Caution

Treat all chemical substances as if they have dangerous properties.

The publisher makes no representation, express or implied, with regard to the accuracy of the information contained in this Dictionary, and cannot accept any legal responsibility or liability for any errors or omissions that may be made.

The specific information in this publication on the hazardous and toxic properties of certain substances is included to alert the reader to possible dangers associated with the use of those compounds. The absence of such information should not however be taken as an indication of safety in use or misuse.

Preface

Although modern analytical chemistry relies heavily on instrumentation and data processing, organic reagents play an important role across the whole range of analytical procedures. Their uses vary from pH buffers to NMR shift reagents, and from chromogenic reagents to enzyme substrates and chromatographic derivatisation reagents. This Dictionary, one of a series derived from the Chapman & Hall Chemical Database, provides extensive and carefully constructed documentation of the (mainly organic) reagents most commonly used by analytical chemists working in academia, industry or the public domain.

Use of the *Dictionary of Analytical Reagents* is greatly facilitated by the innovative indexing systems, which give rapid access to concise, carefully edited information on each reagent, which then provides a convenient reference point for further queries using other printed and on-line sources. Thus, in addition to the usual indexes of reagent name, molecular formula and CAS Registry number, compounds are also indexed according to their use (such as spectrophotometric reagent or NMR shift reagent), inorganic analyte, and class of compound (such as crown ether or β -diketone).

A small proportion of entries in the present Dictionary derive from the Fifth Edition of the *Dictionary of Organic Compounds* (1982) and its supplements, heavily augmented with the addition of large amounts of pertinent information for analytical chemists. However, most of the entries are completely new and have been compiled over the past three years by a team of specialist contributors.

The selection of entries has been carefully reviewed by the Editors at each stage of the development of the Dictionary. We believe that the result will be of the maximum utility for the analytical chemist within the most practicable compact size.

Introduction

1. Using the Dictionary

The Dictionary is arranged alphabetically by entry name. Every entry is numbered to assist ready location. Many reagents are included as derivatives of main entry compounds; the extensive indexing of the Dictionary means that these can be readily located through the Name, Molecular Formula or Type of Compound indexes.

Indexes

There are four printed indexes:

Name Index. This lists every name given throughout the Dictionary, whether it refers to an entry, stereoisomer or derivative, and including some names embedded in the text of entries.

Molecular Formula Index. This lists all molecular formulae given in the Dictionary in Hill convention order. Molecular formulae are reported for all reagents but not normally for derivatives such as hydrates or salts of neutral compounds. Cationic compounds are given a molecular formula which is that of the cation and the various salts are listed as derivatives, together with their molecular formulae.

CAS Registry Number Index. Lists all CAS (Chemical Abstracts Service) Registry numbers given throughout the Dictionary in serial order.

Type of Compound Index. This valuable index classifies all reagents included in the Dictionary under three or more of approximately 200 headings according to analyte (e.g. copper), compound group (e.g. phenothiazine) and analytical application (e.g. chromatographic derivatisation reagent). A full list of the headings used is given at the beginning of the Index.

2. Compound selection policy

In compiling this Dictionary the aim of the International Editorial Board has been to select all those reagents thought to be of interest to the majority of analytical chemists. This has been done by consulting laboratory chemical suppliers' catalogues, IUPAC analytical reagent recommendations and by searching the primary literature. It does not include macromolecular materials, such as enzymes, ion-exchange resins and antibodies which, although widely used in analytical procedures, cannot readily be defined by a molecular formula.

3. Chemical names and synonyms

The Dictionary contains a wide range of synonyms which may be (a) those found in the primary literature, (b) *Chemical Abstracts* names, (c) a small proportion of names added editorially to achieve as much consistency as possible, or (d) tradenames and *Colour Index* names.

Most entries are headed by a systematic name but in the case of very well known reagents the trivial name is preferred. Care has been taken to incorporate as many helpful synonyms as possible, including trivial and semitrivial names, generic names and tradenames (including *Colour Index* names).

Frequently a trivial name of a reagent strictly applies to a derivative of the parent compound (e.g. a sodium salt or a hydrochloride) but for ease of use the trivial name is used as the entry name and an appropriate note to this effect is added to the entry.

Names corresponding to those used by CAS during the 8th and 9th Collective Index Periods (1967–1971 and 1972–1976 respectively) are labelled with the suffixes 8CI, 9CI. Names first introduced since 1976 are referred to as 9CI as there have been no substantial changes of CA nomenclature affecting organic compounds since that date.

If a compound cannot be located immediately in the main body of the entries, **it is important to use the indexes.**

Tautomerism

Some of the analytical reagents with more than one functional group are capable of tautomerism, the nature of which may be influenced by solvation and, especially, complexation.

The following example shows the type of tautomerism frequently encountered amongst azo compounds in particular, and which may lead to difficulties in registering the compound in *Chemical Abstracts* and in this Dictionary.

The tautomeric equilibrium even in neutral solution will be shifted according to the precise structure of the reagent, and for a particular compound may or may

Introduction

not have been investigated in detail. The CAS policy for registering such compounds is generally to index them under the azo tautomer whether this is the predominant tautomer or not. There are some exceptions to this, for example acetoacetanilide azo derivatives are indexed under the ketohydrazone tautomer. The Dictionary policy is to list the compound under the CAS name but to present the structure of the more favourable tautomer. A comment to indicate the likelihood of tautomer formation is usually added (see for example entry no. H-00391). Where CAS numbers have been assigned to individual tautomers these are listed at the end of the entry in brackets.

4. Bibliographic references and literature coverage

The selection of references is made with the aim of facilitating entry into the literature for the user who wishes to locate more detailed information about a particular compound. Reference contents are indicated using suffixes e.g. (*detn*, *Au*).

Journal abbreviations generally follow the practice of the Chemical Abstracts Service Source Index (CASSI). In patent references, no distinction is made between patent applications and granted patents. Wherever possible, English-language patent equivalents are quoted.

In compiling this Dictionary the primary literature has been surveyed to early 1992 and extensive reference has been made to reviews available at that time.

5. Hazard Information

Many reagents are toxic. Information on their toxicity is highlighted by the use of the symbol \triangleright , which also appears in the indexes. Whilst every effort has been made to alert the user to potential hazards associated with particular reagents, **the absence of such information cannot be taken as a guarantee of safety in use or misuse**. The information provided is given in good faith but the Editors cannot be held responsible for any inaccuracies therein.

Analytical Reagents

Despite the major advances that have been made in analytical instrumentation in the past decade, it is still rare for an analytical measurement to be made on a sample without the use of chemical reagents. Pre-treatment of the sample may simply be the adjustment of pH or precipitation of unwanted compounds, or it can involve conversion of the analyte into a form suitable for quantitation by a particular instrumental technique. Examples of the latter are the use of chromogenic reagents for the spectrophotometric determination of metal ions and the derivatisation of organic compounds prior to gas chromatographic separation and detection. Most reagents used for such purposes are organic compounds, and it is such compounds that are described in this Dictionary. Uniquely in the Dictionary, the reagents are also indexed according to their analytical application, inorganic analyte and type of reagent. More detailed discussions of the applications of analytical reagents are available in numerous textbooks and review articles.

1. Description of main applications of analytical reagents

In this Dictionary, the following analytical application areas are identified. Reagents having entries in the Dictionary are indicated in boldface type.

1.1. Amperometric reagent

Amperometry is the determination of a species by titration with a reagent whilst monitoring the change in the voltammetric current. The current may be that produced by oxidation or reduction of the analyte or the titrant, or both. The end-point of the titration is indicated by a sharp break in the titration graph.

The titrant may react with the analyte to form a complex which is not electroactive at the potential used, or a precipitate.

1.2. Buffer (pH)

pH buffers are substances that resist a change in the pH of a solution when acid or base is added. Simple buffers are mixtures of, e.g. a weak acid and its anion (acetic acid/sodium acetate), and are widely used. However, in some instances, the buffer components interact in undesirable ways with the analytical system, especially when biochemical studies are being undertaken, e.g. by forming complexes or by inhibiting enzymes. To minimize such interactions, a series of zwitterionic *N*-substituted amino-sulfonic acids (the so-called “Good” buffers) have been introduced, which include compounds such as **4-(2-Hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES)**. The pH of particular buffer solutions may be calculated from the pK_a values for the buffering compound, or found in one of numerous compilations.

1.3. Chemiluminescence generation agent

Chemiluminescence (CL) is the light generated by a chemical reaction. The product of the reaction is formed in an excited state, which can then emit light, or transfer its energy to another species (sensitizer, fluorophore) which then emits. The most common CL reaction is the oxidation of **Luminol** (5-amino-2,3-dihydrophthalazine-1,4-dione, catalysed by various metal ions) in alkaline solution, to form the emitter 3-aminophthalate:

Analytical applications of CL measurements based on luminol involve determination of the oxidant, or trace metal catalyst, or monitoring various enzyme-catalysed reactions which produce hydrogen peroxide, which is then determined by CL. Glucose determination using glucose oxidase:

is a typical example.

A useful way of generating sensitized CL is by the use of aryl oxalates such as **Bis(2,4,6-trichlorophenyl) oxalate**. On oxidation they only emit very weak CL, but they are capable of stimulating intense

luminescence from a wide range of fluorophores, including polyaromatic hydrocarbons and rhodamine-type compounds. The reactions are usually used for determination of fluorophores, often on-line after liquid chromatographic separation.

1.4. Chromatographic derivatisation agent

Gas and liquid chromatography are extremely popular analytical techniques for analysis of multi-component mixtures. Supercritical fluid chromatography, capillary electrophoresis and ion-exchange chromatography have also become popular in the last decade. Derivatisation in chromatography is often required either to improve the amenability of the analytes to chromatographic separation or to improve their detectability. For example, methylation or silylation is often used to make compounds more volatile, so that they can be separated and determined by gas chromatography. Analytes can be converted to fluorescent derivatives (before or after liquid chromatographic separation) so that they can be detected with great sensitivity by their derivative's fluorescence. A typical example is the reaction of amines with **1,2-Benzenedicarboxaldehyde** in the presence of 2-mercaptoethanol to produce a fluorescent derivative:

1.5. Enzyme substrate or co-factor

Enzyme-catalysed reactions are widely used for analytical purposes, for the determination of substrates (e.g. glucose oxidase for determination of glucose) and of inhibitors (such as pesticides, by their inhibition of cholinesterase) and activators. Although enzymes are very useful as analytical reagents, they are not classified individually in this Dictionary. However, enzymes themselves are extensively assayed by clinical chemists, biochemists, forensic scientists and food chemists, and the substrates used for such assays are carefully chosen to achieve optimum sensitivity, selectivity and reliability. Such substrates are listed in this Dictionary, as are the co-enzymes (co-factors) required by many redox enzymes, for example nicotinamide adenine dinucleotide (NAD^+/NADH) which is a co-enzyme for many dehydrogenases, e.g.

1.6. Extractant

Analytes can be separated from the sample matrix (or vice versa) or from other analytes by extraction into a water-immiscible liquid phase. Such extractions are carried out for a number of reasons (removal of, or from interfering species, increasing the analyte concentration, improving the detectability of the analyte). For most organic analytes, extraction takes place without the aid of another reagent, although recently the improved extraction achieved with the aid of micelles or cyclodextrins has been extensively investigated. The main exceptions are the extraction

Analytical Reagents

of charged species, such as quaternary ammonium ions, or long chain sulfonate ions, which is achieved after ion-pair formation with a bulky anion (e.g. **Methyl orange**) or cation (e.g. **Methylene blue**), respectively. In such instances, the highly coloured extracted species are readily detected by spectrophotometry.

Inorganic ions can also be extracted with the aid of organic reagents. Oxoanions such as $\text{Cr}_2\text{O}_7^{2-}$ can be extracted as ion pairs with bulky cations e.g. benzyltributylammonium ions. Metal ions can be converted into chelates. If the chelate is uncharged, as, for example, in tris(8-quinolinolato)aluminium:

it is likely to be readily extractable (and to precipitate from aqueous solution). If it is charged, as in **Tris-(1,10-phenanthroline- N^1, N^{10})iron(II)(2+)** (ferroin), a polarizable counterion e.g. iodide or thiocyanate can be added to facilitate extraction.

1.7. Fluorescent label

Fluorimetry provides a very sensitive means of detection in organic and inorganic analysis. Most analyte species, however, are not fluorescent, or are only weakly so. Thus, if they are to be detected fluorimetrically, they have to be 'tagged' or 'labelled' with a fluorophore by reaction with derivatives of molecules such as **Fluorescein**, **Anthracene** or **Rhodamine B**. Such derivatives are valuable for liquid chromatographic detection. They are also useful for labelling of antibodies or antigens in immunoassay procedures, and for labelling of DNA fragments.

1.8. Gravimetric reagent

Most inorganic ions can be determined by precipitation, collection of the precipitate, and either weighing the dry precipitate as such or after conversion to another (more stable) compound, usually by heating. Certain organic reagents have been particularly effective as gravimetric precipitants because the compounds formed are readily filtered off, have a reproducible, stoichiometric composition, and can readily be dried and weighed. The analyte element proportion of the precipitate is often quite small, so that a small amount of analyte gives rise to a large weight of precipitate, which can be weighed relatively precisely. For example, reaction of aluminium with 8-quinolinol produces a precipitate that contains 5.9% by weight of aluminium.

1.9. Indicator

An indicator is a compound that is added to a solution being titrated to indicate the equivalence point of the titration. During the titration, there is an abrupt change in a visual property of the compound, denoted the 'end-point' which, if the indicator has been properly chosen, will be coincident with the equivalence point. The visual property involved is usually colour, i.e. there is a distinct colour change at the end point, but there are many examples of fluorescent indicators and chemiluminescent indicators, where the end-point is usually indicated by the appearance or disappearance of luminescence.

The mode of action of the indicator depends on the type of titration:

(a) Acid-base

An acid-base indicator is a weak acid or weak base, whose conjugate forms have distinctly different colours, e.g. for an indicator A which is a weak acid,

A and A^{\ominus} have different colours. The colour of the solution during the titration depends on their relative concentrations, which in turn depends on the pH of the solution and the acid dissociation constant of the indicator (k_A). A colour change is visible approximately from $[A] = 10[A^{\ominus}]$ to $[A] = 0.1[A^{\ominus}]$, so the pH range for the colour change is given by $(0.1 - 10) k_A$. A typical example is **Methyl orange**.

(b) Argentimetric (adsorption)

The end-point of a precipitation titration of substances (usually halides and pseudohalides) with silver ions can be detected by the change in colour of certain compounds adsorbed on the precipitate. The colour change results from a change of the charge on the precipitate surface at the equivalence point, which leads to a change in the light absorption properties of the adsorbed indicator. The best-known example is **Fluorescein**, which changes from colourless to pink when silver ions become in excess in the solution.

(c) Compleximetric

Almost all compleximetric titrations of metal ions are carried out with EDTA or related compounds as titrant. The equivalence point, when all the metal ion

has just been complexed by titrant, can be located by using chromogenic complexing agents which form significantly weaker complexes with the metal ion than does EDTA. The final drops of titrant remove the metal ion from its coloured complex, thus causing an abrupt colour change. A large range of spectrophotometric reagents for metals can be used as compleximetric indicators. Typical examples are **Xylenol orange** (an iminodiacetic acid derivative) and **Chrome black special** (Eriochrome black T, an azo dye). A limited number of fluorescent indicators is also available. These become fluorescent when their metal chelates are dissociated at the end-point.

(d) Redox

The equivalence point of a given redox titration occurs at a particular electrochemical potential, governed by the standard redox potentials of the reactants and the reaction conditions. A redox indicator is a compound that reversibly changes its colour (or, rarely, luminesces) at a particular potential. Thus the indicator is chosen so that its transition potential overlaps the equivalence potential of the titration system.

There are two main types of indicator. One involves a complex of a metal ion, which changes colour when the oxidation state of the metal ion changes. The iron-1,10-phenanthroline system is a typical example, the iron(II) chelate (ferroin) being red, the iron(III) chelate (ferrion) being essentially colourless (actually very pale blue). The transition potential is about 1.1 V, so the indicator is very suitable for use in titrations with cerium(IV) in sulphuric acid. The second type of indicator comprises various types of organic compound (aromatic amines, triphenylmethane dyestuffs, for example) which can be oxidised and reduced reversibly, and change colour on doing so. **N,N'-Diphenylbenzidine** is a typical example.

1.10. Masking agent

A masking agent is a molecule that binds with another species to form a soluble product, thus preventing it from reacting with a particular analytical reagent and interfering with an analytical measurement. In most instances, such masking agents are complexing agents, and act by complexing with the potential interferent so that it does not participate in the

Analytical Reagents

analytical reaction. The analytical reaction may itself be a complexing reaction, but also could be, for example, precipitation, a redox reaction (including an electrochemical process), or extraction. Some typical examples are given below. Small amounts of Cu(II) can be separated from Hg(II) by extraction with **Dithizone**, if a 1M bromide solution is used to mask (i.e. complex with) the Hg. Oxalate, tartrate or citrate can prevent precipitation of the hydrated oxides of Fe(III) or Al. Triethanolamine masks Al and Fe(III), thus allowing the titration of Ca with EDTA in the presence of these other ions using murexide as indicator. In this last example, the masking agent also prevents reaction of Fe(III) and Al with the indicator. These ions block the indicator action in that the Fe(III) and Al complexes of murexide are not broken down by EDTA.

1.11. NMR shift reagent

Such reagents are used to disperse the NMR peaks obtained for certain types of compound over a larger frequency range, thus often allowing overlapping peaks to be separated. These reagents are usually complexes of the paramagnetic ions Eu³⁺ or Pr³⁺, e.g. the dipivalomethanato complex of Pr(III) [**Tris(2,2,6,6-tetramethyl-3,5-heptanedionato-O,O')-praseodymium(III)**, Pr(thd)₃], generally dissolved in non-polar solvents such as CCl₄, CDCl₃ or C₆D₆, to avoid competition of the solvent with the analyte for sites on the metal ion. The shift is caused by the interaction with the analyte of the magnetic field generated by the large magnetic moment of the paramagnetic ions in the reagent complex.

1.12. Scintillator

A scintillator is a compound which, when dissolved in an appropriate solvent, is raised to an excited state by collision with β -particles. The β -particles mainly excite the solvent molecules, and the excitation energy is then transferred to the scintillator. The subsequent de-excitation results in the emission of a photon. Excitation is caused even by low energy β -particles, such as those emitted by ³H, ¹⁴C, ³⁵S and ¹²⁵I, so that the scintillation process is widely used to monitor such emitters, the detector being a photomultiplier tube. Scintillation counting is used in a wide range of analytical procedures, especially in radioimmunoassay and radiotracer studies.

The solvent used is usually an aromatic hydrocarbon (toluene or xylene are most common), or sometimes dioxan. The scintillator is a polyaromatic fluorophore, such as **2,5-Diphenyloxazole** (PPO). In the past it has sometimes been necessary to add a secondary scintillator to which the energy is transferred from the primary scintillator. Secondary scintillators, of which **2,2'-(1,4-Phenylene)bis-[5-phenyloxazole]** (POPOP) is the most well known, are somewhat larger molecules, with more delocalisation than the primary scintillators: they emit at longer wavelengths at which photomultiplier tube sensitivity is greater.

1.13. Spectrofluorimetric reagent

Relatively few organic compounds, and only a handful of inorganic species are sufficiently fluorescent to be detectable at trace levels by direct monitoring of their native fluorescence. In order to provide sensitive spectrofluorometric procedures for most analytes, therefore, reagents have to be used which convert the analyte into fluorescent derivatives. For metal ions, such reagents are generally chelating agents (and which can often also be used as extractants). A typical example is **8-Hydroxy quinoline**, which forms fluorescent chelates with a number of metal ions. For organic compounds, a wide variety of reagents is available, which themselves are generally highly fluorescent, and produce intensely fluorescent products. Typical reagents are **1,2-Benzenedicarboxaldehyde** or **Dansyl chloride**, which form fluorescent derivatives with amines. Some of these reagents are used as chromatographic

derivatizing agents in conjunction with fluorimetric detection.

1.14. Spectrophotometric reagent

Absorption spectrophotometry in the UV-visible region is arguably the most common analytical technique in current use, being employed in batch analysis, flow systems (including chromatography and electrophoresis), and in optical sensors (opt(r)odes). Many inorganic and organic species are sufficiently absorbing at particular wavelengths within the UV-visible range that they can be determined without further treatment. However, for poorly absorbing species, or for increasing the sensitivity or changing the wavelength at which absorbance measurements are made, reaction with appropriate reagents is commonplace. For metal ions, reaction with chromogenic chelating agents is the usual procedure. For example, iron(II) gives an intense red, water soluble complex with 1,10-phenanthroline $[\text{Fe}(1,10\text{-phen})_3]^{2\oplus}$ which has a molar absorptivity of $1.1 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$. The most highly absorbing chelates have molar absorptivities of the order of $10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$, and consequently provide a means of high sensitivity detection.

There is a great variety of chromogenic reactions for inorganic compounds; sulphur dioxide, for example, is frequently determined spectrophotometrically after reaction with Tris(4-aminophenyl)-methanol (pararosaniline). There is also an extremely large selection of reagents available for organic compounds, either for classes of compounds (for example, amines, carbonyl compounds) or for individual species.

1.15. Surfactant

Surfactants find a variety of uses in analytical processes. One is the formation of micelles (or microemulsions) which can provide protective environments for analytes or reagents which may enhance stability, or luminescence intensity, for example, or allow reagents to act in conditions not normally accessible to them. They also find application in sample pretreatment including flotation procedures, electro-analytical measurements (e.g. suppression of polarographic maxima) and flow systems.

1.16. Titrant

A titration is the process of determining the quantity of a substance by adding measured increments of another substance, the titrant. The latter is almost always added as a standardised solution (or by electrolyte generation, as in a coulometric titration). The end-point of the titration, which should indicate the addition of an exact chemical equivalence, is recognized by a visual indicator or instrumentally. Titrations are based on acid-base reactions (for determination of acids or bases), redox reactions (for determining oxidants or reductants), chelating reactions (usually with EDTA-type compounds, for determination of metal ions) or precipitations (usually of halides or pseudohalides with silver ions).

2. Description of main classes of analytical reagents

The ability of a reagent to react with metal ions is generally derived from a particular feature of the molecule, the functional group, as was clearly stated by Feigl many decades ago. For example, all molecules containing the grouping $-\text{N}=\text{C}-\text{C}=\text{N}-$ will be expected to complex strongly with Fe(II) and Cu(I) , and form highly coloured chelates. Compounds bearing the $\text{HN}-\text{C}=\text{S}$ grouping will bind strongly with Hg(I) , (II) , Ag(I) and the noble metal ions. The measurable properties of the complexes formed depend on other features of the reagent, such as the presence of chromophoric groups (in a spectrophotometric reagent) or of electroactive groups (in an electroanalytical reagent).

This Dictionary classifies such reagents, where appropriate, on the basis of the following most commonly encountered functional groups or compound types.

1.17. Turbidimetric/Nephelometric reagent

Many analytes can be determined by measuring the light-scattering that occurs after they have been converted into a colloidal suspension by addition of a suitable reagent under appropriate conditions. The reagents used are generally precipitants, but the conditions for the reaction are chosen so that a highly dispersed precipitate is formed. In turbidimetry, the light absorbed by the suspension is measured (equivalent to spectrophotometry), whereas in nephelometry the intensity of the scattered light is monitored.

2.1. Aminobiphenyl compounds

Compounds with the general structure:

and related compounds are used analytically in two ways. One is as a precipitant for certain oxoanions, especially sulphate. The traditional reagent was benzidine (**4,4'-Diaminobiphenyl**) but it is no longer used because it is a carcinogen. Alternative, non-carcinogenic derivatives are available, such as **4-Amino-4'-chlorobiphenyl**. The other uses of such compounds are as redox indicators. **N,N'-Diphenylbenzidine** is a typical example, which is reversibly oxidized to *N,N*-diphenylbenzidine violet:

This indicator is used in iron(II) - dichromate titrations.

2.2. Anthraquinones

Anthraquinone itself is:

Many of its hydroxy derivatives form strong complexes with metal ions. For example, Alizarine (**1,2-Dihydroxyanthraquinone**) forms coloured suspensions or solutions by complexing with one of a wide range of metal ions, including Zr, Th, Ga, In, Ti and U. The red-violet Zr(IV) chelate is decolourised by F[⊖], by preferential complexation of F[⊖] with Zr(IV), thus providing the basis of a popular spectrophotometric method for the determination of fluoride.

Alizarine fluorine blue is the 3-methylamino-*N,N*-bisacetic acid derivative of alizarine, the Ce or La chelate of which binds with fluoride ions to form a ternary complex. This was the first reagent that could be used for the direct spectrophotometric determination of fluoride.

2.3. Azo compounds

Azo compounds, especially those with at least one coordinating group on an aromatic ring ortho to the azo group, form strongly bound, highly coloured metal chelates, and thus find use as spectrophotometric reagents and compleximetric indicators. Many of these compounds were originally developed as

dyestuffs, and are classified in the Colour Index. A typical example is **Chrome black special** which forms a red, soluble chelate with Mg^{2⊕} and can thus be used as an indicator for the EDTA titration of Mg^{2⊕}, and as a spectrophotometric reagent for that metal. Other azo compounds, such as **1-(2-Pyridyl-azo)-2-naphthol (PAN)** were developed specifically as metallochromic reagents.

Hydroxy-substituted azo compounds frequently exhibit tautomerism which can lead to difficulties with nomenclature and CAS registration (see note in Introduction).

2.4. 2,2-Bipyridyl and related compounds:

Compounds containing the functional group:

chelate with many metal ions via the two nitrogen atoms. However, of the common metal ions only Cu(I) and Fe(II) produce intensely coloured complexes which are used for spectrophotometric measurements and, in the case of the iron(II) complexes, as redox indicators. The complexes of the other metal ions are colourless, absorbing only in the UV region. This allows such ligands to be used as effective masking agents for these other metal ions. The generic example of such a compound is **2,2'-Bipyridine (bipy)** which forms charged and therefore water soluble complexes of the type [Fe(bipy)₃]^{2⊕}. Considerable effort has been made to synthesize more elaborate derivatives which have improved analytical properties such as greater molar absorptivity or changed redox potential for its iron(II) complex.

Many other reagents contain this functional group, including phenyl-2-pyridyl ketoxime

and **Dimethylglyoxime**.

2.5. Crown ethers and cryptands

Crown ethers are macrocyclic polyethers, forming charged metal ion complexes by ion-dipole interactions. These complexes, with an appropriate counter-ion, are usually soluble in organic solvents. A simple example is dicyclohexyl-18-crown-6 (18 atoms in the ring, 6 heterocyclic oxygen atoms).

Selectivity is achieved in such reagents by changing the size and shape of the cavity, introduction of other heteroatoms, etc. Of the simple crown ethers, potassium is most strongly complexed by dicyclohexyl-18-crown-6 because the cavity diameter (0.26–0.32 nm) is almost the same as that of the potassium ion (0.27 nm), but a ring of 15–18 atoms binds more strongly to the smaller sodium ion, and one of 18–21 atoms is optimal for the larger caesium ion. Such reagents can be used for extraction of metal ions, especially the alkali and alkaline earth metals, and can be used in ion-selective electrodes for such cations. Addition of chromophores to the basic crown structure produces spectrophotometric extractants and reagents that can be used in ion-selective opt(r)odes.

Cryptands are essentially 3-dimensional (cage) analogues of crown ethers. A simple series of cryptands is as follows:

They bind strongly with alkali metal ions that can be accommodated within the cage. Their uses are similar to those of the cryptands, as are those of the calixarenes and spherands, which are similar molecules with a partial cage structure.

2.6. Dansyl compounds

These are compounds that are used to react with non-fluorescent organic compounds to produce fluorescent derivatives, which can then be determined directly by spectrofluorimetry, or by liquid chromatography with fluorescence detection. For example, amines may be determined by coupling with dansyl chloride (**5-Dimethylamino-1-naphthalene-sulfonyl chloride**)

2.7. Diazo compounds

Diazonium compounds ($R-N_2^{\oplus}$) are used to couple to aromatic rings, thus producing intensely coloured derivatives which can be monitored by spectrophotometry. Reaction with 8-quinolinol (**8-Hydroxyquinoline**) is a typical example. They are also used for coupling with enzymes in order to produce immobilised enzymes in order to produce immobilised enzymes, or for labelling antibodies.

Diazo compounds such as **4-Diazobenzenesulfonic acid** gives colours on reaction with H_2S and certain other inorganic species.

2.8. β -Diketones

These compounds have the general formulae:

They form strongly bound chelates with a wide range of metal ions. Generally the chelates are uncharged, and are readily soluble in organic solvents. The aluminium chelate, for example, is AL_3 . Such reagents are widely used for liquid-liquid extraction of metal ions. They also find use as spectrophotometric reagents, as ligands for producing volatile metal chelates which can be used for gas chromatographic separation of metal ions, and, more recently, for use in liquid chromatography of metal ions. Certain rare earth β -diketone chelates have also been used as fluorescent labels in immunoassay procedures

where a relatively long-lived emission is required to distinguish the analyte signal from endogenous matrix emissions.

2.9. Dithiocarbamates

A wide range of dithiocarbamates has been investigated as potential analytical reagents for metal ions, largely as extractants followed by spectrophotometric measurement. The compounds have the general formula:

and form uncharged chelates with metal ions, such as CuL_2 , by binding via the S and, probably, N atoms. The compounds break down in sufficiently acidic solution:

2.10. Dithiols

These are usually 1,2-dithiols:

which form precipitates with heavy metals and As and Sb in acidic aqueous media. The precipitate can usually be extracted into organic solvents for spectrophotometric measurements. Such reagents have also

been used to prevent interference by certain metals in EDTA titrations.

2.11. Dithizone derivatives

Dithizone ($\text{PhN}=\text{NCSNHNHPh}$) forms uncharged, water insoluble complexes with most heavy metals, especially Hg (forming HgL_2), Ag and Cu, which can be extracted into organic solvents and measured spectrophotometrically. Various derivatives of dithizone have been prepared in an attempt to improve on its analytical properties and its stability. Its metal complexes are subject to photochemical decomposition. Dithizones are potentially capable of tautomerism to SH-forms, leading to difficulties of nomenclature and CAS registration (see note on page xi).

2.12. EDTA-type compounds

Compounds containing the iminodiacetic acid functional group:

chelate with most metal ions via the nitrogen and oxygen atoms in many instances forming very strongly bound water soluble complexes. Molecules of this type, especially EDTA (**Ethylenediaminetetraacetic acid**) itself are used as compleximetric titrants for metal ions because the chelates formed are almost always 1 : 1 metal : ligand species, and are colourless unless the metal ion itself is coloured. Such compounds are also very useful masking agents for metal ions.

Introduction of the iminodiacetic acid group into highly coloured molecules produces chromogenic metal binding reagents that form water soluble complexes. Such reagents (of which **Xylenol orange** is typical) are employed as very sensitive spectrophotometric reagents or as indicators for compleximetric titrations.

2.13. Formazans

Formazans have the general formula:

Analytical Reagents

They bind transition metal ions to form highly coloured, extractable metal chelates.

Formazans exhibit tautomerism which can lead to difficulties with nomenclature and CAS registration (see note in Introduction).

2.14. Hydrazine derivatives and hydrazones

Hydrazones are formed from the reaction between hydrazine derivatives and carbonyl compounds:

These are usually highly coloured, and are widely used for detection and spectrophotometric determination of carbonyl compounds.

Many hydrazones form highly coloured chelates with metal ions, and thus find use as spectrophotometric reagents. **2-Pyridinecarboxaldehyde 2-pyridylhydrazone** is a typical example. **Luminol** is also a hydrazine derivative, widely used for its chemiluminescent property.

2.15. Hydroxylamine derivatives

A number of types of compound can be considered as hydroxylamine derivatives. *Hydroxamic acids* have the general formula $\text{RC}(\text{OH})\text{NOH}$ and can be used to precipitate or extract a range of metal ions, including Zr, Th, Fe and Cr. **Cupferron** (ammonium *N*-nitroso-*N*-phenylhydroxylamine) and *N*-substituted phenylhydroxylamines such as ***N*-Benzoyl-*N*-phenylhydroxylamine** behave similarly to the hydroxamic acids, and are used for similar purposes.

Numerous other oximes and nitroso compounds are also used as reagents for metal ions, including hydroxoximes such as salicylaldoxime and derivatives:

α -Dioximes and α -ketomonoximes are discussed separately below.

2.16. Organophosphorus compounds

Such compounds find extensive use as metal ion extractants. Solutions of compounds such as **Tributylphosphate** (TBT) in cyclohexane or CCl_4 enable salts such as $\text{UO}_2(\text{NO}_3)_2$ and $\text{Th}(\text{NO}_3)_4$ to be extracted because the TBT solvates the metal ion via its strongly basic oxygen, forming, e.g. $\text{UO}_2(\text{NO}_3)_2 \cdot 2\text{TBT}$. Phosphonium ions such as **Tetraphenylphosphonium** (1+) $[\text{PPh}_4]^{\oplus}$ are used as ion-pairing cations for the extraction of anions such as ClO_4^{\ominus} , ReO_4^{\ominus} and SbCl_6^{\ominus} . Quaternary ammonium salts and arsonium salts behave similarly. Some phosphoric acids have been proposed as metal ion precipitants.

2.17. Oximes: α -dioximes

α -Dione dioximes:

have achieved greatest fame as precipitants for Ni and Pd ions, forming uncharged chelates such as:

The Ni and Pd chelates are insoluble in water not only because they are uncharged, but also because the molecules stack along an axis of Ni-Ni bonds. The complexes of other metal ions, such as $\text{Co}^{2\oplus}$ or $\text{Fe}^{2\oplus}$ are coloured but are soluble because of the lack of metal-metal bonding. Soluble complexes can be used for spectrophotometric measurements.

2.18. Oximes: α -ketomonoximes

α -Ketomonoximes have achieved limited popularity as analytical reagents, as precipitants or extractants for metal ions. 4-Isonitroso-3-methyl-*N*-phenyl-5-pyrazolone (**3-Methyl-1-phenyl-1H-pyrazole-4,5-dione 4-oxime**) and violuric acid (**2,4,5,6(1H,3H)-Pyrimidinetetrone 5-oxime**) give coloured precipitates or soluble complexes with several metal ions. α -Benzilmonoxime and related compounds behave similarly:

Ketomonoximes frequently exhibit tautomerism which can lead to difficulties with nomenclature and CAS registration (see note in Introduction).

2.19. Phenazines and Phenothiazines

Phenazines form precipitates with Cu(I) and Hg, and form coloured complexes with Bi, Cd and Pb. **Phenothiazine** reacts with Ag, Fe and Pd.

2.20. Phenylfluorones

Phenylfluorones are a variety of chelating xanthene molecules which form sparingly soluble coloured complexes with certain inorganic species. Phenylfluorone (**2,6,7-Trihydroxy-9-phenyl-3H-xanthen-3-one**) itself, for example, forms a reddish suspension with Ge(IV), Ga(III), Sn(IV), Sb(III) and other species. The coloured suspensions can be stabilized with a protective polymer such as poly(vinyl alcohol) for spectrophotometric measurement.

2.21. Porphines

These are molecules based on the porphyrin type structure:

They are used as chromogenic chelating agents for transition metals.

2.22. Quaternary ammonium salts

Compounds of general formula $RR^1R^2R^3N^{\oplus}X^{\ominus}$ are widely used as extractants by forming ion-pairs with anions, including anionic complexes (e.g. $PtCl_6^{2\ominus}$)

and heteropoly anions (e.g. 12-molybdophosphate) as well as simple anions such as SCN^{\ominus} and MnO_4^{\ominus} . Compounds of this type also find use as cationic surfactants.

2.23. 8-Quinolinol derivatives

8-Quinolinol (**8-Hydroxyquinoline**, oxine, HQ) is a classical organic reagent for metal ions.

It forms coloured, often fluorescent metal chelates such as AlQ_3 and ZnQ_2 . These complexes are uncharged and precipitate from aqueous solution, so can be used for gravimetric purposes. The chelates can be extracted into various water-insoluble organic solvents, thus providing a means of separating and preconcentrating metal ions, and of spectrophotometric or spectrofluorimetric determination. Numerous derivatives have been synthesised in attempts to improve the analytical properties of these reagents. The 8-thio derivative, **8-Quinolinethiol**, also complexes strongly with a wide range of metal ions, especially the 'heavy' and noble metals. Coloured precipitates are again formed.

2.24. Rhodanines

Rhodanines are 5-membered heterocyclic compounds of the general form:

They react with Cu(I), Ag(I), Hg(I), (II) and the noble metals. When R = H, reaction occurs with loss of H^{\oplus} , to give polymeric, insoluble complexes, with bonding to S and N. Incorporation of a chromogenic group at R^1R^2 gives highly coloured colloidal complexes. When R is an alkyl or aryl group, and

Analytical Reagents

R^1R^2 is a chromogen, intense colours are again produced by the above metal ions, but the mechanism of the reaction is unclear.

2.25. Semicarbazones

Semicarbazides react with carbonyl compounds to produce semicarbazones:

which are used for characterising carbonyl compounds. Many semicarbazones form highly coloured metal chelates which are used for spectrophotometric determination of metals. A few derivatives have also found use as gravimetric and spectrofluorimetric reagents.

2.26. Silyl derivatives

There are many areas of analytical chemistry in which silyl compounds are useful. In gas chromatography, 'active' OH groups on the solid phase silicate material can be deactivated by silanization, by treatment, for example, with dimethyl dichlorosilane:

The volatility of many compounds can be increased by silanization, so as to improve their amenability to gas chromatographic separation. Trimethylsilylimidazole in pyridine is a typical reagent, useful for carbohydrate silylation. Silylating agents also find use

in solid phase pretreatment for attachment of enzymes, antibodies or chelating moieties.

2.27. Thiazoles and related compounds

The most common thiazole used analytically is 2-mercaptobenzothiazole (**2-Benzothiazolethiol**), related to rhodanine, and which precipitates a range of metal ions (Ag^\oplus , $\text{Pb}^{2\oplus}$, Cu^\oplus , and the noble metals). **2-Mercaptobenzimidazole** and its derivatives behave similarly.

2.28. Thiourea derivatives

Thiourea (Tu) and its derivatives ($\text{RR}'\text{NCSNR}^2\text{R}^3$) form strongly bound, water soluble complexes with Ag and the noble metals in acidic media. The Ag complex, for example, is $[\text{AgTu}_3]^\oplus$, so that thiourea under these conditions serves as an excellent masking agent for Ag. As the pH is increased, however, the nature of the reaction changes, with the thiourea reacting similarly to dithizone or rhodanine, with release of a proton and forming a precipitate.

1-Phenylthiosemicarbazide and its derivatives react with many metal ions, including those of the noble metals, to give coloured complexes which may be used for spectrophotometric determination.

2.29. Triphenylmethane dyes

A number of valuable metallochromic reagents are based on the triphenylmethane structure. A typical example is **Pyrocatechol violet** which is an acid-base indicator, as well as forming coloured (usually blue) chelates with a wide range of metal ions. Compounds such as **Xylenol orange** are also based on this structure, with the addition of two iminodiacetic acid groups.

Highly fluorescent compounds such as **Rhodamine B** which are used as fluorescent sensitizers, or as a fluorescent ion-pair extractants for bulky anions, are also based on the triphenylmethane structure.

2.30. Xanthates

The xanthates are compounds of the type ROCSS^\ominus , usually available as alkali metal salts. They form water insoluble complexes with a wide range of transition metal ions, which are readily extracted into organic solvents.

2-Propanone, 9CI. Dimethyl ketone
[67-64-1]

$\text{C}_3\text{H}_6\text{O}$ M 58.080

A common constit. of plant tissues, e.g. *Ribes nigrum* volatiles. Widely used solvent. Major industrial intermed. used in manuf. of other solvs., methacrylates and bisphenol A. Forms acetonides with diols and Schiff bases with amines for gc or ms anal. Important industrial chemical, 43rd in order of volume for USA in 1990 (production 1.11 million tons/year). Volatile liq. Misc. H_2O , org. solvs. d_{25}^{20} 0.79. Mp -94° . Bp₂₀ 56.2° . Crit. temp. 246.1° .

► Mod. toxic vapour, TLV 2400. Highly flammable, fl. p. -18° . AL3150000.

Agar-agar

[9002-18-0]

Mucilaginous substance extracted from red marine algae (Rhodophyceae). Used as protective colloid in photometric detn. of Sn, Mg, Si, SO₄²⁻. Used as a solid medium for the cultivation of bacteria. A thickener, stabiliser and gelling agent in the food industry. Strips or fine powder. Sl. sol. in hot H₂O. Consists of a mixt. of 2 polysaccharides, agarose and agarpectin.

Agarose

Neutral agarose

A-00069

Composed of repeating units of β-D-Galp (1→4) 3,6-anhydro-α-L-Galp(1→3). Isol. from red seaweed agar. Gives gels of high strength at low concs. in water which are nearly transparent. These are used commercially as gelling agents and for biomedical applications, eg. electrophoresis media, chromatography and immunology assays. There are two other polysaccharides in agar, one is similar to agarose but with 4,6-acetals of pyruvic acid at some of the D-galactose units. The other contains fewer 3,6-anhydro-L-galactose units and is sulfated.

R = L-Araf (1→), L-Rhap (1→), α-D-Galp (1→3)-L-Araf (1→)

Most common components

A highly branched polysaccharide composed of L-Arabinose, D-Galactose, L-Rhamnose and D-Gluconic acid in an approximate 3:3:1:1 ratio. Salt-free polysaccharide formed by precipitation from an acidified soln. of gum arabic.

Per-Ac: $[\alpha]_D -21^\circ$ (c, 0.94 in $CHCl_3$).

Me ester: $[\alpha]_D^{19} -47^\circ$ (c, 1.0 in $CHCl_3$).

Mixed salts: Gum arabic

Exudate from *Acacia senegal*. Used as protective colloid to prevent settling of ppts. in some photometric and turbidimetric detns. Yellowish-amber lumps. Dissolves slowly in H_2O .

Mixed salts, per-Me: $[\alpha]_D -48^\circ$ (c, 1.0 in $CHCl_3$).

$C_6H_{10}O_5$ M 162.142

An unbranched polymer composed of 1,4 β -linked glucopyranose units. Polymeric. Minimum formula given. The most abundant organic material found in plants forming the principal constit. of their cell walls giving them structural strength. Cotton is almost pure cellulose. Wood is the most important industrial source. Basic material for textile and paper manuf. Used in the isoln. of heavy metals. Insol. H_2O , most solvs., but forms sol. complexes in conc. aq. $ZnCl_2$, copper-amine solutions and with Fe sodium tartrate solution.

Ac: [9004-35-7]. *Cellulose acetate*, 9CI

Used in manuf. of photographic film, gramophone discs, lacquers and fibres.

Nitrate: [9004-70-0]. *Nitrocellulose*. *Collodion cotton*. *Collodion wool*. *Colloxylin*

Used in explosives (propellants), lacquers, adhesives, plastics (e.g. Celluloid).

2-Hydroxy-1,2,3-propanetricarboxylic acid, 9*Cl*. 2-Hydroxytricarballic acid

[77-92-9]

C₆H₈O₇ M 192.125

Occurs in the free state in lemons, currants, beetroot etc. and the seeds and juices of many flowers and plants. Constit. of fruit drinks, pharmaceutical syrups, for adjusting pH of foods etc. Component of anticoagulant citrate solns. Used as masking agent for many polyvalent metals and as a component of buffers. Commercially available. Cryst. + 1H₂O (H₂O), losing H₂O at 70-5°. V. sol. H₂O, EtOH, mod. sol. Et₂O. Mp 135° (monohydrate), Mp 153° (anhydrous). p*K*_{a1} 3.13; p*K*_{a2} 4.78; p*K*_{a3} 6.43 (25°).
