex without a change in the basic wall chirality.

The observations in Fig. 13 were carried out on a metallic glass which had been annealed in the presence of a domain wall. Along the line at which the wall has been 'baked in', a special induced anisotropy pattern is left. A 'pinned' wall that occupies this position is particularly wide. The interaction of this pinned wall with 'free' walls leads to particular magnetization loops which can be used in special sensor applications [24].

The peculiar surface structure of domain walls in soft magnetic materials was first predicted by theory [25]. The first experimental confirmation was achieved by a magnetooptical scanning technique [26]. Optical microscopy was tried for a long time without success (partly also because researchers looked for the absent polar component at the surface), until the digital difference image technique offered an easy access to this world [7]. Optical microscopy can even see domain walls that are narrower than the resolution limit, although the image of these narrow objects is, of course, widened. Integrating over the image gives access to the true domain wall width. This is a consequence of the linear relation [Eq. (4)] between image and source in magnetooptical imaging, and was demonstrated, for example, by Schäfer et al. [27]. Nevertheless, there is no way of measuring the detailed profiles of

domain walls with optical methods, let alone the structure of their subunits such as the so-called Bloch lines, i.e., the transition between wall segments. Higher resolution methods are available in electron microscopy, as will be discussed in the following sections.

15.3.2 Electron Polarization Techniques in Scanning Electron Microscopy

Secondary electrons emitted from a clean-surface ferromagnet are spin-polarized [28], the sign of the polarization being opposite to the magnetization vector in the surface of the material. Scanning a sample with electrons and analyzing the secondary electrons offers a direct, high resolution, and quantitative image of the surface magnetization of the sample. This idea was first demonstrated by Koike and Hayakawa [29] and soon after by other groups [30–32]. The acronym SEMPA (secondary electron microscopy and polarization analysis), introduced by Unguris et al. [30], has been widely adopted for this technique. Figure 14 shows an example of a quantitative, high resolution image obtained in this way [33]. While Kerr microscopy is limited to about 200 nm, a resolution of better than 20 nm was demonstrated for the electron polarization technique [34]. Every electron polarization picture displays one component of the magnetization vector. Two components can be recorded simultaneously with two sets of detectors. The third component is accessible after an adequate spin-rotation operation.

Scanning the recorded images immediately gives the profiles of the chosen magnetization component through the walls for the top one or two atomic layers of the sample. In Scheinfein et al. [35] a convincing agreement between numerical micromagnetic calculations and measured surface profiles was demonstrated for an iron crystal. Polarized electron techniques are also particularly valuable for the investigation of ultrathin films, as demonstrated in Fig. 14 [36].

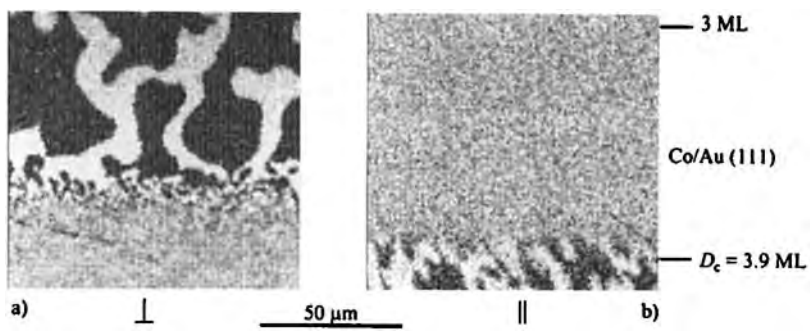

Figure 14. High resolution image of a magnetic microstructure in an ultrathin, 'wedge-shaped' cobalt film, the thickness of which increases from top to bottom. The observed pattern indicates a transition from a preference to the vertical direction for films that are thinner than about 0.6 nm (top) to a planar structure for thicker films (bottom). The two different magnetization components [(a) vertical and (b) parallel to the thickness gradient] are made visible by electron polarization analysis in different detectors. Interesting is the finely divided domain structure in the transition region. (Courtesy of S. Speckmann, H. P. Oepen, Jülich and Halle.)

The limitation of the electron polarization method still lies in its unfavorable imaging statistics. First, the used electrons have about a thousandfold higher energy than the photons used in optical microscopy. For a given sample energy load, the number of quanta per time interval is necessarily much smaller, leading to correspondingly larger exposure times for the same image quality. This applies to most nonoptical microscopical techniques and constitutes a disadvantage of these methods even if the relative strength of the basic physical effects may be larger than in the case of the magnetooptical effects.

In the case of electron polarization analysis, the problem is aggravated by the low efficiency of available polarization analyzers. While optical analyzers lose none (for crystal analyzers) or at most one half (for sheet analyzers) of the favorably polarized photons, electron analyzers have an efficiency of the order of 10^{-4}. Much effort has been spent in order to push this value into more favorable ranges. Until this goal has been achieved, electron polarization microscopy will have its place among specialized investigations of details in the surface magnetization of bulk materials which cannot be performed by other methods.

15.3.3 Quantitative Transmission Electron Microscopy Techniques

Transmission electron microscopy of magnetic materials is based on the Lorentz deflection of the electrons and is therefore independent of electron polarization. The optical analogue of a magnetic specimen consisting of several domains is a set of flat prisms, as shown in Fig. 15. The prism analogy also demonstrates that magnetic contrast is a kind of phase contrast: The different thicknesses of the glass generate corresponding phase differences of the light waves. Any of the different options of phase microscopy can be applied in electron microscopy in order to make magnetic information visible. An excellent introduction to these techniques entitled 'Lorentz Microscopy' can be found in Chap. 4.1.7 of Vol. I of this Handbook.

Defocusing is the oldest such technique [37], also called the Fresnel method from the Fresnel interference experiment. It is

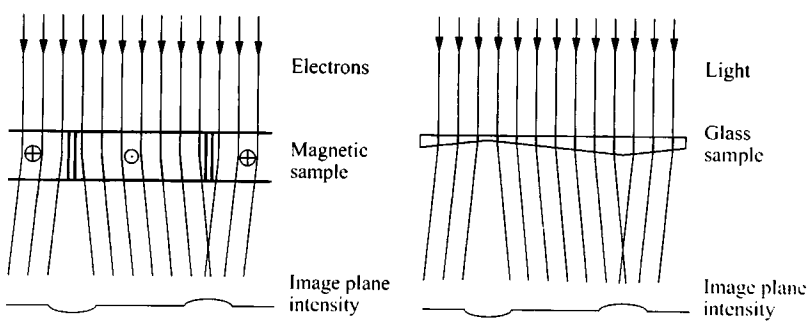

Figure 15. The analogy between magnetic electron deflection and optical deflection by prisms, at the same time illustrating image formation in the defocused mode.

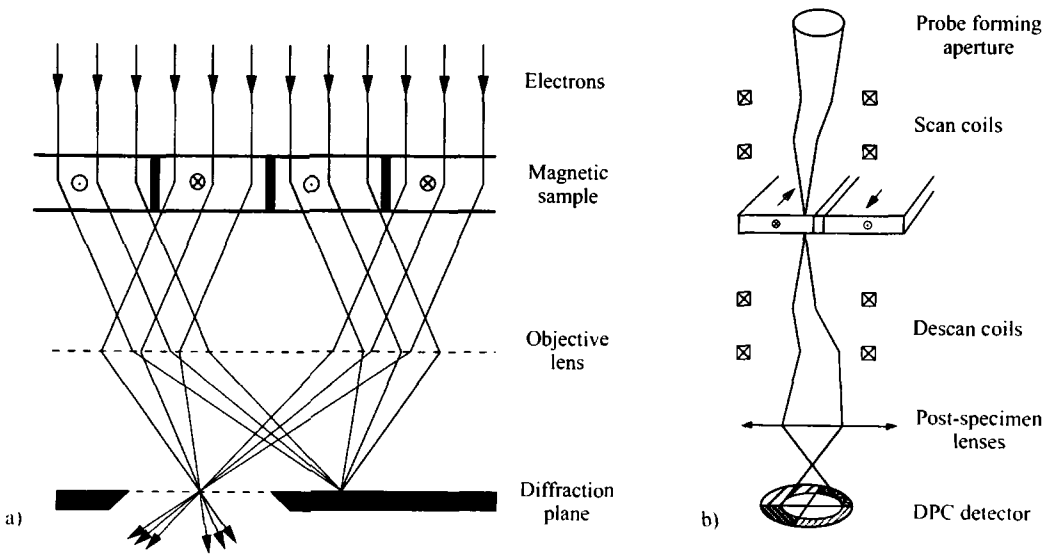

Figure 16. (a) The principles of the Foucault or schlieren method of transmission electron microscopy and (b) differential scanning electron microscopy. In (b) a split detector is employed. The difference signal proves to be a linear function of the magnetic deflection.

still used for detailed investigations of domain walls and inhomogeneities in the domain magnetization. Unfortunately, it is not a high resolution technique and the connection between the obtained images and the magnetic structure is indirect. The same is true for the shadow or schlieren method [38], also known as the Foucault technique. Here, the part of the imaging bundle coming from one class of domains is obstructed in the aperture plane of the microscope, so that mainly electrons from domains of opposite magnetization contribute to the image (Fig. 16a). The result resembles pictures taken with the magnetooptical Kerr effect. A disadvantage of this method is that details of the diaphragm edge determine the imaging of the details of the transition between domains. Advances in microfabrication techniques have led to a revival of this in-focus technique [39]. Particularly attractive is a variant which makes use of modern, highly coherent electron sources. Images taken with this so-called coherent Foucault technique [40, 39] closely resemble images taken with electron holography [41, 42], another technique which combines very clear pictures with high demands on the equipment and on the suitability of the samples.

A truly quantitative and high resolution technique was developed based on the scanning transmission electron microscope [43, 44]. The directional selectivity needed in magnetic microscopy is achieved by a differential detector, as shown in Fig. 16b. The method was called DPC (differential phase contrast) by its inventors based on the mentioned correspondence between electron deflection and phase effects. A field emission electron gun is recommended to achieve the necessary beam quality. It is also useful to discard the central part of the electron bundle and to use annular detectors [45].

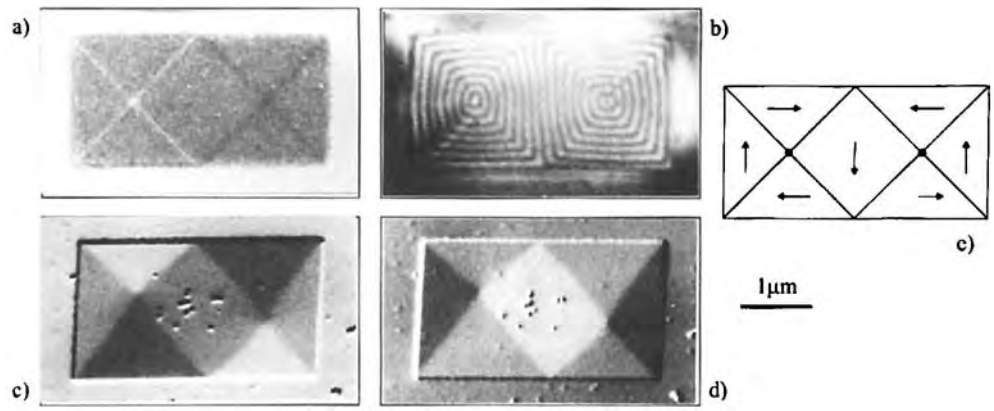

Figure 17. The same type of domain pattern in a thin film element made visible with various techniques: (a) the Fresnel or defocusing technique, (b) the coherent Foucault technique or in-line holography, indicating lines of elementary flux, (c, d) the differential scanning or differential phase contrast method displaying two orthogonal magnetization components of the same pattern and (e) schematic diagram. (Courtesy of S. McVitie, J. Chapman, Glasgow.)

Excellent results can be obtained with this method. The image contrast is linear in the magnetic flux components and quantitative down to at least 100-nm resolution. Its problem is expensive equipment and long image collection times. Usually an overview of a situation is obtained, for example, with the Foucault or Fresnel method, followed by a detailed analysis with the DPC method. Figure 17 shows a comparison of various methods [46].

An interesting variant which promises to offer the advantages of the DPC method without its drawbacks was proposed by Daykin and Petford-Long [47]. It is based on the reciprocity principle between scanning and conventional microscopy, using a series of Foucault images which are digitally combined to become (as claimed) equivalent to the differential phase contrast method. Generally, digital image processing is playing an increasing role in electron microscopy, thus following the example of magnetooptical microscopy.

15.4 Information Storage Media and Mechanical Scanning Methods

15.4.1 Optical Investigation of Magnetic Storage Media

The classical carriers of magnetic recording are particulate media, consisting of small single domain particles embedded in an organic binder. No characteristic magnetic domains can be observed in such materials, and magnetic microscopy can contribute little to their analysis. Things differ with the modern thin film recording media that are always used in magnetooptic recording, which are studied for future vertical recording schemes, and which are increasingly used in conventional longitudinal recording. Anyway, micromagnetic studies on recording media are difficult because magnetic recording relies on nonequilibrium patterns which must be stabilized

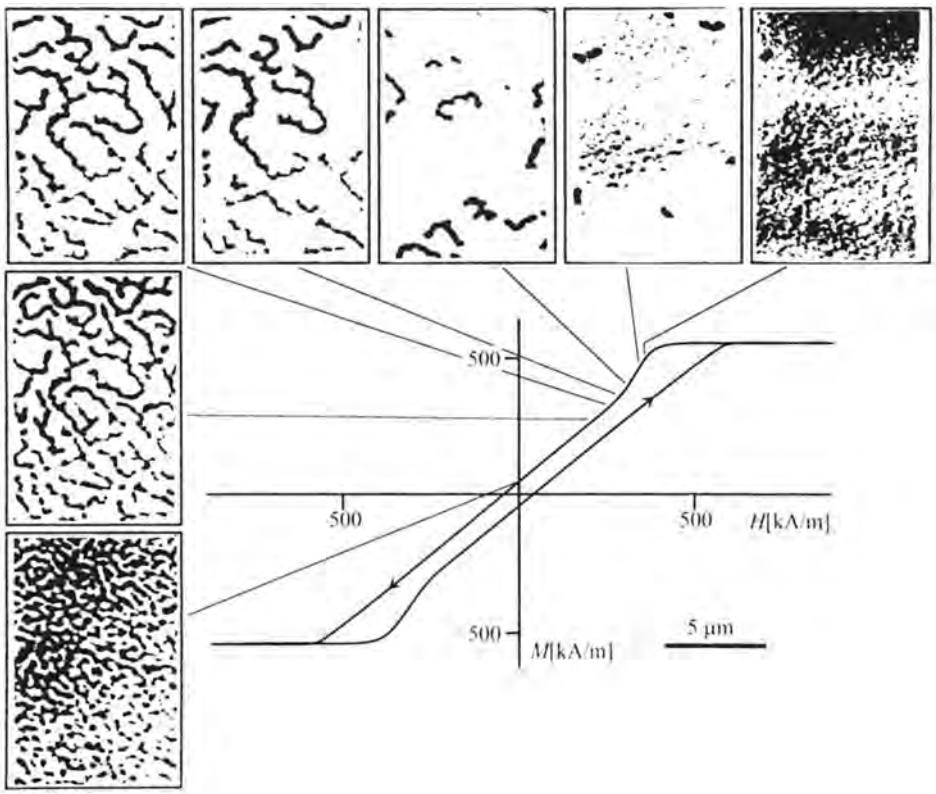

Figure 18. Magnetooptical observation of the magnetization process in a CoCr (17 at. %) perpendicular recording medium (thickness 530 nm). Starting from saturation, opposite domains are first nucleated, then strip-out until they fill the whole sample close to the demagnetized state.

by corresponding media inhomogeneities. Optical observation methods can offer only limited results; other methods are often better suited and tend to largely replace magnetooptics in this area. Some examples of optical observations on recording media may, however, still be reported.

The first observation of magnetic domains in CoCr perpendicular media was achieved by the magnetooptical digital difference technique [48]. The observed patterns approached the limit of optical resolution, but a number of important features could be seen, in particular because the method can be applied at arbitrarily high magnetic fields (Fig. 18). Better resolution could later be achieved by the classical Bitter colloid technique when combined with scanning electron microscopic evaluation [49, 50].

Magnetooptical recording media seem to be natural candidates for optical investigation. This is true to a limited extent. In recording, the numerical aperture of the writing and reading optics is limited to about half the value available in microscopy. More details can therefore be seen in the latter, as demonstrated for example in Weller et al. [51]. In particular, the thermally activated magnetization processes observed under high applied fields in these media can be well studied

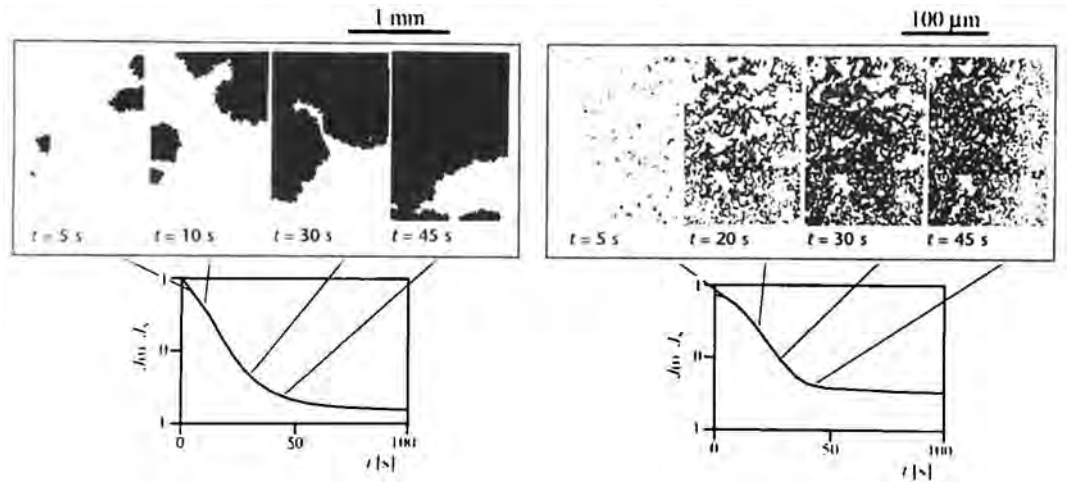

Figure 19. Domain creeping processes in optical recording media consisting of amorphous thin films with perpendicular easy axis. The vertical magnetization component is recorded and displayed by the polar magnetooptical Kerr effect. The character of the reverse domain formation depends on material parameters such as the saturation magnetization, the film thickness, and the coercivity. (a) $Tb_{20.7}Fe_{67.4}Co_{11.9}$, an example of a material with few domain nuclei and a predominance of domain growth processes. (b) $Tb_{26.8}Fe_{56}Co_{17.2}$, a material with many nuclei and dendritic domain growth.

using optical methods, as shown in Fig. 19 [52]. Such studies contribute to a deeper understanding of the material.

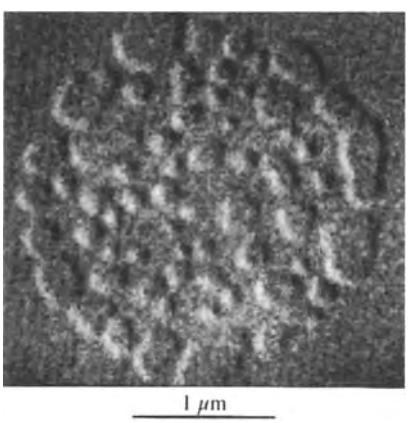

Figure 20. Written spot in a TbFe magnetooptical recording medium, made visible by Fresnel mode transmission electron microscopy. The mark was written in an insufficient magnetic field of only $80\,A\,cm^{-1}$, resulting in an assembly of tiny subdomains instead of the one compact domain needed in recording applications. (Courtesy of C.-J. F. Lin, IBM Research, Almaden, CA.)

In actual recording patterns, details are often hidden below the optical resolution limit, and these details, which contribute to the noise, can only be explored by high resolution methods such as electron microscopy or magnetic force microscopy [53–55]. An example of such observations on written tracks is shown in Fig. 20 [56]. Depending on the writing power, the spots contain an internal substructure which is invisible in optical microscopy.

15.4.2 The Potential of Magnetic Force Microscopy

Impressive high resolution pictures have been produced by the magnetic force microscopy (MFM) of written recording tracks. As this technique is discussed in a separate chapter of this Handbook, we will restrict ourselves here to an evaluation of

the method in comparison with competing techniques.

MFM is sensitive to the magnetic stray field above a sample. In most applications this is a drawback, but not for recording media that in most cases rely on the stray field for readout.

The exact contrast mechanism is disputed; it depends on the details of the probe and of the operation mode. The most confusing aspect of MFM is the interaction of the magnetic probe with the sample. In soft magnetic materials this leads to hard-to-analyze phenomena which are still under active study [57]. This danger is very small for recording materials owing to the intrinsically hard nature of these materials.

Mechanical scanning techniques cannot compete with optical or electron direct imaging techniques with respect to speed. This is not a disadvantage in the investigation of written information so long as the recording pattern and not the recording process is of interest.

The technique can work even through coating layers and on arbitrary substrates. Its resolution is much better than optical resolution, and is comparable with electron optical techniques which need expensive preparations to make them applicable.

Altogether, magnetic force microscopy is developing into the method of choice for the analysis of magnetically recorded information. Figure 21 shows an example of written tracks observed with this technique.

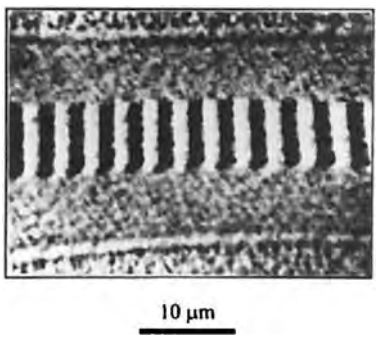

Figure 21. Written track pattern observed in a magnetic force microscope. The periodic pattern is flanked on both sides by a zone in which the previous pattern has been erased prior to writing. (Courtesy of D. Rugar, IBM Research, Almaden, CA.)

15.5 Further Problems and Methods

In the following sections a number of special problems and available methods not covered by the three main fields are reviewed. The selected references should give access to the respective fields rather than being exhaustive.

15.5.1 Domains Under Nontransparent Functional Coatings

In some particularly technical applications, magnetic materials are coated with opaque layers for functional reasons. Electrical steel sheets, for example, must be electrically isolated from each other. In grain-oriented transformer steel, the coating is often used to transmit mechanical stresses. Mineral coatings of a few micrometers thickness are used for this purpose. These coatings preclude the application of the conventional methods of domain observation discussed above. A strong need to get an idea of the micromagnetic processes, nevertheless, led to the development of special techniques.

Most important among these is a special variant of the scanning electron microscope. It relies on the backscattered electrons, and on an oblique incidence of the electrons. Sufficiently high energy electrons penetrate the coating layer and 'see' the magnetic microstructure with reasonable resolution. An introduction to the technique and its applications can be found in the literature [58–61].

As the experimental cost for high-energy scanning electron microscopy is not negligible, many simpler methods have been proposed and applied over the years. Worth mentioning are field scanning methods [62–64] and modified methods based on magnetic particles [65, 66] or even on magnetic bacteria [67, 68].

15.5.2 Magnetic Surfaces and Interfaces

The study of magnetic surfaces and interfaces has attracted increasing interest in recent years. While magnetooptical methods render information from a depth corresponding to the (amplitude) penetration depth of the light (typically 20 nm for metals), there are other methods that are able to probe the very surface on an atomic scale. The already mentioned polarized electron scanning method (Sec. 15.3.2) belong to this category, but there are also other, less developed methods with a strong potential. One is an electron microscope based on spin-polarized low-energy electron diffraction (SPLEEM) [69–71], which is a quite demanding technique but promises much higher image acquisition speeds compared to scanning methods. Another interesting new development is based on nonlinear optics. High intensity laser beams generate second harmonics depending on the symmetry of the scattering medium. The surface or interfaces in layered media are particularly effective in second harmonics, and if the scattered light is analyzed in a similar way as in conventional magnetooptics, magnetic surface and interface structures can be detected [72, 73].

15.5.3 Element-Specific Microscopy

In complex magnetic multilayers it would be interesting to be able to observe magnetic structures in any of the elementary layers. This becomes possible with element-specific X-ray scattering effects. Phenomena analogous to the conventional magnetooptic effects, which are based on the valence electrons, are also present for core electron states and can be detected by X-ray spectroscopy. The effects are associated in this case with narrow core levels which are element specific [74–76].

15.5.4 Methods for Domain Investigation in the Bulk

How to explore the magnetic microstructure in the interior of bulk magnetic materials is a largely unsolved problem. Some quite limited techniques are available, but in most cases the observation of magnetic domains on the surface combined with theoretical arguments for their

continuation into the interior remains the preferred approach.

There are a few direct methods for domain observation in the bulk. X-ray diffraction topography, particularly if based on synchrotron radiation sources, can image the domains due to the slight magnetostrictive lattice distortions usually connected with the magnetic microstructure. Most applications are focused on transformer steel materials, undeformed single crystal sheets of about a tenth of a millimeter in thickness [77–80]. The high cost of this technique together with its limited applicability has not favored its widespread use.

Neutron topography is based on similar principles and is able to penetrate even thicker material. The method has been demonstrated for various ferromagnetic and antiferromagnetic samples [81–84], but the relatively poor resolution and high picture acquisition times cast doubts about its usefulness for ferromagnetic materials (as opposed to antiferromagnets, where it is very valuable due to the lack of other methods).

A unique technique was demonstrated by Libovický [85]. In high-silicon iron alloys an annealing treatment leads to the precipitation of certain oriented particles which are aligned along the local magnetization direction. This structure can later be studied in detail metallographically by dissecting and etching the sample.

Another possible approach is based on neutron depolarization [86, 87]. If the prospect could be realized for this technique to be evaluated in a model-independent, computer-tomographic fashion [88], it would offer an interesting new possibility.

15.5.5 Magnetooptical Microfield Detection

Using magnetooptic indicator films in order to detect magnetic fields above materials that do not display magnetooptic effects themselves has a long tradition in the microscopy of magnetic structures of superconductors. The method relies on induced polar magnetooptic effects generated by perpendicular fields emerging from the sample. Such fields are also present in many magnetic applications connected with hard magnetic materials and magnetic recording. Originally, cerium-doted glass indicators were used for low resolution investigations [89]. Much better resolution could be achieved with evaporated paramagnetic europium chalcogenide films [90–93]. Ferrimagnetic garnet films similar to those used for bubble memories but with an in-plane anisotropy have the advantage of high contrast and sensitivity [94, 95]. An overview of these techniques as applied to superconductors is given in Koblischka and Wijngaarden [96].

15.5.6 Observing Magnetic Structures in Superconductors

Superconductors have magnetic microstructures which are in many respects analogous to ferromagnetic domains [18]. They consist of normal and superconducting domains and can be observed, for example, by the techniques mentioned in the last subsection. Of a special nature are magnetic structures in so-called Type II superconductors which consist of elementary flux lines, the dimensions of which are smaller than the optical resolution limit.

As most technically important superconducting materials are such type II materials, the development of techniques for the observation of flux lines has always attracted attention. The first direct observation of the flux line lattice was achieved by a modified powder technique in which ferromagnetic material is evaporated in a moderate helium vacuum forming a metal particle smoke which decorates the emerging flux lines [97–99].

The renewed interest in superconducting materials stimulated by the discovery of high temperature superconductivity also stimulated the development of new methods which go beyond simply decorating the flux lines. The most direct new method is based on scanning tunneling microscopy. It maps the superconducting electron energy gap and is able to image both flux line lattices and the fine structure of flux lines [100–104]. Another new approach is based on transmission electron microscopy and in particular on electron holography [42, 105–106]. With this method the magnetic flux emerging from flux lines or flux tubes can be displayed directly and very sensitively, and even the dynamics of such magnetic structures can be followed by employing computer-aided image processing.

1 Small Particles

1.1 Introduction

Small particles play a crucial role in many fields such as catalysis [1], nanophase or nanocrystalline materials [2], clusters [3], and magnetic recording materials [4]. They are applied or occur everywhere in our environment, for example smoke, aerosols, colloidal suspensions, geological erosion, paints, coatings, and materials for grinding and cleaning. Each material and each field of application requires its own type of investigation, which can vary so much that it will be impossible to discuss these within the scope of this contribution, even more so because many different characterization techniques can be applied. Therefore, the emphasis in this contribution is on the specific features and difficulties in the characterization by microscopy techniques and in particular by high-resolution electron microscopy (HREM). Most examples and information given are part of the characterization of catalysts because we are most experienced in this field. The examples are, however, good illustrations for the problems of specimen preparation and image interpretation encountered in the characterization of other small particles. The electron microscope images presented in this contribution were taken with a Philips CM30ST-FEG, except for Figs 11 and 14, which were taken with a JEOL 200CX.

Table 1 lists the type of information needed for a limited number of groups of small-particle materials. A number of examples are given to provide an impression of the relation between the properties, applications, and the characterization methods required. In Section 1.2, relevant characterization methods are briefly given. Section 1.3 give some information on a number of small particle materials. The required information is outlined in Section 1.4. Sections 1.5–1.8 deal with aspects of imaging in transmission electron microscopy (TEM), specimen preparation and specimen handling which are related to small-particle characterization.

1.2 Characterization Methods

1.2.1 Use of Scanning Electron Microscopy, Transmission Electron Microscopy and Scanning Probe Microscopy

The characterization of small particles requires techniques with a high spatial resolution. This requirement implies that

Table 1. Schematic classification of small-particle materials, with wom examples and the most common characterization methods used.

	Catalysts	Dense nanophase materials	Open nanophase materials	Precipitates	Isolated particles	Magnetic materials	Section in which discussed
Examples	$Ni-MoS_2$ (hydrotreating) [5] Pt–Rh (exhaust gas) [11]	Cu (larger hardness) [6] TiO_2 (less brittle) [12]	Ni–Al oxide (catalysis) [7] Al_2O_3 (membranes) [13]	Mg–Si in Al (strength) [8] Y_2O_3 in $YBa_2Cu_3O_7$ (flux pinning) [14]	Er in Al_2O_3 (luminescence) [9] H bubbles in Si (solar cells) [15]	Fe–Cr thin films (recording) [10] Co–Cr particles (recording) [16]

++, very important; +, important; 0, less important; –, not important.

[a] The activity and the selectivity of many catalytic reactions [17] are very sensitive to the size of the particles [18].

[b] Small semiconductor particles, for instance in SiO_2 show photoluminescence with a high efficiency. The luminescence is caused by recombination of exitons confined in the nanocrystals, in which the exitons act as quantum dots, which show a size dependence. For instance, cadmium phosphide, which is black in the bulk material, can be made in all colors of the visible spectrum by varying the particle size between 2 and 10 nm [19].

[c] The effectiveness of the precipitates in the improvement of the properties (e.g., thermal expansion, wear resistance, high elastic modulus and high strength) depend on their structure, their orientation in the matrix and their shape and size.

[d] For instance, the giant magnetoresistance of Fe–Cr depends strongly on the thicknesses of the magnetic and nonmagnetic layers [20].

[e] The structure of small catalytic particles is very important. The catalysis requires an adsorption on the surface, the rate of which depends strongly on the presence of surface steps and surface facets.

[f] Promoters are elements added to a catalytic system but which are not catalytically active themselves [21]. They are added to improve the activity, selectivity and/or stability. For instance, the addition of vanadium to $Rh-SiO_2$ results in an increase of the rate of methane formation from CO and H_2O [22]. To understand the promoter effect the location of the promoter atoms on the surface must be known.

[g] The activity and selectivity of catalysts consisting of metal particles on supports which are relatively easy to reduce (e.g., the selectivity of rhodium or platinum on TiO_2 [23]) can change strongly upon reduction at temperatures in the range of 200–500°C. This phenomenon, called strong metal–support interaction (SMSI), is due to a very thin layer (0.2–0.6 nm) of partly reduced substrate (e.g., TiO_{2-x}) covering the metal particles.

[h] In the case of Raney nickel catalysts [24], which are composed of nickel, aluminum and oxygen, the addition of a small amount of, for instance, chromium or iron does result in improved performance for some reactions [25]. These added metals could be dispersed on or close to the surface, thus resulting in a significant change in activity or selectivity.

[i] The hardness of copper consisting of 10 nm particles is five times greater than that of copper consisting of 100 mm grains [26]. This increase in hardness is related to the atomic structure at the grain boundaries, which are abundantly present in the material with 10 nm particles.

[j] Ceramic membranes are used for various applications depending on the pore sizes [27]. Membranes with pores in the size range 1–2 nm are used for instance for gas purification. One of the earliest uses of such membranes was the enrichment of ^{235}U [28]. A major requirement of these membranes is a high thermal stability, which is for a major part determined by the grain boundaries.

[k] Precipitates are often introduced into steels and intermetallic alloys [29] by choosing proper compositions and annealing conditions to improve mechanical properties such as creep resistance and flow strength at high temperatures. The improvement of mechanical properties is due to the pinning of dislocations at precipitates, for instance metal carbides in steel [30], or ordered Ni_3Al in nickel–base alloys [31]. In the latter case, the movement of dislocations in the disordered g phase (f.c.c.) is impeded by the precipitates, since these dislocations are not perfect in the ordered phase, that is, are bounded by high-energy antiphase boundaries or superlattice intrinsic stacking faults. However, if too many dislocations are piled up at the precipitate dislocation, slip can occur, resulting in a poorer performance.

[l] Nanocrystalline alloys consist of a uniform mixture of crystallites with different chemical compositions. However, at the grain boundaries a mixing of the two chemical compositions occurs, resulting in new properties.

[m] Ageing in automobile exhaust catalysts (existing of Pt/Rh with CeO_2 as the promoter and Al_2O_3 as the support) occurs, because of sintering of the metal particles or the CeO_2. In an ageing study, one follows the deactivation of the catalyst in relation to microstructural and chemical changes.

[n] Hydrogen is added to amorphous silicon in photocells to passify defects. At present, up to 10 at.% of hydrogen is incorporated. Most of the hydrogen is dissolved in the amorphous silicon, but hydrogen bubbles can be formed, in particular during extensive testing.

electron microscopy and scanning probe microscopy (SPM) are invaluable tools in the research of small particles. Still other characterization techniques are equally important because they allow bulk characterizations yielding information which should be in agreement with the microscopic information. The techniques most often used for information averaged over the surface are X-ray photoemission spectroscopy (XPS), electron energy loss spectroscopy (EELS), and secondary ion mass spectroscopy (SIMS), whereas bulk information is obtained by Mössbauer spectroscopy, infrared spectroscopy, extended X-ray absorption fine structure (EXAFS), and low-angle X-ray diffraction. These techniques can provide information (e.g., surface composition, relaxation at grain boundaries, and electronic states) which is essential for the understanding of the performance of a given material, and which is difficult or impossible to obtain by the microscopy techniques given above. Thus, microscopy techniques are almost always used in combination with a number of other techniques.

Since the limitations of scanning electron microscopy (SEM) and TEM on one side (a good vacuum is required, allowing no real atmosphere conditions) and STM on the other side (a rather flat specimen is required, making the study of real catalytic materials impossible) are complementary, a combination of both methods can be very fruitful.

1.2.1.1 Scanning Electron Microscopy

SEM is mainly used for (i) the identification and distribution of phases and (ii) size and morphology determination. The applicability of SEM for these determinations is strongly related to the ratio of the particle size to the resolution of the electron microscope. Hirsch et al. [32] report that one can optimize the visibility of particles of a certain size by tuning the acceleration voltage. In particular, for the determination of orientation relations of neighboring grains in dense nanocrystalline materials the use of scanning electron microscope diffraction [33] can be very useful.

Charging is observed for quite a number of small-particle materials, such as catalyst particles on highly porous ceramics. The conventional method of preventing charging – coverage with a layer of metal (usually palladium or gold applied by sputtering, with a thickness ranging between 3 and 30 nm) or carbon – can only be applied if the details one wants to study are not significantly obscured by the coverage. The most straightforward approach to prevent charging without coverage of the specimen is that of operating the scanning electron microscope at an accelerating voltage at which the secondary electron emission coefficient is unity, thereby preserving charge neutrality in the specimen. Most conventional scanning electron microscopes are capable of operation in this regime (1–2 kV); however, as most instruments are designed for optimum performance at around 30 kV the resolving power at 1 kV is considerably less than what is theoretically attainable. Thus, one does not generally reach a resolution which is of interest for the study of small particles with conventional scanning electron microscopes. A different approach to the specimen charging problem is that of surrounding the specimen with a low-pressure atmosphere, such as water

vapor, that is capable of conducting away the induced charge. A third route entails discharging the specimen surface by tracking the electron beam closely with a carefully controlled beam of positive ions. Such a dual-beam instrument can have several additional features that utilize the focused ion beam such as ion milling, etching and deposition.

An advantage of SEM over TEM is that one can sample the surface by tuning the acceleration voltage. This allows the determination of the fraction of catalytic material on the surface. To show the importance of this, consider the distribution of metal particles in a zeolite crystal. A zeolite is an open-framework structure with pores between 0.4 and 1 nm in diameter. The zeolite framework is used to allow only specific catalytic reactions, which are governed by the size of the channels. This shape-selective catalysis requires that as few catalytic particles as possible are located on the outside of the zeolite crystals, which can be checked better with SEM than with TEM. STM is not possible because of the roughness of the zeolite.

1.2.1.2 Transmission Electron Microscopy

The need for TEM investigations can be divided into six areas: (i) identification of phases, (ii) distribution of a certain phase, (iii) size and shape determination, (iv) determination of the atomic arrangement, (v) determination of the local element composition, and (vi) the determination of the local electronic structure.

Phase Identification

Phase identification can be done based on the unit cell, the atomic structure or the composition, using electron diffraction, HREM and element analysis, respectively.

Phase Distribution

The distribution of a certain phase can best be done by dark field imaging (if the phase is crystalline) or by element mapping. The latter one can be realized in the scanning TEM (STEM) mode or by using energy-filtered imaging.

In dark field imaging, only the information from a selected part of the diffraction pattern is used for imaging. This allows selection of an area in diffraction space which contains only information from the small particles of interest (e.g., niobium carbonitride precipitates in ferrite [34]). Frequently the small particles have a random orientation (e.g., platinum particles on alumina [35]), resulting in rings in the diffraction pattern. By selecting only a segment of such a ring, one images only a small fraction of the particles. This problem can be overcome by using an objective aperture which consist of a thin circular slit at the right Bragg angle [36]. This method is, however, very difficult in practice because only one diffraction angle can be applied with a given aperture. A much easier method is to use a tilted beam which is modified electronically such that it describes a hollow cone [37]. The latter method allows selection of any Bragg angle for imaging, and the width of the Bragg angle can be selected with the size of the objective aperture. One should take into account that the smaller the size of the objective aperture the larger the uncertainty in the determination of the particle sizes will be.

Determination of Size and Shape

The ease of determination of the size and

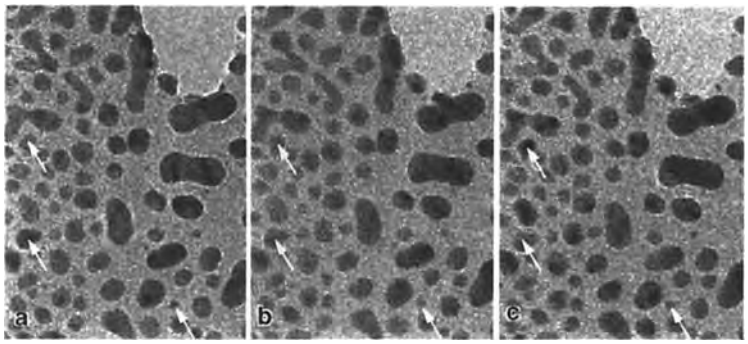

Figure 1. Gray value images of gold particles for three different orientations (0, 5, and 10° tilt), showing the variation of the relative gray values of the particles. The speciment was made by sputtering gold on a thin carbon foil. Some particles showing the change in contrast are indicated by arrows. In this example the support is very thin and amorphous with clearly visible particles, but if the specimen was thicker or (partly) crystalline the part of the particles having a low contrast would be difficult to detect.

the shape depends strongly on the visibility of the particles. If the particle is crystalline, its visibility is strongly influenced by its orientation. If the particle is in an orientation in which it diffracts strongly it is much more visible than in an orientation in which diffraction is only weak. Thus, it can be advantageous to take images at specimen orientations which are rotated with respect to each other (Fig. 1).

Determination of the Atomic Arrangement

The atomic arrangement with a resolution of about 0.17 nm can be obtained through straightforward HREM experiments. The resolution can be further improved by image reconstruction methods up to the information limit of the electron microscope, which is about 0.12 nm for a microscope with a field emission gun.

Determination of the Local Elemental Composition

The local elemental composition can be determined with the standard techniques of EDX and EELs. The only requirement is that for a given small spot size the signal-to-noise ratio is sufficient. Since the smaller the particle to be analyzed the larger the effect of specimen drift, for particles smaller than 5 nm one needs a high electron beam intensity, which can be readily obtained with microscopes equipped with a field emission gun. If one uses such a high electron dose the specimen itself can change (e.g., the irradiated area can be amorphized or removed (hole drilling)). The composition of only the surface and subsurface (depth 1–2 nm) can be determined using Auger electrons. Apart from commercially available scanning Auger microscopes (with a resolution of about 100 nm) this is also possible in specially designed transmission [38] and scanning [39] electron microscopes. This technique is especially interesting for catalysis research, since a spot size less than 5 nm is now obtainable.

Determination of the Local Electronic Structure

The electronic structure of an area of a particle can in principle be determined

from EELS data, since the loss of energy of the inelastically scattered electrons is determined by the electron–specimen interactions, which are not only atom-dependent (coarse structure of EELS spectrum) but depend also on the environment of the atom (fine structure of the EELS spectrum). EELS is presently possible with a resolution of approximately 0.5 eV due to the energy spread of the primary electrons. However, it is to be expected that with a number of adaptations of the electron microscope the resolution can be improved to about 30 meV. This can provide important additional information such as the site and surroundings of a specific atom, the bonding of an atom and/or the electronic structure.

1.2.1.3 Scanning Transmission Electron Microscopy

STEM is used for the same kinds of investigations as outlined above for TEM. With respect to TEM, the strength of STEM is that a variety of signals are available with a spatial resolution of down to about 0.2 nm [40], for example energy loss, characteristic X ray, secondary electron emission, Auger electron emission, annular dark field, and high-angle annular dark field imaging [41]. The versatility of a scanning transmission electron miscroscope, especially in dark field imaging and element mapping, makes it well suited for studies of particles and precipitations. In particular, for the imaging of very small particles STEM can be superior to TEM. Howie showed that by using a high collection angle it is possible to obtain a higher and more reliable contrast from single atoms and randomly oriented clusters than in traditional dark field techniques [42].

When using the normal annular dark field detector, an image based on Bragg scattering can be obtained similar to the TEM hollow cone condition, only the collection efficiency is better in the STEM case. This is normally used when one deals with a particle or an ensemble of particles which can then be 'highlighted'. Other ways of highlighting are by elemental mapping using EELS, EDX or a combination of several of the collected signals.

Alternatively, high-angle incoherent scattering can be exploited to form an image which depends only on the scattering of the projected potential (Z contrast), with a $Z^{3/2}$ dependence. The image formed with this set-up is intuitively interpretable, but the signal-to-noise ratio is inferior to what can be obtained by conventional HREM. High-angle scattering has successfully been used in catalysis to image small metal clusters [43].

Because the signals from STEM detectors are measured electronically, they can be manipulated mathematically. In this way the imaging capability of fine particles can be enhanced by applying ratio techniques [44], thus reducing the contribution of a substrate.

1.2.1.4 Scanning Probe Microscopy

The usefulness of SPM in the characterization of small particles is restricted because of the geometry of the scanning tip and because many technologically important small particles are isolators or are located on isolating supports. The latter restriction applies to scanning tunneling microscopy (STM). Concerning

the first restriction, one requires a scanning tip which is much sharper than the particle itself, because the SPM image is a convolution of the specimen shape with the shape function of the SPM tip. Apart from the small size of the particles, an additional problem can arise from the supporting material. For industrial catalysts this support is highly irregular, making SPM or atomic force microscopy (AFM) impossible. Therefore, only very flat substrates (e.g., SiO_2 on a silicon wafer) are used as model supports in SPM and AFM studies. The studies with these substrates are limited to the determination of the size distributions of the catalytic particles. Ma et al. [45] obtained SPM images of 1–2 nm platinum and nickel clusters on flat graphite surfaces. They observed that some clusters disappear between two scans with a time interval of only 5 s, which they explain by diffusion of those clusters which have only little interaction with the substrate. However, it cannot be excluded that given the small particle–substrate interaction the small metal particles are displaced by the tip.

The sharpness of the tip is crucial in the study of small particles. This has been illustrated by Sheiko et al. [46]. They used a faceted surface of $SrTiO_3$ containing (1 0 1) and (1 0 3) facets with atomically sharp edges. The angles of these facets with the overall surface (3 0 5) was +14 and −13°, respectively, indicating that the change in slope was fairly small. These sharp facets could only be imaged with a small fraction (<10%) of the commercial high-quality Si_3N_4 tips. They proposed that such a $SrTiO_3$ surface can be used to test the quality of a tip. In the case of small metal particles the changes in slope will be much more drastic than in the case of the $SrTiO_3$, setting even stricter limitations to the sharpness of the tip.

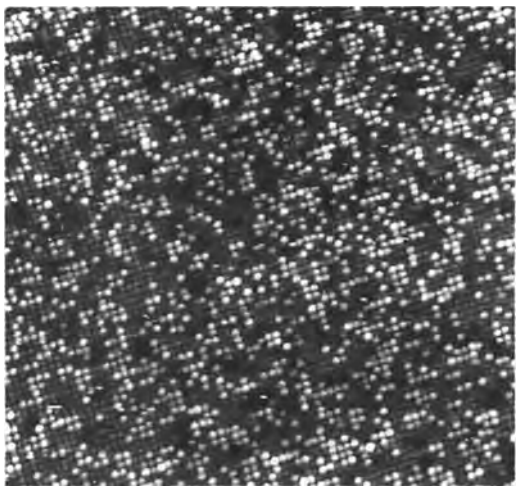

Figure 2. STM image of a flat (1 0 0) Pt–Rh surface. The platinum atoms (white dots) can be distinguished from the rhodium atoms due to a difference in height of 0.02 nm.

STM and AFM are used in the study of catalysts, but in these cases large (single-crystal) metal surfaces are used. These kinds of substrates allow the imaging of individual atoms at the surface or absorbates on the surface, which also allow spectroscopy on single adsorbed molecules [47]. An example of the possibilities of STM on flat metal surfaces is shown in Fig. 2. In this STM image one can distinguish platinum and rhodium atoms on a (1 0 0) surface of a Pt–Rh alloy by a difference in height of 0.02 nm [48]. Another important possibility of STM is the monitoring of surface changes upon a given reaction (e.g., an oxidation) as long as this change is not too fast. Since STM can be done under atmospheric pressure, or even higher pressures, this option allows the study of model materials (e.g., flat surfaces of single crystals) under conditions which are close to the conditions

Table 2. Some characterization methods applied in the analysis of small particles.

Method	Application
Surface-sensitive techniques	
X-ray photoemission spectroscopy [50, 51]	Composition, absorption, atom coordination
Auger spectroscopy [51]	Composition, depth profiling
Low electron energy loss spectroscopy [51]	Composition, atom coordination
Secondary ion mass spectroscopy [51, 52]	Composition
Temperature-programmed techniques [54]	Absorption, decomposition
Bulk techniques	
Mössbauer spectroscopy [55, 56]	Atom coordination
Infrared spectroscopy [57]	Absorbed molecules
Extended X-ray adsorption fine structure [58]	Atom coordination, size
X-ray diffraction, neutron diffraction [59]	Average size, structure
Low-angle diffraction [60]	Size distribution
Whole diffraction pattern analysis [61]	Size distribution, average grain boundary relaxations
Nuclear magnetic resonance [62]	Atom coordination/symmetry

used to perform the catalysis (in which case small particles are used). The third important research subject is the imaging and spectroscopy (scanning tunneling spectroscopy (STS)) of single adsorbed molecules on flat surfaces [49]. In the case of STS the variation in the density of states of the adsorbed atom are probed by varying the size of the energy window, which defines the energy range of the contributing states. The density of occupied and unoccupied states is thus reflected in the tunneling current.

1.2.2 Other Characterization Methods

Of course, many other characterization methods are applied for small particle analysis. In Table 2 a number of methods are given with references to books or review papers. Only the methods most frequently used and their main applications in the characterization of small particles are listed.

1.3 Small-Particle Materials

1.3.1 Catalysts

Catalysts are used in a wide range of processes. In this chapter only the heterogeneous catalysts will be considered. These are for instance used in the petrochemical industry. In catalytic reforming, molecules with a low octane number are converted into molecules with a high octane number. This process is used for more than 10^9 kg per day. One uses a silica–alumina matrix containing zeolite crystals as the catalyst. Hydrotreating in the oil refinery process involves conversions due to reaction with hydrogen, and it is in particular used for the removal of hetero-atoms (e.g. sulfur, nitrogen, and oxygen). One method uses supported mixed phases of, for example, CoS and MoS_2 or NiS and MoS_2 as catalysts.

The heterogeneous catalysts consist usually of two or more components: the support and one or more active phases. The active phase usually constitutes

between 0.1 and 20% of the total catalyst, and is normally in the form of small crystallites (1–50 nm). The support is usually considered to be catalytically inactive by itself. However, in partnership with the active phase it can contribute in an important way to the total reaction. The substrate material should have a high surface area. Typical high surface area substrates are silica and γ-alumina, having surface areas in the range of 100–800 $m^2 g^{-1}$.

Catalyst preparation is still, at least for a significant part a sort of alchemy, in which by trial and error one develops a catalyst which works, without knowing in detail why it works (better than another catalytic material). For instance, the performance of a certain nickel-on-a-silica catalyst can be different from a similar one which has been prepared from a different batch of silica but which should have the same properties according to the manufacturer of the silica. In this section only the most important preparation routes will be outlined.

One preparation method in which the support and active phase are reacted together is based on selective removal of, for instance, water and oxygen. An example of this is an old but still important iron-based catalyst for ammonia synthesis. This is made by melting Fe_3O_4, alumina, and potassium oxide and subsequently removing most of the oxygen by reduction. This yields highly porous and mechanically strong particles.

More often one uses methods of depositing the active phase on a separately produced support. In this case one can use precipitation, impregnation, adsorption and ion exchange. When more than one active component has to be deposited, one can use co-precipitation, which, however, is difficult to control and to reproduce. In all cases the main goal is to distribute as randomly as possible the active atoms or molecules over the substrate. Furthermore, during the process steps towards activation of the catalytic phase(s), a good dispersion should either be maintained or obtained. To reduce the costs of a catalyst one generally aims at such a dispersion that an as large as possible fraction of the atoms of the active phase is at the surface without losing its activity or stability. An example of impregnation is an alumina-supported platinum catalyst. which is made by impregnating a preshaped support with an aqueous solution of H_2PtCl_6; the acid adsorbs strongly on the alumina support. Next the support is dried, calcined and reduced, to remove the water, chlorine and oxygen, respectively.

Another approach to the deposition of small particles is to produce the small particles first with a fixed number of atoms per particle, as has been described by Schmid and co-workers [63]. In this synthesis route one obtains metal particles with a skin formed by large organic groups. The metal core is built from the central atom by surrounding it by a number of close packed layers, yielding distinct numbers of atoms thus forming a series 1, 13, 55, 147, 309, 561, ... The advantage of this route is that only particles with a fixed number of atoms occur, allowing direct correlation between particle size and catalytic performance. An example of palladium clusters is shown in Fig. 17.

Apart from the actual catalytic particles, the morphology of the support can play a large role. For instance, for the catalytic refinement of crude oil the catalyst comprises a well-balanced

conglomerate of particles, such that they have a 'chain' of pores which narrow down from pore sizes of several hundreds of nanometers at the surface to pores of about 1 nm. The conglomerate consists of zeolite Y crystals, silica, γ-Al_2O_3, and platinum metal particles. Zeolite Y contains pores of about 1 nm, and γ-Al_2O_3 and silica are used not only as the binder but also to provide the larger pores. The acid sites in the zeolite and on the γ-Al_2O_3 catalyse cracking (C–C bond breaking) and isomerization (forming different C–C sequences), whereas the metal particles catalyse mainly hydrogenation (adding hydrogen atoms to the carbon chains). Since bond breaking and hydrogenation should preferably occur at approximately the same location it is essential that the platinum particles are finely dispersed. An additional reason for a fine dispersion is that one can reduce the cost of the platinum. If the platinum particles become too small (<1 nm) they are more likely to migrate and cluster into larger ones.

A review on TEM of zeolites is given by Terasaki [64]. Zeolites are open-framework structures, of which the framework consists of $(Si,Al)O_2$ with silicon and aluminum in tetrahedral coordination forming a one-, two-, or three-dimensional array of channels, with diameters from 0.4 to 1 nm. The pore system allows access by and transport of those molecules which fit into the pores. As such, they act as molecular sieves with an invaluable shape selectivity for reactants as well as products. Some zeolites do occur in nature, but most of them are synthetic. The synthesis of zeolites is done under hydrothermal conditions. Many different structures have been synthesized by the use of specific templates, organic molecules which fit in the pores of one zeolite but not in others thus governing the synthesis of particular zeolites. Obviously a major effort has been put into the synthesis of zeolites with a pore diameter significantly larger than 1 nm. Only some limited results have been obtained, such as 1.2–1.3 nm pores in a zeolite called VPI-5 [65]. Recently the limited pore size barrier was broken by the discovery of a new family of ordered mesoporous molecular sieves by researchers at Mobil [66]. These new materials, called MCM, are synthesized under hydrothermal conditions from (alumino-)silicate gels containing organic surfactant molecules such as hexadecyltrimethylammonium chloride (C_{16}TMACl). By the choice of the length of the carbon chain one is able to choose the diameter of the pores, which can range from 1.5 to 10 nm. These materials open the way to the use of shape-selective catalysis to convert molecules which are too large to fit into the zeolite lattices. MCM is formed by the solidification of $(Si,Al)O_2$ around the sphere-like or pillar-like micelles composed of the surfactant molecules, thus forming tubes or plates. MCM can occur in various morphologies [68, 86]: a rather chaotic one, in which tubes are strongly curved and have several interconnections; (ii) a hexagonal stacking of the tubes, of which an example is shown in Fig. 3; (iii) a cubic arrangement of interconnecting tubes; and (iv) a plate-like morphology. The last one is not so interesting because the structure collapses when the template (the surfactant molecules) is removed. The tube walls do not show a periodicity along the direction of the tube and it should be considered as an amorphous component. Apart from the pore size, the thickness of the pore walls can also be manipulated.

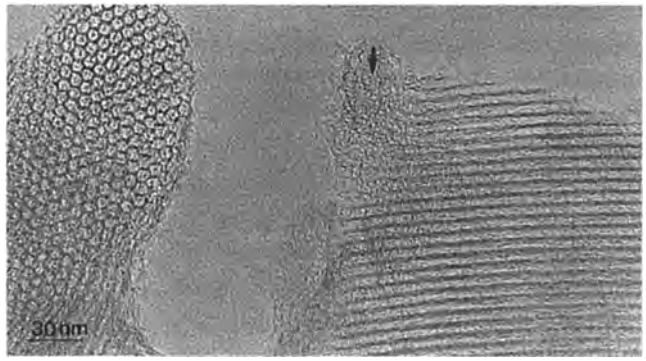

Figure 3. A TEM image of two MCM crystals on an amorphous carbon grid. The MCM has a hexagonal structure with an *a* axis of 7 nm. The crystal on the left is viewed along the hexagonal axis, and shows a sixfold symmetry for the tube arrangement. Note that the bottom part if this crystal is misoriented. This local change in orientation is observed in many MCM crystals. The crystal on the right is viewed perpendicular to the channels. Note that one cannot observe any lattice fringes except those of the channels themselves, indicating that the wall of the tubes is amorphous.

Since heterogeneous catalysis occurs at the surface of the catalytic particles, a description on the atomic level is needed. This requires a very local characterization, in particular because most catalysts are very complex systems. Quite often the catalysts are prepared with the addition of other elements about which it is known only that their presence results in a better activity or selectivity or in an improved stability of the catalyst. Such additives are called promoters. In all cases the ultimate goal is an understanding of why a certain catalyst shows such a good performance, to allow the search for further improvements in a systematic way.

The complexity of a given catalyst makes it necessary in most instances to do HREM investigations on a series of catalysts. For instance, in a recent study [68] of the activity of the hydrodesulfurization of the sulfur-containing molecules thiophene and dibenzothiophene using W–Ni–S on γ-Al_2O_3 it was found that the activities for thiophene and dibenzothiophene were respectively not dependent and quite strongly dependent on the temperature of the preparation of the catalysts (calcination and sulfidation). The most frequently reported HREM feature of these catalysts is the presence of dark contrast bands in the HREM images, which are due to slabs of WS_2 possibly with some incorporation of nickel [69]. In the literature these slabs are reported to be the active component for the hydrodesulfurization. The catalysts with the higher activity for desulfurization of dibenzothiophene were shown, however, to contain very few or no slabs but very small clusters (about 0.5 nm) which were barely visible. These clusters probably contain nickel, tungsten, and sulfur. Catalysts prepared with higher sulfidation temperatures showed no small clusters but only slabs to be present. However, these catalysts still showed a significant activity for desulfurization of dibenzothiophene (about one-third that of the catalyst containing the clusters), indicating that the slabs are catalytically active but less than the small clusters. HREM images of both

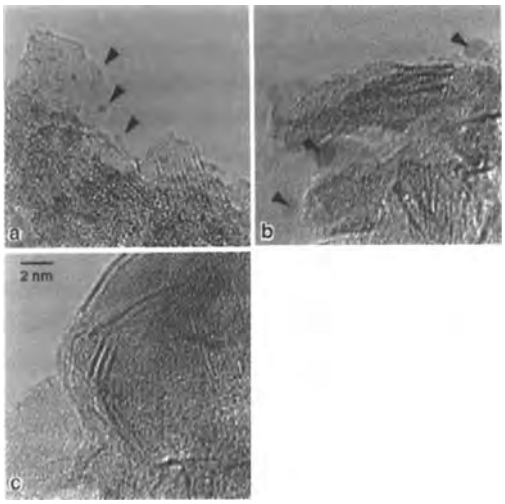

Figure 4. Two HREM images of W–Ni–S on g-Al_2O_3. (a) A specimen obtained by calcination at 650°C and sulfidation at 400°C. Only small black spots can be seen (some of them are indicated with an arrow). (b) A specimen calcined at 400°C and sulfidated at 650°C. Black lines corresponding to WS_2 slabs can be observed throughout the image. For some reactions the small spots in (a), which are barely visible by HREM, show the highest catalytic activity.

catalysts are shown in Fig. 4. The clusters are difficult to distinguish, and it should be noted that due to the high scattering potential of tungsten the imaging conditions are favorable for this catalyst. This example shows that one should take into account the possibility that the most active phase is very difficult to detect by HREM. Local element analysis can be very helpful in this case as can be a careful HREM characterization of a series of catalysts showing different activities.

Another area in which microscopy techniques are used is the study of deactivation (ageing) of a catalyst during use. For instance, during the catalytic cracking of oil the catalyst tends to lose 90% of its activity within 1 s, due to the deposition of a thin carbon layer (coke). An elegant solution has been found to this problem by performing the catalytic cracking in one reactor and the regeneration of the catalyst in another one placed in series in which the deposited coke is burned off. Other deactivation processes involve the sintering of particles, poisoning by other elements (e.g., the deactivation by lead of catalysts for cleaning exhaust gases in cars), and changes in the porosity of the substrate. Two approaches can be used to study the deactivation; in both cases the catalyst is investigated before and after ageing. In the first approach one investigates different specimens; by undertaking a statistical analysis one can reveal the differences. In the second approach one investigates the same areas before and after ageing; this requires more careful specimen handling (see Sec. 1.8.5 of this Chapter) but has the advantage that one can easily determine the changes.

Most catalytic reactions occur at elevated temperatures and pressures. Thus the conditions during the catalytic reaction are much different from the conditions in the electron microscope. This points to two disadvantages of electron microscopy, even under ideal conditions. In the first place one has to take into account that the catalytically active phase can be changed by the vacuum of the microscope. In the second place, reactions cannot be followed in situ (see also Sec. 1.8.4 of this Chapter). For ageing studies, STM can be a very useful tool because it does not require a vacuum.

1.3.2 Nanophase Materials

Nanophase materials consist of synthetic materials with an average grain size below

100 nm [70]. The various grains can be of different phases or structures. The basic idea behind nanophase materials is the generation of materials with new atomic structural arrangements by introducing a very high density of defects such as grain boundaries, interphase boundaries, and dislocations resulting in new macroscopic properties. The density of metallic nanocrystalline materials varies between 75 and more than 90% of the crystalline density. Nanocrystalline materials have also been called ultrafine grain materials, nanophase materials, or nanometer-sized crystalline materials. The interest in these materials is rapidly growing because it has been shown that some of their properties are superior to 'conventional' materials, which are composed of much larger grain sizes [71]. Nanophase materials span a wide range of compounds, for example metals, oxides, nitrides, and semiconductors. The use of these nanophase materials is also very broad. In the case of metals, they show—when compacted to almost fully dense materials—a greater hardness (e.g., the hardness of copper consisting of 10 nm particles is five times greater than that of copper consisting of 100 μm grains [72]. On the other hand, the uncompacted metal can have a very high surface/bulk ratio, making it suitable for catalysis (e.g., Raney nickel [73]). Ceramics (e.g., TiO_2 and ZnO [74]) consisting of very small particles are less brittle than materials with grains of conventional sizes. Small semiconducting particles (e.g., silicon in amorphous SiO_2) can show interesting luminescence properties [75] and can exhibit quantum phenomena. Multilayers, consisting of layers of small particles, can be used as X-ray mirrors (e.g., Pd–C [76]) or can be used to study amorphization phenomena (e.g., Ni–Ti interfaces [77]).

The manufacturing of nanophase materials has been reviewed by Gleiter [78], and can be classified into three groups.

The first group of fabrication techniques is cluster assembly. This again covers a broad field with chemical precipitations from solutions [79] and sputtering (for instance into an oil to separate the particles or onto a substrate to form multilayers). In particular, gas condensation is increasingly used, especially in the preparation of ceramic materials.

The second group is mechanical attrition, which is usually done by ball milling [80]. Using this technique, ultrafine particles can be obtained in a cheap way, but some contamination from the ball milling device is likely to occur.

The third group of methods is implantation by high-energy ions, for example the implantation of erbium into amorphous SiO_2 [81]. By an additional annealing process the deposited ions can cluster, resulting in nanoparticles, the size of which depends on the dose and the annealing conditions. This technique is very expensive, since it requires an accelerator.

Nanocrystalline alloys may be generated by simultaneously evaporating or sputtering several components, which can result under favorable conditions in a uniform mixture of crystallites with different chemical compositions. A major advantage of such materials is that chemically different atoms can be mixed at the grain boundary interfaces [82].

The diversity of compounds and applications is also the actual reason for using electron microscopy techniques.

Evidently, size and shape can be easily determined by TEM, whereas small angle X-ray and neutron diffraction allow determination of the size distribution. In dense nanophase materials the grain boundary structure is the most important part, since this affects the improvements in the mechanical properties such as hardness and brittleness. Determination of the grain boundary structure is, however, an almost impossible task. It requires that the grain boundary is (almost) parallel to the electron beam, without steps in that direction, and is continuous throughout the specimen (Fig. 5). The grains on both sides of the boundary should also be in such an orientation that the structures of both grains are imaged. Finally, the specimen should not be covered with an amorphous layer. An additional problem is the delocalization of information, which is discussed in Sec. 1.5.1 of this Chapter.

Since the boundary core structure depends on the interatomic bonding forces and the boundary crystallography and since many different grain orientations and grain boundary orientations occur, a large variety of grain boundary core structures will occur in a given specimen. Therefore, an HREM study can only provide fragmented information, describing at best only a part of the grain boundary structure. A study of the atomistic structure of grain boundaries in metal nanocrystalline materials by HREM suggested that these grain boundaries are similar to the grain boundaries in conventional polycrystalline materials [83]. In this favorable condition, specimens with larger particles can be used as model specimens for the

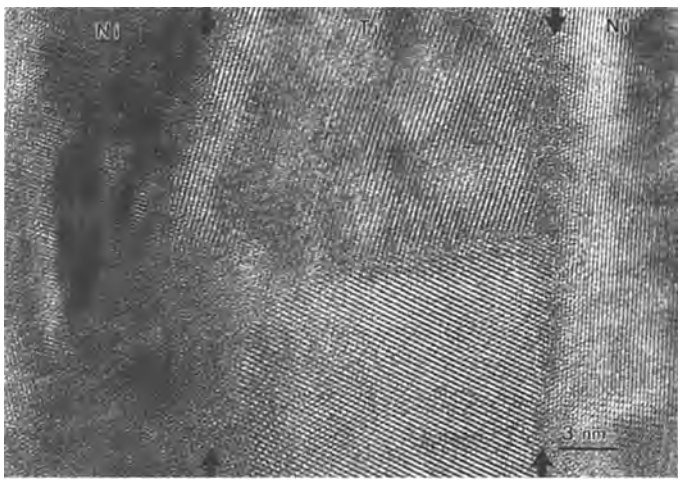

Figure 5. HREM image of a part of a Ni–Ti multilayer, composed of nanocrystalline nickel and titanium. The multilayer is grown from right to left. One can observe a number of grain boundaires, between grains in neighboring nickel and titanium layers and between two grains in the titanium layer. In this example the grain boundaries are almost parallel to the electron beam, but due to misalignment of the crystals the atomic structure of the grain boundary cannot be determined. The chance that both grains are in a low index orientation with the grain boundary straight and parallel to the electron beam and continuous throughout the thickness of the specimen is small. Furthermore, the nickel and, in particular, the titanium surfaces will be partly oxidized when the specimen is exposed to air. Since diffusion along grain boundaries is much more rapid than bulk diffusion it is to be expected that the oxide surface layer extends farther into the specimen at the grain boundaries.

nanophase material one actually wants to characterize. Even in such favorable conditions the data obtained by HREM always have to be completed with more bulk-sensitive techniques. A method which is quite powerful, in particular in the characterization of the grain boundary structures, is total X-ray diffraction pattern analysis [84].

1.3.3 Precipitates

In most modern multicomponent materials, precipitates play an important part whether or not by intention. The nature of precipitation hardening, for example, aluminum with small amounts of other elements (e.g., magnesium, manganese, iron, copper, and silicon) is a classical example of process and materials understanding which could only progress in close relation with the development of the electron microscope [85].

Precipitates are introduced into aluminum, steel, and other metals and alloys to increase the strength of these. The nucleation, distribution, shape, and composition of the precipitation is of major importance to the performance of the composite [86]. In high-temperature superconductors, homogeneously distributed secondary phases can have a positive effect on flux pinning, thus increasing the critical current density [87]. In other materials the presence of impurities can lead to precipitation which may degrade the properties of, for example, semiconductor devices. Particles can be precipitated by chemical precipitation, temperature treatments (e.g., annealing of irradiated samples) or by mechanical working (defect-mediated solid state diffusion).

Microscopy techniques are used on precipitates to obtain information on phase identification, determination of the orientation relation between the precipitate and the matrix, and the relation between the size and morphology and the performance.

For phase identification and determination of size and morphology one can either separate the precipitates by dissolving the matrix, or thin the matrix and precipitates to electron transparency. The latter is done best by ion milling, although the precipitates can drop out from the specimen due to differences in ion milling rates; thus, a small angle of incidence of the ion beam is generally required. With a thin specimen of matrix plus precipitates the particles are in general more stable, but contamination is usually much greater. Phase identification can be done by electron diffraction, chemical analysis or HREM. If the particle is not continuous through the specimen, thickness difficulties arise, for example a background signal from the matrix in EDX analysis, Moiré interference fringes in high-resolution imaging, and unclear grain boundaries. Moiré fringes could also be used for identification of the precipitate and its orientation. Normally, either dark field techniques or elemental mapping are used for collective imaging of precipitates and determination of the distribution of precipitates.

The determination of the orientation relations between precipitates and matrix should be done by electron diffraction, either in SEM if the precipitates are sufficiently large or in TEM. If the precipitates are very small, a transmission electron microscope or scanning transmission electron microscope equipped with a field emission gun is essential. Similar difficulties occur as for the phase determination.

For TEM and STEM one uses an ion-milled specimen. For SEM, one needs a polished and clean surface. The effect of strain on the interaction between precipitates and matrix can be studied using strain holders [88].

1.3.4 Magnetic Materials

Evidently, magnetic materials are of enormous importance in the present methods for storage of information. An important development is the continuing miniaturization of magnetic particles, thus allowing a higher storage density. This is for a major part achieved by the fabrication of thin films. A comprehensive review of the state of the art of the fabrication and characterization of surface, interface and thin film magnetism is given by Falicov et al. [89]. The magnetic properties of fine particles are reviewed by Dorman et al. [90].

The microstructure can drastically affect the magnetic properties of a material. Micromagnetic properties such as hysteresis and the positions of domain walls depend critically on the presence of grain boundaries, free surfaces, defects, and voids. Properties pertaining to classical magnetism, such as magnetization and crystalline anisotropy, can also be substantially changed by irregularities in the atomic positions, in particular when the latter are different from the bulk positions due to the presence of a surface, a defect, or a grain boundary. Victoria [91] has used theoretical techniques to show the relation between magnetic behavior and microstructure.

By layering a magnetic material with a nonmagnetic material it is possible to produce thin films with unique properties, such as giant magnetoresistance [92], an enhanced magneto-optical Kerr effect [93], or a large perpendicular magnetic anisotropy [94]. Because of the large perpendicular magnetic anisotropy of ultrathin cobalt layers (about 0.4 nm) and the large polar Kerr effect, the Co–Pt multilayer [95] is one of the candidates for rewritable magneto-optical disks [96].

The properties of the multilayers are quite different from the properties of the bulk materials, due to the artificially fabricated microstructures. For instance, the giant magnetoresistance of Fe–Cr depends strongly on the thicknesses of the magnetic and nonmagnetic layers [97]. Since these properties are intimately related to the microstructure, a thorough description of all the microstructural features is required. Such a description includes the crystalline characteristics (e.g., grain sizes, orientations, orientation relationships, compositions, and compositional changes along the multilayer) and the magnetic microstructure (magnetization directions and domain walls).

Magnetic force microscopy (MFM) [98] is derived from AFM. It allows imaging of magnetic structures on a 50 nm scale. A review is given by Grütter et al. [99]. MFM has found applications in recording studies and the development of several types of recording materials [100].

Other techniques for observing magnetic microstructures include measurement of the magneto-optical Kerr effect [101], spin-polarized electron microscopy [102], electron holography [103], Lorentz microscopy, and the Bitter decoration technique [104].

Two specific problems in the electron microscopical characterization of magnetic particles occur because of the interaction

between the magnetic particles and the magnetic field of the objective lens. In the first place the magnetic field of the particles results in a distortion of the magnetic field of the objective lens. This can be easily adjusted with astigmators, but the adjustment has to be repeated after every change in specimen position. It is best to use as little magnetic material as possible. The second problem is that the particles or conglomerates of particles can be broken out from the specimen by the magnetic field of the objective lens which can lead to a 'permanent' contamination of the objective lens. If a high resolution is not needed, one can use a microscope with a switched-off objective lens. In particular with an extra post-column lens one can obtain magnifications up to about 60 000 times. Without the objective lens no high-resolution imaging is possible because the quality of all lenses except for the objective lens is not high enough.

Regarding multilayers, their magnetic properties depend strongly on structural details such as the texture, layer roughness, sharpness of the interfaces between the layers, and the presence of defects; consequently, these properties depend also on the synthesis conditions. Thus, a detailed characterization of the microstructure using HREM in relation to the synthesis conditions and the properties is required.

1.4 Required Characterizations

In this section the required characterizations as listed in Table 1 are discussed, with a strong emphasis on the use of TEM.

1.4.1 Size and Shape of the Particles

In the assessment of the size of small particles a whole range of microscopy and other techniques have been applied. For the very small sizes only SEM, TEM, STEM, and, partly, STM give a direct and individual image of the particles. Conventional X-ray and neutron powder diffraction only yield an indirect and averaged estimate of particle size through their size effect on line broadening. With these techniques, particles in agglomerates or part of twinned particles are detected as single particles, resulting in an overestimation of the available surface area. On the other hand, low-angle diffraction registers density variations such that agglomerates and single particles cannot be distinguished.

Intrinsic drawbacks in the use of STM in particle size analysis are that the resulting image is a convolution of the tip and the particle profile, and that one images only the surface of the particle; thus the shape at the side of the support cannot be detected.

If the size of isolated particles (for instance in a fluid) is needed, they have to be mounted on a support for TEM as well as SPM investigations. This mounting may change the morphology because of the particle–support interaction [105].

Inclusions and precipitates (not possible to image using STM) occur in their natural surroundings. Thus, determination of the size and shape of the particles is not hampered by changes provided the sample preparation does not lead to artefacts. However, one has to take into account that the TEM image is the two-dimensional projection of the

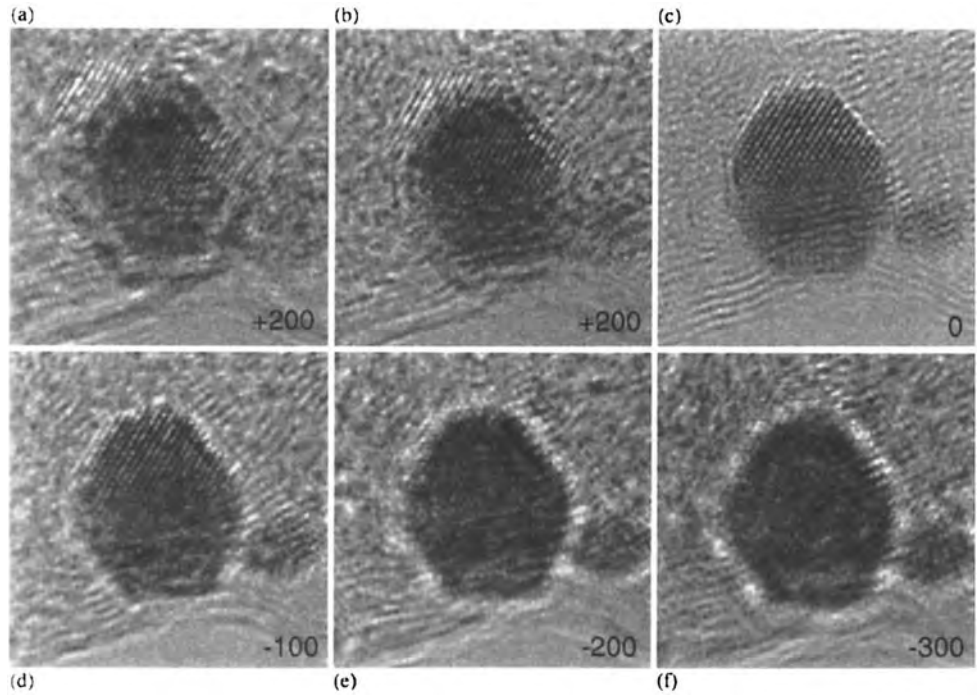

Figure 6. The effect of defocus on the size of a small particle. (a)–(f) A gold particle at focus values of about −200, −100, 0, 100, 200, and 300 nm, respectively. Note that the apparent size of the particle changes considerably and that at overfocus, in particular, the size cannot be determined.

three-dimensional shape of the particle. Thus, the apparent particle size (size distribution) in the TEM image can be affected by the shape and of the thin foil. It is then necessary to use some theoretical considerations to correlate the apparent size with the real size [106].

The TEM imaging conditions can strongly influence the apparent size of the particle. An example of this is given in Fig. 6, which shows a focus series in which the apparent size changes when the focus is changed. The observed discrepancy can be as large as 100% due to delocalization of information. Note that the size is especially difficult to estimate for an overfocus situation.

1.4.2 Structure of the Particles

1.4.2.1 Comparison of Transmission Electron Microscopy with X-Ray or Neutron Diffraction

The limited size of small particles has always brought about difficulties in their structural characterization. The line broadening in X-ray or neutron diffraction patterns due to the limited size of the particles has to be taken into account in the structural characterization, and thus knowledge about size and shape are required. The latter kind of data can be obtained by conventional electron microscopy, after which structure determination from X-ray or neutron powder diffraction

is more feasible. A more straightforward technique, however, is the use of HREM, which allows a direct structure determination, provided the specimen is sufficiently thin and images can be made in several low-index orientations. Information in diffraction space of the TEM goes down to more than $12\,nm^{-1}$, whereas information in HREM imaging depends on the quality of the objective lens and the energy spread of the electrons, and is about $7\,nm^{-1}$ for conventional high-resolution electron microscopes. Quite often one can verify with HREM whether the structure of the particle is the same as the bulk structure. An additional reason for the use of HREM is that many small metal particles tend to be multiply twinned. The structure of multiply twinned particles cannot be solved by conventional diffraction techniques if the twinning density is high.

If the basic structure of a metal particle is known and relatively simple (simple single-element metals), and if the twin boundary is simple and straight along the electron beam, one can deduce the structure of the twin boundary relatively easily from a conventional HREM image. In the case of more complex structures the deduction of the structure of the twin boundary can be very complicated. An important reason for this is the presence of delocalization, caused by the transfer function of the electron microscope. An example of this can be seen in Fig. 7, which shows an Si–Al precipitate in an aluminum matrix.

Evidently, structure analysis by HREM is local. On the one hand this allows structure determination of a minority phase, which is not possible by X-ray or neutron diffraction. On the other hand, the

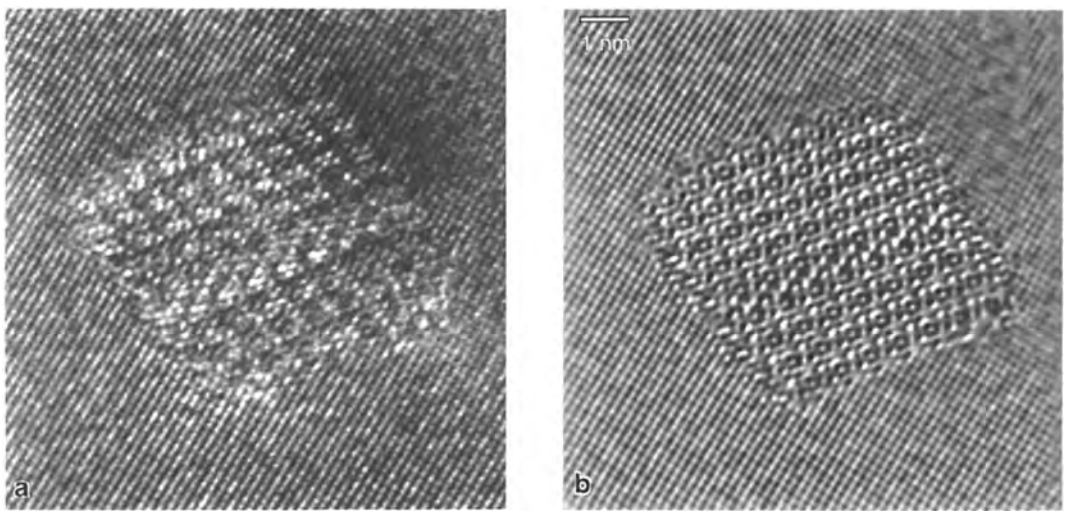

Figure 7. HREM images of an Mg–Si precipitate in an aluminum matrix, showing the effect of delocalization of information. The images were made with a Philips CM30ST-FEG. (a) An experimental image taken at a focus of approximately −70 nm. (b) The exit wave (phase part of the complex image), which is calculated from a series of 20 experimental images of which (a) is the second image. The exit wave shows sharp precipitate–substrate interfaces and a defect in the precipitate which is localized in one layer, whereas the interfaces in image (a) are vague and the defect seems to expand over about 1 nm. The less sharp image features in (a) are the result of delocalization of information.

specimen has to be very thin, which can lead to artefacts.

1.4.2.2 Use of the Electron Microscope

Unit Cell Determination

If one is interested only in the determination of the unit cell of a small particle, nanodiffraction using a spot size smaller than the particle is a very quick and easy method. For this, diffraction data are needed for several orientations of the particle. In principle these orientation could be chosen at random, as only the orientation relationships between the electron diffraction patterns should be known. However, it is easier to orient the small particle in a low-index zone and subsequently tilt it about one of the (small) reciprocal lattice vectors.

Structure Determination Using Kinematic Diffraction Theory

One can also determine the structure from the electron diffraction data by a kinematic approach is the diffracting area is very thin (<3 nm). This small thickness is essential because the interaction of the electrons with a specimen is very strong, resulting in dynamic scattering, which changes the intensities of all reflections with respect to each other as a function of the specimen thickness. If the dynamic diffraction is large, the intensities of the reflections cannot be used for structure determination unless the dynamic scattering is taken into account. Provided the crystal is very thin (2–4 nm), a structure refinement based on the kinematic diffraction theory yields acceptable results. In this case one can use the structure refinement programs, which are well developed for X-ray diffraction and neutron diffraction. Refinement of simulated electron diffraction data shows that kinematic refinement of electron diffraction data requires the specimen thickness to be in the range of 1–5 nm, depending on the scattering potential of the specimen. The advantage of a kinematic refinement is that the standard structure refinement techniques used in X-ray single-crystal diffraction can be used.

Structure Determination Using Dynamic Diffraction Theory

Four techniques have been reported in which dynamic diffraction is taken into account in the refinement process:

(i) Zuo and Spence [107] use convergent beam diffraction to refine structure factors. From these, structural parameters can be deduced. The method is limited to small unit cells.

(ii) Tsuda and Tanaka were able to refine a small number of positional and thermal parameters of $SrTiO_3$ using convergent beam patterns [108]. It proved to work for very thick crystals for which the thickness can be estimated with convergent beam techniques. The usefulness of this method is limited because of the large calculation time. Since many CBED patterns have to be calculated, only a very limited number of parameters can be taken into account. More parameters will increase the computing time exponentially. All current Debye–Waller factors and positional parameters were reported to be refined.

(iii) Sha et al. [109] propose a different approach using normal diffraction patterns. They correct for dynamic

Table 3. Atomic positions obtained by refinement of several sets of [0 0 1] electron diffraction (ED) patterns of $Ce_5Cu_{12}P_{19}$.

Atom	(position)	x (XSD)	x (ED)	y (XSD)	y (ED)
Ce1	$(\frac{2}{3}, \frac{1}{3}, 0)$				
Ce2	$(x, 0, \frac{1}{2})$	0.8067(1)	0.813(2)		
Cu1	$(0, 0, 0)$	0.2878(2)	0.287(2)		
Cu2	$(x, 0, \frac{1}{2})$				
Cu3	$(x, y, 0)$	0.3783(2)	0.378(1)	0.1725(2)	0.174(2)
Cu4	$(x, y, \frac{1}{2})$	0.6359(2)	0.636(2)	0.1185(2)	0.117(2)
Cu5	$(x, 0, 0)$	0.4508(4)	0.445(2)		
P1	$(x, 0, 0)$	0.1768(5)	0.178(2)		
P2	$(x, 0, 0)$	0.6298(5)	0.641(2)		
P3	$(x, y, \frac{1}{2})$	0.3216(4)	0.319(1)	0.8454(4)	0.830(1)

$Ce_5Cu_{12}P_{19}$ has a hexagonal space group P-632, with $a = 1.24$ nm and $c = 0.40$ nm. Crystal thicknesses were refined, and ranged from 12 to 15 nm. For comparison, the atomic positions for $La_5Cu_{12}P_{19}$, obtained from X-ray single-crystal diffraction (XSD) are given. The R value was 5.2%.

diffraction based on a rough atomic model to create a resulting quasi-kinematic data set, which can subsequently be used in a standard kinematic refinement procedure.

(iv) Jansen et al. [110] have developed a computer program, multi slice least square fit (MSLS), which incorporates the dynamic diffraction theory into the structure refinement process. The program combines two known algorithms: the multislice method and a least-squares fitting procedure. The calculation takes into account the curvature of the Ewald sphere and multiple scattering. Using this method, one can use much thicker crystals (e.g., 14 nm for $Ce_5Cu_{12}P_{19}$) [111] than can be used for a kinematic refinement (see Table 3).

The diffraction data, used for the refinement of $Ce_5Cu_{12}P_{19}$, were taken from areas with a diameter of about 10 nm. Thus, this procedure allows a detailed structure determination of particles with sizes from 5 nm and larger, which makes it a quite powerful method for structure determination of small particles; it also gives a figure of merit for the refined model.

1.4.3 Composition (Overall) of Particles

The composition can be determined with the well-developed techniques of energy dispersive X-ray analysis (EDX), wavelength dispersive X-ray analysis (WDX), and EELS. In the case of EDX and/or WDX the technique is generally called electron probe microanalysis (EPMA). Evidently, the technique to be applied depends on the particle size and what information and accuracy is needed. A restriction in the use of element analysis of small particles can be the broadening of the electron beam due to the electron–specimen interaction. For instance, using

100 keV electrons the beam broadening is 1 nm for 30 nm thick γ-Al_2O_3 (and 20 nm for a thickness of 200 nm) [112].

EPMA is an accessible and often used method for determining the element distribution in micrometer-sized particles. For smaller particles, however, the difficulties with quantitative EPMA (absorption, geometry, fluorescence, and atomic number) experienced in ordinary samples are accentuated [113]. These difficulties are related to beam broadening, resulting in a strong loss of resolution. The resolution limit can be improved by changing to a lower electron acceleration voltage, or by using thin sections (similar to TEM) of embedded (if not already in a matrix) particles. Thin sections can be obtained by, for example, ultramicrotomy.

A problem in the composition determination using X-rays in TEM is spurious radiation, resulting in X-ray generation outside the area illuminated with the electron beam. This radiation can be due to X-rays generated by stray electrons somewhere in the microscope column and not stopped by apertures, or by secondary electrons created in the illuminated area of the specimen. Evidently the first cause can be reduced by the design of the microscope, but the latter is inherent to the technique.

In many systems it is only necessary to detect or confirm that a certain element is present, or to locate precipitates and inclusions within a matrix or grain. This can be done by elemental mapping using EDX and/or EELS in a scanning transmission electron microscope or in transmission electron microscope (in nanoprobe/scanning mode) or by electron spectroscopic imaging using energy filtering [114]. When the individual composition of each particle is required, a widespread technique is quantitative X-ray analysis using the microscope response factors for the various elements [115]. For many simple particle systems, such as single-element particles or bi-element particles, this is the fastest and easiest method. It becomes increasingly difficult to quantify reliably the light elements due to absorption effects. It also should be taken into account that the reproducibility of a window-less detector is lost if contamination has accumulated on the detector during the period of investigation. For small and/or light element particles, EELS may be advantageous due to its better sensitivity to light elements, sensitivity to chemical bonding, and higher collection efficiency. With more complex multi-element systems and compounds containing light and heavy elements (e.g., oxides), a combination of several techniques should be used. Lyman et al. [116] observed a correlation between the composition and the size of supported metal catalysts, in which it is sufficient to measure the particle size. If the composition is strictly related to a structure (e.g., some metal oxides or inclusions) one can also perform microdiffraction to distinguish a certain particle.

Problems in TEM and STEM that have to be faced in quantitative analysis of nanometer-sized particles are drift, the trade-off between a high count rate (good statistics) and the high electron intensity that the particle can sustain (decomposition). Since the smaller the particle to be analysed the larger the effect of specimen drift, one needs for particles smaller than 5 nm a high electron beam intensity, which can be readily obtained with microscopes equipped with a field emission gun.

1.4.4 Structure of the Surface

1.4.4.1 Polarity of the Surface

In the case of small particles of oxides or other partly ionic compounds, the interruption of the lattice at the surface must lead to some changes of the surface layer to obtain charge compensation. The simplest situation occurs if the ending layer is charge-neutral. In that case the layer is stable in itself, and, by a small relaxation of the outer atoms, the effect of the broken bonds can be reduced. If the ending layer is not neutral it will have a high surface energy, which makes it unlikely that such a surface plane can exist. However, different atoms can be physisorbed or chemisorbed (e.g., OH^- groups on an MgO surface), which can result in a reduction of the surface energy such that the surface becomes more stable. Consequently, the atmosphere in which the particles are formed in crucial in the morphology of these small particles.

1.4.4.2 Imaging Surface Relaxation by Transmission Electron Microscopy Profile Imaging

The extent of surface contraction or repulsion has been studied by Marks [117], who has done extensive calculations on this subject. He showed that the apparent expansion at the surface, as measured from a high-resolution electron micrograph, depends on the defocus of the electron microscope. Thus the observed positions of the surface atoms are only equal to the actual atom positions if the correct focus is chosen. He also indicated that when one takes into account the noise level of the images, the real position of the atomic columns could be determined with an accuracy of about 5% of the lattice parameter.

The problem of artefacts due to the focus of the transmission electron microscope can be partly overcome by the use of exit wave reconstructions (see Chap. IV, Sec. 1.1.2 of Vol. 1 of this handbook). As in conventional HREM, the absolute focus is not known in the exit wave reconstruction. This requires a method of finding the absolute focus. Tang et al. have shown that this can be done after the reconstruction of the absolute focus using a maximum entropy method [118], yielding the absolute focus with a precision better than 5 nm. Figure 8 shows the effect of +5, 0 and −5 nm focus shifts from the absolute focus for an exit wave of a (1 0 0) surface of NiO. The focus shifts of +5 and −5 nm result in shifts of −0.02 and +0.02 away from the bulk, respectively.

The atomic structure of steps, adatoms, vacancies, and other surface defects can be readily investigated with STM [119]. A lateral resolution of 1 Å and a vertical resolution of 0.1 Å are achieved routinely.

1.4.4.3 Can One Detect Ad-Atoms?

It is not likely that one is able to image adatoms by HREM with a detail that allows one to draw conclusions. Probably the best HREM configuration is to use profile imaging. However, to image a single adatom next to columns of atoms of the surface layer is difficult. This becomes

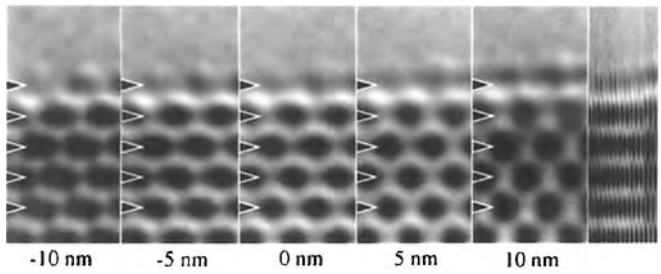

Figure 8. The effect of a focus propagation on profile images of the (0 0 1) surface of NiO. The applied focus propagations are given below the images. The image on the far right represents the same series of images but compressed in the horizontal direction, which is approximately the same as looking at a glancing angle in the horizontal direction. The position of the row of dots at the surface is shifted away from the bulk when a negative focus propagator is applied.

even more difficult if the ad-atom has a large Debye–Waller factor, which is highly likely to occur, because it has relatively few bonds with the substrate. A high Debye–Waller factor results in a further decrease in the contrast of the ad-atom. The effect of a high Debye–Waller factor is illustrated in Fig. 9, showing exit wave profile images of the (0 0 1) surface of NiO. The dots of the nickel columns in the amplitude at the surface are less dark, which is due to the larger thermal vibration (and not to fewer atoms in the nickel column), which is quite normal for atoms at the surface.

For the imaging of ad-atoms, SPM is a better technique. Many illustrations of the unique possibilities of this technique have already been reported [120]. For instance, STM on a closed ad-layer of sulfur on a rhenium (0 0 1) surface is reported by Ogletree et al. [121] to form a $2\sqrt{3} \times 2\sqrt{3})R30^\circ$ superstructure, whereas CO on a ruthenium (0 0 1) surface forms 2×2 superstructure [122]. Individual ad-atoms are, for instance, observed for carbon on aluminum (1 1 1) [123]. Examples of processes at the metal–gas interface are changes in the oxygen coverage of ruthenium (0 0 1) [124] and the movement of oxygen strings on copper (110) [125].

1.4.5 Composition of Particle Surfaces

The accuracy of TEM or STEM for the determination of the composition of the surface of small particles is much less than that of surface-sensitive techniques such as SIMS and XPS. Thus, it is not useful to apply TEM or STEM for this purpose; also, it is often desired to probe the surface as a function of temperature or exposure to certain gases, which cannot be done in electron microscopes. STM could be used, but one needs very precise knowledge on the density of states of the surface atoms to allow interpretation of the images (see Sec. 1.5.2 of this Chapter).

If the surface composition can be associated with a specific structure feature by HREM, then the surface composition can be inferred from atomic profile imaging of the particle surface, for example ZnO on $ZnCrFeO_4$ [126] or TiO on TiO_2 [127].

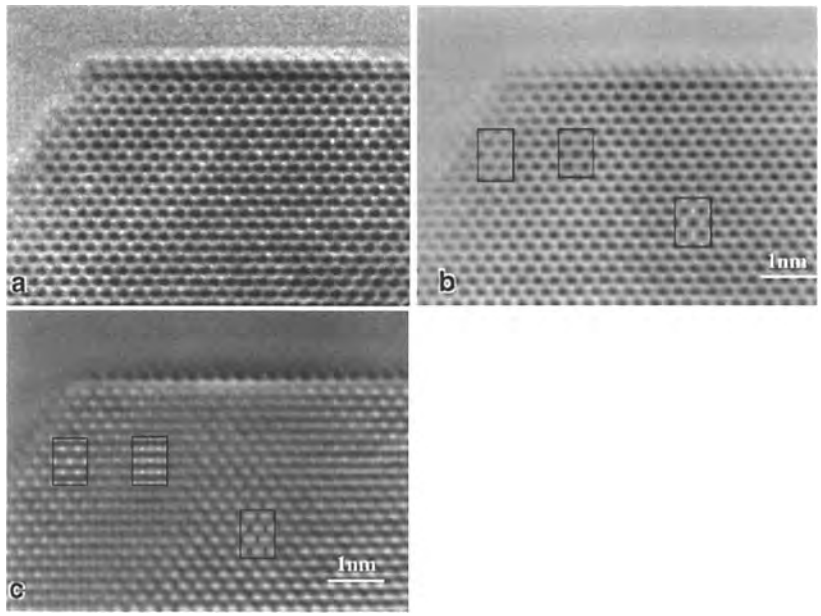

Figure 9. Profile images of the (0 0 1) surface of NiO. (a) An experimental image taken at −100 nm with a Philips CM30ST. (b,c) The amplitude and phase of the exit wave, calculated from a through-focus series of 15 images, of which image (a) is the first image. The black dots correspond to nickel columns in the viewing direction. The nickel atoms are imaged as black dots in the amplitude, whereas the white dots in the phase image correspond to the nickel positions in the thin part of the crystal and to oxygen positions in the thicker part. The black dots of the nickel columns in the amplitude at the surface are less dark, due to the larger thermal vibration, which is quite normal for atoms at the surface. The experimental image does not show this feature of less contrast at the surface because of delocalization and because it contains information from both the amplitude and the phase of the exit wave (the phase is less sensitive to differences in thermal vibration).

1.4.6 Structure of Grain Boundaries and Orientation Relationships of Adjacent Grains

The determination of grain boundary structures requires another approach to the determination of the orientation relationships between adjacent grains. Two important questions in the study of grain boundaries to consider are the structure of the grain boundary and the orientation of the grains.

The determination of the orientation relationships between adjacent grains of micrometer-sized particles can be done using SEM in either of the two modes, giving either an electron back-scatter pattern [128] or a selected-area channeling pattern [129]. For submicrometer particles, the orientation can be revealed by taking TEM diffraction patterns of each grain, or microdiffraction patterns if the grains are small. For ensembles of rather low-angle grain boundaries, methods have been developed based on obtaining Kikuchi patterns for each individual grain [130]. With the help of a computer this method is relatively fast and precise.

In many cases, sufficient knowledge of the grain boundary can be inferred from knowing the orientation of the adjacent crystals. Then the task reduces to a determination of crystal orientations. The only

way to obtain direct information of the grain boundary structure, for example how the atoms are arranged or whether there is an amorphous interlayer, is to reveal it using HREM. This, however, is far from trivial as many experimental conditions have to be satisfied:

(1) the boundary plane needs to be (almost) parallel to the electron beam;
(2) one low-order zone axis of both crystals needs to be aligned with the beam; and
(3) not too much strain should be present.

These conditions are usually only fulfilled for low-angle grain boundaries or special grain boundaries (e.g., pure tilt, symmetrical). The chance of getting close to fulfilling the stated conditions is increased for extremely thin specimens. However, other difficulties do occur with such ultrathin specimens: (i) it is difficult to prepare a very thin specimen with equal thickness over the area of interest, in particular because etching rates are orientation-dependent, and (ii) the structure of the grain boundary can be changed due to exposure to air or due to relaxation.

1.4.7 Composition of Particle Grain Boundaries

As in the composition analysis of surfaces the analysis of the composition of a grain boundary by TEM techniques is very difficult. Additional to the problems with the surface analysis, it is necessary to consider the orientation of the boundary plane with respect to the plane spanned by the detector and the electron beam, because this can influence the accuracy (or at least the spatial accuracy) of a quantitative analysis. Surface-sensitive techniques can be applied only if the material can be fractured at the grain boundaries.

1.4.8 Ageing

The performance of most materials changes in time, which is called ageing in catalyst research. To establish the mechanisms involved in ageing, a sequence of samples can be taken as ageing progresses. From the characterization of these samples, it is possible to determine the mechanisms, but in an indirect way. A more direct way is to perform the ageing on a region which is constantly monitored by a microscopic technique or to investigate the same area at certain moments of the ageing process. The first approach is restricted by the conditions required for performing the microscopic technique (TEM—vacuum, electron transparent specimen; STM—only the surface can be imaged). In this respect one can use an in situ cell (see Sec. 1.8.5 of this Chapter) or special TEM specimen holders, which allow cooling, heating, or applying strain to the specimen. Regarding the second approach, one needs a vacuum transfer system from the ageing equipment into the electron microscope and vice versa (see Sec. 1.8.6 of this Chapter).

1.5 Detailed Structure Imaging

1.5.1 Delocalization of Information

A significant problem in the characterization of small particles by HREM is the

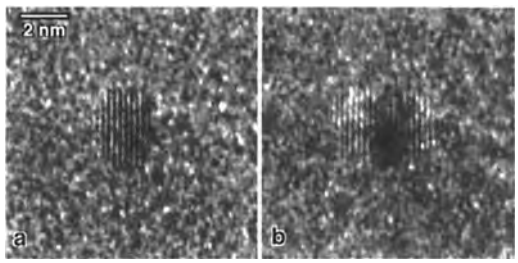

Figure 10. Delocalization of (1 1 1) fringes of platinum particles on a silica substrate. (a) The particle at about Scherzer focus (−60 nm). The (1 1 1) fringes are located close to the actual position of the particle. (b) The same particle but at a focus of −300 nm. The (1 1 1) and ( ) fringes are shifted in a direction parallel to the corresponding $\boldsymbol{g}$ vectors. The shift of these fringes is equal to gel where e and l are the defocus change and the wavelength respectively.

delocalization of information. Delocalization is illustrated in Fig. 10, which shows a platinum particle at approximately −60 and −300 nm defocus. The image at −60 nm (about Scherzer focus) shows the platinum particle with its (1 1 1) fringes at the same position as the dark feature due to the amplitude contrast of the particle. With changing focus the (1 1 1) fringes shift, resulting in a shift of about 1.5 nm for a defocus of −300 nm. The (1 1 1) and ( ) fringes are shifted in opposite directions. The shift of these fringes is equal to $\boldsymbol{g} \times \Delta f \times \lambda$ where $\boldsymbol{g}$, Δf, and λ are the reciprocal lattice vector, the defocus change, and the wavelength, respectively. Since most frequencies describing the shape of the diffraction contrast image of the particle are small, the shape is still easily visible in Fig. 10b, and is located at the actual position of the particle.

The effect of the delocalization on grain boundaries is illustrated in Fig. 7, showing an Mg–Si precipitate in an aluminum matrix. The figure shows an experimental image taken at −70 nm with a Philips CM30ST and an exit wave, calculated from a through-focus series of 20 images of which the image at −70 nm defocus is the second image. The Mg–Si precipitate contains a defect. There are three differences between the two images. The first difference is that the single image is much noisier, which is logical because for the exit wave the information from 20 images is taken, resulting in a reduction of the random noise. The second difference is that the defect in the Mg–Si precipitate is quite sharply imaged in the exit wave whereas in the experimental image the defect region seems to be much broader, which is the result of the delocalization. The third difference is that the image of the periodic structure of the precipitate is much clearer in the exit wave image, which is due to a correction for the delocalization, as for the grain boundaries.

Another advantage of the use of through-focus exit wave reconstruction is that one can use the phase and amplitude information in combination. Figure 11 shows an example of a MoS_2 slab on g-Al_2O_3. An experimental image and the exit wave reconstructed from a series of 15 images is shown. Whereas the phase image shows dark dots at the molybdenum and sulfur columns, the amplitude image highlights the molybdenum columns.

1.5.2 Image Calculations

In TEM there exist two types of image simulations: HREM (phase contrast) simulation and diffraction contrast calculation (amplitude contrast). The ultimate aim is to relate simulated contrast quantitatively to the experimental contrast, and in this way to extract important

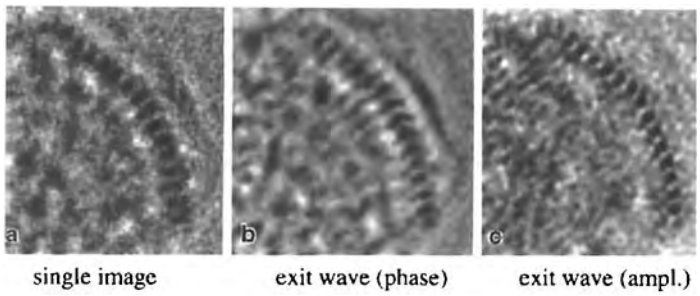

Figure 11. An experimental HREM image and an exit wave (phase and amplitude) of an MoS_2 slab on g-Al_2O_3. The exit wave is reconstructed from a through-focus series of 15 HREM images, of which the experimental image is the first. Whereas the phase of the exit wave shows dark dots at the molybdenum and sulfur columns, the amplitude of the exit wave highlights only the molybdenum atoms.

parameters about a particle. A general problem is to include inelastic scattering or electron beam-induced changes.

Simulation of HREM images of small particles can be done with most existing software packages. The unit cell needed to do a calculation is typically the whole particle, for example a spherical copper cluster with a diameter of 3 nm is roughly 1100 atoms. Experiments and HREM contrast simulation have been performed on clusters/clouds of, for example, gold and carbon on a gold support [131]. The calculations become more complex if an unknown particle–support interaction has to be taken into account. Giorgio et al. have done experiments and simulations on a Pd–MgO system where a lattice distortion due to the substrate interaction was found for 1–2 nm particles [132]. In the selection of models for such a particle–support interaction it may be helpful to perform molecular dynamics calculations (or similar) rather than using ad hoc constructed models.

Diffraction contrast calculation can be used to show not only the strain field around defects and stacking faults [133] but also around coherent precipitates, and the adhesion strain field in small particles [134]. Extinction rings in particles down to 10 nm can be observed in bright field and can be compared to simulated images [135]. Extinction rings can even be observed in smaller particles using weak beam dark field techniques [136]. Thus, adhesion strain fields allow extraction of such information as surface energy or the chemical fingerprint of a particle. In the process of proposing and calculating models of strain fields of defects, precipitates, and adhesion, it may prove advantageous to do molecular dynamics calculations as well. Since the latter calculations are able to handle more than 10^6 atoms they allow calculations of defects with a volume as large as $25 \times 25 \times 25\,nm^3$ [137].

Whereas by STM the atomic structure of steps, ad-atoms, vacancies, and other surface defects can be readily investigated [138], the interpretation of these images is certainly not straightforward. It is necessary to perform image calculations, for which one needs the local densities of states. Software to do total energy calculations of surfaces has been developed for metal surfaces, but is still under development for more complicated systems such as oxide surfaces or metal particles on an oxide substrate (one could say that image

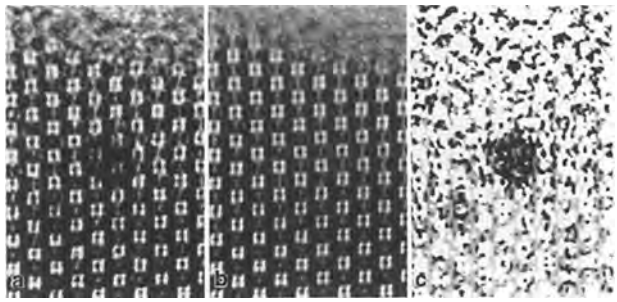

Figure 12. Image processing on an HREM image of a platinum particle in zeolite ZSM-5. (a) The raw HREM image. (b) The image after patching the area next to the platinum particle on the area of the platinum particle and averaging over four unit cells (2 × 2). (c) The difference between (a) and (b). (c) It can be seen that the platinum particle is circular, indicating a spherical particle. This particle is too large (about 2 nm) to fit into the pores of ZSM-5 (which are about 0.7 nm).

calculation for SPM is now at the level where image calculation on HREM images was about 10 years ago).

1.5.3 Averaging of Images

Averaging of images can be done in time or in space. In the latter case one averages several copies of the same image which are displaced over n times a lattice vector. In general, this is done if the information required is periodic over the vectors over which it is averaged, giving an image in which noise and local changes, which are not related to the required information, are reduced. Averaging in time is, of course, done for a given exposure time. Because of specimen drift, the exposure time has to be limited but a series of images can be taken, which by cross-correlation can be added, thus increasing the exposure time markedly [139]. Both methods are particularly useful in the investigation of materials which are beam-sensitive. An example of averaging in space is given in Fig. 12, which shows an image of Pt-loaded ZSM-5 [140]. In this example the image of the zeolite is averaged, giving an average lattice image; next, this averaged lattice image is subtracted from an image of the zeolite with a platinum particle, yielding an image from which the shape of the platinum particle can be much better determined.

1.6 Beam-Induced Phenomena

Electron beam-induced changes are mostly either a function of electron dose or electron flux. Thus, one can reduce these changes by working fast or using a lower electron flux, respectively. If one starts with a new type of material, it is advisable to record also the information (images or electron diffraction patterns) as a function of beam current. An example of electron beam-stimulated decomposition is shown in Fig. 13. This figure shows a series of HREM images of the decomposition of a single WS_2 slab into tungsten. It was found that this decomposition is strongly enhanced if the specimen is exposed to air, which indicates that adsorbed molecules

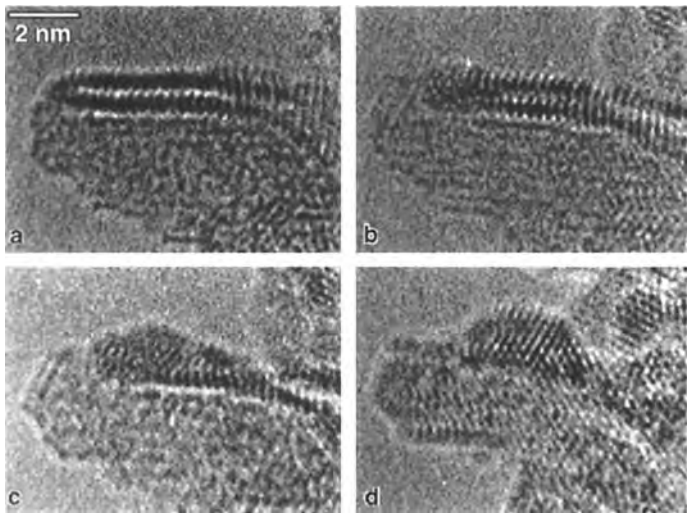

Figure 13. Series of HREM images from the same area recorded with time intervals of 2 min. The series shows the decomposition of a single WS_2 slab into tungsten. The decomposition starts at the edges of the WS_2 slab, indicating this area to have the lowest stability.

from the air (H_2O, OH^-) are an important factor in the decomposition. This points to the need for better specimen preparation procedures.

Apart from the decomposition of a phase, the surface of a specimen can be etched/evaporated by an intense electron beam. For instance, 100 keV electrons have been observed to etch holes in thin foils of crystalline and amorphous aluminum [141], creating voids and holes on a nanometer scale (1 nm in diameter) parallel to the electron beam. MgO molecules/clusters were observed to be desorbed from MgO thin films, producing square indentations and holes [142]. Similar square indentations/holes have been observed by the author to appear in $SrTiO_3$ particles under heavy electron radiation. Small particles are basically subject to similar extreme conditions when irradiated by a high-energy electron beam. Mass loss due to electron irradiation is probably closely related to particle temperature and the build-up of an electric field (charging, Auger process), possibly both in combination. Many indications have been reported that particles on supports are as susceptible to radiation damage in the sense of electron-stimulated structure alteration. There have been frequent observations of, for example, the movement and growth of metal clusters, atomic displacement, and crystal orientation changes [143]. Suddenly disappearing particles and particles vibrating violently are examples of charging effects.

Electron beam-stimulated structure fluctuations and atom desorption was suggested to be picoseconds temperature jumps above the melting temperature for gold clusters of about 1000 atoms. The mechanism reponsible for the increase in temperature was explained by M-shell ionization followed by an Auger relaxation/cascade [144]. Hobbs [145] and Reimer [146] give a general treatment of the energy deposition from an electron beam. Roughly two lines of explanation for the structural fluctations emerge [147]: (i) that a melting–recrystallization process takes place or (ii) that there is more than one 'ground state' structure that the particle can adopt when minimizing the energy.

A thorough treatment of the models and literature is given by Marks [148], alongside of which is suggested a model with a so-called 'quasi-molten' state which basically is linked to the broadening of the first-order transition by finite-size effects as found by molecular dynamics calculations [149]. The often observed difference between the beam intensity needed to start structural fluctuations and to sustain it can simply be related to the adhesive energy between particle and substrate that has to be overcome. The Auger process is further treated in detail by Cazaux [150], who emphasizes it as a major driving force for atom displacement and desorption especially in electrically insulating compounds. Extensive reference is given to example materials such as NaCl, SiO_2, Al_2O_3, MgO, and TiO_2.

1.6.1 Changes in Orientation of Particles and Particle Drifts

Some metal particles change their orientation almost continuously. Evidently, in these cases the possibility of imaging lattice fringes depends on the timescale of the orientation variations. They can be so rapid that one will not or only scarcely see some lattice fringes on a real-time camera. Quite often the rate of this change can be strongly increased or decreased by increasing or reducing the intensity of the electron beam, respectively. The most important parameter in this respect is the number of electrons per square nanometer, but quite often the total beam current on the specimen is important as well (due to heating of the surrounding area). Figure 14 shows a series of three images taken with time intervals of 2 s of gold particles on a carbon film. Due to the movement of the small metal particle towards the small one, a collapse into one particle occurs. As in this example, many other small particles also show an incorporation into a larger particle. Quite often one observes a slow movement of the particles and suddenly a very rapid movement (over 1–2 nm) of the small particle towards the larger one, such that they touch each other. Next, a sintering into one particle can occur, but one also

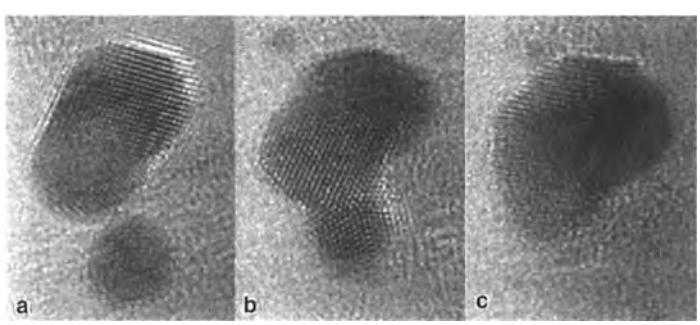

Figure 14. An example of orientation changes and sintering of gold particles, due to an intense electron beam which was about 20 times more intense than that used for normal recording of HREM images. (a)–(c) Images taken at time intervals of 3 s. In (a) two separate particles can be observed. In (b) the particles are connected, whereas they are just one particle in (c). Apart from this sintering to a larger particle, one can also observe the orientation changes of the larger particle.

observes quite often that the small particle is fixed to the larger one without sintering. This could be caused by an electrostatic repulsion or a surface layer on the particles.

1.6.2 Charging of Particles

Often catalyst/support specimens do charge. In particular, support bases on amorphous SiO_2 are susceptible to charging. Charging leads to vibration of the image and to an apparent objective astigmatism. If one is not interested in the surface of the catalytic particles, the charging can be reduced by coating the complete specimen (supported catalyst on the carbon-coated holey film) with a thin carbon layer (1–2 nm thick) (see also Sec. 1.6.5 of this Chapter). In our experience, charging can be mostly prevented by taking a few precautions:

(i) taking only small particles or ensembles which are well separated from larger particles or ensembles;
(ii) using a small probe size; and
(iii) selecting only those particles which are well supported by the carbon grid.

1.6.3 Contamination

The rate of contamination can vary strongly from one specimen to another. If that is the case, the contamination is not so much caused by the microscope but rather by the specimen itself. For instance, we have investigated a MoS_2–Al_2O_3 specimen in which with a relatively small beam (diameter 10 nm) no contamination was observed on MoS_2–Al_2O_3 particles that were over a hole in the carbon holey film, whereas a rapid contamination was observed when the beam was slightly shifted to an area where both MoS_2–Al_2O_3 particles and the supporting carbon film were irradiated.

1.6.4 Amorphization

Several catalytic materials (supports as well as the active phase) are susceptible to amorphization by the microscope. This process can be the result of the knock out of atoms (e.g., the amorphization of $YBa_2Cu_3O_7$ when 800 kV electrons are used) or of ionization. The latter is the process which leads to the amorphization of zeolites. For instance, a sodium-containing zeolite loses almost all its sodium by a reduction in Na^+ ions. Since these atoms stabilize the structure of the zeolite, to neutralize the partial substitution of Si^{4+} by Al^{3+}, it is logical that the removal or displacement of these atoms results in a collapse of the structure. Obviously the zeolite lattice is generally more stable for higher Si/Al ratios. The stability of zeolites can be improved by ion exchange with Li^+ or UO_2^{2+} ions [151].

The amorphization of zeolites can also be used in a positive way. In principle, metal particles inside the zeolite lattice can be detected, if the image is not too disrupted by the substrate. Obviously this requires that the zeolite is thin. However, the lattice of the zeolite must also not dominate. The effect of the zeolite lattice is shown in Fig. 15. If the zeolite is in a low-index orientation, most metal particles cannot be detected, no matter how

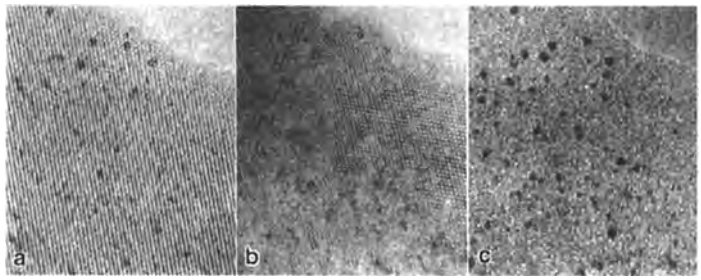

Figure 15. Platinum particles in a ZSM-5 zeolite lattice. (a) The zeolite tilted a few degrees from the [1 0 0] orientation. A number of platinum particles can be observed. (b) Image recorded after (a) and taken with the crystal in the [1 0 0] orientation. Hardly any platinum particles can be observed, which is due to the fact that the zeolite lattice is very dominant in this orientation. (c) The same area but after the zeolite has been amorphized by an intense electron beam. Platinum particles in the range from 0.7 to 2 nm can be clearly observed.

thin the crystal is. One can improve the visibility considerably by tilting the crystal out of the low-index orientation. But the visibility is greatly improved by amorphization of the zeolite lattice. An obvious question is whether the amorphization has led to sintering of the metal particles. This can be determined by comparison of the images with the zeolite lattice intact but in an orientation rotated from a low-index zone axis with an image with the same crystal orientation but after amorphization, for example Fig. 15.

1.6.5 Reduction of Surfaces

As is discussed below, the intense electron beam can cause radiolysis or even electron-stimulated desorption of atom species. This may be observed as complete depletion of a particle surface or as an alteration in the surface structure. Many observations have been reported of both oxidation and reduction under a 100–400 kV electron beam [152]. Figure 16a shows an example of the reduction of TiO_2 after

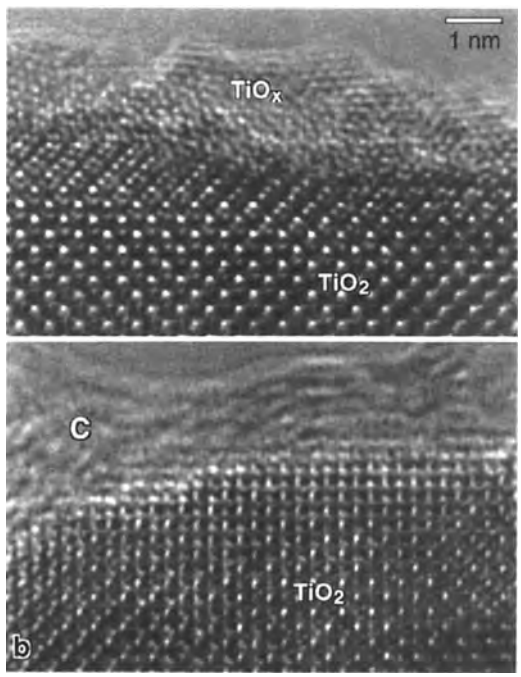

Figure 16. Example of the surface reduction of TiO_2. (a) A TiO_2 grain in the [0 0 1] orientation with a deviating structure at the edge, which is the result of the reduction of TiO_2 into TiO. This reduction progresses from the surface into the bulk upon continuing irradiation by the electron beam. (b) When TiO_2 surface is covered with a thin carbon layer, such a reduction does not occur.

10 min of exposure to an electron beam with an intensity used for HREM imaging. This reduction starts immediately and progresses steadily into the TiO_2 grain. Interestingly, however, in a similar experiment a thin carbon layer is apparently sufficient to protect the surface against radiolysis, as seen in Fig. 16b. Here the lattice image of the TiO_2 lattice parameter changes abruptly into that of amorphous carbon.

1.7 Typical Characterization Problems Related to Small Size

1.7.1 Effect of Substrate

The study of very small catalyst particles in the range of 0.3 to 1.0 nm is handicapped by the support on which the particles are located. Changes in the thickness of the support or rearrangements of the atoms at the surface of the support can lead to contrast features, which are quite similar to the contrast of the catalyst particles. In a number of cases one can do HREM to image the lattice fringes of the small particles, but quite often such catalyst particles are too small to distinguish clear lattice fringes. An example image of very small particles is shown in Fig. 4. These small particles are seen best when they are situated on very thin supports or when the surface of the substrate is thin and parallel to the electron beam. In all cases one should select those areas in which the support is very thin and, if crystalline, in an orientation in which no strong scattering occurs. Small particles can be seen best in profile imaging of very thin supports. An example of the effect of the blurring of the lattice image of a small particle by a crystalline support is shown in Fig. 17.

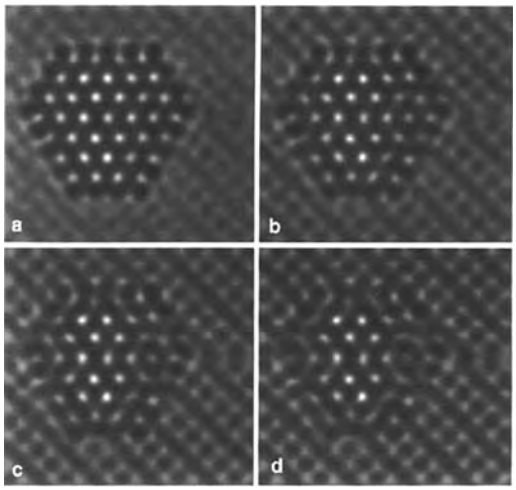

Figure 17. Image calculation of MoS_2 on a crystalline g-Al_2O_3 support. Images calculated for a single slab of MoS_2 with a thickness of 0.6 nm on top of the substrate with thicknesses of 1, 2, 3, and 4 nm are shown. The hexagonal MoS_2 lattice is only clearly visible for substrate thicknesses of 1 and 2 nm, in particular when random noise is added to the image.

In the case where one cannot observe any image features, owing to small particles, it is useful to do either local element analysis or to anneal this area with an intense electron beam, which generally results in a sintering of the very small clusters (if present) into larger ones which are detectable with TEM.

1.7.2 Inhomogeneous Distribution of Small Particles

When one deals with inhomogeneous distributions of small particles, such as catalytic metal particles in pellets (platinum in pellets of alumina, prepared by impregnation of the complete pellet resulting in a much higher platinum density near the

surface of the pellet) or an inhomogeneous size, shape, and composition distribution of precipitates (e.g., aluminum-containing Si–Mg precipitates), ultramicrotomy may be a good approach (see Sec. 1.8.1 of this Chapter).

1.7.3 Collection of Small Particles which are Finely Dispersed in a Fluid or Air

The collection of small particles finely dispersed in a fluid onto some sort of support can lead to artefacts, because of specimen support interaction and because of agglomeration. In this case one could consider the ultramicrotomy of fast-frozen specimens, as is done routinely in cryo-electron microscopy of biological specimens. As with biological specimens, using this method the 'natural' surroundings of the particles and their dispersion are maintained.

In the case of loose particles in air, these first have to be collected. Unlike dispersions in a fluid, this collection has to be done on some support or in a fluid, which is likely to result in a nonrepresentive sampling. Once the particles have been collected they can be embedded, for example in epoxy. An improved strength or density can be obtained by curing the epoxy at an elevated temperature either in a vacuum (to extract the air bubbles) or under pressure. For porous materials a complete impregnating procedure has to be applied. The epoxy 'ensemble' can be ultramicrotomed.

1.7.4 Various Special Applications

The area of particle analysis is so broad that clearly it is not possible to categorize all the special applications in this contribution. In the following, a few interesting examples (by no means comprehensive) of special applications are mentioned.

In a few cases when the particles are extremely homogeneous in all respects, these can settle into a three-dimensional superstructure [153]. Such superstructures may be interesting model systems to study hexagonal and cubic close-packed structures of large molecules. An example of the spontaneous close-packed stacking of particles is shown in Fig. 18.

In special cases where one is concerned with macromolecules (e.g., proteins) it is

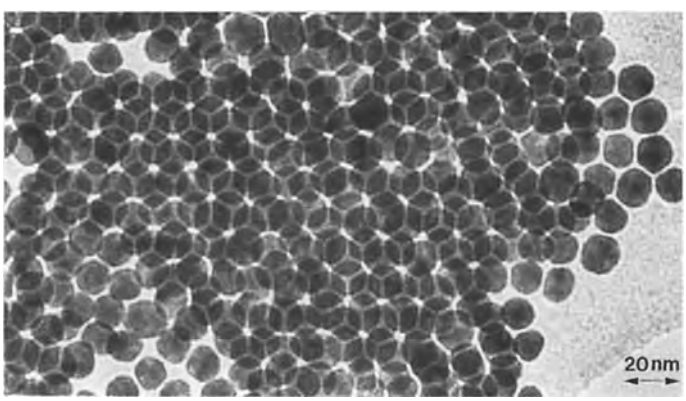

Figure 18. Example of the spontaneous stacking of large platinum clusters in an almost perfect close-packed arrangement on a carbon thin film, even though the clusters show a variation in size. This arrangement was obtained by dissolving a large agglomerate of these clusters which was already positioned on the carbon thin film. In the agglomerate the clusters did not show any ordering. The clusters were set free from the agglomate by dissolving the skin of large organic molecules (sodium sulfanifate).

possible to crystallize these into a two-dimensional crystal at a liquid–liquid interface [154]. The advantage of this technique is that it becomes possible to perform electron diffraction, thus extracting average structure information even from very beam-sensitive specimens.

It is frequently necessary to use image processing to extract useful information from the often noise-dominated electron micrograph. An ingenious example of image processing is reported in the literature [155], where 12- and 13-fold rotational symmetry is detected by rotational image averaging over a number of individual macromolecules.

In some cases one can circumvent the particle–substrate interaction by performing electron diffraction on a beam of supersonic clusters [156]. In these experiments it is possible to extract information on the mean size, the morphology, and the mean cluster temperature.

1.8 Specimen Preparation Related Topics

1.8.1 Preparation of Specimens and Supports

Four ways of sample preparation are employed: (1) crushing resulting in small, sometimes wedge-shaped fragments with a thin edge; (2) chemical polishing with a jet-stream of polishing liquid; (3) ion milling in which ions are focused onto a specimen under a low angle thus sputtering atoms and conglomerates of atoms from the surface; and (4) ultramicrotomy in which very thin slices are cut from the sample. The first technique is generally applied to some homogeneous bulk materials and can almost never be used for the study of grain boundaries and interfaces and for materials which change under the pressure of the crushing (metals). With this method the thin area is very small. The second and third techniques, presently most widely used in materials science, can provide very thin specimens. However, an inherent problem of these techniques is the presence of a layer (amorphous or crystalline) on the surface which is different from the 'real' material. The fourth method has as major disadvantages the creation of artefacts and the method of collection of the specimen, which is still done on a water surface and can result in changes at the surface of the slices. However, most artefacts created by ultramicrotomy can be identified as being due to this technique.

The surface contaminations can be divided into two groups: those due to the thinning method and those due to a reaction with the atmosphere. To minimize the first type of contamination one has to choose the best thinning method. To minimize the reaction with the atmosphere one has to perform the thinning and insertion of the specimen into the microscope in a controlled atmosphere (see Sec. 1.8.6).

Ultramicrotomy is widely used for making cuts of biological materials, and is optimized in particular for these types of specimens, but it is increasingly being used by materials scientists, in particular for polymers and catalysts [157]. It might be necessary to change the collection of the cut slices, which is routinely done on a water surface, since many specimens in materials science are sensitive to water. Cutting can be performed in a controlled atmosphere, as is done routinely

in the cryo-ultramicrotomy of biological specimens.

1.8.2 Passification of Small Metal Particles

Quite a number of catalysts consist of small metal particles, which are only stable in a reducing atmosphere. With most electron microscopes, however, one can only insert the specimen into the microscope by exposing the specimen to air. If this exposure is done instantaneously, most metal particles will be completely oxidized. In fact, such a catalyst can catch fire when exposed to air. This complete oxidation can be prevented by a process which is called passification: the catalyst is exposed to an atmosphere in which the oxygen partial pressure is slowly increased. A typical example of a too long exposure to air is shown in Fig. 19. This figure shows a nickel particle which is covered with an NiO film, due to reaction with air.

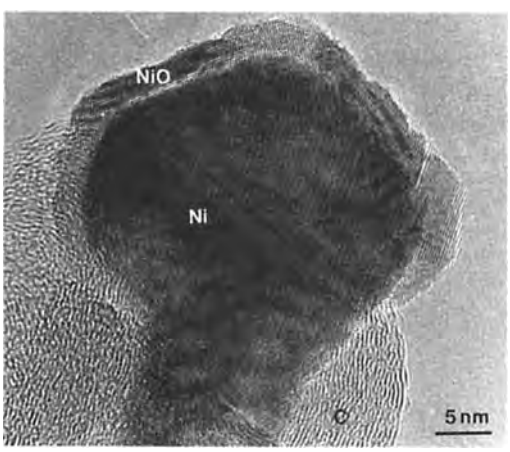

Figure 19. HREM image of a nickel particle on a carbon wire, showing the oxidation of the nickel surface due to exposure to air. Notice that no oxidation has taken place on the Ni–C interface.

1.8.3 Preparation of Holey Films and Very Thin (2 nm) Carbon Foils

Since the availability of a good thin foil support is essential to much catalyst research, we will briefly describe the preparation of thin holey films and very thin carbon films.

First, 0.2 g of Triafol is dissolved in 100 ml of ethyl acetate. After stirring for 1 h the nondissolved Triafol is separated by filtration. Next, approximately 50 ml of ethyl acetate is added to reduce the Triafol concentration (this is an essential step because if a fully saturated Triafol solution is used one may obtain a holey film with poorly developed holes). To this solution about 0.25 ml of glycerol is added, after which the solution is stirred vigorously for 30–60 min in combination with ultrasonic agitation. Next, carefully cleaned microscope glass slides are dipped into the solution. The film present on the microscope slide is floated off on a water–air interface by slowly lowering the slide under an angle of 20–45° into water. Grids are placed on the film. The whole ensemble of grids and film is removed from the water surface using filter paper with small pores. Finally, a thin carbon layer is deposited onto the ensemble, after which the grids can be taken off for storage.

For the preparation of a very thin carbon film, one starts with the holey film grids, described in the previous paragraph, but with a rather thick carbon layer deposited (the filter paper is rather gray in this case). The Triafol of the holey film grid is

dissolved, by dipping the grid in ethyl acetate. This grid is placed on a thin continuous Triafol film floating on a water surface (prepared as above but without the addition of glycerol). The grid–film ensemble is removed from the water surface by filter paper. After drying, a very thin carbon layer is deposited (in this case the filter paper has not visibly changed in color). Finally, the Triafol film is removed by ethyl acetate.

Evidently, with the present techniques of thin film deposition other types of films can be obtained by changing the carbon deposition step. This allows, for instance, the preparation of very thin films of germanium or MoSi which can be used for the determination of the information limit of the electron microscope. Another film which is more useful for catalysis research is the SiO_2 film.

1.8.4 Stability of Holey Films and Other Supports on (ex situ or in situ) Heating

If one is interested in performing TEM or HREM on exactly the same area with intermittent heating in specific atmospheres, a support is needed which is stable in these atmospheres and at these temperatures. We have experience with four types of supports:

(i) A holey carbon film on a copper or gold grid. If the temperature is higher than about 150°C a copper grid can no longer be used because copper from the grid diffuses (probably surface diffusion) into the carbon grid, thus forming a carbon grid covered with small copper or CuO particles. For this reason, it is much better to use a gold grid. The use of a gold grid is also recommended because gold is very inert in almost all catalytic reactions, such that it does not cause side-effects. One has to be aware of impurities in the gold grid, as mentioned by Datye et al. [158]. We have done reduction experiments in H_2 and H_2S up to 600°C without a noticeable change in the holey carbon film, except for very thin carbon films of about 2 nm.

(ii) A grid like that above but changed in such a way that a thin silicon layer is deposited under an N_2 atmosphere onto the carbon holey film grid, after which the grid is annealed at 400°C in air to burn off the carbon and the polymer [159]. Although the N_2 atmosphere was intended to make an Si_3N_4 film, such a film was not completely formed, which was evident from the still good electrical conductivity of the film (no charging occurred) and the rather low nitrogen signal in an EDX spectrum. Such films allow heating in air or oxygen up to 600°C.

(iii) A gold or platinum grid without any film. Particles are in this case supported by the grid itself. With this method the only limitation is that the number of particles in positions which allow TEM is small, in particular if one also wants to perform EDX element analysis, since about half of the particles are shielded from the detector by the grid.

(iv) A thin Si_3N_4 membrane on a silicon wafer with a window in the silicon wafer [160]. These membranes are

also stable against heating. A disadvantage is that the silicon wafer is rather thick (about 1 mm), making it less usable for microscopes with a small gap between the objective pole pieces.

For catalysis research several other substrates have also been reported: thin substrates have been made by ion milling or dimpling [161]; and thin planar films of an oxide are formed on a substrate, after which the substrate is removed [162], similar to the preparation of holey carbon films as discussed in Section 1.8.3 of this Chapter.

The advantage of the first four methods is that real catalytic materials can be used, whereas for the latter methods one uses the thin film or thinned area as the substrate. Another disadvantage is that the geometry of the particles on the substrate along the viewing direction does not allow imaging of the particle–substrate interface.

1.8.5 In situ Transmission Electron Microscopy

If one wants to study the surface in the state in which it was applied, one needs to create this environment in the characterization equipment. This is relatively easy to obtain in scanning tip microscopes but is generally impossible for electron microscopes. The strong interaction of electrons with atoms requires a low gas pressure. In particular, in the case of catalysts it is almost impossible to approach the real conditions, because the catalytic reactions are performed at high pressures. One can try to approach the required environment in several ways: (i) by placing an environmental cell inside the microscope or (ii) by performing all stages of specimen preparation and specimen transfer in an atmosphere under which the surface of the catalyst is not significantly changed from the arrangement during the catalytic reaction.

1.8.5.1 An Environmental Cell

Several transmission electron microscopes allow the mounting of an environmental cell between the pole pieces of the objective lens. Since this requires a large separation of the pole pieces such a cell does not allow HREM. Also, the gas inside the cell does not allow a high resolution. The gas pressure is still quite far from the conditions under which the catalysts were applied. Still, interesting studies have been done [163], in particular the sintering of metal particles and the effect of cycles of oxidation and subsequent reduction on the shape and size of metal–metal oxide particles [164]. Parkinson [165] obtained a resolution of 0.3 nm with an environmental cell with a pressure of 2.6×10^6 Pa of nitrogen. Doole et al. [166] reported an in situ cell with pressures up to 2×10^4 Pa and temperatures up to 700°C with the maintenance of good resolution.

1.8.5.2 Specimen Handling and Specimen Transfer in a Controlled Atmosphere

An alternative to an environmental cell is a method in which the catalytic reaction is performed outside the transmission electron microscope in a dedicated reactor and

with a transfer system which allows transport of the specimen from the reactor into the microscope and vice versa. This requires a transfer system allowing control of the atmosphere such that it does not cause a significant change to the catalyst particles. Obviously, one limitation of this method is the vacuum of the microscope; thus the transfer system does not require a considerably better vacuum than that of the microscope. The main advantage of this method is that the reactions can be performed under real reaction conditions. The transfer system is discussed in Sec. 1.8.6 of this Chapter.

1.8.6 Specimen Transfer under Protective Atmospheres

Although most electron microscopy techniques have become well established and appreciated, the insertion of specimens is still very primitive. Except for a few TEM and dedicated STEM instruments the transfer of specimens is done through air. The transfer through air can create serious artefacts, which will result in a situation completely different from that which one would like to study. With the high-resolution electron microscopes used nowadays even a monoatomic layer can be seen; thus, when one aims to study surface-related processes the surface must be as close as possible to its state in the catalytic reaction. Also, since for HREM very thin specimens (less than 10 nm is often the best experimental condition) are needed, even a thin surface layer of 1–2 nm (which is 10–30% of the thin foil in the viewing direction) can have a devastating effect on the images.

In the study of catalytic metal particles, the metal particles have to be passified before transport to the transmission electron microscope, by slowly increasing the partial pressure of oxygen, resulting in a thin oxide layer thus preventing further oxidation. This will produce a quite different state to that of the catalytic reaction. If this is not done carefully or if the time of exposure to air is too long, a rather thick reaction layer can be observed, as is shown in Fig. 19.

In Delft we have developed specimen-handling systems which allow transfer in a controlled atmosphere, and a specimen manipulation chamber which allows the preparation and transfer of specimens under controlled conditions; of particular interest are several specimen holders, for example the double-tilt holder, which can be used in an electron microscope with an objective pole piece separation of about 6 mm or more (e.g., Philips CM30T) and the single-tilt holder, requiring an objective pole piece separation of only 2.3 nm (Fig. 20). Other less restrictive precautions

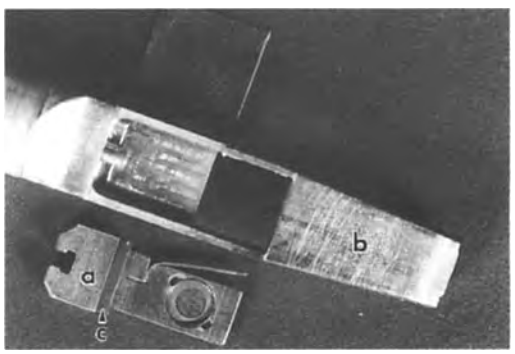

Figure 20. One of the vacuum sample holders developed in Delft. The specimen is positioned in a 'drawer' (a), which can be pushed into the tip (b) of the holder and can be closed air-tight by a flat piece of Viton (c). The mechanical stability of this holder is as good as that of a standard single-tilt holder.

are sometimes sufficient. For instance, Zhang et al. [167] made a box around the microscope with an over-pressure of nitrogen to prevent air leaking in.

1.8.7 Surface Clean Specimens

Chemical polishing with a jet-stream of polishing liquid, and ion milling in which ions are focused on a specimen under a low angle thus shooting atoms and conglomerates of atoms from the surface, presently most widely used in materials science, can provide very thin specimens. However, a problem inherent to these techniques is the occurrence of a layer (amorphous or crystalline) on the surface which is different from the 'real' material. The formation of a contamination layer can occur because of damage to the lattice by the thinning medium, redeposition on the surface of material removed from another area, and the deposition of reaction products. Lattice damage will occur predominantly with ion milling. This can be minimized by a final ion milling step at low ion energy (2 keV) and with a very small incidence angle. Redeposition forming an amorphous surface layer can also occur with ion milling. In ion milling, an amorphous layer is partly removed by finishing the process with a low ion energy and incidence angle. The deposition of reaction products will occur mainly with electropolishing. This can be reduced by using an optimized polishing liquid and minimizing the time interval between the actual polishing and the removal of the polishing liquid after the polishing is stopped. However, although the presence of an amorphous layer can be minimized by careful working, it cannot be prevented, especially when the composition or the structure of the specimen is complex (e.g., $Bi_2Sr_2CaCu_2O_8$ or grain boundaries of more simple structures).

An additional problem of TEM investigations of thinned specimen is the contamination which occurs in the electron beam. This contamination is in particular a problem when small probe sizes are used. Thus, although field emission guns as the electron source make it feasible to work with probe sizes in the range 1–10 Å, allowing the analysis of very small defects and inclusions, this analysis is often hampered by a fast contamination. With such small probe sizes the contamination can grow rapidly, thus obscuring the HREM image very quickly (within a few seconds), making it impossible to check whether or not the electron beam is still focused at the same position on the sample.

To create as little damage as possible in the top layer of the etched specimen it is necessary to transfer the minimum amount of energy to the surface atoms of the specimen. Theoretically this low-energy transfer can be achieved by directing a high energy (kiloelectronvolt) ion beam at glancing angles on the specimen. In this geometry most of the ion energy is carried away by the scattered ions. However, because of the presence of steps on the surface of the specimen a considerable fraction of the ions will enter the sample and may penetrate deeply. Low-energy transfer can also be achieved by using low-energy ions with perpendicular incidence. By doing so the problem of penetration of fast particles into the sample can be avoided.

Theoretical models for sputtering and damage production by impinging particles

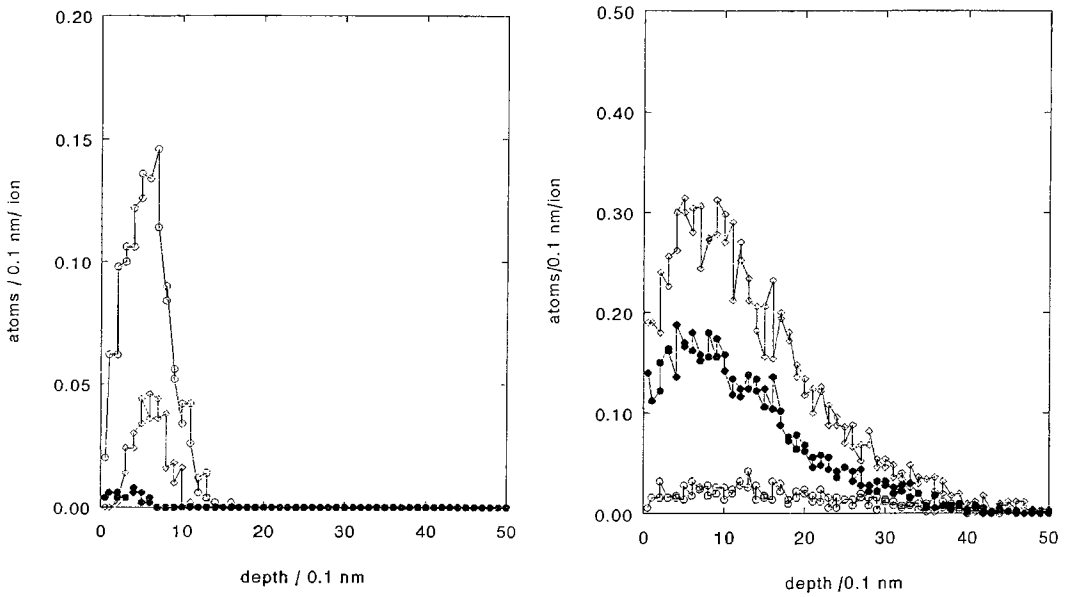

Figure 21. Range distributions of implanted and displaced atoms in $YBa_2Cu_3O_7$ calculated using the TRIM software. Depth profiles are shown of neon, copper, and oxygen (open circles, open squares, and full circles, respectively) when the high-temperature superconductor $YBa_2Cu_3O_7$ is irradiated with 40 eV perpendicularly incident Ne^+ ions (left) and 1 keV ions at an angle of 20° to surface (right).

(using the TRIM software package) indicate that it is possible to minimize the defect layer to less than 0.5 nm if light ions with an energy of about 40 eV are used. Low-energy plasma thinning and plasma cleaning are used in the fabrication of electronic devices. In order to create as little damage as possible to the remaining material, plasma energies of 50–200 eV are mostly applied. Examples of calculations for $YBa_2Cu_3O_7$ are shown in Fig. 21. There is a dramatic reduction in the range and number of displaced copper atoms when 40 eV rather than 1 keV ions are used. This occurs to the same extent for other cations. These calculations show that a low-energy sputtering treatment will preserve the structure much better. At 1 keV an amorphous layer of at least 3 nm is expected.

2 Structural Phase Transformations

2.1 Introduction

Ever since sorbite was named after Henry Clifton Sorby (1826–1908) and martensite after Adolf Martens (1850–1914) for their pioneering work in microstructural research on transformations in steels, analysis by microscopy has played a dominant role in the study of structural phase transformations. Because of the continuing importance of microscopy for the characterization of steels it is not surprising that one of the most comprehensive, systematic monographs treating phase transformations on the basis of microscopic evidence is entitled 'De Ferri Metallographia' [1]. In the present context it will not be possible to cover the subject systematically. Therefore a short overview of the main aspects of structural phase transformations and their classification will be followed by a number of examples.

2.2 Phase Transitions and Structural Phase Transformations

Phase transitions in the solid state can be associated with changes of several variables of state such as composition, crystal structure, magnetic and electrical polarization, and conductivity. The experimental study of phase transitions by structure and property measurements and their theoretical treatment are large fields of solid state physics and materials science. The term 'phase transition' refers to the thermodynamic definition by Ehrenfest [2]. It should be noted that heterogeneous transformations which can be analyzed by microscopy are first-order phase transitions, whereas transformations which do not proceed through a heterogeneous state are higher-order phase transitions and can be analyzed microscopically only if secondary features such as stress relaxation twinning of the transformation product occur.

Among the phase transitions the first-order structural phase transformations are particularly pertinent to the understanding and development of materials. The most common, diffusion controlled structural phase transformations, are associated with changes in crystal structure and composition and proceed by nucleation and growth. In some cases the crystal structure does not change (isostructural decomposition), in others the structural transformation is not accompanied by compositional changes, most noticeably in the case of diffusionless transformations. Structural

Table 1. Classification of structural phase transformations according to growth processes (after [3])

Thermally activated		Diffusionless/displacive
Short-range transport controlled	Diffusion controlled	
Polymorphic Massive	Continuous: Precipitation Isostructural decomposition Discontinuous: Precipitation Eutectoidal decomposition	Martensitic Antiferromagnetic Ferroelectric

phase transformations can proceed by a wide variety of mechanisms which, in turn, are associated with different rate-controlling processes such that the characterizing features of each transformation are essentially its *mechanism* and its *kinetics*.

Attempts to classify structural phase transformations (e.g. [3]) are invariably hampered by the multitude of factors of influence, operative mechanisms and resulting microstructural features. It will still be useful to recollect the main types of structural phase transformations in terms of features of their growth mechanisms as compiled in Table 1 (after [3]). Special features have to be taken into account regarding, for example, order–disorder, bainitic and ω phase transformations; these, however, go beyond the scope of the present discussion.

2.3 Recent Advances

The investigation of structural phase transformations has progressed substantially along with the advances in microscopic methods as described in Vol. I of this Handbook. Particularly relevant among these are:

- High resolution methods: transmission electron microscopy (TEM), field ion microscopy (FIM), scanning tunneling microscopy (STM)/atomic force microscopy (AFM).
- In situ methods.
- Image processing and automated quantitative image analysis.

The increase in lateral resolution down to atomic dimensions and the advances in methods for localized chemical, structural, and topological analysis have been decisive in gaining new and greatly improved knowledge in the field of structural phase transformations. Moreover, improved and automated methods of structural or chemical analysis have become indispensable complementary tools for the quantitative microstructural analysis of structural phase transformations. For example:

- Field evaporation of FIM surfaces and quantitative analysis by time-of-flight mass spectrometry in an atom probe.
- X-ray and neutron small-angle scattering analysis.

- Time-resolved wide-angle conventional and synchrotron X-ray diffraction analysis of structural phase transformation on heated samples.

2.4 In Situ Observations

The quantitative investigation of structural phase transformations can be extended significantly by in situ sample treatment. Inside the electron microscope thermal and irradiation interaction processes can be realized [4]. Thus different phase transformations can be studied quantitatively both at surfaces and in thin films under well-defined conditions. Table 2 gives a summary of possible electron microscopy (EM) in situ techniques. However, it should be noted that in situ techniques, especially when applied to thin films, may lead to qualitative and quantitative modifications of structural phase transformations. Some important considerations are:

- Free surfaces can be locations for heterogeneous nucleation and may lead to an increase in the rate of nucleation.
- Free surfaces are paths of high diffusion rate and may modify the growth rate.
- Free surfaces permit stress relaxation to occur such that transformation strains may be released in a different way compared to in the bulk.
- At free surfaces, heating may lead to a number of effects which can modify the mechanism and kinetics of a phase transformation; for example, the formation of oxide and other surface layers, surface faceting and grooving, and a change of chemical composition due to evaporation or absorption of components.

These indications may suffice to suggest a careful analysis of each result obtained from thin film and free surface in situ observation regarding possible deviations from bulk behavior.

Since the kinetics of structural phase transformations are often strongly affected by the structure and morphology of the reaction front, observations of growth processes at elevated temperatures by in situ TEM investigation are a powerful tool, as will now be shown for two cases. As a first example, Fig. 1 shows a sequence of phase transformations in the system MgO/TiO_2 as observed in a high voltage TEM by Hesse et al. [5, 6]. A cross-sectional sample of a TiO_2 layer on an MgO substrate was heated up to 1400 K during

Table 2. In situ EM techniques for structural phase transformations

Technique	Parameters	Reactions
Thermal treatment	Temperature, size and shape distribution of nuclei and growing particles	Nucleation, growth and coarsening processes
Sample irradiation by: Electron beam Ion beam Laser beam	Power density, plasma parameters, sample temperature, size distribution of crystalline and/or amorphous phases	Crystallization, amorphization, transformations of crystalline phases

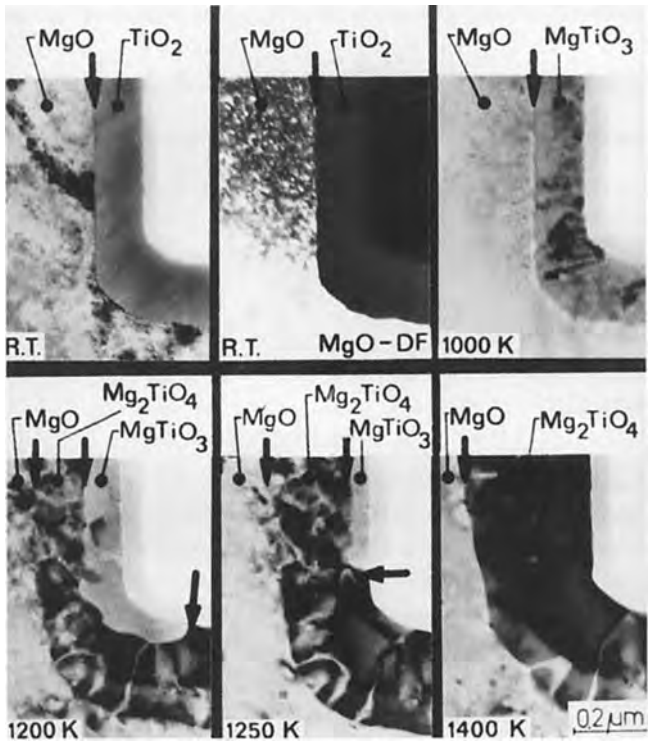

Figure 1. Phase transformation sequence in an MgO/TiO_2 cross-section by in situ annealing in a TEM [5, 6]. R.T., room temperature.

observation. At room temperature a sharp interface is visible, representing a previous cleavage surface. At about 1000 K a fine-grained $MgTiO_3$ layer forms with a high growth rate, followed by the slower formation of the more stable Mg_2TiO_4 phase at even higher temperatures. It grows at the expense of the $MgTiO_3$ layer as a completely monocrystalline phase, as concluded from in situ micro-area electron diffraction results. An interesting feature is the structure of the reaction fronts, as illustrated in Fig. 2. Both MgO and Mg_2TiO_4 crystallize in the face-centered-cubic (fcc) lattice and can form a coherent boundary. The transformation proceeds by cation diffusion, as could be shown by foreign-element marking. The unit cell of the spinel lattice of Mg_2TiO_4 ($a_0 = 0.844$ nm) has a lattice parameter almost exactly twice that of the oxygen sublattice of MgO ($a_0 = 0.421$ nm). Therefore a simple coincident site boundary $(001)_{MgO} \| (001)_{Mg_2TiO_4}$ may form as shown in Fig. 2. The position of oxygen in both lattices are marked by black dots. The cations are not shown, but different hatching indicates the different arrangements of the cations within the spinel lattice. For Mg_2TiO_4 and $MgTiO_3$ no such simple relation exists. $MgTiO_3$ has an hdp oxygen sublattice that may form a semicoherent interface with Mg_2TiO_4, corresponding to $(00.1)_{MgTiO_3} \| (111)_{Mg_2TiO_4}$.

The second example of in situ thermal treatment pertains to the crystallization of an amorphous alloy. The observation of this type of transformation by in situ thermal treatment has been applied ever since amorphous alloys have become a

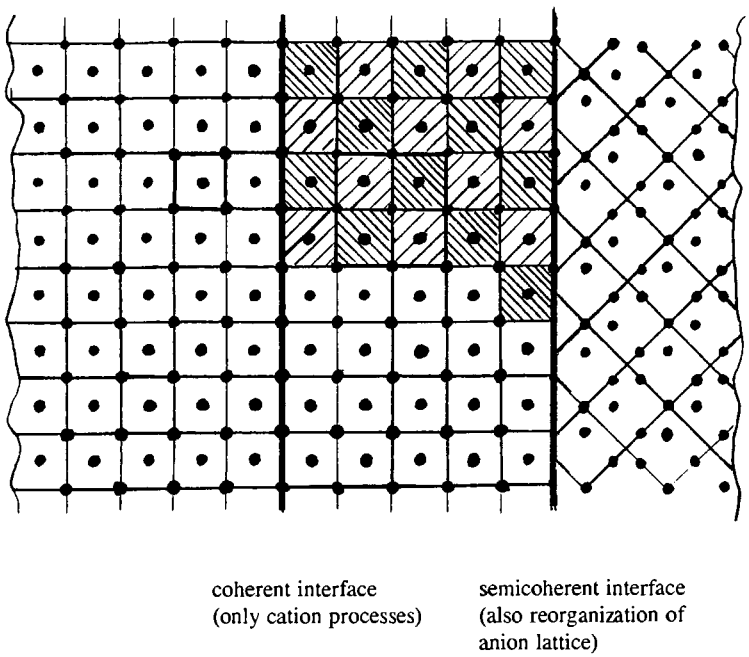

Figure 2. Structure of reaction fronts in the MgO/TiO_2 system.

subject of intensive study [7]. A direct comparison between a bright field image and a diffraction pattern is given in Fig. 3 for an in situ heating experiment of sputtered Ir–Si layers in a 200-kV TEM. Crystallization starts between 300°C and 400°C. Crystallites in the 0.1 μm size range result in ring diagrams, indicating a random orientation distribution. Above 450°C, individual rapidly growing crystals with sizes of some micrometers have formed, giving rise to single-crystal diffraction patterns. The dominant phase formed is orthorhombic IrSi; furthermore, monoclinic $IrSi_3$ precipitates.

As a second group of examples of in situ observations, crystallization and precipitation processes caused by sample irradiation, particularly with electron or laser beams will be considered. The effects are complex and depend on factors such as the type and dose of radiation, the type of sample, the temperature, and the surface state.

A particular case is the finding that the irradiation of crystalline thin layers with high-energy electrons may cause a structural phase transformation. By in situ irradiation in an analytical TEM such a transformation has been observed, as shown in Figs. 4 and 5 for a copper sample [8]. The left-hand side of Fig. 4 shows an ordered, ⟨110⟩ oriented Cu_3Au layer after low-dose ($2.3 \times 10^{27} e\,m^{-2}$) irradiation by

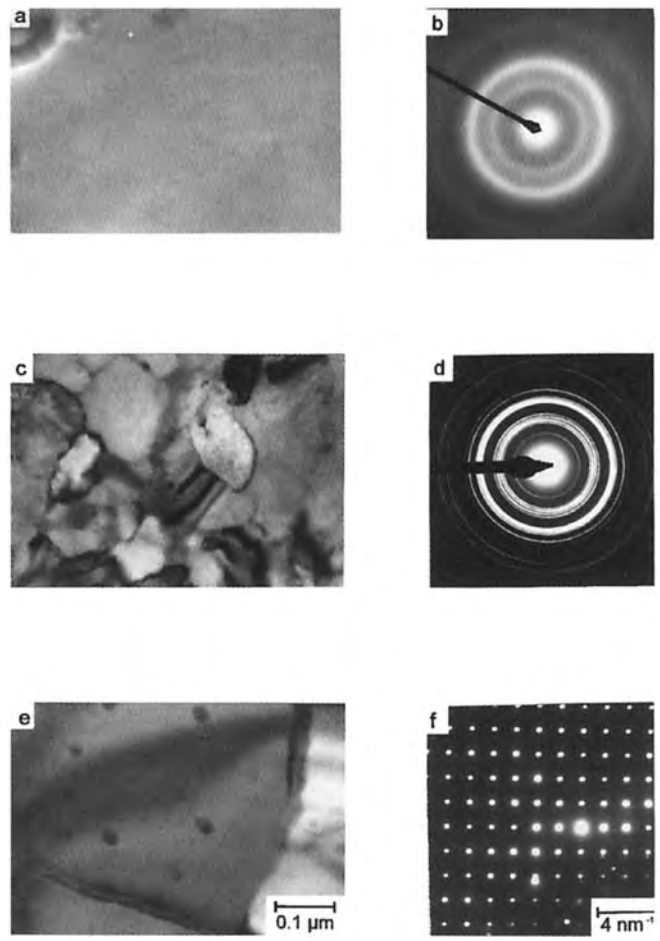

Figure 3. In situ annealing sequences of Ir–Si layers in a TEM (J. Thomas, IFW Dresden). (a, c, e) Bright field images; (b, d, f) diffraction patterns; (a, b) initial state (amorphous); (c, d) annealed up to 400°C—fine-grained, crystallite sizes about 0.2 µm; (e, f) annealed up to 700°C—coarse grained, crystallite sizes >1 µm.

400-keV electrons. The ⟨110⟩ planes of the ordered Cu_3Au phase are still visible in some places (framed). On the right-hand side of the image a transformation into a square lattice with an atomic spacing of 0.23 nm has occurred after an irradiation dose of $3.7 \times 10^{27} e\,m^{-2}$. This lattice does not correspond to any of the stable phases in the Au/Cu system. An element-analytical result was obtained by recording electron energy loss spectra, as shown in Fig. 5. The spectra were measured after electron irradiation of different doses. The net intensity at the Cu L_{23} edge decreases with increasing irradiation dose. The spectra were normalized to the Au M_{45} edge integral after background subtraction. The result was that the Cu/Au ratio in the new phase is about 1 : 1. Furthermore, the fine structure of the spectra does not show any oxidation of copper. From these results one may conclude that a new phase of the Cu/Au system has developed. Its formation may be understood from Fig. 6. With 400-keV electrons the maximum energy transfer is 19 eV to

Figure 4. TEM micrographs of ⟨110⟩ oriented Cu_3Au after 400-keV electron irradiation at total doses of $2.3 \times 10^{27} e\,m^{-2}$ (left) and $3.7 \times 10^{27} e\,m^{-2}$ (right) [8].

copper atoms and only 6 eV to gold atoms. Because the threshold energy of atom displacement in Cu_3Au is about 16–18 eV, such an atom displacement due to replacement collision sequences is possible only for copper atoms. This leads to a decrease of the copper content in the upper surface layer. When a certain concentration is reached a reconstruction occurs in this layer. As a result a new crystal structure is formed in the upper layer. By contrast, the removal of atoms from the lower specimen surface due to electron beam sputtering is possible for both kinds of atoms, because only the sublimation energy is required. This leads to thinning from the lower surface, until areas consisting of only the new phase, or even holes, occur.

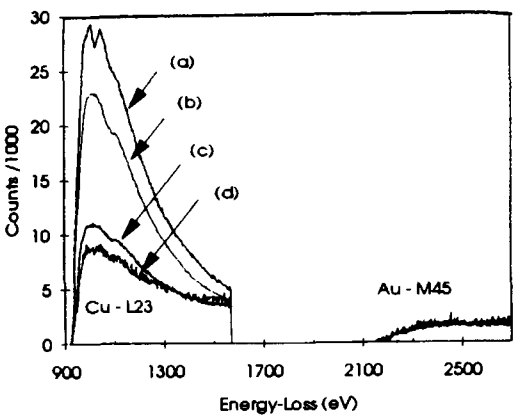

Figure 5. Electron energy loss spectra of Cu_3Au after increasing electron irradiation doses from (a) 0 to (d) $6.2 \times 10^{27} e\,m^{-2}$ [8].

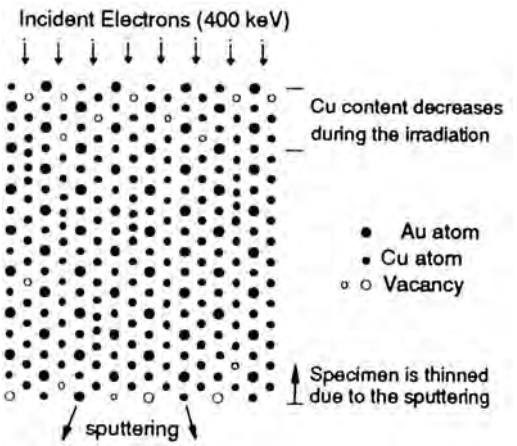

Figure 6. Formation of a new phase in a Cu/Au system [8].

The next example pertains to a phase transformation produced by laser irradiation. Figure 7 shows a transformation in a partially MgO stabilized ZrO_2 sample by in situ laser pulse irradiation in a scanning electron microscope. The sample surface was irradiated using an Nd-YAG high-power pulse laser ($\lambda = 1.06\,\mu m$; $\tau = 5\,ms$; $E'_{max} = 158\,J\,cm^{-2}$) with a Gaussian profile [9]. The depth profile of both the matrix and the laser spot was produced by means of an ion-slope cutting technique [10]. From localized X-ray diffraction patterns taken with an area detector it was

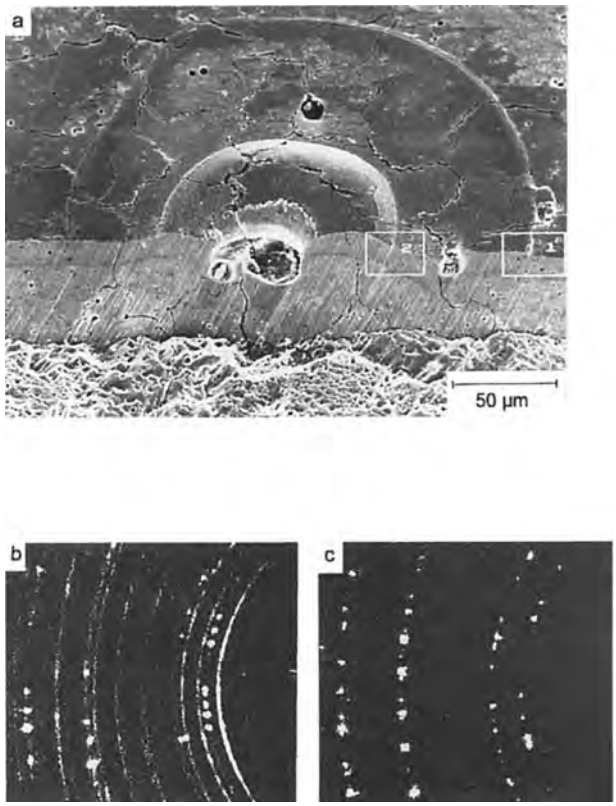

Figure 7. Phase transformation in partially MgO stabilized ZrO_2 by high power pulse laser irradiation [9, 10]: (a) ion slope cut laser spot on ZrO_2; (b) monoclinic ZrO_2 in the spot (from detail 2); (c) cubic ZrO_2 in the matrix (from detail 1).

found that the cubic ZrO_2 phase of the matrix was transformed into a monoclinic phase in the laser spot.

2.5 Investigations of Pretreated Samples

The most common microscopic investigation of structural phase transformations is carried out on pretreated samples; for example, samples annealed at a series of temperatures for different lengths of time. We also present an example of a structural phase transformation caused by ion irradiation. In the case of diffusional transformations, the microstructure observed is usually representative of the state generated by heat treatment.

However, some possible effects of specimen preparation should be kept in mind:

- Inadvertent additional 'annealing' by improper grinding, associated with heat evolution.
- 'Self-annealing' during storage at room temperature of low-melting alloys and interstitial alloys.

Such additional annealing effects may lead to additional growth, modification, or even a new variant of transformation products. In the case of diffusionless

transformations, possible effects during preparation are:

- Stress-induced formation of surface transformation products.
- Additional transformation of thin (e.g. TEM) specimens by stress relaxation effects which promote nucleation and growth [11].
- Reorientation of microstructural variants of a transformation product by stress relaxation effects.

In view of these and other possible processes which may occur in unstable or metastable states, a critical assessment of the microstructural observations is always to be recommended. The subsequent examples have been deliberately taken from a wide variety of materials and transformations.

Resistive Cr/Si films are produced by reactive magnetron sputtering in an oxygen atmosphere. In their final state they consist of conducting Cr/Si phases and isolating oxide phases. The electrical resistivity and its temperature coefficient can be adjusted by varying the oxygen content and the annealing treatment. For TEM investigations, particular thin films were deposited on NaCl; the rock salt was subsequently dissolved such that the films could be investigated by TEM without further preparation. Three examples of the structural phase transformation occurring during annealing at 600°C are shown in Fig. 8.

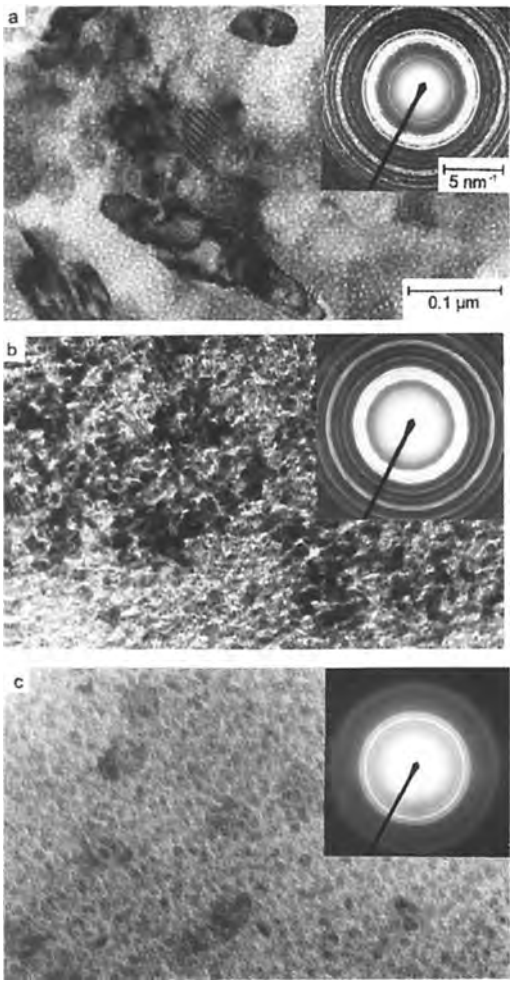

Figure 8. TEM images and electron diffraction patterns of reactively sputtered Cr/Si/O films, subsequently annealed at 600°C [12]. (a) 0 mass % O_2: $CrSi_2$ precipitates, ca. 100 nm. (b) 43 mass %: $CrSi_2$, Cr_5Si_3, and SiO_2 crystallites, ca. 20 nm. (c) 56 mass % O_2: Cr_3Si crystallites, ca. 10 nm, and amorphous SiO_2 matrix.

With increasing oxygen content, the Cr/Si phases precipitated increase in chromium content ($CrSi_2 \rightarrow Cr_5Si_3 \rightarrow Cr_3Si$), SiO_2 forms in crystalline and then amorphous structure, and the size of the precipitates decreases from 100 to 10 nm. The crystallographic analysis was corroborated by quantitative analysis of the diffracted intensities and evaluation of the radial density function derived from the intensity function [12].

We now turn to an example of advanced quantitative analysis of early stages of continuous precipitation. This

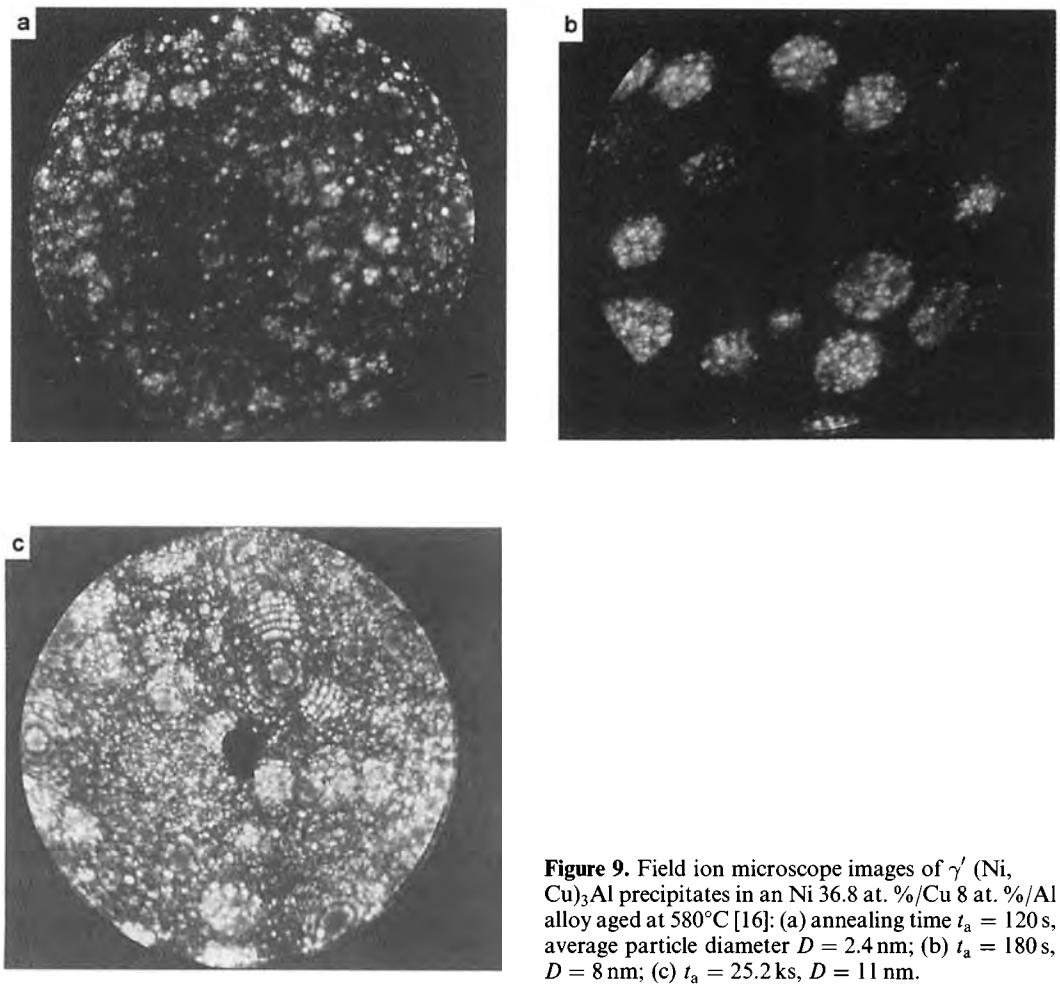

Figure 9. Field ion microscope images of γ' (Ni, Cu)$_3$Al precipitates in an Ni 36.8 at. %/Cu 8 at. %/Al alloy aged at 580°C [16]: (a) annealing time $t_a = 120$ s, average particle diameter $D = 2.4$ nm; (b) $t_a = 180$ s, $D = 8$ nm; (c) $t_a = 25.2$ ks, $D = 11$ nm.

case illustrates that atom probe, field-ion microscopy is a powerful tool. A meticulous study of coherent precipitation in Ni/Al and Ni/Cu/Al alloys was directed towards a quantitative understanding of the kinetics of precipitation from nucleation through growth till coarsening, and a comparison with theoretical treatments [13–16]. In these investigations the specimens were homogenized, quenched, and annealed in wire form at different temperatures for varying lengths of time. They were subsequently prepared into FIM tips and investigated by controlled pulsed field evaporation in combination with atom probe mass spectrometry. Typical FIM images are shown in Fig. 9, which shows progressive evolution of γ' (Ni, Cu)$_3$Al precipitates as a function of annealing time. Based on counts and analyses of field evaporated atoms, the time dependence of the average particle diameter D and the volume fraction of the precipitates, and thus the course of the transformation process, could be studied with sufficient accuracy to compare it with

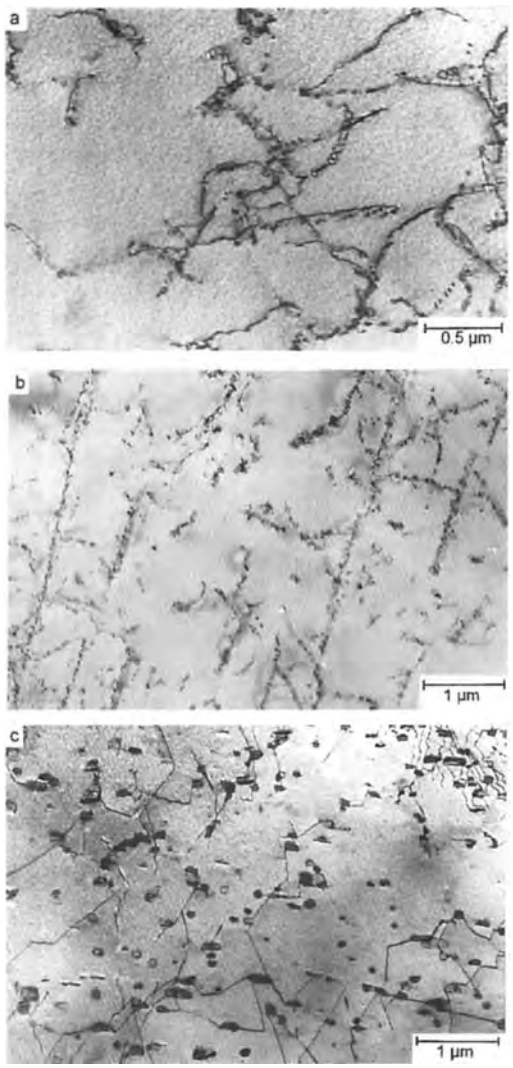

Figure 10. Vanadium nitride precipitation from α-iron solid solution in an Fe 0.1 mass %/V 0.01 mass %/N alloy via heterogeneous nucleation [17]: (a) cooled at 10 K s^{-1} from 900 to 700°C; (b) annealed for 300 s at 850°C; (c) annealed for 3.6 ks at 850°C.

the kinetics predicted by different theoretical models.

A case of heterogeneous nucleation and subsequent growth and coarsening is shown by the next example, which was based on observations of an Fe 0.1 mass %/V 0.01 mass %/N alloy [17]. Rapid cooling at 20 K s^{-1} from the α solid solution range (>900°C) to 700°C leads to the formation of dislocation loops from pre-existing dislocations (Fig. 10a). This process may be promoted by solute segregation (rather than vacancy diffusion) to the dislocations. On subsequent annealing at 850°C the loops serve as nucleation sites (Fig. 10b) by the combined effect of local solute enrichment and strain fields that reduce the strain energy per unit volume of a nucleus. Finally, prolonged annealing leads to coarsening of the particles and straightening of the dislocations (Fig. 10c). The latter observation indicates that the transient segregation effects have given way to the approach to equilibrium between the α solid solution and the vanadium nitride phase.

As a final example, transformation by ion irradiation resulting in amorphization is demonstrated in Fig. 11 [18] which shows the cross-section of a nuclear particle track caused by a 1.33 GeV uranium ion in GeS. The longer axis of the elliptic cross-section is aligned along the crystal direction with the smallest lattice parameter (i.e. with the highest density of atomic packing). The surface is parallel to (010) and irradiated perpendicularly. Whereas the lattice resolution is visible in the parent crystal, the center of the ion track has been transformed into an amorphous phase.

2.6 Concluding Remarks

High magnification and high resolution microscopic methods combined with

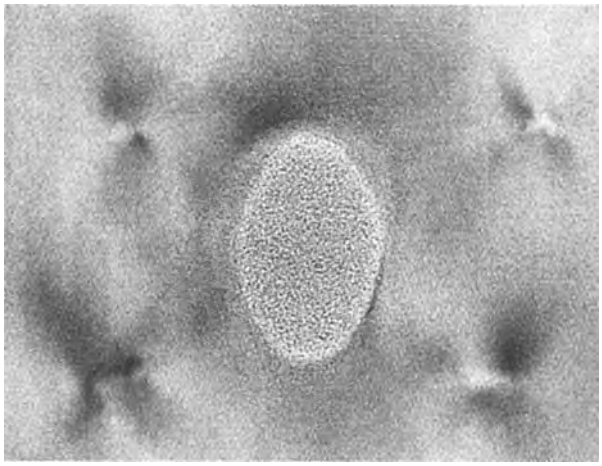

Figure 11. Amorphous track of a uranium ion in GeS, recorded using high resolution TEM [18].

diffraction and spectroscopic methods are obviously powerful tools for elucidating structural phase transformations. Advances in instrumentation and methods permitting increasingly detailed microstructural analyses for quantitative evaluation of mechanisms and kinetics, essentially down to the atomic level [19] have allowed considerable advances to be made in the understanding of transformations.

3 Preparation Techniques for Transmission Electron Microscopy

3.1 Indirect Investigation of Materials

3.1.1 Surface Investigation in Transmission Electron Microscopy: Replica Techniques

The geometry of the growth surface of thin films, powder materials, growth or fracture surfaces of bulk crystals, effects of different actions on the surface morphology (i.e. ion bombardment, thermal evaporation, dissolution, etc.) provide plenty of information on the material under investigation. Surface structure details below 0.1 μm are inaccessible to optical microscopy, and even with scanning electron microscopy it is difficult to resolve fine detail at sufficient contrast of the surface structure below this limit. A powerful complementary technique to light microscopy and scanning electron microscopy (SEM) is the transmission electron microscopy (TEM) replica technique [1–3].

The different replica techniques can be classified as follows:

(i) Single-stage replicas.
(ii) Two-stage replicas.
(iii) Diffuse (covering) replicas of C + P*t*.
(iv) Extraction replicas.

Except for technique (ii), these techniques damage the sample being investigated, usually by dissolution. Technique (ii) may preserve the sample, as only a plastic imprint is removed from its surface.

3.1.1.1 Preparation of Single-Stage Replicas

These replicas can be prepared from materials surfaces, which can be dissolved in an appropriate solvent, leaving a thin carbon layer and shadowing film intact. This is applicable for most metals and semiconductors.

The surface from which a replica is to be prepared must be clean. The most suitable surfaces are freshly prepared surfaces.

The sample needs to be evacuated to a pressure of about 10^{-4} mbar, then a thin shadowing film (Pt in most cases, but W, Ta or WO_3 can also be used) is deposited on the sample surface at an oblique incidence (Fig. 1). The more grazing the shadowing angle is, the longer are the shadows that surface irregularities form. Immediately after shadowing, C is deposited on the same surface to fix the Pt (W,

Ta or WO_3) pattern formed previously. The direction of C deposition is unimportant, though it must remain at 60–90° to the surface.

In the case of a C + Pt replica, one usually uses a combined source (Fig. 2) for the deposition of both Pt and C. This source can be two carbon (graphite) rods, one of them thinned at its tip and having a hole in this tip for Pt, or Pt is screwed onto it [2, 4]. Pt is usually used in the form of a thin (e.g. 0.2 mm) wire. When heating up the carbon rod by direct heating, Pt evaporates, shadowing the sample, and then C follows, fixing the Pt distribution.

The sample–source distance is usually around 10 cm. The Pt + C replicas are then floated off in an appropriate solvent of the sample or simply in water, and the pieces collected on microgrids, usually 200 mesh, but other microgrids can also be used. The sample can be washed in distilled water a
