Preface to the Second Edition

When this book first appeared in 1984 it rapidly established itself as one of the foremost textbooks and references on the subject. It was enthusiastically adopted by both students and teachers and has already been translated into several European and Asian languages. The novel features which it adopted (see Preface to the First Edition) were clearly much appreciated and we have been pressed for some time now to bring out a second edition. Accordingly we have completely revised and updated the text and have incorporated over 2000 new literature references to work which has appeared since the first edition was published. In addition, innumerable modifications and extensions incorporating recent advances have been made throughout the text and, indeed, no single page has been left unaltered. However, by judicious editing we have ensured that all the features which made the first edition so attractive to its readers have been retained.

The main plan of the book has been left unchanged except that the general section on organometallic chemistry has been removed from Chapter 8 (Carbon) and has been incorporated, together with a summary of other aspects of coordination chemistry, in a restyled Chapter 19. However, the chemistry of even the simplest elements has been considerably enriched during the past few years, sometimes by quite dramatic advances. Thus the chemistry of the alkali metals has a complexity that was undreamt of one or two decades ago and lithium, for example, is now known in at least 20 coordination geometries having coordination numbers from 1 to 12. Compounds of alkali metal anions and even electrides are known. Likewise, there is expanding interest in the organometallic chemistry of the heavier congeners of magnesium, particularly those with bulky ligands. Boron continues to amaze and confound, and its cluster chemistry continues to expand, as does sulfur–nitrogen chemistry, heteropolyacid chemistry, bioinorganic aspects of the chemistry of many of the elements, lower-valent lanthanide element chemistry, and so on through each of the chapters, up to the synthesis and characterization of the heaviest trans-actinide element, Z = 112. It is salutory to reflect that there are now 49 more elements known than the 63 known to Mendeleev when he devised the periodic table of the elements.

A further indication of the rapid advances that have occurred in the chemistry of the elements during the past 15 years can be gauged from the several completely new sections which have been added to review work in what were previously both nonexistent and unsuspected areas. These include (a) coordination compounds of dihapto-dihydrogen, (b) the fullerenes and their many derivatives, (c) the metcars, and (d) high-temperature oxide superconductors.
Preface to the Second Edition

We hope that this new edition of Chemistry of the Elements will continue to stimulate and inform its readers, and that they will experience something of the excitement and fascination which we ourselves feel for this burgeoning subject. We should also like to thank our many correspondents who have kept us informed of their work and the School of Chemistry in the University of Leeds for providing us with facilities.

N. N. Greenwood
A. Earnshaw
August, 1997
In this book we have tried to give a balanced, coherent and comprehensive account of the chemistry of the elements for both undergraduate and postgraduate students. This crucial central area of chemistry is full of ingenious experiments, intriguing compounds and exciting new discoveries. We have specifically avoided the term inorganic chemistry since this emphasizes an outmoded view of chemistry which is no longer appropriate in the closing decades of the 20th century. Accordingly, we deal not only with inorganic chemistry but also with those aspects which might be called analytical, theoretical, industrial, organometallic, bio-inorganic or any other of the numerous branches of the subject currently in vogue.

We make no apology for giving pride of place to the phenomena of chemistry and to the factual basis of the subject. Of course the chemistry of the elements is discussed within the context of an underlying theoretical framework that gives cohesion and structure to the text, but at all times it is the chemical chemistry that is emphasized. There are several reasons for this. First, theories change whereas facts do so less often — a greater permanency and value therefore attaches to a treatment based on a knowledge and understanding of the factual basis of the subject. We recognize, of course, that though the facts may not change dramatically, their significance frequently does. It is therefore important to learn how to assess observations and to analyse information reliably. Numerous examples are provided throughout the text. Moreover, it is scientifically unsound to present a theory and then describe experiments which purport to prove it. It is essential to distinguish between facts and theories and to recognize that, by their nature, theories are ephemeral and continually changing. Science advances by removing error, not by establishing truth, and no amount of experimentation can “prove” a theory, only that the theory is consistent with the facts as known so far. (At a more subtle level we also recognize that all facts are theory-laden.)

It is also important to realize that chemistry is not a static body of knowledge as defined by the contents of a textbook. Chemistry came from somewhere and is at present heading in various specific directions. It is a living self-stimulating discipline, and we have tried to transmit this sense of growth and excitement by reference to the historical development of the subject when appropriate. The chemistry of the elements is presented in a logical and academically consistent way but is interspersed with additional material which illuminates, exemplifies, extends or otherwise enhances the chemistry being discussed.

Chemistry is a human activity and its results have a substantial impact on our daily lives. However, we have not allowed ourselves to become obsessed by “relevance”. Today’s relevance is tomorrow’s obsolescence. On the other hand, it would be obtuse in the modern world not to recognize that chemistry, in addition to being academically stimulating and aesthetically satisfying, is frequently also useful. This gives added point to much of the chemistry of the elements and indeed a great deal of that chemistry has been specifically developed because of society’s needs. To many this is one of the most attractive aspects of the subject — its potential usefulness. We therefore wrote to over 500 chemically based firms throughout the world asking for information about the chemicals they manufactured or used, in what
quantities and for what purposes. This produced an immense wealth of technical information which has proved to be an invaluable resource in discussing the chemistry of the elements. Our own experience as teachers had already alerted us to the difficulty of acquiring such topical information and we have incorporated much of this material where appropriate throughout the text. We believe it is important to know whether a given compound was made perhaps once in milligram amounts, or is produced annually in tonne quantities, and for what purpose.

In a textbook devoted to the chemistry of the elements it seemed logical to begin with such questions as: where do the elements come from, how were they made, why do they have their observed terrestrial abundances, what determines their atomic weights, and so on. Such questions, through usually ignored in textbooks and certainly difficult to answer, are ones which are currently being actively pursued, and some tentative answers and suggestions are given in the opening chapter. This followed by a brief description of chemical periodicity and the periodic table before the chemistry of the individual elements and their group relationships are discussed on a systematic basis.

We have been much encouraged by the careful assessment and comments on individual chapters by numerous colleagues not only throughout the U.K. but also in Australia, Canada, Denmark, the Federal Republic of Germany, Japan, the U.S.A and several other countries. We believe that this new approach will be widely welcomed as a basis for discussing the very diverse behaviour of the chemical elements and their compounds.

It is a pleasure to record our gratitude to the staff of the Edward Boyle Library in the University of Leeds for their unfailing help over many years during the writing of this book. We should also like to express our deep appreciation to Mrs Jean Thomas for her perseverance and outstanding skill in preparing the manuscript for the publishers. Without her generous help and the understanding of our families this work could not have been completed.

Contents

Preface to the second edition xix
Preface to the first edition xxii

Chapter 1 Origin of the Elements. Isotopes and Atomic Weights 1
  1.1 Introduction 1
  1.2 Origin of the Universe 1
  1.3 Abundances of the Elements in the Universe 3
  1.4 Stellar Evolution and the Spectral Classes of Stars 5
  1.5 Synthesis of the Elements 9
    1.5.1 Hydrogen burning 9
    1.5.2 Helium burning and carbon burning 10
    1.5.3 The α-process 11
    1.5.4 The e-process (equilibrium process) 12
    1.5.5 The s- and r-processes (slow and rapid neutron absorption) 12
    1.5.6 The p-process (proton capture) 13
    1.5.7 The x-process 13
  1.6 Atomic Weights 15
    1.6.1 Uncertainty in atomic weights 16
    1.6.2 The problem of radioactive elements 18

Chapter 2 Chemical Periodicity and the Periodic Table 20
  2.1 Introduction 20
  2.2 The Electronic Structure of Atoms 21
  2.3 Periodic Trends in Properties 23
    2.3.1 Trends in atomic and physical properties 23
    2.3.2 Trends in chemical properties 27
  2.4 Prediction of New Elements and Compounds 29

Chapter 3 Hydrogen 32
  3.1 Introduction 32
  3.2 Atomic and Physical Properties of Hydrogen 34
    3.2.1 Isotopes of hydrogen 35
    3.2.2 Ortho- and para-hydrogen 35
    3.2.3 Ionized forms of hydrogen 36
  3.3 Preparation, Production and Uses 38
    3.3.1 Hydrogen 38
    3.3.2 Deuterium 39
    3.3.3 Tritium 41
  3.4 Chemical Properties and Trends 43
    3.4.1 The coordination chemistry of hydrogen 44

8.12 Cyanides and Other Carbon-Nitrogen Compounds 313
8.13 Organometallic Compounds 319

Chapter 9 Silicon 328

9.1 Introduction 328
9.2 Silicon 329
9.2.1 Occurrence and distribution 329
9.2.2 Isolation, production and industrial uses 330
9.2.3 Atomic and physical properties 330
9.2.4 Chemical properties 331
9.3 Compounds 335
9.3.1 Silicides 335
9.3.2 Silicon hydrides (silanes) 337
9.3.3 Silicon halides and related complexes 340
9.3.4 Silica and silicic acids 342
9.3.5 Silicate minerals 347
Silicates with discrete units 347
Silicates with chain or ribbon structures 349
Silicates with layer structures 349
Silicates with framework structures 354
9.3.6 Other inorganic compounds of silicon 359
9.3.7 Organosilicon compounds and silicones 361

Chapter 10 Germanium, Tin and Lead 367

10.1 Introduction 367
10.2 The Elements 368
10.2.1 Terrestrial abundance and distribution 368
10.2.2 Production and uses of the elements 369
10.2.3 Properties of the elements 371
10.2.4 Chemical reactivity and group trends 373
10.3 Compounds 374
10.3.1 Hydrides and hydrohalides 374
10.3.2 Halides and related complexes 375
Germanium halides 376
Tin halides 377
Lead halides 381
10.3.3 Oxides and hydroxides 382
10.3.4 Derivatives of oxoacids 387
10.3.5 Other inorganic compounds 389
10.3.6 Metal-metal bonds and clusters 391
10.3.7 Organometallic compounds 396
Germanium 396
Tin 399
Lead 404

Chapter 11 Nitrogen 406

11.1 Introduction 406
Contents

11.2 The Element
   11.2.1 Abundance and distribution
   11.2.2 Production and uses of nitrogen
   11.2.3 Atomic and physical properties
   11.2.4 Chemical reactivity

11.3 Compounds
   11.3.1 Nitrides, azides and nitrido complexes
   11.3.2 Ammonia and ammonium salts
   11.3.3 Other hydrides of nitrogen
   11.3.4 Thermodynamic relations between N-containing species
   11.3.5 Nitrogen halides and related compounds
   11.3.6 Oxides of nitrogen
   11.3.7 Oxoacids, oxoanions and oxoacid salts of nitrogen

Chapter 12 Phosphorus

12.1 Introduction

12.2 The Element
   12.2.1 Abundance and distribution
   12.2.2 Production and uses of elemental phosphorus
   12.2.3 Allotropes of phosphorus
   12.2.4 Atomic and physical properties
   12.2.5 Chemical reactivity and stereochemistry

12.3 Compounds
   12.3.1 Phosphides
   12.3.2 Phosphine and related compounds
   12.3.3 Phosphorus halides
   12.3.4 Oxhalides and thiohalides of phosphorus
   12.3.5 Phosphorus oxides, sulfides, selenides and related compounds
   12.3.6 Oxoacids of phosphorus and their salts
Chapter 13  Arsenic, Antimony and Bismuth  
13.1 Introduction  
13.2 The Elements  
13.2.1 Abundance, distribution and extraction  
13.2.2 Atomic and physical properties  
13.2.3 Chemical reactivity and group trends  
13.3 Compounds of Arsenic, Antimony and Bismuth  
13.3.1 Intermetallic compounds and alloys  
13.3.2 Hydrides of arsenic, antimony and bismuth  
13.3.3 Halides and related complexes  
  Trihalides, MX₃  
  Pentahalides, MX₅  
  Mixed halides and lower halides  
  Halide complexes of M³⁺ and M⁵⁺  
  Oxide halides  
13.3.4 Oxides and oxo compounds  
  Oxo compounds of M³⁺  
  Mixed-valence oxides  
  Oxo compounds of M⁵⁺  
13.3.5 Sulfides and related compounds  
13.3.6 Metal-metal bonds and clusters  
13.3.7 Other inorganic compounds  
13.3.8 Organometallic compounds  
  Organoaarsenic(III) compounds  
  Organobismuth(III) compounds  
  Physiological activity of arsencals  
  Organoantimony and organobismuth compounds  

Chapter 14  Oxygen  
14.1 The Element  
14.1.1 Introduction  
14.1.2 Occurrence  
14.1.3 Preparation  
14.1.4 Atomic and physical properties  
14.1.5 Other forms of oxygen  
  Ozone  
  Atomic oxygen  
14.1.6 Chemical properties of dioxygen, O₂  
14.2 Compounds of Oxygen  
14.2.1 Coordination chemistry: dioxygen as a ligand  
14.2.2 Water  
  Introduction  
  Distribution and availability  
  Physical properties and structure  
  Water of crystallization, aquo complexes and solid hydrates  
  Chemical properties  
  Polywater  
14.2.3 Hydrogen peroxide  
  Physical properties  
  Chemical properties  
14.2.4 Oxygen fluorides  
14.2.5 Oxides  
  Various methods of classification  
  Nonstoichiometry
Chapter 15  Sulfur

15.1  The Element
15.1.1  Introduction
15.1.2  Abundance and distribution
15.1.3  Production and uses of elemental sulfur
15.1.4  Allotropes of sulfur
15.1.5  Atomic and physical properties
15.1.6  Chemical reactivity
  Polyatomic sulfur cations
  Sulfur as a ligand
  Other ligands containing sulfur as donor atom
15.2  Compounds of Sulfur
15.2.1  Sulfides of the metallic elements
  General considerations
  Structural chemistry of metal sulfides
  Anionic polysulfides
15.2.2  Hydrides of sulfur (sulfanes)
15.2.3  Halides of sulfur
  Sulfur fluorides
  Chlorides, bromides and iodides of sulfur
15.2.4  Oxohalides of sulfur
15.2.5  Oxides of sulfur
  Lower oxides
  Sulfur dioxide, SO₂
  Sulfur dioxide as a ligand
  Sulfur trioxide
  Higher oxides
15.2.6  Oxoacids of sulfur
  Sulfuric acid, H₂SO₄
  Peroxosulfuric acids, H₂SO₅ and H₂S₂O₈
  Thiosulfuric acid, H₂S₂O₃
  Dithionic acid, H₂S₂O₆
  Polythionic acids, H₂SₙO₆
  Sulfurous acid, H₂SO₃
  Disulfurous acid, H₂S₂O₅
  Dithionous acid, H₂S₂O₄
15.2.7  Sulfur–nitrogen compounds
  Binary sulfur nitriles
  Sulfur–nitrogen cations and anions
  Sulfur imides, Sₙ⁻ₙ(NH)ₙ
  Other cyclic sulfur–nitrogen compounds
  Sulfur–nitrogen–halogen compounds
  Sulfur–nitrogen–oxygen compounds

Chapter 16  Selenium, Tellurium and Polonium

16.1  The Elements
16.1.1  Introduction: history, abundance, distribution
16.1.2  Production and uses of the elements
16.1.3  Allotropy
16.1.4  Atomic and physical properties
16.1.5  Chemical reactivity and trends
16.1.6  Polyatomic cations, Mₙ⁺
16.1.7  Polyatomic anions, Mₙ⁻
16.2  Compounds of Selenium, Tellurium and Polonium
16.2.1  Selenides, tellurides and polonides
16.2.2  Hydrides
16.2.3  Halides
  Lower halides
  Tetrahalides
Chapter 17  The Halogens: Fluorine, Chlorine, Bromine, Iodine and Astatine

17.1  The Elements
17.1.1  Introduction
17.1.2  Abundance and distribution
17.1.3  Production and uses of the elements
17.1.4  Atomic and physical properties
17.1.5  Chemical reactivity and trends
   General reactivity and stereochemistry
   Solutions and charge-transfer complexes
17.2  Compounds of Fluorine, Chlorine, Bromine and Iodine
17.2.1  Hydrogen halides, HX
   Preparation and uses
   Physical properties of the hydrogen halides
   Chemical reactivity of the hydrogen halides
   The hydrogen halides as nonaqueous solvents
17.2.2  Halides of the elements
   Fluorides
   Chlorides, bromides and iodides
17.2.3  Interhalogen compounds
   Diatomic interhalogens, XY
   Tetra-atomic interhalogens, XY₃
   Hexa-atomic and octa-atomic interhalogens, XF₅ and IF₇
17.2.4  Polyhalide anions
17.2.5  Polyhalonium cations XY₂⁺
17.2.6  Halogen cations
17.2.7  Oxides of chlorine, bromine and iodine
   Oxides of chlorine
   Oxides of bromine
   Oxides of iodine
17.2.8  Oxoacids and oxoacid salts
   General considerations
   Hypohalous acids, HOX, and hypohalites, XO⁻
   Halous acids, HOXO, and halites, XO₂⁻
   Halic acids, HOXO₂, and halates, XO₃⁻
   Perhalic acid and perhalates
   Perclochloric acid and perchlorates
   Perbromic acid and perbromates
   Periodic acids and periodates
17.2.9  Halogen oxide fluorides and related compounds
   Chlorine oxide fluorides
   Bromine oxide fluorides
   Iodine oxide fluorides
17.2.10  Halogen derivatives of oxoacids
17.3  The Chemistry of Astatine
Contents

Chapter 18 The Noble Gases: Helium, Neon, Argon, Krypton, Xenon and Radon

18.1 Introduction
18.2 The Elements
  18.2.1 Distribution, production and uses
  18.2.2 Atomic and physical properties of the elements
18.3 Chemistry of the Noble Gases
  18.3.1 Clathrates
  18.3.2 Compounds of xenon
  18.3.3 Compounds of other noble gases

Chapter 19 Coordination and Organometallic Compounds

19.1 Introduction
19.2 Types of Ligand
19.3 Stability of Coordination Compounds
19.4 The Various Coordination Numbers
19.5 Isomerism
  Conformational isomerism
  Geometrical isomerism
  Optical isomerism
  Ionization isomerism
  Linkage isomerism
  Coordination isomerism
  Polymerization isomerism
  Ligand isomerism
19.6 The Coordinate Bond
19.7 Organometallic Compounds
  19.7.1 Monohapto ligands
  19.7.2 Dihapto ligands
  19.7.3 Trihapto ligands
  19.7.4 Tetrahapto ligands
  19.7.5 Pentahapto ligands
  19.7.6 Hexahapto ligands
  19.7.7 Heptahapto and octahapto ligands

Chapter 20 Scandium, Yttrium, Lanthanum and Actinium

20.1 Introduction
20.2 The Elements
  20.2.1 Terrestrial abundance and distribution
  20.2.2 Preparation and uses of the metals
  20.2.3 Properties of the elements
  20.2.4 Chemical reactivity and trends
20.3 Compounds of Scandium, Yttrium, Lanthanum and Actinium
  20.3.1 Simple compounds
  20.3.2 Complexes
  20.3.3 Organometallic compounds

Chapter 21 Titanium, Zirconium and Hafnium

21.1 Introduction
21.2 The Elements
  21.2.1 Terrestrial abundance and distribution
  21.2.2 Preparation and uses of the metals
  21.2.3 Properties of the elements
  21.2.4 Chemical reactivity and trends
21.3 Compounds of Titanium, Zirconium and Hafnium
  21.3.1 Oxides and sulfides
Chapter 22 Vanadium, Niobium and Tantalum

22.1 Introduction
22.2 The Elements
  22.2.1 Terrestrial abundance and distribution
  22.2.2 Preparation and uses of the metals
  22.2.3 Atomic and physical properties of the elements
  22.2.4 Chemical reactivity and trends
22.3 Compounds of Vanadium, Niobium and Tantalum
  22.3.1 Oxides
  22.3.2 Polymetallates
  22.3.3 Sulfides, selenides and tellurides
  22.3.4 Halides and oxohalides
  22.3.5 Compounds with oxoanions
  22.3.6 Complexes
    Oxidation state V (d⁵)
    Oxidation state IV (d⁴)
    Oxidation state III (d³)
    Oxidation state II (d²)
  22.3.7 The biochemistry of vanadium
  22.3.8 Organometallic compounds

Chapter 23 Chromium, Molybdenum and Tungsten

23.1 Introduction
23.2 The Elements
  23.2.1 Terrestrial abundance and distribution
  23.2.2 Preparation and uses of the metals
  23.2.3 Properties of the elements
  23.2.4 Chemical reactivity and trends
23.3 Compounds of Chromium, Molybdenum and Tungsten
  23.3.1 Oxides
  23.3.2 Isopolymetallates
  23.3.3 Heteropolymetallates
  23.3.4 Tungsten and molybdenum bronzes
  23.3.5 Sulfides, selenides and tellurides
  23.3.6 Halides and oxohalides
  23.3.7 Complexes of chromium, molybdenum and tungsten
    Oxidation state VI (d⁶)
    Oxidation state V (d⁴)
    Oxidation state IV (d³)
    Oxidation state III (d²)
    Oxidation state II (d¹)
  23.3.8 Biological activity and nitrogen fixation
  23.3.9 Organometallic compounds

Chapter 24 Manganese, Technetium and Rhenium

24.1 Introduction
24.2 The Elements
Chapter 25  Iron, Ruthenium and Osmium  1070

25.1  Introduction  1070
25.2  The Elements Iron, Ruthenium and Osmium  1071
   25.2.1  Terrestrial abundance and distribution  1071
   25.2.2  Preparation and uses of the elements  1071
   25.2.3  Properties of the elements  1074
   25.2.4  Chemical reactivity and trends  1075
25.3  Compounds of Iron, Ruthenium and Osmium  1079
   25.3.1  Oxides and other chalcogenides  1079
   25.3.2  Mixed metal oxides and oxoanions  1081
   25.3.3  Halides and oxohalides  1082
   25.3.4  Complexes
      Oxidation state VIII (d0)  1085
      Oxidation state VII (d1)  1085
      Oxidation state VI (d2)  1085
      Oxidation state V (d3)  1086
      Oxidation state IV (d4)  1086
      Oxidation state III (d5)  1088
      Oxidation state II (d6)  1091
      Mixed valence compounds of ruthenium  1097
      Lower oxidation states  1098
   25.3.5  The biochemistry of iron
      Haemoglobin and myoglobin  1098
      Cytochromes  1099
      Iron-sulfur proteins  1101
   25.3.6  Organometallic compounds
      Carbonyls  1104
      Carbonyl hydrides and carbonylate anions  1105
      Carbonyl halides and other substituted carbonyls  1108
      Ferrocene and other cyclopentadienyls  1109

Chapter 26  Cobalt, Rhodium and Iridium  1113

26.1  Introduction  1113
26.2  The Elements  1113
   26.2.1  Terrestrial abundance and distribution  1113
   26.2.2  Preparation and uses of the elements  1114
   26.2.3  Properties of the elements  1115
   26.2.4  Chemical reactivity and trends  1116
26.3  Compounds of Cobalt, Rhodium and Iridium  1117
Chapter 27  Nickel, Palladium and Platinum

27.1 Introduction
27.2 The Elements
  27.2.1 Terrestrial abundance and distribution
  27.2.2 Preparation and uses of the elements
  27.2.3 Properties of the elements
  27.2.4 Chemical reactivity and trends
27.3 Compounds of Nickel, Palladium and Platinum
  27.3.1 The Pd/H2 system
  27.3.2 Oxides and chalcogenides
  27.3.3 Halides
  27.3.4 Complexes
    Oxidation state IV (d5)
    Oxidation state III (d6)
    Oxidation state II (d7)
    Oxidation state I (d8)
  27.3.5 The biochemistry of nickel
  27.3.6 Organometallic compounds
    σ-Bonded compounds
    Carbonyls
    Cyclopentadienyls
    Alkene and alkyne complexes
    π-Allylic complexes

Chapter 28  Copper, Silver and Gold

28.1 Introduction
28.2 The Elements
  28.2.1 Terrestrial abundance and distribution
  28.2.2 Preparation and uses of the elements
  28.2.3 Atomic and physical properties of the elements
  28.2.4 Chemical reactivity and trends
28.3 Compounds of Copper, Silver and Gold
  28.3.1 Oxides and sulfides
  28.3.2 High temperature superconductors
  28.3.3 Halides
  28.3.4 Photography
  28.3.5 Complexes
    Oxidation state III (d5)
    Oxidation state II (d6)
    Electronic spectra and magnetic properties of copper(II)
    Oxidation state I (d10)
    Gold cluster compounds
  28.3.6 Biochemistry of copper
  28.3.7 Organometallic compounds
Chapter 29  Zinc, Cadmium and Mercury  

29.1 Introduction  
29.2 The Elements  
29.2.1 Terrestrial abundance and distribution  
29.2.2 Preparation and uses of the elements  
29.2.3 Properties of the elements  
29.2.4 Chemical reactivity and trends  
29.3 Compounds of Zinc, Cadmium and Mercury  
29.3.1 Oxides and chalcogenides  
29.3.2 Halides  
29.3.3 Mercury(I)  
29.3.4 Zinc(II) and cadmium(II)  
29.3.5 Mercury(II)  
29.3.6 Organometallic compounds  
29.3.7 Biological and environmental importance  

Chapter 30  The Lanthanide Elements (Z = 58–71)  

30.1 Introduction  
30.2 The Elements  
30.2.1 Terrestrial abundance and distribution  
30.2.2 Preparation and uses of the elements  
30.2.3 Properties of the elements  
30.2.4 Chemical reactivity and trends  
30.3 Compounds of the Lanthanides  
30.3.1 Oxides and chalcogenides  
30.3.2 Halides  
30.3.3 Magnetic and spectroscopic properties  
30.3.4 Complexes  
30.3.5 Organometallic compounds  

Chapter 31  The Actinide and Transactinide Elements (Z = 90–112)  

31.1 Introduction  
31.2 The Actinide Elements  
31.2.1 Terrestrial abundance and distribution  
31.2.2 Preparation and uses of the actinide elements  
31.2.3 Properties of the actinide elements  
31.2.4 Chemical reactivity and trends  
31.3 Compounds of the Actinides  
31.3.1 Oxides and chalcogenides of the actinides  
31.3.2 Mixed metal oxides  
31.3.3 Halides of the actinide elements  
31.3.4 Magnetic and spectroscopic properties  
31.3.5 Complexes of the actinide elements

1

Origin of the Elements. Isotopes and Atomic Weights

1.1 Introduction

This book presents a unified treatment of the chemistry of the elements. At present 112 elements are known, though not all occur in nature: of the 92 elements from hydrogen to uranium all except technetium and promethium are found on earth and technetium has been detected in some stars. To these elements a further 20 have been added by artificial nuclear syntheses in the laboratory. Why are there only 90 elements in nature? Why do they have their observed abundances and why do their individual isotopes occur with the particular relative abundances observed? Indeed, we must also ask to what extent these isotopic abundances commonly vary in nature, thus causing variability in atomic weights and possibly jeopardizing the classical means of determining chemical composition and structure by chemical analysis.

Theories abound, and it is important at all times to distinguish carefully between what has been experimentally established, what is a useful model for suggesting further experiments, and what is a currently acceptable theory which interprets the known facts. The tentative nature of our knowledge is perhaps nowhere more evident than in the first few sections of this chapter dealing with the origin of the chemical elements and their present isotopic composition. This is not surprising, for it is only in the last few decades that progress in this enormous enterprise has been made possible by discoveries in nuclear physics, astrophysics, relativity and quantum theory.

1.2 Origin of the Universe

At present, the most widely accepted theory for the origin and evolution of the universe to its present form is the "hot big bang". It is supposed that all the matter in the universe

---

was once contained in a primeval nucleus of immense density ($\sim 10^{96}$ g cm$^{-3}$) and temperature ($\sim 10^{32}$ K) which, for some reason, exploded and distributed radiation and matter uniformly throughout space. As the universe expanded it cooled; this allowed the four main types of force to become progressively differentiated, and permitted the formation of various types of particle to occur. Nothing scientific can be said about the conditions obtaining at times shorter than the Planck time, $t_p = (G\lambda/c^4)^{1/2} = 1.33 \times 10^{-43}$ s at which moment the forces of gravity and electromagnetism, and the weak and strong nuclear forces were all undifferentiated and equally powerful. At $10^{-43}$ s after the big bang ($T = 10^{31}$ K) gravity separated as a distinct force, and at $10^{-35}$ s ($10^{28}$ K) the strong nuclear force separated from the still combined electro-weak force. These are, of course, inconceivably short times and unimaginably high temperatures: for example, it takes as long as $10^{-24}$ s for a photon (travelling at the speed of light) to traverse a distance equal to the diameter of an atomic nucleus. When a time interval of $10^{-10}$ s had elapsed from the big bang the temperature is calculated to have fallen to $10^{15}$ K and this enabled the electromagnetic and weak nuclear forces to separate. By $6 \times 10^{-6}$ s ($1.4 \times 10^{12}$ K) protons and neutrons had been formed from quarks, and this was followed by stabilization of electrons. One second after the big bang, after a period of extensive particle–antiparticle annihilation to form electromagnetic photons, the universe was populated by particles which sound familiar to chemists — protons, neutrons and electrons.

Shortly thereafter, the strong nuclear force ensured that large numbers of protons and neutrons rapidly combined to form deuterium nuclei ($p + n$), then helium ($2p + 2n$). The process of element building had begun. During this small niche of cosmic history, from about $10^{-5}$ s after the big bang, the entire universe is thought to have behaved as a colossal homogeneous fusion reactor converting hydrogen into helium. Previously no helium nuclei could exist — the temperature was so high that the sea of radiation would have immediately decomposed them back to protons and neutrons. Subsequently, the continuing expansion of the universe was such that the particle density was too low for these strong (but short-range) interactions to occur. Thus, within the time slot of about eight minutes, it has been calculated that about one-quarter of the mass of the universe was converted to helium nuclei and about three-quarters remained as hydrogen. Simultaneously, a minute $10^{-3}$% was converted to deuterons and about $10^{-6}$% to lithium nuclei. These remarkable predictions of the big bang cosmological theory are borne out by experimental observations. Wherever one looks in the universe — the oldest stars in our own galaxy, or the “more recent” stars in remote galaxies — the universal abundance of helium is about 25%. Even more remarkably, the expected concentration of deuterium has been detected in interstellar clouds. Yet, as we shall shortly see, stars can only destroy deuterium as soon as it is formed; they cannot create any appreciable equilibrium concentration of deuterium nuclei because of the high temperature of the stellar environment. The sole source of deuterium in the universe seems to be the big bang. At present no other cosmological theory can explain this observed ratio of H:He:D.

Two other features of the universe find ready interpretation in terms of the big bang theory. First, as observed originally by E. Hubble in 1929, the light received on earth from distant galaxies is shifted increasingly towards the red end of the spectrum as the distance of the source increases. This implies that the universe is continually expanding and, on certain assumptions, extrapolation backwards in time indicates that the big bang occurred some 15 billion years ago. Estimates from several other independent lines of evidence give reassuringly similar values for the age of the universe. Secondly, the theory convincingly explains (indeed predicted) the existence of an all-pervading isotropic cosmic black-body radiation. This radiation (which corresponds to a temperature of $2.735 \pm 0.06$ K according to the most recent measurements) was discovered in
1.3 Abundances of the Elements in the Universe

Information on the abundances of at least some of the elements in the sun, stars, gaseous nebulae and the interstellar regions has been obtained from detailed spectroscopic analysis using various regions of the electromagnetic spectrum. This data can be supplemented by direct analysis of samples from the earth, from meteorites, and increasingly from comets, the moon, and the surfaces of other planets and satellites in the solar system. The results indicate extensive differentiation in the solar system and in some stars, but the overall picture is one of astonishing uniformity of composition. Hydrogen is by far the most abundant element in the universe, accounting for some 88.6% of all atoms (or nuclei). Helium is about eightfold less abundant (11.3%), but these two elements together account for over 99.9% of the atoms and nearly 99% of the mass of the universe. Clearly nucleosynthesis of the heavier elements from hydrogen and helium has not yet proceeded very far.

Various estimates of the universal abundances of the elements have been made and, although these sometimes differ in detail for particular elements, they rarely do so by more than a factor of 3 (10^{0.5}) on a scale that spans more than 12 orders of magnitude. Representative values are plotted in Fig. 1.1, which shows a number of features that must be explained by any satisfactory theory of the origin of the elements. For example:

(i) Abundances decrease approximately exponentially with increase in atomic mass number $A$ until $A \sim 100$ (i.e. $Z \sim 42$); thereafter the decrease is more gradual and is sometimes masked by local fluctuations.

(ii) There is a pronounced peak between $Z = 23-28$ including V, Cr, Mn, Fe, Co and Ni, and rising to a maximum at Fe which is $\sim 10^3$ more abundant than expected from the general trend.

(iii) Deuterium (D), Li, Be and B are rare compared with the neighbouring H, He, C and N.

(iv) Among the lighter nuclei (up to Sc, $Z = 21$), those having an atomic mass number $A$ divisible by 4 are more abundant than their neighbours, e.g. $^{16}$O, $^{20}$Ne, $^{24}$Mg, $^{28}$Si, $^{32}$S, $^{36}$Ar and $^{40}$Ca (rule of G. Oddo, 1914).

(v) Atoms with $A$ even are more abundant than those with $A$ odd. (This is seen in Fig. 1.1 as an upward displacement of the curve for $Z$ even, the exception at beryllium being due to the non-existence of $^8$Be, the isotope $^9$Be being the stable species.)

Two further features become apparent when abundances are plotted against $A$ rather than $Z$:

(vi) Atoms of heavy elements tend to be neutron rich; heavy proton-rich nuclides are rare.

(vii) Double-peaked abundance maxima occur at $A = 80, 90; A = 130, 138$; and $A = 196, 208$ (see Fig. 1.5 on p. 11).

It is also necessary to explain the existence of naturally occurring radioactive elements whose half-lives (or those of their precursors) are substantially less than the presumed age of the universe.

As a result of extensive studies over the past four decades it is now possible to give a detailed and convincing explanation of the experimental abundance data summarized above. The historical sequence of events which led to our present

---

Figure 1.1 Cosmic abundances of the elements as a function of atomic number $Z$. Abundances are expressed as numbers of atoms per $10^6$ atoms of Si and are plotted on a logarithmic scale. (From A. G. W. Cameron, Space Sci. Rev. 15, 121–46 (1973), with some updating.)
understanding is briefly summarized in the Panel. As the genesis of the elements is closely linked with theories of stellar evolution, a short description of the various types of star is given in the next section and this is then followed by a fuller discussion of the various processes by which the chemical elements are synthesized.

1.4 Stellar Evolution and the Spectral Classes of Stars

In broad outline stars are thought to evolve by the following sequence of events. First, there is self-gravitational accretion from the cooled primordial hydrogen and helium. For a star the size and mean density of the sun (mass = 1.991 x 10^30 kg = 1 M☉) this might take ~20 y. This gravitational contraction releases heat energy, some of which is lost by radiation; however, the continued contraction results in a steady rise in temperature until at ~10^7 K the core can sustain nuclear reactions. These reactions release enough additional energy to compensate for radiational losses and a temporary equilibrium or steady state is established.

When ~10% of the hydrogen in the core has been consumed gravitational contraction again occurs until at a temperature of ~2 x 10^8 K helium burning (fusion) can occur. This is followed by a similar depletion, contraction and temperature rise until nuclear reactions involving

still heavier nuclei \((Z = 8-22)\) can occur at \(\sim 10^9\) K. The time scale of these processes depends sensitively on the mass of the star, taking perhaps \(10^{12}\) y for a star of mass 0.2 M\(_\odot\), \(10^{10}\) y for a star of 1 solar mass, \(10^7\) y for mass 10 M\(_\odot\), and only \(8 \times 10^4\) y for a star of 50 M\(_\odot\); i.e. the more massive the star, the more rapidly it consumes its nuclear fuel. Further catastrophic changes may then occur which result in much of the stellar material being ejected into space, where it becomes incorporated together with further hydrogen and helium in the next generation of stars. It should be noted, however, that, as iron is at the maximum of the nuclear binding energy curve, only those elements up to iron \((Z = 26)\) can be produced by exothermic processes of the type just considered, which occur automatically if the temperature rises sufficiently. Beyond iron, an input of energy is required to promote further element building.

The evidence on which this theory of stellar evolution is based comes not only from known nuclear reactions and the relativistic equivalence of mass and energy, but also from the spectroscopic analysis of the light reaching us from the stars. This leads to the spectral classification of stars, which is the cornerstone of modern experimental astrophysics. The spectroscopic analysis of starlight reveals much information about the chemical composition of stars — the identity of the elements present and their relative concentrations. In addition, the “red shift” or Doppler effect can be used to gauge the relative motions of the stars and their distance from the earth. More subtly, the surface temperature of stars can be determined from the spectral characteristics of their “blackbody” radiation, the higher the temperature the shorter the wavelength of maximum emission. Thus cooler stars appear red, and successively hotter stars appear progressively yellow, white, and blue. Differences in colour are also associated with differences in chemical composition as indicated in Table 1.1.

If the spectral classes (or temperatures) of stars are plotted against their absolute magnitudes (or luminosities) the resulting diagram shows several preferred regions into which most of the stars fall. Such diagrams were first made, independently, by E. Hertzsprung and H. N. Russell about 1913 and are now called HR diagrams (Fig. 1.2). More than 90% of all stars fall on a broad band called the main sequence, which covers the full range of spectral classes and magnitudes from the large, hot, massive O stars at the top to the small, dense, reddish M stars at the bottom. However, it should be emphasized that the terms “large” and “small” are purely relative since all stars within the main sequence are classified as dwarfs.

\(^{(a)}\) Further division of each class into 10 subclasses is possible, e.g. . . . F8, F9, G0, G1, G2, . . . The sun is G2 with a surface temperature of 5780 K. This curious alphabetical sequence of classes arose historically and can perhaps best be remembered by the mnemonic “Oh Be A Fine Girl (Guy), Kiss Me”. 
The next most numerous group of stars lie above and to the right of the main sequence and are called red giants. For example, Capella and the sun are both G-type stars yet Capella is 100 times more luminous than the sun; since they both have the same temperature it is concluded that Capella must have a radiating surface 100 times larger than the sun and thus has about 10 times its radius. Lying above the red giants are the supergiants such as Antares (Fig. 1.3), which has a surface temperature only half that of the sun but is 10,000 times more luminous: it is concluded that its radius is 100 times that of the sun. By contrast, the lower left-hand corner of the HR diagram is populated with relatively hot stars of low luminosity which implies that they are very small. These are the white dwarfs such as Sirius B which is only about the size of the earth though its mass is that of the sun: the implied density...
of $\sim 5 \times 10^{4} \text{ g cm}^{-3}$ indicates the extraordinarily compact nature of these bodies.

It is now possible to connect this description of stellar types with the discussion of the thermonuclear processes and the synthesis of the elements to be given in the next section. When a protostar begins to form by gravitational contraction from interstellar hydrogen and helium, its temperature rises until the temperature in its core can sustain proton burning (p. 9). A star of approximately the mass of the sun joins the main sequence at this point and spends perhaps 90% of its life there, losing little mass but generating colossal amounts of energy. Subsequent exhaustion of the hydrogen in the core (but not in the outer layers of the star) leads to further contraction to form a helium-burning core which forces much of the remaining hydrogen into a vast tenuous outer envelope — the star has become a red giant since its enormous radiating surface area can no longer be maintained at such a high temperature as previously despite the higher core temperature. Typical red giants have surface temperatures in the range $3500 - 5500 \text{ K}$; their luminosities are about $10^{2} - 10^{4}$ times that of the sun and diameters about $10 - 100$ times that of the sun. Carbon burning (p. 10) can follow in older red giants followed by the $\alpha$-process (p. 11) during its final demise to white dwarf status.

Many stars are in fact partners in a binary system of two stars revolving around each other. If, as frequently occurs, the two stars have different masses, the more massive one will evolve faster and reach the white-dwarf stage before its partner. Then, as the second star expands to become a red giant its extended atmosphere encompasses the neighbouring white dwarf and induces instabilities which result in an outburst of energy and transfer of matter to the more massive partner. During this process the luminosity of the white dwarf increases perhaps ten-thousandfold and the event is witnessed as a nova (since the preceding binary was previously invisible to the naked eye).

As we shall see in the description of the $e$-process and the $\gamma$-process (p. 12), even more spectacular instabilities can develop in larger main sequence stars. If the initial mass is greater than about 3.5 solar masses, current theories suggest that gravitational collapse may be so catastrophic that the system implodes beyond nuclear densities to become a black hole. For main sequence stars in the mass range $1.4 - 3.5 \text{ M}_\odot$, implosion probably halts at nuclear densities to give a rapidly rotating neutron star (density $\sim 10^{14} \text{ g cm}^{-3}$) which may be observable as a pulsar emitting electromagnetic radiation over a wide range of frequencies in pulses at intervals of a fraction of a second. During this process of star implosion the sudden arrest of the collapsing core at nuclear densities yields an enormous temperature ($\sim 10^{12} \text{ K}$) and high pressure which produces an outward-moving shock wave. This strikes the star's outer envelope with resulting rapid compression, a dramatic rise in temperature, the onset of many new nuclear reactions, and explosive ejection of a significant fraction of the star's mass. The overall result is a supernova up to $10^{8}$ times as bright as the original star. At this point a single supernova is comparable in brightness to the whole of the rest of the galaxy in which it is formed, after which the brightness decays exponentially, often with a half-life of about two months. Supernovae, novae, and unstable variables from dying red giants are thus all candidates for the synthesis of heavier elements and their ejection into interstellar regions for subsequent processing in later generations of condensing main sequence stars such as the sun. It should be stressed, however, that these various theories of the origin of the chemical elements are all very recent and the detailed processes are by no means all fully understood. Since this is at present a very active area of research, some of the conclusions given in this chapter are correspondingly tentative, and will undoubtedly be modified and refined in the light of future experimental and theoretical studies. With this caveat we now turn to a more detailed description of the individual nuclear processes thought to be involved in the synthesis of the elements.
1.5 Synthesis of the Elements\(^5\)\(^\text{—}\)\(^9\)

The following types of nuclear reactions have been proposed to account for the various types of stars and the observed abundances of the elements:

(i) Exothermic processes in stellar interiors: these include (successively) hydrogen burning, helium burning, carbon burning, the \(\alpha\)-process, and the equilibrium or \(\varepsilon\)-process.

(ii) Neutron capture processes: these include the \(s\)-process (slow neutron capture) and the \(r\)-process (rapid neutron capture).

(iii) Miscellaneous processes: these include the \(p\)-process (proton capture) and spallation within the stars, and the \(x\)-process which involves spallation (p. 14) by galactic cosmic rays in interstellar regions.

### 1.5.1 Hydrogen burning

When the temperature of a contracting mass of hydrogen and helium atoms reaches about \(10^7\) K, a sequence of thermonuclear reactions is possible of which the most important are as shown in Table 1.2.

The overall reaction thus converts 4 protons into 1 helium nucleus plus 2 positrons and 2 neutrinos:

\[
4^1\text{H} \rightarrow 4^\text{He} + 2e^+ + 2\nu_e; \quad Q = 26.72 \text{ MeV}
\]

\(^6\)E. M. Burbidge, G. R. Burbidge, W. A. Fowler and F. Hoyle, Synthesis of the elements in stars, *Rev. Mod. Phys.* 29, 547—650 (1957). This is the definitive review on which all later work has been based.

</tbody>
</table>

\(^{(a)}\)The reaction time quoted is the time required for half the constituents involved to undergo reaction — this is sensitively dependent on both temperature and density; the figures given are appropriate for the centre of the sun, i.e. \(1.3 \times 10^7\) K and \(200\) g cm\(^{-3}\).

1 MeV per atom = \(96.485 \times 10^6\) kJ mol\(^{-1}\).

Making allowance for the energy carried away by the 2 neutrinos (\(2 \times 0.25\) MeV) this leaves a total of 26.22 MeV for radiation, i.e. 4.20 pJ per atom of helium or \(2.53 \times 10^9\) kJ mol\(^{-1}\). This vast release of energy arises mainly from the difference between the rest mass of the helium-4 nucleus and the 4 protons from which it was formed (0.028 atomic mass units). There are several other peripheral reactions between the protons, deuterons and \(^3\text{He}\) nuclei, but these need not detain us. It should be noted, however, that only 0.7% of the mass is lost during this transformation, so that the star remains approximately constant in mass. For example, in the sun during each second, some \(600 \times 10^6\) tonnes (\(600 \times 10^9\) kg) of hydrogen are processed into \(595.5 \times 10^6\) tonnes of helium, the remaining \(4.5 \times 10^6\) tonnes of matter being transformed into energy. This energy is released deep in the sun’s interior as high-energy \(\gamma\)-rays which interact with stellar material and are gradually transformed into photons with longer wavelengths; these work their way to the surface taking perhaps \(10^6\) years to emerge.

In fact, the sun is not a first-generation main-sequence star since spectroscopic evidence shows the presence of many heavier elements thought to be formed in other types of stars and subsequently distributed throughout the galaxy for eventual accretion into later generations of main-sequence stars. In the presence of heavier elements, particularly carbon and nitrogen, a catalytic sequence of nuclear reactions aids the fusion of protons to helium (H. A. Bethe
can occur. The hydrogen forms a vast tenuous envelope around this core with the result that the star evolves rapidly from the main sequence to become a red giant (p. 7). It is salutary to note that hydrogen burning in main-sequence stars has so far contributed an amount of helium to the universe which is only about 20% of that which was formed in the few minutes directly following the big bang (p. 2).

1.5.2 Helium burning and carbon burning

The main nuclear reactions occurring in helium burning are:

\[ ^{4}\text{He} + ^{4}\text{He} \rightarrow ^{8}\text{Be} \]

and

\[ ^{8}\text{Be} + ^{4}\text{He} \rightarrow ^{12}\text{C}^* \rightarrow ^{12}\text{C} + \gamma \]

The nucleus \(^{8}\text{Be}\) is unstable to \(\alpha\)-particle emission \((t_{1/2} \sim 2 \times 10^{-16}\text{ s})\) being 0.094 MeV less stable than its constituent helium nuclei; under the conditions obtaining in the core of a red giant the calculated equilibrium ratio of \(^{8}\text{Be}\) to \(^{4}\text{He}\) is \(\sim 10^{-9}\). Though small, this enables the otherwise improbable 3-body collision to occur. It is noteworthy that, from consideration of stellar nucleogenesis, F. Hoyle predicted in 1954 that the nucleus of \(^{12}\text{C}\) would have a radioactive excited state \(^{12}\text{C}^* \) 7.70 MeV above its ground state, some three years before this activity was observed experimentally at 7.653 MeV. Experiments also indicate that the energy difference \(Q(^{12}\text{C}^* - ^{3}\text{He})\) is 0.373 MeV, thus leading to the overall reaction energy

\[ ^{3}\text{He} \rightarrow ^{12}\text{C} + \gamma; \quad Q = 7.281\text{ MeV} \]

Further helium-burning reactions can now follow during which even heavier nuclei are synthesized:

\[ ^{12}\text{C} + ^{4}\text{He} \rightarrow ^{16}\text{O} + \gamma; \quad Q = 7.148\text{ MeV} \]

\[ ^{16}\text{O} + ^{4}\text{He} \rightarrow ^{20}\text{Ne} + \gamma; \quad Q = 4.75\text{ MeV} \]

\[ ^{20}\text{Ne} + ^{4}\text{He} \rightarrow ^{24}\text{Mg} + \gamma; \quad Q = 9.31\text{ MeV} \]
§1.5.3 The α-process

These reactions result in the exhaustion of helium previously produced in the hydrogen-burning process and an inner core of carbon, oxygen and neon develops which eventually undergoes gravitational contraction and heating as before. At a temperature of \( \sim 5 \times 10^8 \) K carbon burning becomes possible in addition to other processes which must be considered. Thus, ageing red giant stars are now thought to be capable of generating a carbon-rich nuclear reactor core at densities of the order of \( 10^4 \) g cm\(^{-3} \). Typical initial reactions would be:

\[
\begin{align*}
^{12}\text{C} + ^{12}\text{C} & \rightarrow ^{24}\text{Mg} + \gamma; \quad Q = 13.85 \text{ MeV} \\
^{12}\text{C} + ^{12}\text{C} & \rightarrow ^{23}\text{Na} + ^{1}\text{H}; \quad Q = 2.23 \text{ MeV} \\
^{12}\text{C} + ^{12}\text{C} & \rightarrow ^{20}\text{Ne} + ^{4}\text{He}; \quad Q = 4.62 \text{ MeV}
\end{align*}
\]

The time scale of such reactions is calculated to be \( \sim 10^5 \) y at \( 6 \times 10^8 \) K and \( \sim 1 \) y at \( 8.5 \times 10^8 \) K. It will be noticed that hydrogen and helium nuclei are regenerated in these processes and numerous subsequent reactions become possible, generating numerous nuclides in this mass range.

1.5.3 The α-process

The evolution of a star after it leaves the red-giant phase depends to some extent on its mass. If it is not more than about 1.4 M\(_\odot\) it may contract appreciably again and then enter an oscillatory phase of its life before becoming a white dwarf (p. 7). When core contraction following helium and carbon depletion raises the temperature above \( \sim 10^9 \) K the γ-rays in the stellar assembly become sufficiently energetic to promote the (endothermic) reaction \(^{20}\text{Ne}(\gamma,\alpha)^{16}\text{O}\). The α-particle released can penetrate the coulomb barrier of other neon nuclei to form \(^{24}\text{Mg}\) in a strongly exothermic reaction:

\[
^{20}\text{Ne} + \gamma \rightarrow ^{16}\text{O} + ^{4}\text{He}; \quad Q = -4.75 \text{ MeV}
\]

\[
^{20}\text{Ne} + ^{4}\text{He} \rightarrow ^{24}\text{Mg} + \gamma; \quad Q = +9.31 \text{ MeV}
\]

i.e. \( 2^{20}\text{Ne} \rightarrow ^{16}\text{O} + ^{24}\text{Mg} + \gamma; \quad Q = +4.56 \text{ MeV} \)

Some of the released α-particles can also scour out \(^{12}\text{C}\) to give more \(^{16}\text{O}\) and the \(^{24}\text{Mg}\) formed can react further by \(^{24}\text{Mg}(\alpha,\gamma)^{28}\text{Si}\). Likewise for \(^{32}\text{S}, ^{36}\text{Ar}\) and \(^{40}\text{Ca}\). It is this process that is considered to be responsible for building up the decreasing proportion of these so-called α-particle nuclei (Figs. 1.1 and 1.5). The relevant numerical data (including for comparison those for \(^{20}\text{Ne}\) which is produced in helium and carbon burning) are as follows:

<table>

Figure 1.5 Schematic representation of the main features of the curve of cosmic abundances shown in Fig. 1.1, labelled according to the various stellar reactions considered to be responsible for the synthesis of the elements. (After E. M. Burbidge et al.\(^{61}\).)

In a sense the α-process resembles helium burning but is distinguished from it by the quite
different source of the $\alpha$-particles consumed. The straightforward $\alpha$-process stops at $^{40}\text{Ca}$ since $^{44}\text{Ti}^*$ is unstable to electron-capture decay. Hence (and including atomic numbers $Z$ as subscripts for clarity):

$$
^{40}\text{Ca} + ^{4}\text{He} \rightarrow ^{44}\text{Ti}^* + \gamma
$$

$$
^{44}\text{Ti}^* + e^- \rightarrow ^{44}\text{Sc}^* + \nu_+;
\text{t}_{1/2} \sim 49 \text{ yr}
$$

$$
^{44}\text{Sc}^* \rightarrow ^{44}\text{Ca} + \beta^+ + \nu_+;
\text{t}_{1/2} \sim 3.93 \text{ h}
$$

Then $^{44}\text{Ca} + ^{4}\text{He} \rightarrow ^{48}\text{Ti} + \gamma$

The total time spent by a star in this $\alpha$-phase may be $\sim 10^2 - 10^4$ yr (Fig. 1.6).

**Figure 1.6** The time-scales of the various processes of element synthesis in stars. The curve gives the central temperature as a function of time for a star of about one solar mass. The curve is schematic.

### 1.5.4 The $\epsilon$-process (equilibrium process)

More massive stars in the upper part of the main-sequence diagram (i.e. stars with masses in the range $1.4 - 3.5\ M_\odot$) have a somewhat different history to that considered in the preceding sections. We have seen (p. 6) that such stars consume their hydrogen much more rapidly than do smaller stars and hence spend less time in the main sequence. Helium reactions begin in their interiors long before the hydrogen is exhausted, and in the middle part of their life they may expand only slightly. Eventually they become unstable and explode violently, emitting enormous amounts of material into interstellar space. Such explosions are seen on earth as supernovae, perhaps 10,000 times more luminous than ordinary novae. In the seconds (or minutes) preceding this catastrophic outburst, at temperatures above $\sim 3 \times 10^9$ K, many types of nuclear reactions can occur in great profusion, e.g. $(\gamma,\alpha)$, $(\gamma,p)$, $(\gamma,n)$, $(\alpha,n)$, $(p,\gamma)$, $(n,\gamma)$, $(p,n)$, etc. (Fig. 1.6). This enables numerous interconversions to occur with the rapid establishment of a statistical equilibrium between the various nuclei and the free protons and neutrons. This is believed to explain the cosmic abundances of elements from $^{22}\text{Ti}$ to $^{29}\text{Cu}$. Specifically, since $^{56}\text{Fe}$ is at the peak of the nuclear binding-energy curve, this element is considerably more abundant than those further removed from the most stable state.

### 1.5.5 The $s$- and $r$-processes (slow and rapid neutron absorption)

Slow neutron capture with emission of $\gamma$-rays is thought to be responsible for synthesizing most of the isotopes in the mass range $A = 63 - 209$ and also the majority of non-$\alpha$-process nuclei in the range $A = 23 - 46$. These processes probably occur in pulsating red giants over a time span of $\sim 10^7$ yr, and production loops for individual isotopes are typically in the range $10^2 - 10^5$ yr. Several stellar neutron sources have been proposed, but the most likely candidates are the exothermic reactions $^{13}\text{C}(\alpha,n)^{16}\text{O}$ (2.20 MeV) and $^{21}\text{Ne}(\alpha,n)^{24}\text{Mg}$ (2.58 MeV). In both cases the target nuclei ($A = 4n + 1$) would be produced by a $(p,\gamma)$ reaction on the more stable $4n$ nucleus followed by positron emission.

Because of the long time scale involved in the $s$-process, unstable nuclides formed by $(n,\gamma)$ reactions have time to decay subsequently by $\beta^-$ decay (electron emission). The crucial factor in determining the relative abundance of elements...
formed by this process is thus the neutron capture cross-section of the precursor nuclide. In this way the process provides an ingenious explanation of the local peaks in abundance that occur near $A = 90, 138$ and 208, since these occur near unusually stable nuclei (neutron “magic numbers” 50, 82 and 126) which have very low capture cross-sections (Fig. 1.5). Their concentration therefore builds up by resisting further reaction. In this way the relatively high abundances of specific isotopes such as $^{89}\text{Y}$ and $^{90}\text{Zr}$, $^{138}\text{Ba}$ and $^{140}\text{Ce}$, $^{208}\text{Pb}$ and $^{209}\text{Bi}$ can be understood.

In contrast to the more leisureed processes considered in preceding paragraphs, conditions can arise (e.g. at $\approx 10^9$ K in supernovae outbursts) where many neutrons are rapidly added successively to a nucleus before subsequent $\beta^-$ decay becomes possible. The time scale for the r-process is envisaged as $\approx 0.01-10$ s, so that, for example, some 200 neutrons might be added to an iron nucleus in 10–100 s. Only when $\beta^-$ instability of the excessively neutron-rich product nuclei becomes extreme and the cross-section for further neutron absorption diminishes near the “magic numbers”, does a cascade of some 8–10 $\beta^-$ emissions bring the product back into the region of stable isotopes. This gives a convincing interpretation of the local abundance peaks near $A = 80, 130$ and 194, i.e. some 8–10 mass units below the nuclides associated with the s-process maxima (Fig. 1.5). It has also been suggested that neutron-rich isotopes of several of the lighter elements might also be the products of an r-process, e.g. $^{36}\text{S}$, $^{46}\text{Ca}$, $^{48}\text{Ca}$ and perhaps $^{47}\text{Ti}$, $^{49}\text{Ti}$ and $^{50}\text{Ti}$. These isotopes, though not as abundant as others of these elements, nevertheless do exist as stable species and cannot be so readily synthesized by other potential routes.

The problem of the existence of the heavy elements must also be considered. The short half-lives of all isotopes of technetium and promethium adequately accounts for their absence on earth. However, no element with atomic number greater than 83Bi has any stable isotope. Many of these (notably $^{84}\text{Po}$, $^{85}\text{At}$, $^{86}\text{Rn}$, $^{87}\text{Fr}$, $^{88}\text{Ra}$, $^{89}\text{Ac}$ and $^{91}\text{Pa}$) can be understood on the basis of secular equilibria with radioactive precursors, and their relative concentrations are determined by the various half-lives of the isotopes in the radioactive series which produce them. The problem then devolves on explaining the cosmic presence of thorium and uranium, the longest lived of whose isotopes are $^{232}\text{Th}$ ($t_{1/2} 1.4 \times 10^{10} \text{ y}$), $^{238}\text{U}$ ($t_{1/2} 4.5 \times 10^9 \text{ y}$) and $^{235}\text{U}$ ($t_{1/2} 7.0 \times 10^8 \text{ y}$). The half-life of thorium is commensurate with the age of the universe ($\approx 1.5 \times 10^{10} \text{ y}$) and so causes no difficulty. If all the present terrestrial uranium was produced by an r-process in a single supernova event then this occurred $6.6 \times 10^9 \text{ y}$ ago (p. 1257). If, as seems more probable, many supernovae contributed to this process, then such events, distributed uniformly in time, must have started $\approx 10^{10} \text{ y}$ ago. In either case the uranium appears to have been formed long before the formation of the solar system ($4.6-5.0 \times 10^9 \text{ y}$ ago. More recent considerations of the formation and decay of $^{232}\text{Th}$, $^{235}\text{U}$ and $^{238}\text{U}$ suggest that our own galaxy is $(1.2-2.0) \times 10^{10} \text{ y}$ old.

1.5.6 The p-process (proton capture)

Proton capture processes by heavy nuclei have already been briefly mentioned in several of the preceding sections. The ($p,\gamma$) reaction can also be invoked to explain the presence of a number of proton-rich isotopes of lower abundance than those of nearby normal and neutron-rich isotopes (Fig. 1.5). Such isotopes would also result from expulsion of a neutron by a $\gamma$-ray, i.e. ($\gamma, n$). Such processes may again be associated with supernovae activity on a very short time scale. With the exceptions of $^{113}\text{In}$ and $^{115}\text{Sn}$, all of the 36 isotopes thought to be produced in this way have even atomic mass numbers; the lightest is $^{72}\text{Se}$ and the heaviest $^{196}\text{Hg}$.

1.5.7 The x-process

One of the most obvious features of Figs. 1.1 and 1.5 is the very low cosmic abundance of the stable isotopes of lithium, beryllium and
boron. Paradoxically, the problem is not to explain why these abundances are so low but why these elements exist at all since their isotopes are bypassed by the normal chain of thermonuclear reactions described on the preceding pages. Again, deuterium and \(^3\)He, though part of the hydrogen-burning process, are also virtually completely consumed by it, so that their existence in the universe, even at relatively low abundances, is very surprising. Moreover, even if these various isotopes were produced in stars, they would not survive the intense internal heat since their bonding energies imply that deuterium would be destroyed above \(0.5 \times 10^6\) K, Li above \(2 \times 10^6\) K, Be above \(3.5 \times 10^6\) and B above \(5 \times 10^6\). Deuterium and \(^3\)He are absent from the spectra of almost all stars and are now generally thought to have been formed by nucleosynthesis during the last few seconds of the original big bang; their main agent of destruction is stellar processing.

It now seems likely that the 5 stable isotopes \(^6\)Li, \(^7\)Li, \(^9\)Be, \(^{10}\)B and \(^{11}\)B are formed predominantly by spallation reactions (i.e. fragmentation) effected by galactic cosmic-ray bombardment (the x-process). Cosmic rays consist of a wide variety of atomic particles moving through the galaxy at relativistic velocities. Nuclei ranging from hydrogen to uranium have been detected in cosmic rays though \(^1\)H and \(^4\)He are by far the most abundant components \([\text{H}: 500; \text{He}: 40; \text{all particles} \text{with} \text{atomic numbers} \text{from} \text{3 to} 9: 5; \text{all particles} \text{with} \text{Z} \geq 10: \sim 1]\). However, there is a striking deviation from stellar abundances since Li, Be and B are vastly over abundant as are Sc, Ti, V and Cr (immediately preceding the abundance peak near iron). The simplest interpretation of these facts is that the (heavier) particles comprising the interstellar gas (predominantly \(^1\)H and \(^4\)He) and thereby fragment. This fragmentation, or spallation as it is called, produces lighter nuclei from heavier ones. Conversely, high-speed \(^4\)He particles may occasionally collide with interstellar iron-group elements and other heavy nuclei, thus inducing spallation and forming Li, Be and B (and possibly even some \(^2\)H and \(^3\)He), on the one hand, and elements in the range Sc–Cr, on the other. As we have seen, the lighter transition elements are also formed in various stellar processes, but the presence of elements in the mass range 6–12 suggest the need for a low-temperature low-density extra-stellar process. In addition to spallation, interstellar \((p,\alpha)\) reactions in the wake of supernova shock waves may contribute to the synthesis of boron isotopes:

\[
^{13}\text{C}(p,\alpha)^{10}\text{B} \quad \text{and} \quad ^{14}\text{N}(p,\alpha)^{11}\text{C} \rightarrow ^{11}\text{B}.
\]

A further intriguing possibility has recently been mooted. If the universe were not completely isotropic and uniform in density during the first few minutes after the big bang, then the high-density regions would have a greater concentration of protons than expected and the low-density regions would have more neutrons; this is because the diffusion of protons from high to low density regions would be inhibited by the presence of oppositely charged electrons whereas the electrically neutral neutrons can diffuse more readily. In the neutron-abundant lower-density regions certain neutron-rich species can then be synthesized. For example, in the homogeneous big bang, most of the \(^7\)Li formed is rapidly destroyed by proton bombardment \((^7\text{Li} + p \rightarrow ^2\text{He})\) but in a neutron-rich region the radioactive isotope \(^8\)Li can be formed:

\[
^7\text{Li} + n \rightarrow ^8\text{Li}^* \quad (t_{1/2} = 0.84\ s) \quad \beta^- \rightarrow ^2\text{He}
\]

If, before it decays, \(^8\)Li is struck by a prevalent \(^4\)He nucleus then \(^{11}\)B can be formed \((^8\text{Li}^* + ^4\text{He} \rightarrow ^{11}\text{B} + n)\) and this will survive longer than in a proton-rich environment \((^{11}\text{B} + p \rightarrow ^3\text{He})\). Other neutron-rich species could also be synthesized and survive in greater numbers than would

---

be possible with higher concentrations of protons, e.g.:

\[
\begin{align*}
^7\text{Li} + ^3\text{H} & \longrightarrow ^9\text{Be} + n \\
^9\text{Be} + ^3\text{H} & \longrightarrow ^{11}\text{B} + n
\end{align*}
\]

The relative abundances of the various isotopes of the light elements Li, Be and B therefore depend to some extent on which detailed model of the big bang is adopted, and experimentally determined abundances may in time permit conclusions to be drawn as to the relative importance of these processes as compared to x-process spallation reactions.

In overall summary, using a variety of nuclear syntheses it is now possible to account for the presence of the 270 known stable isotopes of the elements up to \(^{209}\text{Bi}\) and to understand, at least in broad outline, their relative concentrations in the universe. The tremendous number of hypothetically possible internuclear conversions and reactions makes detailed computation extremely difficult. Energy changes are readily calculated from the known relative atomic masses of the various nuclides, but the cross-sections (probabilities) of many of the reactions are unknown and this prevents precise calculation of reaction rates and equilibrium concentrations in the extreme conditions occurring even in stable stars. Conditions and reactions occurring during supernova outbursts are even more difficult to define precisely. However, it is clear that substantial progress has been made in the last few decades in interpreting the bewildering variety of isotopic abundances which comprise the elements used by chemists. The approximate constancy of the isotopic composition of the individual elements is a fortunate result of the quasi-steady-state conditions obtaining in the universe during the time required to form the solar system. It is tempting to speculate whether chemistry could ever have emerged as a quantitative science if the elements had had widely varying isotopic composition, since gravimetric analysis would then have been impossible and the great developments of the nineteenth century could hardly have occurred. Equally, it should no longer cause surprise that the atomic weights of the elements are not necessarily always "constants of nature", and variations are to be expected, particularly among the lighter elements, which can have appreciable effects on physicochemical measurements and quantitative analysis.

1.6 Atomic Weights\(^{12}\)

The concept of "atomic weight" or "mean relative atomic mass" is fundamental to the development of chemistry. Dalton originally supposed that all atoms of a given element had the same unalterable weight but, after the discovery of isotopes earlier this century, this property was transferred to them. Today the possibility of variable isotopic composition of an element (whether natural or artificially induced) precludes the possibility of defining the atomic weight of most elements, and the tendency nowadays is to define an atomic weight of an element as "the ratio of the average mass per atom of an element to one-twelfth of the mass of an atom of \(^{12}\text{C}\)". It is important to stress that atomic weights (mean relative atomic masses) of the elements are dimensionless numbers (ratios) and therefore have no units.

Because of their central importance in chemistry, atomic weights have been continually refined and improved since the first tabulations by Dalton (1803–5). By 1808 Dalton had included 20 elements in his list and these results were substantially extended and improved by Berzelius during the following decades. An illustration of the dramatic and continuing improvement in accuracy and precision during the past 100 y is given in Table 1.3. In 1874 no atomic weight was quoted to better than one part in 200, but by 1903 33 elements had values quoted to one part in 10\(^3\) and 2 of these (silver and

iodine) were quoted to 1 in \(10^4\). Today the majority of values are known to 1 in \(10^4\) and 26 elements have an accuracy exceeding 1 in \(10^6\). This improvement was first due to improved chemical methods, particularly between 1900 and 1935 when increasing use of fused silica ware and electric furnaces reduced the possibility of contamination. More recently the use of mass spectrometry has effected a further improvement in precision. Mass spectrometric data were first used in a confirmatory role in the 1935 table of atomic weights, and by 1938 mass spectrometric values were preferred to chemical determinations for hydrogen and osmium and to gas-density values for helium. In 1959 the atomic weight values of over 50 elements were still based on classical chemical methods, but by 1973 this number had dwindled to 9 (Ti, Ge, Se, Mo, Sn, Sb, Te, Hg and Tl) or to 10 if the coulometric determination for Zn is counted as chemical. The values for a further 8 elements were based on a judicious blend of chemical and mass-spectrometric data, but the values quoted for all other elements were based entirely on mass-spectrometric data.

Accurate atomic weight values do not automatically follow from precise measurements of relative atomic masses, however, since the relative abundance of the various isotopes must also be determined. That this can be a limiting factor is readily seen from Table 1.3: the value for praseodymium (which has only 1 stable naturally occurring isotope) has two more significant figures than the value for the neighbouring element cerium which has 4 such isotopes. In the twelve years since the first edition of this book was published the atomic weight values of no fewer than 55 elements have been improved, sometimes spectacularly, e.g. Ni from 58.69(1) to 58.6934(2).

### 1.6.1 Uncertainty in atomic weights

Numerical values for the atomic weights of the elements are now reviewed every 2 y by the Commission on Atomic Weights and Isotopic

| Table 1.3 Evolution of atomic weight values for selected elements\(^{(a)}\); (the dates selected were chosen for the reasons given below) |
|-----------------|------|------|------|------|------|------|
| H | 1 | 1.008 | 1.008 | 1.0080 | 1.00797 | 1.00794(7) gmr |
| C | 12 | 12.00 | 12.000 | 12.01115 | 12.01115 | 12.0107(8) g r |

| Ag | 108 | 107.93 | 107.880 | 107.880 | 107.870 | 107.8682(2) g |
| I | 127 | 126.85 | 126.932 | 126.91 | 126.9044 | 126.90447(3) |
| Ce | 92 | 140.0 | 140.25 | 140.13 | 140.12 | 140.116(1) g |
| Pr | — | 140.5 | 140.92 | 140.92 | 140.907 | 140.907 65(2) |
| Re | — | 188.7\(^{(b)}\) | 186.22 | 186.22 | 186.207(1) |
| Hg | 200 | 200.0 | 200.61 | 200.61 | 200.59 | 200.59(2) |

\(^{(a)}\)The annotations g, m and r appended to some values in the final column have the same meanings as those in the definitive table (facing inside front cover). The numbers in parentheses are the uncertainties in the last digit of the quoted value.

\(^{(b)}\)The value for rhenium was first listed in 1929.

Note on dates:
1874 Foundation of the American Chemical Society (64 elements listed).
1903 First international table of atomic weights (78 elements listed).
1925 Major review of table (83 elements listed).
1959 Last table to be based on oxygen = 16 (83 elements listed).
1961 Complete reassessment of data and revision to \(^{12}\)C = 12 (83 elements).
1997 Latest available IUPAC values (84 + 28 elements listed).
Abundances of IUPAC (the International Union of Pure and Applied Chemistry). Their most recent recommendations\(^{(13)}\) are tabulated on the inside front fly sheet. From this it is clear that there is still a wide variation in the reliability of the data. The most accurately quoted value is that for fluorine which is known to better than 1 part in 38 million; the least accurate is for boron (1 part in 1500, i.e. 7 parts in \(10^4\)). Apart from boron all values are reliable to better than 5 parts in \(10^4\) and the majority are reliable to better than 1 part in \(10^4\). For some elements (such as boron) the rather large uncertainty arises not because of experimental error, since the use of mass-spectrometric measurements has yielded results of very high precision, but because the natural variation in the relative abundance of the 2 isotopes \(^{10}\)B and \(^{11}\)B results in a range of values of at least ±0.003 about the quoted value of 10.811. By contrast, there is no known variation in isotopic abundances for elements such as selenium and osmium, but calibrated mass-spectrometric data are not available, and the existence of 6 and 7 stable isotopes respectively for these elements makes high precision difficult to obtain: they are thus prime candidates for improvement.

Atomic weights are known most accurately for elements which have only 1 stable isotope; the relative atomic mass of this isotope can be determined to at least 1 ppm and there is no possibility of variability in nature. There are 20 such elements: Be, F, Na, Al, P, Sc, Mn, Co, As, Y, Nb, Rh, I, Cs, Pr, Tb, Ho, Tm, Au and Bi. (Note that all of these elements except beryllium have odd atomic numbers — why?)

Elements with 1 predominant isotope can also, potentially, permit very precise atomic weight determinations since variations in isotopic composition or errors in its determination have a correspondingly small effect on the mass-spectrometrically determined value of the atomic weight. Nine elements have 1 isotope that is more than 99% abundant (H, He, N, O, Ar, V, La, Ta and U) and carbon also approaches this category (\(^{13}\)C 1.11% abundant).

Known variations in the isotopic composition of normal terrestrial material prevent a more accurate atomic weight being given for 13 elements and these carry the footnote r in the Table of Atomic Weights. For each of these elements (H, He, Li, B, C, N, O, Si, S, Ar, Cu, Sr and Pb) the accuracy attainable in an atomic weight determination on a given sample is greater than that implied by the recommended value since this must be applicable to any sample and so must embrace all known variations in isotopic composition from commercial terrestrial sources. For example, for hydrogen the present attainable accuracy of calibrated mass-spectrometric atomic weight determinations is about ±1 in the sixth significant figure, but the recommended value of 1.00794(±7) is so given because of the natural terrestrial variation in the deuterium content. The most likely value relevant to laboratory chemicals (e.g. \(\text{H}_2\text{O}\)) is 1.00797, but it should be noted that hydrogen gas used in laboratories is often inadvertently depleted during its preparation by electrolysis, and for such samples the atomic weight is close to 1.00790. By contrast, intentional fractionation to yield heavy water (thousands of tonnes annually) or deuterated chemicals implies an atomic weight approaching 2.014, and great care should be taken to avoid contamination of “normal” samples when working with or disposing of such enriched materials.

Fascinating stories of natural variability could be told for each of the 13 elements having the footnote r and, indeed, determinations of such variations in isotopic composition are now an essential tool in unravelling the geochemical history of various ore bodies. For example, the atomic weight of sulfur obtained from virgin Texas sulfur is detectably different from that obtained from sulfate ores, and an overall range approaching ±0.01 is found for terrestrial samples; this limits the value quoted to 32.066(6) though the accuracy of atomic weight determinations on individual samples is ±0.000 15. Boron is even more adversely

affected, as previously noted, and the actual atomic weight can vary from 10.809 to 10.812 depending on whether the mineral source is Turkey or the USA.

Even more disconcerting are the substantial deviations in atomic weight that can occur in commercially available material because of inadvertent or undisclosed changes in isotopic composition (footnote m in the Table of Atomic Weights). This situation at present obtains for 8 elements (H, Li, B, Ne, Cl, Kr, Xe and U) and may well also soon affect others (such as C, N and O). The separated or partially enriched isotopes of Li, B and U are now extensively used in nuclear reactor technology and weaponry, and the unwanted residues, depleted in the desired isotopes, are sometimes dumped on the market and sold as “normal” material. Thus lithium salts may unsuspectingly be purchased which have been severely depleted in $^6$Li (natural abundance 7.5%), and a major commercial supplier has marketed lithium containing as little as 3.75% of this isotope, thereby inducing an atomic weight change of 0.53%. For this reason practically all lithium compounds now obtainable in the USA are suspect and quantitative data obtained on them are potentially unreliable. Again, the practice of “milking” fission-product rare gases from reactor fuels and marketing these materials, produces samples with anomalous isotopic compositions. The effect, particularly on physicochemical computations, can be serious and, whilst not wishing to strike an alarmist note, the possibility of such deviations must continually be borne in mind for elements carrying the footnote m in the Table of Atomic Weights.

The related problem arising from radioactive elements is considered in the next section.

1.6.2 The problem of radioactive elements

Elements with radioactive nuclides amongst their naturally occurring isotopes have a built-in time variation of the relative concentration of their isotopes and hence a continually varying atomic weight. Whether this variation is chemically significant depends on the half-life of the transition and the relative abundance of the various isotopes. Similarly, the actual concentration of stable isotopes of several elements (e.g. Ar, Ca and Pb) may be influenced by association of those elements with radioactive precursors (i.e. $^{40}$K, $^{238}$U, etc.) which generate potentially variable amounts of the stable isotopes concerned. Again, some elements (such as technetium, promethium and the transuranium elements) are synthesized by nuclear reactions which produce a single isotope of the element. The “atomic weight” therefore depends on which particular isotope is being synthesized, and the concept of a “normal” atomic weight is irrelevant. For example, cyclotron production of technetium yields $^{97}$Tc ($t_{1/2}$ 2.6 x 10$^6$ y) with an atomic weight of 96.9064, whereas fission product technetium is $^{99}$Tc ($t_{1/2}$ 2.11 x 10$^5$ y), atomic weight 98.9063, and the isotope of longest half-life is $^{98}$Tc ($t_{1/2}$ 4.2 x 10$^6$ y), atomic weight 97.9072.

At least 19 elements not usually considered to be radioactive do in fact have naturally occurring unstable isotopes. The minute traces of naturally occurring $^3$H ($t_{1/2}$ 12.33 y) and $^{14}$C ($t_{1/2}$ 5730 y) have no influence on the atomic weights of these elements though, of course, they are of crucial importance in other areas of study. The radioactivity of $^{40}$K ($t_{1/2}$ 1.28 x 10$^{10}$ y) influences the atomic weights of its daughter elements argon (by electron capture) and calcium (by $\beta^-$ emission) but fortunately does not significantly affect the atomic weight of potassium itself because of the low absolute abundance of this particular isotope (0.0117%). The half-lives of the radioactive isotopes of the 16 other “stable” elements are all greater than 10$^{10}$ y and so normally have little influence on the atomic weight of these elements even when, as in the case of $^{115}$In ($t_{1/2}$ 4.41 x 10$^{14}$ y, 95.7% abundant) and $^{187}$Re ($t_{1/2}$ 4.35 x 10$^{10}$ y, 62.6% abundant), they are the most abundant isotopes. Note, however, that on a geological time scale it has been possible to build up significant concentrations of $^{187}$Os in rhenium-containing
ores (by $\beta^-$ decay of $^{187}$Re), thereby generating samples of osmium with an anomalous atomic weight nearer to 187 than to the published value of 190.23(3). Lead was the first element known to be subject to such isotopic disturbances and, indeed, the discovery and interpretation of the significance of isotopes was itself hastened by the reluctant conclusion of T. W. Richards at the turn of the century that a group of lead samples of differing geological origins were identical chemically but differed in atomic weight — the possible variation is now known to span almost the complete range from 204 to 208. Such elements, for which geological specimens are known in which the element has an anomalous isotopic composition, are given the footnote g in the Table of Atomic Weights. In addition to Ar, Ca, Os and Pb just discussed, such variability affects at least 38 other elements, including Sr (resulting from the $\beta^-$ decay of $^{87}$Rb), Ra, Th and U. A spectacular example, which affects virtually every element in the central third of the periodic table, has recently come to light with the discovery of prehistoric natural nuclear reactors at Oklo in Africa (see p. 1257). Fortunately this mine is a source of uranium ore only and so will not affect commercially available samples of the other elements involved.

In summary, as a consequence of the factors considered in this and the preceding section, the atomic weights of only the 20 mononuclidic elements can be regarded as “constants of nature”. For all other elements variability in atomic weight is potentially possible and in several instances is known to occur to an extent which affects the reliability of quantitative results of even modest precision.
2

Chemical Periodicity and the Periodic Table

2.1 Introduction

The concept of chemical periodicity is central to the study of inorganic chemistry. No other generalization rivals the periodic table of the elements in its ability to systematize and rationalize known chemical facts or to predict new ones and suggest fruitful areas for further study. Chemical periodicity and the periodic table now find their natural interpretation in the detailed electronic structure of the atom; indeed, they played a major role at the turn of the century in elucidating the mysterious phenomena of radioactivity and the quantum effects which led ultimately to Bohr’s theory of the hydrogen atom. Because of this central position it is perhaps not surprising that innumerable articles and books have been written on the subject since the seminal papers by Mendeleev in 1869, and some 700 forms of the periodic table (classified into 146 different types or subtypes) have been proposed.\(^1\) A brief historical survey of these developments is summarized in the Panel opposite.

There is no single best form of the periodic table since the choice depends on the purpose for which the table is used. Some forms emphasize chemical relations and valence, whereas others stress the electronic configuration of the elements or the dependence of the periods on the shells and subshells of the atomic structure. The most convenient form for our purpose is the so-called “long form” with separate panels for the lanthanide and actinide elements (see inside front cover). There has been a lively debate during the past decade as to the best numbering system to be used for the individual

---

§2.2 The electronic structure of atoms

The ubiquitous electron was discovered by J. J. Thompson in 1897 some 25 years after the original work on chemical periodicity by D. I. Mendeleev and Lothar Meyer; however, a further 20 years were to pass before G. N. Lewis and then I. Langmuir connected the electron with valency and chemical bonding. Refinements continued via wave mechanics and molecular orbital theory, and the symbiotic relation between experiment and theory still continues.

Mendelev's Periodic Table

Precursors and Successors

1772 L.B. G. de Morveau made the first table of "chemically simple" substances. A. L. Lavoisier used this in his Traité Elémentaire de Chimie published in 1789.

1817–29 J. W. Döbereiner discovered many triads of elements and compounds, the combining weight of the central component being the average of its partners (e.g. CaO, SrO, BaO, and NiO, CuO, ZnO).

1843 L. Gmelin included a V-shaped arrangement of 16 triads in the 4th edition of his Handbuch der Chemie.

1857 J. B. Dumas published a rudimentary table of 32 elements in 8 columns indicating their relationships.

1862 A. E. B. de Chancourtois first arranged the elements in order of increasing atomic weight; he located similar elements in this way and published a helical form in 1863.

1864 L. Meyer published a table of valences for 49 elements.

1864 W. Odling drew up an almost correct table with 17 vertical columns and including 57 elements.

1865 J. A. R. Newlands proposed his law of octaves after several partial classifications during the preceding 2 years; he also correctly predicted the atomic weight of the undiscovered element germanium.

1868–9 L. Meyer drew up an atomic volume curve and a periodic table, but this latter was not published until 1895.

1869 D. I. Mendeleev enunciated his periodic law that "the properties of the elements are a periodic function of their atomic weights". He published several forms of periodic table, one containing 63 elements.

1871 D. I. Mendeleev modified and improved his tables and predicted the discovery of 10 elements (now known as Sc, Ga, Ge, Tc, Re, Po, Fr, Ra, Ac and Pa). He fully described with amazing prescience the properties of 4 of these (Sc, Ga, Ge, Po). Note, however, that it was not possible to predict the existence of the noble gases or the number of lanthanide elements.

1894–8 Lord Rayleigh, W. Ramsay and M. W. Travers detected and then isolated the noble gases (He), Ne, Ar, Kr, Xe.

1913 N. Bohr explained the form of the periodic table on the basis of his theory of atomic structure and showed that there could be only 14 lanthanide elements.

1913 H. G. J. Moseley observed regularities in the characteristic X-ray spectra of the elements; he thereby discovered atomic numbers Z and provided justification for the ordinal sequence of the elements.

1940 E. McMillian and P. Abelson synthesized the first transuranium element 93Np. Others were synthesized by G. T. Seaborg and his colleagues during the next 15 years.

1944 G. T. Seaborg proposed the actinide hypothesis and predicted 14 elements (up to Z = 103) in this group.
today. It should always be remembered, however, that it is incorrect to “deduce” known chemical phenomena from theoretical models; the proper relationship is that the currently accepted theoretical models interpret the facts and suggest new experiments — they will be modified (or discarded and replaced) when new results demand it. Theories can never be proved by experiment — only refuted, the best that can be said of a theory is that it is consistent with a wide range of information which it interprets logically and that it is a fruitful source of predictions and new experiments.

Our present views on the electronic structure of atoms are based on a variety of experimental results and theoretical models which are fully discussed in many elementary texts. In summary, an atom comprises a central, massive, positively charged nucleus surrounded by a more tenuous envelope of negative electrons. The nucleus is composed of neutrons (\( n \)) and protons (\( p \), i.e. \( {\text{H}}^+ \)) of approximately equal mass tightly bound by the force field of mesons. The number of protons \( (Z) \) is called the atomic number and this, together with the number of neutrons \( (N) \), gives the atomic mass number of the nuclide \( (A = N + Z) \). An element consists of atoms all of which have the same number of protons \( (Z) \) and this number determines the position of the element in the periodic table (H. G. J. Moseley, 1913). Isotopes of an element all have the same value of \( Z \) but differ in the number of neutrons in their nuclei. The charge on the electron \( (e^-) \) is equal in size but opposite in sign to that of the proton and the ratio of their masses is 1/1836.1527.

The arrangement of electrons in an atom is described by means of four quantum numbers which determine the spatial distribution, energy, and other properties, see Appendix I (p. 1285). The principal quantum number \( n \) defines the general energy level or “shell” to which the electron belongs. Electrons with \( n = 1, 2, 3, 4, \ldots \), are sometimes referred to as K, L, M, N, \ldots, electrons. The orbital quantum number \( l \) defines both the shape of the electron charge distribution and its orbital angular momentum. The number of possible values for \( l \) for a given electron depends on its principal quantum number \( n \); it can have \( n \) values running from 0 to \( n - 1 \), and electrons with \( l = 0, 1, 2, 3, \ldots \), are designated s, p, d, f, \ldots, electrons. Whereas \( n \) is the prime determinant of an electron's energy this also depends to some extent on \( l \) (for atoms or ions containing more than one electron). It is found that the sequence of increasing electron energy levels in an atom follows the sequence of values \( n + l \); if 2 electrons have the same value of \( n + l \) then the one with smaller \( n \) is the more tightly bound.

The third quantum number \( m \) is called the magnetic quantum number for it is only in an applied magnetic field that it is possible to define a direction within the atom with respect to which the orbital can be directed. In general, the magnetic quantum number can take up \( 2l + 1 \) values (i.e. 0, ±1, \ldots, ±\( l \)); thus an s electron (which is spherically symmetrical and has zero orbital angular momentum) can have only one orientation, but a p electron can have three (frequently chosen to be the \( x, y, \) and \( z \) directions in Cartesian coordinates). Likewise there are five possibilities for d orbitals and seven for f orbitals.

The fourth quantum number \( m_s \) is called the spin angular momentum quantum number for historical reasons. In relativistic (four-dimensional) quantum mechanics this quantum number is associated with the property of symmetry of the wave function and it can take on one of two values designated as +\( \frac{1}{2} \) and −\( \frac{1}{2} \), or simply \( \alpha \) and \( \beta \). All electrons in atoms can be described by means of these four quantum numbers and, as first enumerated by W. Pauli in his *Exclusion Principle* (1926), each electron in an atom must have a unique set of the four quantum numbers.

It can now be seen that there is a direct and simple correspondence between this description of electronic structure and the form of the periodic table. Hydrogen, with 1 proton and 1 electron, is the first element, and, in the ground state (i.e. the state of lowest energy) it has the electronic configuration 1s\(^1\) with zero orbital angular momentum. Helium, \( Z = 2 \), has the configuration 1s\(^2\), and this completes the first period since no
other unique combination of $n = 1, l = m = 0, m_s = \pm \frac{1}{2}$ exists. The second period begins with lithium ($Z = 3$), the least tightly bound electron having the configuration $2s^1$. The same situation obtains for each of the other periods in the table, the number of the period being the principal quantum number of the least tightly bound electron of the first element in the period. It will also be seen that there is a direct relation between the various blocks of elements in the periodic table and the electronic configuration of the atoms it contains; the s block is 2 elements wide, the p block 6 elements wide, the d block 10, and the f block 14, i.e. $2(2l + 1)$, the factor 2 appearing because of the spins.

In so far as the chemical (and physical) properties of an element derive from its electronic configuration, and especially the configuration of its least tightly bound electrons, it follows that chemical periodicity and the form of the periodic table can be elegantly interpreted in terms of electronic structure.

2.3 Periodic Trends in Properties\(^{(5,6)}\)

General similarities and trends in the chemical properties of the elements had been noticed increasingly since the end of the eighteenth century and predated the observation of periodic variations in physical properties which were not noted until about 1868. However, it is more convenient to invert this order and to look at trends in atomic and physical properties first.

2.3.1 Trends in atomic and physical properties

Figure 2.1 shows a modern version of Lothar Meyer's atomic volume curve: the alkali metals

---

---

Figure 2.1 Atomic volumes (molar volumes) of the elements in the solid state.
appear at the peaks and elements near the centre of each period (B, C; Al, Si; Mn, Fe, Co; Ru; and Os) appear in the troughs. This finds a ready interpretation on the electronic theory since the alkali metals have only 1 electron per atom to contribute to the binding of the 8 nearest-neighbour atoms, whereas elements near the centre of each period have the maximum number of electrons available for bonding. Elements in other groups fall on corresponding sections of the curve in each period, and in several groups there is a steady trend to higher volumes with the increasing atomic number. Closer inspection reveals that a much more detailed interpretation would be required to encompass all the features of the curve which includes data on solids held by very diverse types of bonding. Note also that the position of helium is anomalous (why?), and that there are local anomalies at europium and ytterbium in the lanthanide elements (see Chapter 30). Similar plots are obtained for the atomic and ionic radii of the elements and an inverted diagram is obtained, as expected, for the densities of the elements in the solid state (Fig. 2.2).

Of more fundamental importance is the plot of first-stage ionization energies of the elements, i.e. the energy $I_M$ required to remove the least tightly bound electron from the neutral atom in the gas phase:

$$\text{M(g)} \rightarrow \text{M}^+(\text{g}) + e^-; \quad \Delta H^\circ = I_M$$

These are shown in Fig. 2.3 and illustrate most convincingly the various quantum shells and subshells described in the preceding section. The energy required to remove the 1 electron from an atom of hydrogen is 13.606 eV (i.e. 1312 kJ per mole of H atoms). This rises to 2372 kJ mol$^{-1}$ for He (1s$^2$) since the positive charge on the helium nucleus is twice that of the...
Figure 2.3  First-stage ionization energies of the elements.

proton and the additional charge is not completely shielded by the second electron. There is a large drop in ionization energy between helium and lithium (ls²2s¹) because the principal quantum number $n$ increases from 1 to 2, after which the ionization energy rises somewhat for beryllium (ls²2s²), though not to a value which is so high that beryllium would be expected to be an inert gas. The interpretation that is placed on the other values in Fig. 2.3 is as follows. The slight decrease at boron (ls²2s²2p¹) is due to the increase in orbital quantum number $l$ from 0 to 1 and the similar decrease between nitrogen and oxygen is due to increased interelectronic coulomb repulsion as the fourth p electron is added to the 3 already occupying 2pₓ, 2pᵧ, and 2pᵦ. The ionization energy then continues to increase with increasing $Z$ until the second quantum shell is filled at neon (2s²3p⁶). The process is precisely repeated from sodium (3s¹) to argon (3s²3p⁶) which again occurs at a peak in the curve, although at this point the third quantum shell is not yet completed (3d). This is because the next added electron for the next element potassium ($Z = 19$) enters the 4s shell ($n + l = 4$) rather than the 3d ($n + l = 5$). After calcium ($Z = 20$) the 3d shell fills and then the 4p ($n + l = 5$, but $n$ higher than for 3d). The implications of this and of the subsequent filling of later s, p, d, and f levels will be elaborated in considerable detail in later chapters. Suffice it to note for the moment that the chemical inertness of the lighter noble gases correlates with their high ionization energies whereas the extreme reactivity of the alkali metals (and their prominent flame tests) finds a ready interpretation in their much lower ionization energies.

Electronegativities also show well-developed periodic trends though the concept of electronegativity itself, as introduced by L. Pauling,⁷ is rather qualitative: “Electronegativity is the power of an atom in a molecule to attract electrons to itself.” It is to be expected that the electronegativity of an element will depend to some extent not only on the other atoms to which it is bonded but also on its coordination number and oxidation state; for example, the electronegativity of a given atom increases with increase in its oxidation state. Fortunately, however, these effects do not obscure the main trends. Various measures of electronegativity have been proposed by L. Pauling, by R. S. Mulliken, by A. L. Allred

Figure 2.4 Values of electronegativity of the elements.

and E. Rochow, and by R. T. Sanderson, and all give roughly parallel scales. Figure 2.4, which incorporates Pauling's values, illustrates the trends observed; electronegativities tend to increase with increasing atomic number within a given period (e.g. Li to F, or K to Br) and to decrease with increasing atomic number within a given group (e.g. F to At, or O to Po). Numerous reviews are available.

Many other properties have been found to show periodic variations and these can be displayed graphically or by circles of varying size on a periodic table, e.g. melting points of the elements, boiling points, heats of fusion, heats of vaporization, energies of atomization, etc. Similarly, the properties of simple binary compounds of the elements can be plotted, e.g. heats of formation, melting points and boiling points of hydrides, fluorides, chlorides, bromides, iodides, oxides, sulfides, etc. Trends immediately become apparent, and the selection of compounds with specific values for particular properties is facilitated. Such trends also permit interpolation to give estimates of undetermined values of properties for a given compound though such a procedure can be misleading and should only be used as a first rough guide. Extrapolation has also frequently been used, and to good effect, though it too can be hazardous and unreliable particularly when new or unsuspected effects are involved. Perhaps the classic example concerns the dissociation energy of the fluorine molecule which is difficult to measure experimentally: for many years this was taken to be $\sim265$ kJ mol$^{-1}$ by extrapolation of the values for iodine, bromine, and chlorine (151, 193, and 243 kJ mol$^{-1}$), whereas the

most recent experimental values are close to 159 kJ mol\(^{-1}\) (see Chapter 17). The detection of such anomalous data from periodic plots thus serves to identify either inaccurate experimental observations or inadequate theories (or both).

### 2.3.2 Trends in chemical properties

These, though more difficult to describe quantitatively than the trends in atomic and physical properties described in the preceding subsection, also become apparent when the elements are compared in each group and along each period. Such trends will be discussed in detail in later chapters and it is only necessary here to enumerate briefly the various types of behaviour that frequently recur.

The most characteristic chemical property of an element is its valence. There are numerous measures of valency each with its own area of usefulness and applicability. Simple definitions refer to the number of hydrogen atoms that can combine with an element in a binary hydride or to twice the number of oxygen atoms combining with an element in its oxide(s). It was noticed from the beginning that there was a close relation between the position of an element in the periodic table and the stoichiometry of its simple compounds. Hydrides of main group elements have the formula \( \text{MH}_n \), where \( n \) was related to the group number \( N \) by the equations \( n = N \ (N \leq 4), \) and \( n = 18 - N \) for \( N > 14 \). By contrast, oxygen elicited an increasing valence in the highest normal oxide of each element and this was directly related to the group number, i.e. \( \text{M}_2\text{O}, \text{MO}, \text{M}_2\text{O}_3, \ldots, \text{M}_2\text{O}_7 \). These periodic regularities find a ready explanation in terms of the electronic configuration of the elements and simple theories of chemical bonding. In more complicated chemical formulae involving more than 2 elements, it is convenient to define the “oxidation state” of an element as the formal charge remaining on the element when all other atoms have been removed as their normal ions. For example, nitrogen has an oxidation state of +7 in potassium permanganate \([\text{tetraoxomanganate}(1-) \] [\( \text{KMnO}_4 - (\text{K}^+ + 4\text{O}^{2-}) = \text{Mn}^{7+} \)]). For a compound such as \( \text{Fe}_2\text{O}_4 \) iron has an average oxidation state of +2.67 [i.e. \((4 \times 2)/3\)] which may be thought of as comprising \( 1\text{Fe}^{2+} \) and \( 2\text{Fe}^{3+} \). It should be emphasized that these charges are formal, not actual, and that the concept of oxidation state is not particularly helpful when considering predominantly covalent compounds (such as organic compounds) or highly catenated inorganic compounds such as \( \text{S}_7\text{NH} \).

The periodicity in the oxidation state or valence shown by the elements was forcefully illustrated by Mendeleev in one of his early forms of the periodic system and this is shown in an extended form in Fig. 2.5 which incorporates more recent information. The predictive and interpolative powers of such a plot are obvious and have been a fruitful source of chemical experimentation for over a century.

Other periodic trends which occur in the chemical properties of the elements and which are discussed in more detail throughout later chapters are:

1. The “anomalous” properties of elements in the first short period (from lithium to fluorine) — see Chapters 4, 5, 6, 8, 11, 14 and 17.
2. The “anomalies” in the post-transition element series (from gallium to bromine) related to the d-block contraction — see Chapters 7, 10, 13, 16 and 17.
3. The effects of the lanthanide contraction — see Chapters 21–30.
4. Diagonal relationships between lithium and magnesium, beryllium and aluminium, boron and silicon.
5. The so-called inert pair effect (see Chapters 7, 10 and 13) and the variation of oxidation state in the main group elements in steps of 2 (e.g. \( \text{IF}, \text{IF}_3, \text{IF}_5, \text{IF}_7 \)).
6. Variability in the oxidation state of transition elements in steps of 1.
7. Trends in the basicity and electropositivity of elements — both vertical trends
Figure 2.5  Formal oxidation states of the elements displayed in a format originally devised by Mendeleev in 1889. The more common oxidation states (including zero) are shown in white. Nonintegral values, as in $\text{B}_3\text{H}_6$, $\text{C}_3\text{H}_8$, $\text{HN}_3$, $\text{S}^{2+}$, etc., are not included.
within groups and horizontal trends along periods.

(viii) Trends in bond type with position of the elements in the table and with oxidation state for a given element.

(ix) Trends in stability of compounds and regularities in the methods used to extract the elements from their compounds.

(x) Trends in the stability of coordination complexes and the electron-donor power of various series of ligands.

### 2.4 Prediction of New Elements and Compounds

Newlands (1864) was the first to predict correctly the existence of a “missing element” when he calculated an atomic weight of 73 for an element between silicon and tin, close to the present value of 72.61 for germanium (discovered by C. A. Winkler in 1886). However, his method of detecting potential triads was unreliable and he predicted (non-existent) elements between rhodium and iridium, and between palladium and platinum. Mendeleev’s predictions 1869–71 were much more extensive and reliable, as indicated in the historical panel on p. 21. The depth of his insight and the power of his method remain impressive even today, but in the state of development of the subject in 1869 they were monumental. A comparison of the properties of eka-silicon predicted by Mendeleev and those determined experimentally for germanium is shown in Table 2.1. Similarly accurate predictions were made for eka-aluminium and gallium and for eka-boron and scandium.

Of the remaining 26 undiscovered elements between hydrogen and uranium, 11 were lanthanoids which Mendeleev’s system was unable to characterize because of their great chemical similarity and the new numerological feature dictated by the filling of the 4f orbitals. Only cerium, terbium and erbium were established with certainty in 1871, and the others (except promethium, 1945) were separated and identified in the period 1879–1907. The isolation of the (unpredicted) noble gases also occurred at this time (1894–8).

</table>
The isolation and identification of 4 radioactive elements in minute amounts took place at the turn of the century, and in each case the insight provided by the periodic classification into the predicted chemical properties of these elements proved invaluable. Marie Curie identified polonium in 1898 and, later in the same year working with Pierre Curie, isolated radium. Actinium followed in 1899 (A. Debierne) and the heaviest noble gas, radon, in 1900 (F. E. Dorn). Details will be found in later chapters which also recount the discoveries made in the present century of protactinium (O. Hahn and Lise Meitner, 1917), hafnium (D. Coster and G. von Hevesey, 1923), rhenium (W. Noddack, Ida Tacke and O. Berg, 1925), technetium (C. Perrier and E. Segré, 1937), francium (Marguerite Perey, 1939) and promethium (J. A. Marinsky, L. E. Glendenin and C. D. Coryell, 1945).

A further group of elements, the transuranium elements, has been synthesized by artificial nuclear reactions in the period from 1940 onwards; their relation to the periodic table is discussed fully in Chapter 31 and need not be repeated here. Perhaps even more striking today are the predictions, as yet unverified, for the properties of the currently non-existent superheavy elements.\(^9\) Elements up to lawrencium (\(Z = 103\)) are actinides (5f) and the 6d transition series starts with element 104. So far only elements 104–112 have been synthesized,\(^10\) and, because there is as yet no agreement on trivial names for some of these elements (see pp. 1280–1), they are here referred to by their atomic numbers. A systematic naming scheme was approved by IUPAC in 1977 but is not widely used by researchers in the field. It involves the use of three-letter symbols derived directly from the atomic number by using the following numerical roots:

<table>
<thead>
<tr>
<th>Number</th>
<th>Symbol</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>nil</td>
</tr>
<tr>
<td>1</td>
<td>un</td>
</tr>
<tr>

</tr>
<tr>
<td>9</td>
<td>enn</td>
</tr>
</tbody>
</table>

These names and symbols can be used for elements 110 and beyond until agreed trivial names have been internationally approved. Hence, 110 is un-un-nilium (Uun), 111 is un-un-unium (Uuu), and 112 is un-un-bium, (Uub). These elements are increasingly unstable with respect to \(\alpha\)-decay or spontaneous fission with half-lives of less than 1 s. It is therefore unlikely that much chemistry will ever be carried out on them though their ionization energies, mps, bps, densities, atomic and metallic radii, etc., have all been predicted. Element 112 is expected to be eka-mercury at the end of the 6d transition series, and should be, followed by the 7p and 8s configurations \(Z = 113–120\). On the basis of present theories of nuclear structure an “island of stability” is expected near element 114 with half-lives in the region of years. Much effort is being concentrated on attempts to make these elements, and oxidation states are expected to follow the main group trends (e.g. 113: eka-thallium mainly \(+1\)). Other physical properties have been predicted by extrapolation of known periodic trends. Still heavier elements have been postulated, though it is unlikely (on present theories) that their chemistry will ever be studied because of their very short predicted half-lives. Calculated energy levels for the range \(Z = 121–154\) lead to the expectation of an unprecedented 5g series of 18 elements followed by fourteen 6f elements.

In addition to the prediction of new elements and their probable properties, the periodic table has proved invaluable in suggesting fruitful lines of research in the preparation of new compounds. Indeed, this mode of thinking is now so ingrained in the minds of chemists that they rarely pause to reflect how extraordinarily difficult their task would be if periodic trends were unknown. It is the ability to anticipate the effect of changing an element or a group in a compound which enables work to be planned effectively, though the prudent chemist is always alert to the possibility of

\(^9\) B. Fricke, Superheavy elements, Structure and Bonding 21, 89 (1975). A full account of the predicted stabilities and chemical properties of elements with atomic numbers in the range \(Z = 104–184\).

new effects or unsuspected factors which might surprisingly intervene.

Typical examples taken from the developments of the past two or three decades include:

(i) the organometallic chemistry of lithium and thallium (Chapters 4 and 7);
(ii) the use of boron hydrides as ligands (Chapter 6);
(iii) solvent systems and preparative chemistry based on the interhalogens (Chapter 17);
(iv) the development of the chemistry of xenon (Chapter 18);
(v) ferrocene — leading to ruthenocene and dibenzene chromium, etc. (Chapters 19, 25 and 23 respectively);
(vi) the development of solid-state chemistry.

Indeed, the influence of Mendeleev’s fruitful generalization pervades the whole modern approach to the chemistry of the elements.
3.1 Introduction

Hydrogen is the most abundant element in the universe and is also common on earth, being the third most abundant element (after oxygen and silicon) on the surface of the globe. Hydrogen in combined form accounts for about 15.4% of the atoms in the earth’s crust and oceans and is the ninth element in order of abundance by weight (0.9%). In the crustal rocks alone it is tenth in order of abundance (0.15 wt%). The gradual recognition of hydrogen as an element during the sixteenth and seventeenth centuries forms part of the obscure and tangled web of experiments that were carried out as chemistry emerged from alchemy to become a modern science. Until almost the end of the eighteenth century the element was inextricably entwined with the concept of phlogiston and H. Cavendish, who is generally regarded as having finally isolated and identified the gas in 1766, and who established conclusively that water was a compound of oxygen and hydrogen, actually communicated his findings to the Royal Society in January 1784 in the following words: “There seems to be the utmost reason to think that dephlogisticated air is only water deprived of its phlogiston” and that “water consists of dephlogisticated air united with phlogiston”.

The continued importance of hydrogen in the development of experimental and theoretical chemistry is further illustrated by some of the dates listed in the Panel on the page opposite. Hydrogen was recognized as the essential element in acids by H. Davy after his work on the hydrohalic acids, and theories of acids and bases have played an important role ever since. The electrolytic dissociation theory of S. A. Arrhenius and W. Ostwald in the 1880s, the introduction of the pH scale for hydrogen-ion concentrations by S. P. L. Sørensen in 1909, the theory of acid–base titrations and indicators, and J. N. Brønsted’s fruitful concept of acids and conjugate bases as proton donors and acceptors (1923) are other landmarks (see p. 48). The discovery of ortho- and para-hydrogen in 1924, closely followed by the discovery of heavy hydrogen (deuterium) and

---

§3.1

Introduction

Tritium in the 1930s, added a further range of phenomena that could be studied by means of this element (pp. 34–43). In more recent times, the technique of nmr spectroscopy, which was first demonstrated in 1946 using the hydrogen nucleus, has revolutionized the study of structural chemistry and permitted previously unsuspected phenomena such as fluxionality to be studied. Simultaneously, the discovery of complex metal hydrides such as LiAlH$_4$ has had a major impact on synthetic chemistry and enabled new classes of compound to be readily prepared in high yield (p. 229). The most important compound of hydrogen is, of course, water,

Hydrogen — Some Significant Dates

1671 R. Boyle showed that dilute sulfuric acid acting on iron gave a flammable gas; several other seventeenth-century scientists made similar observations.
1766 H. Cavendish established the true properties of hydrogen by reacting several acids with iron, zinc and tin; he showed that it was much lighter than air.
1781 H. Cavendish showed quantitatively that water was formed when hydrogen was exploded with oxygen, and that water was therefore not an element as had previously been supposed.
1783 A. L. Lavoisier proposed the name “hydrogen” (Greek ὕδωρ γενίμος, water former).
1800 W. Nicholson and A. Carlisle decomposed water electrolytically into hydrogen and oxygen which were then recombined by explosion to resynthesize water.
1810–15 Hydrogen recognized as the essential element in acids by H. Davy (contrary to Lavoisier who originally considered oxygen to be essential — hence Greek ὕδωρ γενίμος, acid former).
1866 The remarkable solubility of hydrogen in palladium discovered by T. Graham following the observation of hydrogen diffusion through red-hot platinum and iron by H. St. C. Deville and L. Troost, 1863.
1878 Hydrogen detected spectroscopically in the sun’s chromosphere (J. N. Lockyer).
1895 Hydrogen first liquefied in sufficient quantity to show a meniscus (J. Dewar) following earlier observations of mists and droplets by others, 1877–85.
1909 The pH scale for hydrogen-ion concentration introduced by S. P. L. Sørensen.
1912 H$_3^+$ discovered mass-spectrometrically by J. J. Thompson.
1923 J. N. Brønsted defined an acid as a species that tended to lose a proton: A $\rightleftharpoons$ B + H$^+$.
1929–30 Concept of quantum-mechanical tunnelling in proton-transfer reactions introduced (without experimental evidence) by several authors.
1931 First hydrido complex of a transition metal prepared by W. Hieber and F. Leutert.
1932 Acidity function $H_0$ proposed by L. P. Hammett for assessing the strength of very strong acids.
1934 Tritium first made by deuteron bombardment of D$_3$PO$_4$ and (ND$_4$)$_2$SO$_4$ (i.e. $^2$D + $^2$D = $^3$T + $^1$H); M. L. E. Oliphant, P. Harteck and E. Rutherford.
1939 Tritium found to be radioactive by L. W. Alvarez and R. Cornog after a prediction by T. W. Bonner in 1938.
1946 Proton nmr first detected in bulk matter by E. M. Purcell, H. C. Torrey and R. V. Pound; and by F. Bloch, W. W. Hansen and M. E. Packard.
1947 LiAlH$_4$ first prepared and subsequently shown to be a versatile reducing agent; A. E. Finholt, A. C. Bond and H. I. Schlesinger.
1950 Tritium first detected in atmospheric hydrogen (V. Faltings and P. Harteck) and later shown to be present in rain water (W. F. Libby et al., 1951).
1954 Detonation of the first hydrogen bomb on Bikini Atoll.
1960s “Superacids” ($10^7$–$10^{19}$ times stronger than sulfuric acid) studied systematically by G. A. Olah’s group and by R. J. Gillespie’s group.
1966 The term “magic acid” coined in G. A. Olah’s laboratory for the non-aqueous system HSO$_3$F/SbFs.
1976–79 Encapsulated H atom detected and located in octahedral polynuclear carbonyls such as [HRu$_6$(CO)$_{18}$]$^-$ and [HCO$_8$(CO)$_{15}$]$^-$ following A. Simon’s characterization of interstitial H in HNb$_6$H$_{11}$.
1984 Stable transition-metal complexes of dihapto-dihydrogen ($\eta^2$-H$_2$) discovered by G. Kubas.
and a detailed discussion of this compound is given on pp. 620–33 in the chapter on oxygen. In fact, hydrogen forms more chemical compounds than any other element, including carbon, and a survey of its chemistry therefore encompasses virtually the whole periodic table. However, before embarking on such a review in Sections 3.4–3.7 it is convenient to summarize the atomic and physical properties of the various forms of hydrogen (Section 3.2), to enumerate the various methods used for its preparation and industrial production, and to indicate some of its many applications and uses (Section 3.3).

3.2 Atomic and Physical Properties of Hydrogen

Despite its very simple electronic configuration (1s\(^1\)) hydrogen can, paradoxically, exist in over 50 different forms most of which have been well characterized. This multiplicity of forms arises firstly from the existence of atomic, molecular and ionized species in the gas phase: H, H\(_2\), H\(^+\), H\(^-\), H\(_2\)^+, H\(_3\)^+ ... H\(_{11}\)^+; secondly, from the existence of three isotopes, \(\text{i}H, \text{D}, \text{T}\) and correspondingly of D, D\(_2\), HD, DT, etc.; and, finally, from the existence of nuclear spin isomers for the homonuclear diatomic species.

3.2.1 Isotopes of hydrogen

Hydrogen as it occurs in nature is predominantly composed of atoms in which the nucleus is a single proton. In addition, terrestrial hydrogen contains about 0.0156% of deuterium atoms in which the nucleus also contains a neutron, and this is the reason for its variable atomic weight (p. 17). Addition of a second neutron induces instability and tritium is radioactive, emitting low-energy \(\beta^-\) particles with a half-life of 12.33 y. Some characteristic properties of these 3 atoms are given in Table 3.1, and their implications for stable isotope studies, radioactive tracer studies, and nmr spectroscopy are obvious.

In the molecular form, dihydrogen is a stable, colourless, odourless, tasteless gas with a very low mp and bp. Data are in Table 3.2 from which it is clear that the values for deuterium and tritium are substantially higher.

\(^3\)The term dihydrogen (like dinitrogen, dioxygen, etc.) is used when it is necessary to refer unambiguously to the molecule H\(_2\) (or N\(_2\), O\(_2\), etc.) rather than to the element as a substance or to an atom of the element. Strictly, one should use “diprotium” when referring specifically to the species H\(_2\) and “dihydrogen” when referring to an undifferentiated isotopic mixture such as would be obtained from materials having the natural isotopic abundances of H and D; likewise “proton” only when referring specifically to H\(^+\), but “hydron” when referring to an undifferentiated isotopic mixture.

(a) Data refer to H$_2$ of normal isotopic composition (i.e. containing 0.0156 atom % of deuterium, predominantly as HD). All data refer to the mixture of ortho- and para-forms that are in equilibrium at room temperature.

(b) 1 atm = 101.325 kNm$^{-2}$ = 101.325 kPa.

For example, the mp of T$_2$ is above the bp of H$_2$. Other forms such as HD and DT tend to have properties intermediate between those of their components. Thus HD has mp 16.60 K, bp 22.13 K, $\Delta H_{\text{fus}}$ 0.159 kJ mol$^{-1}$, $\Delta H_{\text{vap}}$ 1.075 kJ mol$^{-1}$, $T_c$ 35.91 K, $P_c$ 14.64 atm and $\Delta H_{\text{dissoc}}$ 439.3 kJ mol$^{-1}$. The critical temperature $T_c$ is the temperature above which a gas cannot be liquefied simply by application of pressure, and the critical pressure $P_c$ is the pressure required for liquefaction at this point.

Table 3.2 also indicates that the heat of dissociation of the hydrogen molecule is extremely high, the H–H bond energy being larger than for almost all other single bonds. This contributes to the relative unreactivity of hydrogen at room temperature. Significant thermal decomposition into hydrogen atoms occurs only above 2000 K; the percentage of atomic H is 0.081 at this temperature, and this rises to 7.85% at 3000 K and 95.5% at 5000 K. Atomic hydrogen can, however, be conveniently prepared in low-pressure glow discharges, and the study of its reactions forms an important branch of chemical gas kinetics. The high heat of recombination of hydrogen atoms finds application in the atomic hydrogen torch — dihydrogen is dissociated in an arc and the atoms then recombine on the surface of a metal, generating temperatures in the region of 4000 K which can be used to weld very high melting metals such as tantalum and tungsten.

3.2.2 Ortho- and para-hydrogen

All homonuclear diatomic molecules having nuclides with non-zero spin are expected to show nuclear spin isomers. The effect was first detected in dihydrogen where it is particularly noticeable, and it has also been established for D$_2$, T$_2$, $^{14}$N$_2$, $^{15}$N$_2$, $^{17}$O$_2$, etc. When the two nuclear spins are parallel (ortho-hydrogen) the resultant nuclear spin quantum number is 1 (i.e. $\frac{1}{2} + \frac{1}{2}$) and the state is threefold degenerate (2S + 1). When the two proton spins are antiparallel, however, the resultant nuclear spin is zero and the state is non-degenerate. Conversion between the two states involves a forbidden triplet–singlet transition and is normally slow unless catalysed by interaction with solids or paramagnetic species which either break the H–H bond, weaken it, or allow magnetic perturbations. Typical catalysts are Pd, Pt, active Fe$_2$O$_3$ and NO. Para-hydrogen (spins antiparallel) has the lower energy and this state is favoured at low temperatures. Above 0 K (100% para) the equilibrium concentration of ortho-hydrogen gradually increases until, above room temperature, the statistically weighted proportion of 3 ortho:1 para is obtained, i.e. 25% para. Typical equilibrium concentrations of para-hydrogen are 99.8% at 20 K, 65.4% at 60 K, 38.5% at 100 K, 25.7% at 210 K, and 25.1% at 273 K (Fig. 3.1). It follows that, whereas essentially pure para-hydrogen can be obtained, it is never possible to obtain a sample
containing more than 75% of ortho-hydrogen. Experimentally, the presence of both \( o-H_2 \) and \( p-H_2 \) is seen as an alternation in the intensities of successive rotational lines in the fine structure of the electronic band spectrum of \( H_2 \). It also explains the curious temperature dependence of the heat capacity of hydrogen gas.

Similar principles apply to ortho- and para-deuterium except that, as the nuclear spin quantum number of the deuteron is 1 rather than \( \frac{1}{2} \) as for the proton, the system is described by Bose–Einstein statistics rather than the more familiar Fermi–Dirac statistics. For this reason, the stable low-temperature form is ortho-deuterium and at high temperatures the statistical weights are \( 6 \) ortho:3 para leading to an upper equilibrium concentration of 33.3% para-deuterium above about 190 K as shown in Fig. 3.1. Tritium (spin \( \frac{1}{2} \)) resembles \( H_2 \) rather than \( D_2 \).

Most physical properties are but little affected by nuclear-spin isomerism though the thermal conductivity of \( p-H_2 \) is more than 50% greater than that of \( o-H_2 \), and this forms a ready means of analysing mixtures. The mp of \( p-H_2 \) (containing only 0.21% \( o-H_2 \)) is 0.15 K below that of “normal” hydrogen (containing 75% \( o-H_2 \)), and by extrapolation the mp of (unobtainable) pure \( o-H_2 \) is calculated to be 0.24 K above that of \( p-H_2 \). Similar differences are found for the bps which occur at the following temperatures: normal-\( H_2 \) 20.39 K, \( o-H_2 \) 20.45 K. For deuterium the converse relation holds, \( o-D_2 \) melting some 0.03 K below “normal”-\( D_2 \) (66.7% ortho) and boiling some 0.04 K below. The effects for other elements are even smaller.

### 3.2.3 Ionized forms of hydrogen

This section briefly considers the proton \( H^+ \), the hydride ion \( H^- \), the hydrogen molecule ion \( H_2^+ \), the triatomic 2-electron species \( H_3^+ \) and the recently established cluster species \( H_n^+ \)\(^\text{3,4}\).

The hydrogen atom has a high ionization energy (1312 kJ mol\(^{-1}\)) and in this it resembles the halogens rather than the alkali metals. Removal of the 1s electron leaves a bare proton which, having a radius of only about 1.5 \( \times \) 10\(^{-3}\) pm, is not a stable chemical entity in the condensed phase. However, when bonded to other species it is well known in solution and in

\[\text{References:}\]

---

**Figure 3.1** Ortho-para equilibria for \( H_2 \), \( D_2 \) and \( T_2 \).
Ionized forms of hydrogen

solids, e.g. $\text{H}_3\text{O}^+$, $\text{NH}_4^+$, etc. The proton affinity of water and the enthalpy of solution of $\text{H}^+$ in water have been estimated by several authors and typical values that are currently accepted are:

$$\text{H}^+(g) + \text{H}_2\text{O}(g) \rightarrow \text{H}_3\text{O}^+(g); \quad -\Delta H \approx 710 \text{ kJ mol}^{-1}$$

$$\text{H}^+(g) \rightarrow \text{H}_3\text{O}^+(\text{aq}); \quad -\Delta H \approx 1090 \text{ kJ mol}^{-1}$$

It follows that the heat of solution of the oxonium ion in water is $\sim 380 \text{ kJ mol}^{-1}$, intermediate between the values calculated for $\text{Na}^+$ (405 kJ mol$^{-1}$) and $\text{K}^+$ (325 kJ mol$^{-1}$). Reactions involving proton transfer will be considered in more detail in Section 3.5.

The hydrogen atom, like the alkali metals ($ns^1$) and halogens ($ns^2np^5$), has an affinity for the electron and heat is evolved in the following process:

$$\text{H}(g) + e^- \rightarrow \text{H}^-(g); \quad -\Delta H_{\text{calc}} = 72 \text{ kJ mol}^{-1}$$

This is larger than the corresponding value for Li (57 kJ mol$^{-1}$) but substantially smaller than the value for F (333 kJ mol$^{-1}$). The hydride ion $\text{H}^-$ has the same electron configuration as helium but is much less stable because the single positive charge on the proton must now control the 2 electrons. The hydride ion is thus readily deformable and this constitutes a characteristic feature of its structural chemistry (see p. 66).

The species $\text{H}_2^+$ and $\text{H}_3^+$ are important as model systems for chemical bonding theory. The hydrogen molecule ion $\text{H}_2^+$ comprises 2 protons and 1 electron and is extremely unstable even in a low-pressure gas discharge system; the energy of dissociation and the internuclear distance (with the corresponding values for $\text{H}_2$ in parentheses) are:

$$\Delta H_{\text{dissoc}} = 255(436) \text{ kJ mol}^{-1}; \quad r(\text{H}^-\text{H}) = 106(74.2) \text{ pm}$$

The triatomic hydrogen molecule ion $\text{H}_3^+$ was first detected by J. J. Thomson in gas discharges and later fully characterized by mass spectrometry; its relative atomic mass, 3.0235, clearly distinguishes it from HD (3.0219) and from tritium (3.0160). The “observed” equilateral triangular 3-centre, 2-electron structure is more stable than the hypothetical linear structure, and the comparative stability of the species is shown by the following gas-phase enthalpies:

$$\text{H} + \text{H} + \text{H}^+ = \text{H}_3^+; \quad -\Delta H = 855.9 \text{ kJ mol}^{-1}$$

$$\text{H}_2 + \text{H}^+ = \text{H}_3^+; \quad -\Delta H = 423.8 \text{ kJ mol}^{-1}$$

$$\text{H} + \text{H}_2^+ = \text{H}_3^+; \quad -\Delta H = 600.2 \text{ kJ mol}^{-1}$$

The $\text{H}_3^+$ ion is the simplest possible example of a three-centre two-electron bond (see discussion of bonding in boranes on p. 157) and is also a model for the dihapto bonding mode of the ligand $\eta^2$-$\text{H}_2$ (pp. 44–7):

\[
\text{H} + \text{H}^+ \rightarrow \begin{array}{c}
\text{H} \\
\text{H} \\
\text{H}
\end{array}
\]

A series of ions $\text{H}_n^+$ with $n$-odd up to 15 and $n$-even up to 10 have recently been observed mass-spectrometrically and characterized for the first time.$^{[3,4]}$ The odd-numbered species are much more stable than the even-numbered members, as shown in the subjoined table which gives the relative intensities, $I$, as a function of $n$ in $\text{H}_n^+$ obtained in a particular experiment with a high-pressure ion source, relative to $\text{H}_3^+$.$^{(3)}$

The structures of $\text{H}_5^+$, $\text{H}_7^+$ and $\text{H}_9^+$ are related to that of $\text{H}_3^+$ with $\text{H}_2$ molecules added perpendicularly at the corners, whereas those of $\text{H}_4^+$, $\text{H}_6^+$ and $\text{H}_8^+$ feature an added H atom at the first corner. Typical structures are shown below. The structures of higher members of the series, with $n \geq 10$ are unknown but may involve further loosely bonded $\text{H}_2$ molecules above and below the $\text{H}_3^+$ plane. Enthalpies of dissociation are $\Delta H_{300}^o$ ($\text{H}_5^+ \leftrightarrow \text{H}_3^+ + \text{H}_2$) 28 kJ mol$^{-1}$ and $\Delta H_{300}^o$ ($\text{H}_7^+ \leftrightarrow \text{H}_5^+ + \text{H}_2$) 13 kJ mol$^{-1}$.$^{(4)}$
3.3 Preparation, Production and Uses\(^{(5,6)}\)

3.3.1 Hydrogen

Hydrogen can be prepared by the reaction of water or dilute acids on electropositive metals such as the alkali metals, alkaline earth metals, the metals of Groups 3, 4 and the lanthanoids. The reaction can be explosively violent. Convenient laboratory methods employ sodium amalgam or calcium with water, or zinc with hydrochloric acid. The reaction of aluminium or ferrosilicon with aqueous sodium hydroxide has also been used. For small-scale preparations the hydrolysis of metal hydrides is convenient, and this generates twice the amount of hydrogen as contained in the hydride, e.g.:

\[
\text{CaH}_2 + 2\text{H}_2\text{O} \rightarrow \text{Ca(OH)}_2 + 2\text{H}_2
\]

Electrolysis of acidified water using platinum electrodes is a convenient source of hydrogen (and oxygen) and, on a larger scale, very pure hydrogen (\(>99.95\%\)) can be obtained from the electrolysis of warm aqueous solutions of barium hydroxide between nickel electrodes. The method is expensive but becomes economical on an industrial scale when integrated with the chloralkali industry (p. 798). Other bulk processes involve the (endothermic) reaction of steam on hydrocarbons or coke:

\[
\begin{align*}
\text{CH}_4 + \text{H}_2\text{O} & \xrightarrow{1100\degree C} \text{CO} + 3\text{H}_2 \\
\text{C} + \text{H}_2\text{O} & \xrightarrow{1000\degree C} \text{CO} + \text{H}_2 \quad (\text{water gas})
\end{align*}
\]

In both processes the CO can be converted to CO\(_2\) by passing the gases and steam over an iron oxide or cobalt oxide catalyst at 400\(^\circ\)C, thereby generating more hydrogen:

\[
\text{CO} + \text{H}_2\text{O} \xrightarrow{400\degree C, \text{catalyst}} \text{CO}_2 + \text{H}_2
\]

This is the so-called water–gas shift reaction (\(-\Delta G^\circ_{298} = 19.9 \text{kJ mol}^{-1}\)) and it can also be effected by low-temperature homogeneous catalysts in aqueous acid solutions.\(^{(7)}\) The extent of subsequent purification of the hydrogen depends on the use to which it will be put.

The industrial production of hydrogen is considered in more detail in the Panel. The largest single use of hydrogen is in ammonia synthesis (p. 421) but other major applications are in the catalytic hydrogenation of unsaturated liquid vegetable oils to solid, edible fats (margarine), and in the manufacture of bulk organic chemicals, particularly methanol (by the "oxo" or hydroformylation process):

\[
\begin{align*}
\text{CO} + \text{H}_2 & \xrightarrow{\text{cobalt catalyst}} \text{MeOH}
\end{align*}
\]

Direct reaction of hydrogen with chlorine is a major source of hydrogen chloride (p. 811), and a smaller, though still substantial use is in the manufacture of metal hydrides and complex metal hydrides (p. 64). Hydrogen is used in metallurgy to reduce oxides to metals (e.g. Mo, W) and to produce a reducing atmosphere. Direct reduction of iron ores in steelmaking is also now becoming technically and economically feasible.

---

### Industrial Production of Hydrogen

Many reactions are available for the preparation of hydrogen and the one chosen depends on the amount needed, the purity required, and the availability of raw materials. Most (~97%) of the hydrogen produced in industry is consumed in integrated plants on site (e.g. ammonia synthesis, petrochemical works, etc.). Even so, vast amounts of the gas are produced for the general market, e.g. ~6.5 x 10^{10} m^3 or 5.4 million tonnes yearly in the USA alone. Small generators may have a capacity of 100–4000 m^3 h^{-1}, medium-sized plants 4000–10 000 m^3 h^{-1}, and large plants can produce 10^4–16 m^3 h^{-1}.

The dominant large-scale process in integrated plants is the catalytic steam–hydrocarbon reforming process using natural gas or oil-refinery feedstock. After desulfurization (to protect catalysts) the feedstock is mixed with process steam and passed over a nickel-based catalyst at 700–1000°C to convert it irreversibly to CO and H₂, e.g.

\[
\text{C}_3\text{H}_8 + 3\text{H}_2\text{O} \xrightarrow{900°C \text{ catalyst}} 3\text{CO} + 7\text{H}_2
\]

Two reversible reactions also occur to give an equilibrium mixture of H₂, CO, CO₂, and H₂O:

\[
\begin{align*}
\text{CO} + \text{H}_2\text{O} &\rightleftharpoons \text{CO}_2 + \text{H}_2 \\
\text{CO} + 3\text{H}_2 &\rightleftharpoons \text{CH}_4 + \text{H}_2\text{O}
\end{align*}
\]

The mixture is cooled to ~350°C before entering a high-temperature shift convertor where the major portion of the CO is catalytically and exothermically converted to CO₂ and hydrogen by reaction with H₂O. The issuing gas is further cooled to 200°C before entering the low-temperature shift convertor which reduces the CO content to 0.2 vol%. The product is further cooled and CO₂ absorbed in a liquid contactor. Further removal of residual CO and CO₂ can be effected by methanation at 350°C to a maximum of 10 ppm. Provided that the feedstock contains no nitrogen the product purity is about 98%. Alternatively the low-temperature shift process and methanation stage can be replaced by a single pressure-swing absorption (PSA) system in which the hydrogen is purified by molecular sieves. The sieves are regenerated by adiabatic depressurization at ambient temperature (hence the name) and the product has a purity of ≥99.99%.

At present about 77% of the industrial hydrogen produced is from petrochemicals, 18% from coal, 4% by electrolysis of aqueous solutions and at most 1% from other sources. Thus, hydrogen is produced as a byproduct of the brine electrolysis process for the manufacture of chlorine and sodium hydroxide (p. 798). The ratio of H₂:Cl₂:NaOH is, of course, fixed by stoichiometry and this is an economic determinant since bulk transport of the byproduct hydrogen is expensive. To illustrate the scale of the problem: the total world chlorine production capacity is about 38 million tonnes per year which corresponds to 105 000 tonnes of hydrogen (1.3 x 10^{10} m^3). Plants designed specifically for the electrolytic manufacture of hydrogen as the main product, use steel cells and aqueous potassium hydroxide as electrolyte. The cells may be operated at atmospheric pressure (Knowles cells) or at 30 atm (Lonz cells).

When relatively small amounts of hydrogen are required, perhaps in remote locations such as weather stations, then small transportable generators can be used which can produce 1–17 m^3 h^{-1}. During production a 1:1 molar mixture of methanol and water is vaporized and passed over a “base-metal chromite” type catalyst at 400°C where it is cracked into hydrogen and carbon monoxide; subsequently steam reacts with the carbon monoxide to produce the dioxide and more hydrogen:

\[
\begin{align*}
\text{MeOH} &\xrightarrow{400°C \text{ catalyst}} \text{CO} + 2\text{H}_2 \\
\text{CO} + \text{H}_2\text{O} &\rightarrow \text{CO}_2 + \text{H}_2
\end{align*}
\]

All the gases are then passed through a diffuser separator comprising a large number of small-diameter thin-walled tubes of palladium-silver alloy tightly packed in a stainless steel case. The solubility of hydrogen in palladium is well known (p. 1150) and the alloy with silver is used to prolong the life of the diffuser by avoiding troublesome changes in dimensions during the passage of hydrogen. The hydrogen which emerges is cool, pure, dry and ready for use via a metering device.

Another medium-scale use is in oxyhydrogen torches and atomic hydrogen torches for welding and cutting. Liquid hydrogen is used in bubble chambers for studying high-energy particles and as a rocket fuel (with oxygen) in the space programme. Hydrogen gas is potentially a large-scale fuel for use in internal combustion engines and fuel cells if the notional “hydrogen economy” (see Panel on p. 40) is ever developed.

### 3.3.2 Deuterium

Deuterium is invariably prepared from heavy water, D₂O, which is itself now manufactured...
The Hydrogen Economy\(^{6,8-11}\)

The growing recognition during the past decades that world reserves of coal and oil are finite and that nuclear power cannot supply all our energy requirements, particularly for small mobile units such as cars, has prompted an active search for alternatives. One solution which has many attractive features is the “hydrogen economy” whereby energy is transported and stored in the form of liquid or gaseous hydrogen. Enthusiasts point out that such a major change in the source of energy, though apparently dramatic, is not unprecedented and has in fact occurred twice during the past 100 y. In 1880 wood was overtaken by coal as the main world supplier of energy and now it accounts for only about 2% of the total. Likewise in 1960 coal was itself overtaken by oil and now accounts for only 15% of the total. (Note, however, that this does not imply a decrease in the total amount of coal used: in 1930 this was $14.5 \times 10^6$ barrels per day of oil equivalent and was 75% of the then total energy supply whereas in 1975 coal had increased in absolute terms by 11% to $16.2 \times 10^6$ b/d oe, but this was only 18% of the total energy supply which had itself increased 4.6-fold in the interim.) Another change may well be in the offing since nuclear power, which was effectively non-existent as an industrial source of energy in 1950, now accounts for 16% of the world supply of electricity; it has already overtaken coal as a source of energy and may well overtake oil during the next century. The aim of the “hydrogen economy” is to transmit this energy, not as electric power but in the form of hydrogen; this overcomes the great problem of electricity — that it cannot be stored — and also reduces the costs of power transmission.

The technology already exists for producing hydrogen electrically and storing it in bulk. For example huge quantities of liquid hydrogen are routinely stored in vacuum insulated cryogenic tanks for the US space programme, one such tank alone holding over 3400 m\(^3\) (900,000 US gallons). Liquid hydrogen can be transported by road or by rail tankers of 75.7 m\(^3\) capacity (20,000 US gallons). Underground storage of the type currently used for hydrogen — natural gas mixtures and transmission through large pipes is also feasible, and pipelines carrying hydrogen up to 80 km in the USA and South Africa and 200 km in Europe have been in operation for many years. Smaller storage units based on metal alloy systems have also been suggested, e.g. LaNi\(_5\) can absorb up to 7 moles of H atoms per mole of LaNi\(_5\) at room temperature and 2.5 atm, the density of contained hydrogen being twice that in the liquid element itself. Other systems include Mg–MgH\(_2\), Mg–Mg\(_2\)Ni–Mg\(_2\)Ni\(_4\), Ti–TiH\(_2\) and TiFe–TiFeH\(_1.95\).

The advantages claimed for hydrogen as an automobile fuel are the greater energy release per unit weight of fuel and the absence of polluting emissions such as CO, CO\(_2\), NO\(_x\), SO\(_2\), hydrocarbons, aldehydes and lead compounds. The product of combustion is water with only traces of nitrogen oxides. Several conventional internal-combustion petrol engines have already been simply and effectively modified to run on hydrogen. Fuel cells for the regeneration of electric power have also been successfully operated commercially with a conversion efficiency of 70%, and test cells at higher pressures have achieved 85% efficiency.

Non-electrolytic sources of hydrogen have also been studied. The chemical problem is how to transfer the correct amount of free energy to a water molecule in order to decompose it. In the last few years about 10000 such thermochemical water-splitting cycles have been identified, most of them with the help of computers, though it is significant that the most promising ones were discovered first by the intuition of chemists.

The stage is thus set, and further work to establish safe and economically viable sources of hydrogen for general energy usage seems destined to flourish as an active area of research for some while.

on the multitonne scale by the electrolytic enrichment of normal water.\(^{12,13}\) The enrichment is expressed as a separation factor between the gaseous and liquid phases:

\[
s = \frac{(H/D)_g}{(H/D)_l}
\]

---

The equilibrium constant for the exchange reaction

\[
\text{H}_2\text{O} + \text{HD} \rightleftharpoons \text{HDO} + \text{H}_2
\]

is about 3 at room temperature and this would lead to a value of \(s = 3\) if this were the only effect. However, the choice of the metal used for the electrodes can also affect the various electrode processes, and this increases the separation still further. Using alkaline solutions \(s\) values in

the range 5 – 7.6 are obtained for many metals, rising to 13.9 for platinum cathodes and even higher for gold. By operating a large number of cells in cascade, and burning the evolved H₂/D₂ mixture to replenish the electrolyte of earlier cells in the sequence, any desired degree of enrichment can ultimately be attained. Thus, starting with normal water (0.0156% of hydrogen as deuterium) and a separation factor of 5, the deuterium content rises to 10% after the original volume has been reduced by a factor of 2400. Reduction by 66,000 is required for 90% deuterium and by 130,000 for 99% deuterium. If, however, the separation factor is 10, then 99% deuterium can be obtained by a volume reduction on electrolysis of 22,000. Prior enrichment of the electrolyte to 15% deuterium can be achieved by a chemical exchange between H₂S and H₂O after which a fortyfold volume reduction produces heavy water with 99% deuterium content. Other enrichment processes are now rarely used but include fractional distillation of water (which also enriches ¹⁸O), thermal diffusion of gaseous hydrogen, and diffusion of H₂/D₂ through palladium metal.

Many methods have been used to determine the deuterium content of hydrogen gas or water. For H₂/D₂ mixtures mass spectroscopy and thermal conductivity can be used together with gas chromatography (alumina activated with manganese chloride at 77 K). For heavy water the deuterium content can be determined by density measurements, refractive index change, or infrared spectroscopy.

The main uses of deuterium are in tracer studies to follow reaction paths and in kinetic studies to determine isotope effects.¹⁴ A good discussion with appropriate references is in Comprehensive Inorganic Chemistry, Vol. 1, pp. 99 – 116. The use of deuterated solvents is widespread in proton nmr studies to avoid interference from solvent hydrogen atoms, and deuteriated compounds are also valuable in structural studies involving neutron diffraction techniques.

³.³.³ Tritium

Tritium differs from the other two isotopes of hydrogen in being radioactive and this immediately indicates its potential uses and its method of detection. Tritium occurs naturally to the extent of about 1 atom per 1⁰¹⁸ hydrogen atoms as a result of nuclear reactions induced by cosmic rays in the upper atmosphere:

\[ {^{14}}N + ^{1}n = ^{3}H + ^{12}C \]
\[ {^{14}}N + ^{1}H = ^{3}H + \text{fragments} \]
\[ ^{3}H + ^{3}H = ^{3}H + ^{1}H \]

The concentration of tritium increased by over a hundredfold when thermonuclear weapon testing began on Bikini Atoll in March 1954 but has now subsided as a result of the ban on atmospheric weapon testing and the natural radioactivity of the isotope (τ₃/₂ 12.33 y).

Numerous reactions are available for the artificial production of tritium and it is now made on a large scale by neutron irradiation of enriched ⁶Li in a nuclear reactor:

\[ ^{6}\text{Li} + ^{1}n = ^{4}\text{He} + ^{3}H \]

The lithium is in the form of an alloy with magnesium or aluminium which retains much of the tritium until it is released by treatment with acid. Alternatively the tritium can be produced by neutron irradiation of enriched LiF at 450⁰ in a vacuum and then recovered from the gaseous products by diffusion through a palladium barrier. As a result of the massive production of tritium for thermonuclear devices and research into energy production by fusion reactions, tritium is available cheaply on the megacurie scale for peaceful purposes.¹⁵ The most convenient way of storing the gas is to react it with finely divided uranium

† See also p. 18 for the influence on the atomic weight of commercially available lithium in some countries.
to give UT₃ from which it can be released by heating above 400°C.

Besides being one of the least expensive radio-isotopes, tritium has certain unique advantages as a tracer. Like¹⁴C it is a pure low-energy β⁻ emitter with no associated γ-rays. The radiation is stopped by ~6 mm of air or ~6 μm of material of density 1 g cm⁻³ (e.g., water). As the range is inversely proportional to the density, this is reduced to only ~1 μm in photographic emulsion (ρ ~3.5 g cm⁻³) thus making tritium ideal for high-resolution autoradiography. Moreover, tritium has a high specific activity. The weight of tritium equal to an activity of 1 Ci is 0.103 mg and 1 mmol T₂ has an activity of 58.25 Ci. [Note: 1 Ci (curie) = 3.7 × 10¹² Bq (becquerel); 1 Bq = 1 s⁻¹.] Tritium is one of the least toxic of radio-isotopes and shielding is unnecessary; however, precautions must be taken against ingestion, and no work should be carried out without appropriate statutory authorization and adequate radiochemical facilities.

Tritium has been used extensively in hydrological studies to follow the movement of ground waters and to determine the age of various bodies of water. It has also been used to study the adsorption of hydrogen and the hydrogenation of ethylene on a nickel catalyst and to study the absorption of hydrogen in metals. Autoradiography has been used extensively to study the distribution of tritium in multiphase alloys, though care must be taken to correct for the photographic darkening caused by emanated tritium gas. Increasing use is also being made of tritium as a tracer for hydrogen in the study of reaction mechanisms and kinetics and in work on homogeneous catalysis.

The production of tritium-labelled organic compounds was enormously facilitated by K. E. Wilzbach’s discovery in 1956 that tritium could be introduced merely by storing a compound under tritium gas for a few days or weeks: the β⁻ radiation induces exchange reactions between the hydrogen atoms in the compound and the tritium gas. The excess of gas is recovered for further use and the tritiated compound is purified chromatographically. Another widely used method of general applicability is catalytic exchange in solution using either a tritiated solution or tritium gas. This is valuable for the routine production of tritium compounds in high radiochemical yield and at high specific activity (>50 mCi mmol⁻¹). For example, although ammonium ions exchange relatively slowly with D₂O, tritium exchange equilibria are established virtually instantaneously: tritiated ammonium salts can therefore be readily prepared by dissolving the salt in tritiated water and then removing the water by evaporation:

\[(\text{NH}_4)_2\text{SO}_4 + \text{HTO} \rightleftharpoons (\text{NH}_3\text{T})_2\text{SO}_4 + \text{H}_2\text{O}, \text{etc.}\]

For exchange of non-labile organic hydrogen atoms, acid–base catalysis (or some other catalytic hydrogen-transfer agent such as palladium or platinum) is required. The method routinely gives tritiated products having a specific activity almost 1000 times that obtained by the Wilzbach method; shorter times are required (2–12 h) and subsequent purification is easier.

When specifically labelled compounds are required, direct chemical synthesis may be necessary. The standard techniques of preparative chemistry are used, suitably modified for small-scale work with radioactive materials. The starting material is tritium gas which can be obtained at greater than 98% isotopic abundance. Tritiated water can be made either by catalytic oxidation over palladium or by reduction of a metal oxide:

\[2\text{T}_2 + \text{O}_2 \rightleftharpoons \text{Pd} \rightarrow 2\text{T}_2\text{O}\]

\[\text{T}_2 + \text{CuO} \rightarrow \text{T}_2\text{O} + \text{Cu}\]

Note, however, that pure tritiated water is virtually never used since 1 ml would contain 2650 Ci; it is self-luminescent, irradiates itself at the rate of \(6 \times 10^{17} \text{eV ml}^{-1} \text{s}^{-1} \sim 10^9 \text{rad day}^{-1}\), undergoes rapid self-radiolysis, and also causes considerable radiation damage to dissolved species. In chemical syntheses or exchange reactions tritiated water of 1% tritium abundance (580 mCi mmol⁻¹) is usually sufficient to produce compounds having a specific activity of at least 100 mCi mmol⁻¹. Other useful
synthetic reagents are NaT, LiAlH₃T, NaBH₃T, NaBT₄, B₂T₆ and tritiated Grignard reagents. Typical preparations are as follows:

\[
\text{LiH + T₂} \xrightarrow{350°C} \text{LiT + HT}
\]

\[
\text{LiBH₄ + T₂} \xrightarrow{200°C} \text{LiBH₃T + HT}
\]

\[
4\text{LiT + AlBr₃} \xrightarrow{\text{ether}} \text{LiAlT₄ + 3LiBr}
\]

\[
B₂H₆ + T₂ \xrightarrow{55°C} B₂H₅T + HT
\]

\[
3\text{NaBT₄ + 4BF₃.OEt₂} \xrightarrow{700°C} 2\text{B₂T₆ + 3NaBF₄}
\]

\[
2\text{AgCl + T₂} \xrightarrow{700°C} 2\text{TCI + 2Ag}
\]

\[
\text{Br₂ + T₂} \xrightarrow{\text{uv}} 2\text{TBr}
\]

\[
\text{P(red) + I₂ + HTO} \xrightarrow{} \text{TI + HI + ...}
\]

\[
\text{NH₃ + T₂} \xrightarrow{} \text{NH₂T + TH}
\]

\[
\text{Mg₃N₂ + 6T₂O} \xrightarrow{100°C} 2\text{NT₃ + 3Mg(OT)₂}
\]

\[
\text{M} + \frac{x}{2} \text{T₂} \xrightarrow{\text{heat}} \text{MTₙ}
\]

The preparation and use of LiEt₃BT and LiAlT₄ at maximum specific activity (57.5 Ci mmol⁻¹) has also been described.¹⁶

### 3.4 Chemical Properties and Trends

Hydrogen is a colourless, tasteless, odourless gas which has only low solubility in liquid solvents. It is comparatively unreactive at room temperature though it combines with fluorine even in the dark and readily reduces aqueous solutions of palladium(II) chloride:

\[
\text{PdCl₂(aq) + H₂} \xrightarrow{} \text{Pd(s) + 2HCl(aq)}
\]

This reaction can be used as a sensitive test for the presence of hydrogen. At higher temperatures hydrogen reacts vigorously, even explosively, with many metals and non-metals to give the corresponding hydrides. Activation can also be induced photolytically, by heterogeneous catalysts (Raney nickel, Pd, Pt, etc.), or by means of homogeneous hydrogenation catalysts. Industrially important processes include the hydrogenation of many organic compounds and the use of cobalt compounds as catalysts in the hydroformylation of olefins to aldehydes and alcohols at high temperatures and pressures (p. 1140):

\[
\text{RCH=CH₂ + H₂ + CO} \xrightarrow{} \text{RCH₂CH₂CHO}
\]

\[
\text{RCH₂CH₂CHO + H₂} \xrightarrow{} \text{RCH₂CH₂CH₂OH}
\]

An even more effective homogeneous hydrogenation catalyst is the complex [RhCl(PPh₃)₃] which permits rapid reduction of alkenes, alkynes and other unsaturated compounds in benzene solution at 25°C and 1 atm pressure (p. 1134). The Haber process, which uses iron metal catalysts for the direct synthesis of ammonia from nitrogen and hydrogen at high temperatures and pressures, is a further example (p. 421).

The hydrogen atom has a unique electronic configuration 1s¹: accordingly it can gain an electron to give H⁻ with the helium configuration 1s² or it can lose an electron to give the proton H⁺ (p. 36). There are thus superficial resemblances both to the halogens which can gain an electron to give an inert-gas configuration ns²np⁶, and to the alkali metals which can lose an electron to give M⁺ (ns²np⁶). However, because hydrogen has no other electrons in its structure there are sufficient differences from each of these two groups to justify placing hydrogen outside either. For example, the proton is so small (r ~1.5 × 10⁻³ pm compared with normal atomic and ionic sizes of ~50–220 pm) that it cannot exist in condensed systems unless associated with other atoms or molecules. The transfer of protons between chemical species constitutes the basis of acid–base phenomena (see Section 3.5). The hydrogen atom is also frequently found in close association with 2

---

other atoms in linear array; this particularly important type of interaction is called hydrogen bonding (see Section 3.6). Again, the ability to penetrate metals to form nonstoichiometric metallic hydrides, though not unique to hydrogen, is one of its more characteristic properties as is its ability to form nonlinear hydrogen bridge bonds in many of its compounds. These properties will be further discussed during the general classification of the hydrides of the elements in section 3.7. The most important compound of hydrogen is, of course, water and a detailed discussion of this compound is given on pp. 620–33 in the chapter on oxygen.

3.4.1 The coordination chemistry of hydrogen

Perhaps the most exciting recent development in the chemistry of hydrogen is the discovery that, in transition metal polyhydrides, the molecule H₂ can act as a dihapto ligand, \( n^2-H_2 \) (see below). Even the H atom itself can form compounds in which its coordination number (CN) is not just 1 (as expected) but also 2, 3, 4, 5 or even 6. A rich and unexpectedly varied coordination chemistry is thus emerging. We shall deal with the H atom first and then with the H₂ molecule.

By far the most common CN of hydrogen is 1, as in HCl, H₂S, PH₃, CH₄ and most other covalent hydrides and organic compounds. Bridging modes in which the H atom has a higher CN are shown schematically in the next column — in these structures M is typically a transition metal but, particularly in the \( \mu_2 \)-mode and to some extent in the \( \mu_3 \)-mode, one or more of the M can represent a main-group element such as B, Al, C, Si; N etc. Typical examples are in Table 3.3.\(^{17-19} \) Fuller discussion and references, when appropriate, will be found in later chapters dealing with the individual elements concerned.

The crucial experiment suggesting that the H₂ molecule might act as a dihapto ligand to transition metals was the dramatic observation\(^{20} \) that toluene solutions of the deep purple coordinatively unsaturated 16-electron complexes [Mo(CO)₃(PCy₃)₂] and [W(CO)₅(PCy₃)₂] (where Cy = cyclohexyl) react readily and cleanly with H₂ (1 atm) at low temperatures to precipitate yellow crystals of [M(CO)₃H₂(PCy₃)₂] in 85–95% yield. The

§3.4.1 The coordination chemistry of hydrogen

$\text{H}_2$ could be quantitatively removed at room temperature either by partial evacuation or by sparging the solution with argon. Definitive confirmation that the complexes did indeed contain $\eta^2$-$\text{H}_2$ came from X-ray and neutron diffraction studies on the bis(tri $i$-propylphosphine) analogue at $-100^\circ\text{C}$, which revealed the side-on coordination of $\text{H}_2$ as shown in Fig. 3.2.\(^{21}\) During the past decade many other such compounds have been prepared and studied in great detail, and the field has been well reviewed.\(^{22 - 24}\)

![Figure 3.2 The geometry of mer-trans-$[\text{W(CO)}_3(\eta^2$-$\text{H}_2)\text{(PPr}_3)_2]$ from X-ray and neutron diffraction data: $r(\text{H-H})$ 84 pm (compared with 74.14 pm for free $\text{H}_2$), $r(\text{W-H})$ 175 pm. Infrared vibration spectroscopy gives $\nu(\text{H-H})$ 2690 cm$^{-1}$ compared with 4159 cm$^{-1}$ (Raman) for free $\text{H}_2$.](image)

There are two general routes to $\eta^2$-$\text{H}_2$ complexes. The first involves direct addition of molecular $\text{H}_2$ either to an unoccupied coordination site in a 16-electron complex (as above) or by displacement of a ligand such as CO, Cl, $\text{H}_2\text{O}$ in the coordination sphere of an 18-electron complex; in this latter case ultraviolet irradiation may be required to assist in the substitution reaction. Examples are:

\[
[\text{W(CO)}_3(\text{PPr}_3)_2] + \text{H}_2 \rightarrow \text{[W(CO)}_3(\eta^2$-$\text{H}_2)\text{(PPr}_3)_2]
\]

\[
[\text{FeClH(R}_2\text{PCH}_2\text{CH}_2\text{PPr}_2)_2] + \text{H}_2 + \text{NaBPh}_4
\rightarrow \text{[FeH(}\eta^2$-$\text{H}_2)\text{(R}_2\text{PCH}_2\text{CH}_2\text{PPr}_2)_2]^+}
\]

\[+ \text{BPh}_4^- + \text{NaCl}
\]

\[
\text{trans-}[\text{IrH(H}_2\text{O})(\text{PPh}_3)_2\text{(Bq)}]^+ + \text{H}_2 \rightarrow \text{trans-}[\text{IrH(}\eta^2$-$\text{H}_2)(\text{PPh}_3)_2\text{(Bq)}]^+
\]

\[\text{[Cr(CO)}_6] + \text{H}_2 \xrightarrow{\text{hv}} \text{[Cr(CO)}_5(\eta^2$-$\text{H}_2)] + \text{CO}
\]

\[\text{Co(CO)}_3(\text{NO}) + \text{H}_2 \xrightarrow{\text{hv}} \text{[Co(CO)}_2(\eta^2$-$\text{H}_2)(\text{NO})] + \text{CO}
\]

The second general method involves the protonation of a polyhydrido complex using a strong acid such as $\text{HBF}_4\cdot\text{Et}_2\text{O}$. Typical examples involving $d^2$, $d^4$, $d^6$ or $d^8$ metal centres are:

\[\text{(d}^2\text{)} \quad \text{[MoH}_4\text{(dppe)}_2] + 2\text{H}^+ \rightarrow \text{[MoH}_4(\eta^2$-$\text{H}_2)(\text{dppe)}_2]^2+
\]

\[\text{(d}^4\text{)} \quad \text{[IrH}_3\text{(PCy}_3)_2] \xrightarrow{\text{NEt}_3} \text{[IrH}_2(\eta^2$-$\text{H}_2)_2(\text{PCy}_3)_2]^+
\]

\[\text{(d}^6\text{)} \quad \text{[RuH}_2\text{(dppe)}_2] + \text{H}^+ \rightarrow \text{[RuH(}\eta^2$-$\text{H}_2)(\text{dppe)}_2]^+
\]

\[\text{(d}^8\text{)} \quad \text{[RhH}[\text{P(CH}_2\text{CH}_2\text{PPh}_3)_2)] + \text{H}^+ \rightarrow \text{[Rh(}\eta^2$-$\text{H}_2)[\text{P(CH}_2\text{CH}_2\text{PPh}_3)_2]]^+
\]

There is even a rare example involving a $d^6$ polyhydride:\(^{25}\)

\[\text{(d}^6\text{)} \quad \text{[ReH}_3\text{(PCy}_3)_2] \xrightarrow{\text{NEt}_3} \text{[ReH}_2(\eta^2$-$\text{H}_2)_2(\text{PCy}_3)_2]^+
\]

\[\text{H}^+(-80^\circ\text{C})
\]

\[\text{[ReH}_8(\eta^2$-$\text{H}_2)_2(\text{PCy}_3)_2]^+
\]

\[\text{24 A. G. Ginzburg and A. A. Bagatur`ants, Organomet. Chem. in USSR 2, 111–26 (1989).}\]

If deuterio acids are used then $\eta^2$-HD complexes are formed; these are particularly useful in establishing the retention of substantive H–H bonding in the coordinated ligand by observation of a 1:1:1 triplet in the proton nmr spectrum (the proton signal being split by coupling to deuterium with nuclear spin $J = 1$).

The stability of $\eta^2$-H$_2$ complexes varies considerably, from those which can be observed only in low-temperature matrix-isolation experiments to those which are moderately robust even at room temperature and above. Stability depends on the electron configuration of the metal centre, the electronic and steric nature of the co-ligands, the overall charge on the complex, the state of aggregation and, of course, the temperature. Most $\eta^2$-H$_2$ complexes involve transition metals in Groups 6–8, in oxidation states having a formal d$^6$ electron configuration. No $\eta^2$-H$_2$ complexes are yet known for transition metals in Groups 3 or 4 of the periodic table, although examples involving Group 5 metals have recently been reported, e.g. the d$^4$ species $[\text{V}(\eta^2\text{-C}_2\text{H}_4)(\text{CO})_3(\eta^2\text{-H}_2)]$ and $[\text{Nb}(\eta^2\text{-C}_2\text{H}_4)(\text{CO})_3(\eta^2\text{-H}_2)]$. Within a given Group, the first and second members more readily form $\eta^2$-H$_2$ complexes while the third member tends to form polyhydrido species, e.g. $[\text{Fe}(\text{H})_2(\eta^2\text{-H}_2)(\text{PEtPh}_2)_3]$ and $[\text{Ru}(\text{H})_2(\eta^2\text{-H}_2)(\text{PPPh}_3)_3]$ but $[\text{Os}(\text{H})_4(\text{P(o-tol})_3)_3]$. Stability is also enhanced by an overall cationic charge on the complex (remember protonation as a route to $\eta^2$-H$_2$ complexes). In such cases, however, stability of the resulting compound depends on the presence of a non-coordinating anion such as BF$_4^-$, otherwise there is a risk of decomposition by displacement of the more weakly coordinating ($\eta^2$-H$_2$). Neutral complexes are also well known, but no examples of anionic $\eta^2$-H$_2$ complexes have been reported.

Most of the observed facts can be understood in terms of a bonding scheme which envisages donation of electron density from the $\sigma$ bond of H$_2$ into a vacant hybrid orbital on the metal, plus a certain amount of synergic back donation from an occupied d orbital on the metal into the $\sigma^*$ antibonding orbital of H$_2$ (see Fig. 3.3). This is reminiscent of the bonding in the well known metal–alkene complexes (to be discussed in more detail on p. 931) but with two significant differences: (a) the electron density being donated from the H$_2$ ligand is in the single-bond $\sigma$ orbital whereas for alkenes such as H$_2$C=CH$_2$ it is in the $\pi$ component of the double bond; and (b) the H$_2$ antibonding orbital involved in accepting back-donated electron density has $\sigma^*$ symmetry rather than $\pi^*$ as in alkenes. It is clear from this description that an overall positive charge on the metal centre encourages forward donation to form the 3-centre bond, but diminishes the extent of back donation. By contrast, an overall negative charge might be expected to enhance back donation into the $\sigma^*$ antibonding orbital and thus promote rupture of the H$_2$ single bond, with concomitant formation of two new hydrido M–H bonds.

Figure 3.3 Schematic representation of the two components of the $\eta^2$-H$_2$-metal bond: (a) donation from the filled (hatched) $\sigma$-H$_2$ bonding orbital into a vacant hybrid orbital on M; (b) $\pi$-back donation from a filled d orbital (or hybrid) on M into the vacant $\sigma^*$ antibonding orbital of H$_2$.

References:

The bonding scheme is also consistent with the observed lengthening of the H–H distance to about 84–90 pm in the $\eta^2$-H$_2$ complexes (as compared with 74 pm in free molecular H$_2$), and with the lowering of the v(H–H) vibration frequency from 4159 cm$^{-1}$ in free H$_2$ to values typically in the range 2650–3250 cm$^{-1}$ in the complexes.

There is evidently a very fine balance between the two options $\{M(\eta^2$-H$_2)\}$ and $\{M(H)_2\}$; indeed, examples of an equilibrium between the two forms have recently been discovered:(27,29,30)

$$\text{[Nb(}\eta^5$-C$_5$H$_5$)(CO)$_3$(\eta$^2$-H$_2$)] \rightarrow 78^\circ \text{ to } +25^\circ \rightarrow \text{[Nb(}\eta^5$-C$_5$H$_5$)(CO)$_3$(H)$_2$]$$

$$\text{[Re(CO)(}\eta^2$-H$_2$)(H)$_2$(PMe$_2$Ph)$_3$] \rightarrow -85^\circ \text{ to } -65^\circ \rightarrow \text{[Re(CO)(H)$_4$(PMe$_2$Ph)$_3$]$$

$$\text{[Ru(}\eta^2$-H$_2$)(\eta$^2$-O$_2$CCF$_3$)(PCy$_3$)$_2$] \leftrightarrow \text{[Ru(H)$_3$(}\eta$^2$-O$_2$CCF$_3$)(PCy$_3$)$_2$]$$

In the niobium system(27) the $\eta^2$-H$_2$ form is marginally the more stable, with $\Delta H = 2.0$ kJ mol$^{-1}$, whereas in the rhenium system,(29) it is the tetrahydrido form which is the more stable, with $-\Delta G_{208} = 2.5$ kJ mol$^{-1}$ and $-\Delta H = 4.6$ kJ mol$^{-1}$.

In a sense the formation of $\eta^2$-H$_2$ complexes can be thought of as an intermediate stage in the oxidative addition of H$_2$ to form two M–H bonds and, as such, the complexes might serve as a model for this process and for catalytic hydrogenation reactions by metal hydrides.(31) Indeed, intermediate cases between $\eta^2$-H$_2$ and $\sigma$-H$_2$ coordination are occasionally observed, as in $[\text{ReH}_{7}(P(\rho$-tol)$_3]_2$, where neutron-diffraction studies(32) have revealed one H⋯H contact of 137.7(7) pm whereas all other H⋯H distances in the complex are greater than 174 pm. (This distance of 137.7 pm is seen to be intermediate between values of ca. 80 pm typical of $\eta^2$-H$_2$ complexes and values greater than ca. 160 pm which are found in classical hydrido complexes.) Likewise, some trihydrogen complexes, such as $[\text{Ir(}\eta^5$-C$_5$H$_5$)H$_3$(PMe$_3$)],(33) have nmr behaviour which suggests the presence of a bent (or possibly triangular) $\eta^3$-H$_3$ ligand which is bonded “side-on” rather like an allylic group (pp. 933–35).

The possibility of $\eta^1$-H$_2$ “end-on” coordination has also been mooted. For example, deposition of Pd atoms onto a krypton matrix doped with H$_2$ at 12 K apparently yields both Pd($\eta^1$-H$_2$) and Pd($\eta^2$-H$_2$) species, whereas with a Xe/H$_2$ matrix only Pd($\eta^2$-H$_2$) was obtained.(34) Again, the complex $[\text{ReCl(H}_2)(\text{PMePh}_2)_4]$ appears to feature an asymmetrically-bonded H$_2$ ligand which may well be $(\eta^1$-H$_2$).(35)

Nearly one hundred $\eta^2$-H$_2$ complexes have so far been prepared and the crystal and molecular structure of about half a dozen have been determined by X-ray/neutron diffraction. Some are dinuclear, such as the homobimetallic $[(\text{P-N})(\eta^2$-H$_2)$Ru(\mu-\text{Cl})$_2$(\mu-H)Ru(H)(\text{PPh}_3)$_2]$(36) and the heterobimetallic $[(\text{PPh}_3)_2\text{HRe}(\mu-$H)(\mu-\text{Cl})$_2$(\mu-CO)Ru(\eta$^2$-H$_2$)(\text{PPh}_3)$_2]$(37)

The coordination chemistry of hydrogen is still being intensively studied and new developments are continually being reported.

3.5 Protonic acids and bases\(^{(38)}\)

Many compounds that contain hydrogen can donate protons to a solvent such as water and so behave as acids. Water itself undergoes ionic dissociation to a small extent by means of autoprotolysis; the process is usually represented formally by the equilibrium

\[
H_2O + H_2O \rightleftharpoons H_3O^+ + OH^{-}
\]

though it should be remembered that both ions are further solvated and that the time a proton spends in close association with any one water molecule is probably only about \(10^{-13}\) s. (See also pp. 630–2 for structural studies on \([\text{H(OH}_2\text{)}_n]^+\ n = 1 - 6\).) Depending on what aspect of the process is being emphasized, the species \(H_3O^+(aq)\) can be called an oxonium ion, a hydrogen ion, or simply a solvated (hydrated) proton. The equilibrium constant for autoprotolysis is

\[
K_1 = [H_3O^+][OH^-]/[H_2O]^2
\]

and, since the concentration of water is essentially constant, the ionic product of water can be written as

\[
K_w = [H_3O^+][OH^-]/mol^2 l^{-2}
\]

The value of \(K_w\) depends on the temperature, being \(0.69 \times 10^{-14}\) mol\(^2\) l\(^{-2}\) at 0°C, \(1.00 \times 10^{-14}\) at 25°C and \(47.6 \times 10^{-14}\) at 100°C. It follows that the hydrogen-ion concentration in pure water at 25°C is \(10^{-7}\) mol l\(^{-1}\). Acids increase this concentration by means of the reaction

\[
HA + H_2O \rightleftharpoons H_3O^+ + A^{-};
\]

\[
K = [H_3O^+][A^-]/[HA][H_2O]
\]

It is to be understood that all the species are in aqueous solution and the symbol \(HA\) implies only that the (aquated) species can act as a proton donor: it can be a neutral species (e.g. \(H_2S\)), an anion (e.g. \(H_2PO_4^-\)) or a cation such as \([\text{Fe(H}_2\text{O}_6)]^{3+}\). The hydrogen-ion concentration is usually expressed as pH (see Panel). In dilute solution the concentration of water molecules is constant at 25°C (55.345 mol l\(^{-1}\)), and the dissociation of the acid is often rewritten as

\[
HA \rightleftharpoons H^+ + A^{-};
\]

\[
K_a = [H^+][A^-]/[HA]\text{ mol l}^{-1}
\]

The acid constant \(K_a\) can also be expressed by the relation

\[
pK_a = - \log K_a. \quad \text{Hence, as } K_a = 55.345 K
\]

\[
pK_a = pK - 1.734
\]

Further, as the free energy of dissociation is given by

\[
\Delta G^\circ = -RT \ln K = -2.3026RT \log K,
\]

the standard free energy of dissociation is

\[
\Delta G^\circ_{298.15} = 5.708 pK
\]

\[
= 5.708(pK_a + 1.734)\text{ kJ mol}^{-1}
\]

Textbooks of analytical chemistry should be consulted for further details concerning the ionization of weak acids and bases and the theory of indicators, buffer solutions, and acid–alkali titrations.\(^{(39–41)}\)

Various trends have long been noted in the acid strengths of many binary hydrides and oxoacids.\(^{(38)}\) Values for some simple hydrides are given in Table 3.4 from which it is clear that acid strength increases with atomic number both in any one horizontal period and in any

The Concept of pH

The now universally used measure of the hydrogen-ion concentration was introduced in 1909 by the Danish biochemist S. P. L. Sørensen during his work at the Carlsberg Breweries (Biochem. Z. 21. 131, 1909):

\[ \text{pH} = -\log[H^+] \]

The symbol pH derives from the French puissance d'hydrogène, referring to the exponent or “power of ten” used to express the concentration. Thus a hydrogen-ion concentration of 10^{-7} mol^{-1} is designated pH 7, whilst acid solutions with higher hydrogen-ion concentrations have a lower pH. For example, a strong acid of concentration 1 mmol^{-1} has pH 3, whereas a strong alkali of the same concentration has pH 11 since [H_3O^+] = 10^{-14}/[OH^-] = 10^{-11}.

Unfortunately, it is far simpler to define pH than to measure it, despite the commercial availability of instruments that purport to do this. Most instruments use an electrochemical cell such as

\[
\text{glass electrode} | \text{test solution} | 3.5 \text{ M } \text{KCl(aq)} | \text{Hg}_2\text{Cl}_2 | \text{Hg}
\]

Assuming that the glass electrode shows an ideal hydrogen electrode response, the emf of the cell still depends on the magnitude of the liquid junction potential \( E_j \) and the activity coefficients \( \gamma \) of the ionic species:

\[
E = E^* - \frac{RT}{F} \ln \gamma_{\text{Cl}^-} + E_j - \frac{RT}{F} \ln \gamma_{\text{H}^+}
\]

For this reason, the pH as measured by any of the existing national standards is an operational quantity which has no simple fundamental significance. It is defined by the equation

\[
\text{pH}(X) = \text{pH}(S) + \frac{(E_X - E_S)F}{RT \ln 10}
\]

where pH(S) is the assigned pH of a standard buffer solution such as those supplied with pH meters.

Only in the case of dilute aqueous solutions (<0.1 mol^{-1}) which are neither strongly acid or alkaline (2 < pH < 12) is pH(X) such that

\[
\text{pH}(X) = -\log[H^+] \gamma_k \pm 0.02
\]

where \( \gamma_k \), the mean ionic activity coefficient of a typical uni-univalent electrolyte, is given by

\[
-\log \gamma_k = A I^\frac{1}{2} (1 + I)^{-\frac{1}{2}}
\]

In this expression \( I \) is the ionic strength of the solution and \( A \) is a temperature-dependent constant (0.511 \text{ mol}^{-\frac{1}{2}} \text{ at } 25^\circ \text{C} ; 0.501 \text{ mol}^{-\frac{1}{2}} \text{ at } 15^\circ \text{C}). It is clearly unwise to associate a pH meter reading too closely with pH unless under very controlled conditions, and still less sensible to relate the reading to the actual hydrogen-ion concentration in solution.

vertical group. Several attempts have been made to interpret these trends, at least qualitatively, but the situation is complex. The trend to increasing acidity from left to right in the periodic table could be ascribed to the increasing electronegativity of the elements which would favour release of the proton, but this is clearly not the dominant effect within any one group since the trend there is in precisely the opposite direction. Within a group it is the diminution in bond strength with increasing atomic number that prevails, and entropies of solvation are also important. It should, perhaps, also be emphasized that thermodynamic computations do not “explain” the observed acid strengths; they merely allocate the overall values of \( \Delta G \),
\( \Delta H \) and \( \Delta S \) to various notional subprocesses such as bond dissociation energies, ionization energies, electron affinities, heats and entropies of hydration, etc., which themselves have empirically observed values that are difficult to compute \textit{ab initio}.

Regularities in the observed strengths of oxoacids have been formulated in terms of two rules by L. Pauling and others:

(i) for polybasic mononuclear oxoacids, successive acid dissociation constants diminish approximately in the ratios \( 1:10^{-5}:10^{-10}:\ldots; \)

(ii) the value of the first ionization constant for acids of formula \( \text{XO}_m(\text{OH})_n \) depends sensitively on \( m \) but is approximately independent of \( n \) and \( X \) for constant \( m \), being \( \leq 10^{-8} \) for \( m = 0 \), \( \sim 10^{-2} \) for \( m = 1 \), \( \sim 10^{3} \) for \( m = 2 \), and \( >10^{5} \) for \( m = 3 \).

Thus to illustrate the first rule:

\[
\begin{align*}
H_3\text{PO}_4 \rightleftharpoons H^+ + H_2\text{PO}_4^-; \\
K_1 = \frac{[H^+][H_2\text{PO}_4^-]}{[H_3\text{PO}_4]} = 7.11 \times 10^{-3} \text{ mol l}^{-1}; \\
pK_1 = 2.15
\end{align*}
\]

\[
H_2\text{PO}_4^- \rightleftharpoons H^+ + \text{HPO}_4^{2-};
\]

\[
K_2 = \frac{[H^+][\text{HPO}_4^{2-}]}{[H_2\text{PO}_4^-]} = 6.31 \times 10^{-8} \text{ mol l}^{-1}; \\
pK_2 = 7.20
\]

\[
\text{HPO}_4^{2-} \rightleftharpoons \text{H}^+ + \text{PO}_4^{3-};
\]

\[
K_3 = \frac{[H^+][\text{PO}_4^{3-}]}{[\text{HPO}_4^{2-}]} = 4.22 \times 10^{-13} \text{ mol l}^{-1}; \\
pK_3 = 12.37
\]

Qualitatively, a reduction in \( pK_a \) for each successive stage of ionization is to be expected since the proton must separate from an anion of increasingly negative charge, though the approximately constant reduction factor of \( 10^5 \) is more difficult to rationalize quantitatively.

Acids which illustrate the second rule are summarized in Table 3.5. The qualitative explanation for this regularity is that, with increasing numbers of oxygen atoms the single negative charge on the anion can be spread more widely, thereby reducing the electrostatic energy attracting the proton and facilitating the ionization. On this basis one might expect an even more dramatic effect if the anion were monoatomic (e.g. \( \text{S}^2^- \), \( \text{Se}^2^- \), \( \text{Te}^2^- \)) since the attraction of these dianions for protons will be very strong and the acid dissociation constant of \( \text{SH}^- \), \( \text{SeH}^- \) and \( \text{TeH}^- \) correspondingly small; this is indeed observed and the ratio of

| Table 3.5 Values of \( pK_a \) for some mononuclear oxoacids \( \text{XO}_m(\text{OH})_n \) (\( pK_a \approx 8-5n \)) |
|-----------------|-----------------|-----------------|-----------------|-----------------|
| \( \text{X(OH)}_n \) (very weak) | \( \text{XO(OH)}_n \) (weak) | \( \text{XO}_2(\text{OH})_n \) (strong) | \( \text{XO}_3(\text{OH})_n \) (very strong) |
| Cl(OH) | 7.2 | NO(OH) | 3.3 | NO_2(OH) | -1.4 | ClO_3(OH) | (-10) |
| Br(OH) | 8.7 | ClO(OH) | 2.0 | ClO_2(OH) | -1 | MnO_3(OH) | - |
| I(OH) | 10.0 | CO(OH)_2 | 3.9(a) | I_2(OH) | <0 | |
| B(OH)_3 | 9.2 | SO(OH)_2 | 1.9 | SO_2(OH)_2 | <0 | |
| As(OH)_3 | 9.2 | SeO(OH)_2 | 2.6 | SeO_2(OH)_2 | <0 | |
| Sb(OH)_3 | 11.0 | TeO(OH)_2 | 2.7 | | | |
| Si(OH)_4 | 10.0 | PO(OH)_3 | 2.1 | | | |
| Ge(OH)_4 | 8.6 | AsO(OH)_3 | 2.3 | | | |
| Te(OH)_6 | 8.8 | IO(OH)_3 | 1.6 | | | |
| HPO(OH)_2 | 1.8(b) | | | | | |
| H_2PO(OH) | 2.0(b) | | | | | |

(a) Corrected for the fact that only 0.4% of dissolved \( \text{CO}_2 \) is in the form of \( \text{H}_2\text{CO}_3 \); the conventional value is \( pK_a 6.5 \).

(b) Note that the value of \( pK_a \) for hypophosphorous acid \( \text{H}_3\text{PO}_3 \) is consistent with its (correct) formulation as \( \text{HPO(OH)}_2 \) rather than as \( \text{P(OH)}_3 \), which would be expected to have \( pK_a > 8 \). Similarly for \( \text{H}_3\text{PO}_2 \), which is \( \text{H}_2\text{PO(OH)} \) rather than \( \text{HP(OH)}_2 \).

</tbody>
</table>

The first and second dissociation constants is \( \sim 10^8 \) rather than \( 10^5 \) (Table 3.6).

The results for dinuclear and polynuclear oxoacids are also consistent with this interpretation. Thus for phosphoric acid, \( H₄P₂O₇ \), the successive \( pK_a \) values are 1.5, 2.4, 6.6 and 9.2; the \( \sim 10 \)-fold decrease between \( pK₁ \) and \( pK₂ \) (instead of a decrease of \( 10^5 \)) is related to the fact that ionization occurs from two different PO₄ units. The third stage ionization, however, is \( \sim 10^5 \) less than the first stage and the difference between the mean of the first two and the last two ionization constants is \( \sim 5 \times 10^5 \).

Another phenomenon that is closely associated with acid–base equilibria is the so-called hydrolysis of metal cations in aqueous solution, which is probably better considered as the protolysis of hydrated cations, e.g.:

“hydrolysis”:

\[
Fe^{3+} + H₂O \rightleftharpoons [Fe(OH)]^{2+} + H⁺
\]

protolysis:

\[
[Fe(H₂O)₆]^{3+} + H₂O \rightleftharpoons [Fe(H₂O)₅(OH)]^{2+} + H₃O⁺; \quad pK_a 3.05
\]

\[
[Fe(H₂O)₄(OH)]^{2+} + H₂O \rightleftharpoons [Fe(H₂O)₃(OH)₂]^{+} + H₃O⁺; \quad pK_a 3.26
\]

It is these reactions that impart the characteristic yellow to reddish-brown coloration of the hydroxoaquo species to aqueous solutions of iron(III) salts, whereas the undissociated ion \( [Fe(H₂O)₆]^{3+} \) is pale mauve, as seen in crystals of iron(III) alum \( ([Fe(H₂O)₆][K(H₂O)₆][SO₄]₂) \) and iron(III) nitrate \( ([Fe(H₂O)₆](NO₃)₃·3H₂O) \). Such reactions may proceed to the stage where the diminished charge on the hydrated cation permits the formation of oxobridged, or hydroxobridged polynuclear species that eventually precipitate as hydroxides (see discussion of the chemistry of many elements in later chapters). A useful summary is in Fig. 3.4. By contrast, extensive studies of the \( pK_a \) values of hydrated metal ions in solution has generated a wealth of numerical data but no generalizations such as those just discussed for the hydrides and oxoacids of the non-metals. \(^{42}\)

Typical \( pK_a \) values fall in the range 3–14 and, as expected, there is a general tendency for protolysis to be greater (\( pK_a \) values to be lower) the higher the cationic charge. For example, aqueous solutions of iron(III) salts are more acidic than solutions of the corresponding iron(II) salts. However, it is difficult to discern any regularities in \( pK_a \) for series of cations of the same ionic charge, and it is clear that specific “chemical” effects must also be considered.

Børnsøtet acidity is not confined to dilute aqueous solutions and the ideas developed in the preceding pages can be extended to proton donors in nonaqueous solutions. \(^{43,44}\) In organic solvents and anhydrous protonic liquids the concepts of hydrogen-ion concentration and pH, if not actually meaningless, are certainly operationally inapplicable and acidity must be defined on some other scale. The one most frequently used is the Hammett acidity function \( H_0 \) which enables various acids to be compared in a given solvent and a given acid to be compared in various solvents. For the equilibrium between a base and its conjugate acid (frequently a coloured indicator)

\[
B + H⁺ \rightleftharpoons BH^+
\]

the acidity function is defined as

\[
H_0 = pK_{BH⁺} - \log([BH⁺]/[B])
\]

In very dilute solutions

\[
K_{BH⁺} = [B][H⁺]/[BH⁺]
\]

so that in water $H_0$ becomes the same as pH. Some values for typical anhydrous acids are in Table 3.7 and these are discussed in more detail in appropriate sections of later chapters.

Table 3.7 Hammett acidity functions for some anhydrous acids

</tbody>
</table>

It will be noted that addition of SbF$_5$ to HF considerably enhances its acidity and the same effect can be achieved by other fluoride acceptors such as BF$_3$ and TaF$_5$:

$$2\text{HF} + \text{MF}_n \rightleftharpoons \text{H}_2\text{F}^+ + \text{MF}_{n+1}^-$$

The enhancement of the acidity of HSO$_3$F by the addition of SbF$_5$ is more complex and the equilibria involved are discussed on p. 570.

3.6 The Hydrogen Bond$^{45-7}$

The properties of many substances suggest that, in addition to the "normal" chemical bonding between the atoms and ions, there exists some further interaction involving a hydrogen atom placed between two or more other groups of atoms. Such interaction is called hydrogen bonding and, though normally weak (10–60 kJ per mol of H-bonded H), it frequently has a decisive influence on the structure and properties of the substance. A hydrogen bond can be said to exist between 2 atoms A and B when these atoms approach more closely than would otherwise be expected in the absence of the hydrogen atom and when, as a result, the system has a lower total energy. The bond is represented

---

§3.6.1 Hydrogen bonds: influence on properties

Figure 3.5 Some examples of branched H bonds: (a) the bifurcated bond in 1,3-dioxan-5(49); and trifurcated bonds in (b) N,N-bis(2-hydroxyethyl)glycine(50) and (c) the nitrilotriacetate dianion.(51)

as A–H⋯B and usually occurs when A is sufficiently electronegative to enhance the acidic nature of H (proton donor) and where the acceptor B has a region of high electron density (such as a lone pair of electrons) which can interact strongly with the acidic hydrogen. In fact, the H bond in A–H⋯B can be either linear as in schematic structure (1) or significantly non-linear as in structures (1b) and (1c). H-bonds can also join three adjacent atoms (bifurcated) as in structure (2) or even four atoms (trifurcated) as in structure (3).

\[ A - H \cdots B \]

(1a)

\[ A - H \cdots B_1 \]

(1b)

\[ A - H \cdots B_2 \]

(1c)

\[ A - H \cdots B_1 \]

(2)

\[ A - H \cdots B_1 \]

(3)

Thus, in a recent survey of 1509 N–H⋯O=C hydrogen bonds in organic carboxyls or carboxylates, nearly 80% (1199) were unbranched, some 20% (304) were bifurcated, but only 0.4% (6) were trifurcated.(48) Some examples are in Fig. 3.5.

It will be convenient first to indicate the range of phenomena which are influenced by H bonding and then to discuss more specifically the nature of the bond itself according to current theories. The experimental evidence suggests that strong H bonds can be formed when A is F, O or N; weaker H bonds are sometimes formed when A is C or a second row element, P, S, Cl or even Br, I. Strong H bonds are favoured when the atom B is F, O or N; the other halogens Cl, Br, I are less effective unless negatively charged and the atoms C, S and P can also sometimes act as B in weak H bonds. Recent examples of C–H⋯N and C–H⋯C bonds are in bis(phenylsulfonyl)trimethylbutylamine (4)(52) and the carbanion of [1.1]ferrocenophane (5),(53)

Thus, in a recent survey of 1509 N–H⋯O=C hydrogen bonds in organic carboxyls or carboxylates, nearly 80% (1199) were unbranched, some 20% (304) were bifurcated, but only 0.4% (6) were trifurcated.(48) Some examples are in Fig. 3.5.

3.6.1 Influence on properties

It is well known that the mps and bps of NH₃, H₂O and HF are anomalously high when compared with the mps and bps of the hydrides of other elements in Groups 15, 16 and 17, and the
same effect is noted for the heats of vaporization, as shown in Fig. 3.6. The explanation normally given is that there is some residual interaction (H bonding) between the molecules of NH₃, H₂O and HF which is absent for methane, and either absent or much weaker for heavier hydrides. This argument is probably correct in outline but is deceptively oversimplified since it depends on the assumption that only some of the H bonds in solid HF (for example) are broken during the melting process and that others are broken on vaporization, though not all, since HF is known to be substantially polymerized even in the gas phase. The mp is the temperature at which there is zero free-energy change on passing from the solid to the liquid phase:

\[ \Delta G_m = \Delta H_m - T_m \Delta S_m = 0; \]

hence \( T_m = \Delta H_m / \Delta S_m \)

It can be seen that a high mp implies either a high enthalpy of melting, or a low entropy of melting, or both. Similar arguments apply to vaporization and the bp, and indicate the difficulties in quantifying the discussion.

Other properties that are influenced by H bonding are solubility and miscibility, heats of mixing, phase-partitioning properties, the

**Figure 3.6** Plots showing the high values of mp, bp and heat of vaporization of NH₃, H₂O and HF when compared with other hydrides. Note also that the mp of CH₄ (−182.5°C) is slightly higher than that of SiH₄ (−185°C).
existence of azeotropes, and the sensitivity of chromatographic separation. Liquid crystals (or mesophases) which can be regarded as "partly melted" solids also frequently involve molecules that have H-bonded groups (e.g. cholesterol, polypeptides, etc.). Again, H bonding frequently results in liquids having a higher density and lower molar volume than would otherwise have been expected, and viscosity is also affected (e.g. glycerol, anhydrous H₂SO₄, H₃PO₄, etc.).

Electrical properties of liquids and solids are sometimes crucially influenced by H bonding. The ionic mobility and conductance of H₃O⁺ and OH⁻ in aqueous solutions are substantially greater than those of other univalent ions due to a proton-switch mechanism in the H-bonded associated solvent, water. For example, at 25°C the conductance of H₃O⁺ and OH⁻ are 350 and 192 ohm⁻¹ cm² mol⁻¹, whereas for other (viscosity-controlled) ions the values fall mainly in the range 50–75 ohm⁻¹ cm² mol⁻¹. (To convert to mobility, \( \mu \text{cm}² \text{s}⁻¹ \text{V}⁻¹ \), divide by 96,485 C mol⁻¹.) It is also notable that the dielectric constant is not linearly related to molecular dipole moments for H-bonded liquids being much higher due to the orientating effect of the H bonds: large domains are able to align in an applied electric field so that the molecular dipoles reinforce one another rather than cancelling each other due to random thermal motion. Some examples are given in Fig. 3.7, which also illustrates the substantial influence of temperature on the dielectric constant of H-bonded liquids presumably due to the progressive thermal dissociation of the H bonds. Even more dramatic are the properties of ferroelectric crystals where there is a stable permanent electric polarization (see Fig. 3.8). Hydrogen bonding is one of the important ordering mechanisms

Figure 3.7 Dielectric constant of selected liquids.
Figure 3.8  Anomalous temperature dependence of relative dielectric constant of ferroelectric crystals at the transition temperature (Curie point).

Most of these effects correlate roughly with the strength of the H bond and are particularly noticeable when the bond is strong. For example, for isolated non-H-bonded hydrogen groups, \( \nu(O-H) \) normally occurs near 3500–3600 cm\(^{-1} \) and is less than 10 cm\(^{-1} \) broad whereas in the presence of O-H...O bonding \( \nu_{\text{antisym}} \) drops to ~1700–2000 cm\(^{-1} \), is several hundred cm\(^{-1} \) broad, and much more intense. A similar effect of \( \Delta \nu \approx 1500–2000 \text{ cm}^{-1} \) is noted on F-H...F formation and smaller shifts have been found for N-H...F (\( \Delta \nu \leq 1000 \text{ cm}^{-1} \)), N-H...O (\( \Delta \nu \leq 400 \text{ cm}^{-1} \)), O-H...N (\( \Delta \nu \leq 100 \text{ cm}^{-1} \)), etc. A full discussion of these effects, including the influence of solvent, concentration, temperature and pressure, is given in ref. 45. Suffice it to note that the magnitude of the effect is much greater than expected on a simple electrostatic theory of hydrogen bonding, and this implies appreciable electron delocalization (covalency) particularly for the stronger H bonds.

Proton nmr spectroscopy has also proved valuable in studying H-bonded systems. As might be expected, substantial chemical shifts are observed and information can be obtained responsible for this phenomenon as discussed in more detail in the Panel opposite.\(^{54,55}\)

Intimate information about the nature of the H bond has come from vibrational spectroscopy (infrared and Raman), proton nmr spectroscopy, and diffraction techniques (X-ray and neutron). In vibrational spectroscopy the presence of a hydrogen bond A–H...B is manifest by the following effects:

(i) the A–H stretching frequency \( \nu \) shifts to lower wave numbers;
(ii) the breadth and intensity of \( \nu(A-H) \) increase markedly, often more than tenfold;
(iii) the bending mode \( \delta(A-H) \) shifts to higher wave numbers;
(iv) new stretching and bending modes of the H bond itself sometimes appear at very low wave numbers (20–200 cm\(^{-1} \)).

Ferroelectric Crystals

A ferroelectric crystal is one that has an electric dipole moment even in the absence of an external electric field. This arises because the centre of positive charge in the crystal does not coincide with the centre of negative charge. The phenomenon was discovered in 1920 by J. Valasek in Rochelle salt, which is the H-bonded hydrated d-tartrate NaC2H2O6.4H2O. In such compounds the dielectric constant can rise to enormous values of 10^3 or more due to presence of a stable permanent electric polarization. Before considering the effect further, it will be helpful to recall various definitions and SI units:

\[
\begin{align*}
\text{electric polarization} & \; P = D - \varepsilon_0 E \quad \text{(C m}^{-2}\text{)} \\
\text{where} & \; D \quad \text{is the electric displacement (C m}^{-2}\text{)} \\
\text{and} & \; E \quad \text{is the electric field strength (V m}^{-1}\text{)} \\
\text{and} & \; \varepsilon_0 \quad \text{is the permittivity of vacuum (F m}^{-1}\text{)} \\
\text{dielectric constant} & \; \varepsilon = \frac{\varepsilon_0 E + P}{\varepsilon_0 E} = 1 + \chi \quad \text{(dimensionless)}
\end{align*}
\]

where \( \chi = \varepsilon - 1 = P/\varepsilon_0 E \) is the dielectric susceptibility.

There are two main types of ferroelectric crystal:

(a) those in which the polarization arises from an ordering process typically by H bonding;
(b) those in which the polarization arises by a displacement of one sublattice with respect to another, as in perovskite-type structures like barium titanate (p. 963).

The ferroelectricity usually disappears above a certain transition temperature (often called a Curie temperature) above which the crystal is said to be paraelectric; this is because thermal motion has destroyed the ferroelectric order. Occasionally the crystal melts or decomposes before the paraelectric state is reached. There are thus some analogies to ferromagnetic and paramagnetic compounds though it should be noted that there is no iron in ferroelectric compounds. Some typical examples, together with their transition temperatures and spontaneous permanent electric polarization \( P_s \), are given in the Table.

\( ^{\text{a}} \)To convert to the basic SI unit of C m\(^{-2}\) divide the tabulated values of \( P_s \) by 10\(^2\); to convert to the CGS unit of esu cm\(^{-2}\) multiply by 3 \times 10\(^4\). For a full compilation see E. C. Subbarao, \textit{Ferroelectrics} 5, 267 (1973).

(b) Triglycine sulfate and selenate.

In KH2PO4 and related compounds each tetrahedral \([\text{PO}_2\text{OH}_2]^-\) group is joined by H bonds to neighbouring \([\text{PO}_2\text{OH}_2]^+\) groups; below the transition temperature all the short O–H bonds are ordered on the same side of the PO4 units, and by appropriate application of an electric field, the polarization of the H bonds can be reversed. The dramatic effect of deuterium substitution in raising the transition temperature of such compounds can be seen from the Table: this has been ascribed to a quantum-mechanical effect involving the mass dependence of the de Broglie wavelength of hydrogen. Other examples of H-bonded ferroelectrics are (NH4)2H2PO4, (NH4)2H2AsO4, Ag2H2TeO6, (NH4)Al(SO4)2.6H2O and (NH4)4SO4. Rochelle salt is unusual in having both an upper and a lower critical temperature between which the compound is ferroelectric.

Panel continues
The closely related phenomenon of antiferroelectric behaviour is also known, in which there is an ordered, self-cancelling arrangement of permanent electric dipole moments below a certain transition temperature; H bonding is again implicated in the ordering mechanism for several ammonium salts of this type, e.g. (NH₄)₂PO₄ 424 K, (NH₄)H₂AsO₄ 216 K, (NH₄)D₂PO₄ 242 K, (NH₄)H₂AsO₄ 167 K, (NH₄)D₂AsO₄ 304 K and (NH₄)H₃IO₆ 254 K. As with ferroelectrics, antiferroelectrics can also arise by a displacive mechanism in perovskite-type structures, and typical examples, with their transition temperatures, are:

- PbZrO₃ 506 K, PbHfO₃ 488 K, NaNbO₃ 793. 911 K, WO₃ 1010 K.

Ferroelectrics have many practical applications: they can be used as miniature ceramic capacitors because of their large capacitance, and their electro-optical characteristics enable them to modulate and deflect laser beams. The temperature dependence of spontaneous polarization induces a strong pyroelectric effect which can be exploited in thermal and infrared detection. Many applications depend on the fact that all ferroelectrics are also piezoelectrics. Piezoelectricity is the property of acquiring (or altering) an electric polarization \( P \) under external mechanical stress, or conversely, the property of changing size (or shape) when subjected to an external electric field \( E \). Thus ferroelectrics have been used as transducers to convert mechanical pulses into electrical ones and vice versa, and find extensive application in ultrasonic generators, microphones, and gramophone pickups; they can also be used as frequency controllers, electric filters, modulating devices, frequency multipliers, and as switches, counters and other bistable elements in computer circuits. A further ingenious application is in delay lines by means of which an electric signal is transformed piezoelectrically into an acoustic signal which passes down the piezoelectric rod at the velocity of sound until, at the other end, it is reconverted into a (delayed) electric signal.

It should be noted that, whereas ferroelectrics are necessarily piezoelectrics, the converse need not apply. The necessary condition for a crystal to be piezoelectric is that it must lack a centre of inversion symmetry. Of the 32 point groups, 20 qualify for piezoelectricity on this criterion, but for ferroelectric behaviour a further criterion is required (the possession of a single non-equivalent direction) and only 10 space groups meet this additional requirement. An example of a crystal that is piezoelectric but not ferroelectric is quartz, and indeed this is a particularly important example since the use of quartz for oscillator stabilization has permitted the development of extremely accurate clocks (1 in \( 10^8 \)) and has also made possible the whole of modern radio and television broadcasting including mobile radio communications with aircraft and ground vehicles.

Concerning H-bond dissociation, proton exchange times, and other relaxation processes. The chemical shift always occurs to low field and some typical values are tabulated below for the shifts which occur between the gas and liquid phases or on dilution in an inert solvent:

<table>

</tbody>
</table>

The low-field shift is generally interpreted, at least qualitatively, in terms of a decrease in diamagnetic shielding of the proton: the formation of A−H···B tends to draw H towards B and to repel the bonding electrons in A−H towards A thus reducing the electron density about H and reducing the shielding. The strong electric field due to B also inhibits the diamagnetic circulation within the H atom and this further reduces the shielding. In addition, there is a magnetic anisotropy effect due to B; this will be positive (upfield shift) if the principal symmetry axis of B is towards the H bond, but the effect is presumably small since the overall shift is always downfield.

Ultraviolet and visible spectra are also influenced by H bonding, but the effects are more difficult to quantify and have been rather less used than ir and nmr. It has been found that the \( n \rightarrow \pi^* \) transition of the base B always moves to high frequency (blue shift) on H-bond formation, the magnitude of \( \Delta \nu \) being \(~300–4000\) cm\(^{-1}\) for bands in the region 15 000–35 000 cm\(^{-1}\). By contrast \( \pi \rightarrow \pi^* \) transitions on the base B usually move to lower frequencies (red shift) and shifts are in the range \(~500–2300\) cm\(^{-1}\) for bands in the region 30 000–47 000 cm\(^{-1}\). Detailed interpretations of these data are somewhat complex and obscure, but it will be noted that the shifts are approximately of the same magnitude as the enthalpy of formation of many H bonds (83.59 cm\(^{-1}\) per atom \(\equiv 1\) kJ mol\(^{-1}\)).
§3.6.2 Hydrogen bonds: influence on structure

The crystal structure of many compounds is dominated by the effect of H bonds, and numerous examples will emerge in ensuing chapters. Ice (p. 624) is perhaps the classic example, but the layer lattice structure of B(OH)₃ (p. 203) and the striking difference between the α- and β-forms of oxalic and other dicarboxylic acids is notable (Fig. 3.9). The more subtle distortions that lead to ferroelectric phenomena in KH₂PO₄ and other crystals have already been noted (p. 57). Hydrogen bonds between fluorine atoms result in the formation of infinite zigzag chains in crystalline hydrogen fluoride with F–H···F distance 249 pm and the angle HFH 120.1°. Likewise, the crystal structure of NH₄HF₂ is completely determined by H bonds, each nitrogen atom being surrounded by 8 fluorines, 4 in tetrahedral array at 280 pm due to the formation of N–H···F bonds, and 4 further away at about 310 pm; the two sets of fluorine atoms are themselves bonded pairwise at 232 pm by F–H–F interactions. Ammonium azide NH₄N₃ has the same structure as NH₄HF₂, with N–H···N 298 pm. Hydrogen bonding also leads NH₄F to crystallize with a structure different from that of the other ammonium (and alkali) halides: NH₄Cl, NH₄Br and NH₄I each have a low-temperature CsCl-type structure and a high-temperature NaCl-type structure, but NH₄F adopts the wurtzite (ZnS) structure in which each NH₄⁺ group is surrounded tetrahedrally by 4 F to which it is bonded by 4 N–H···F bonds at 271 pm. This is very similar to the structure

---

of ordinary ice. Typical values of \(A-H-B\) distances found in crystals are given in Table 3.8.

The precise position of the H atom in crystalline compounds containing H bonds has excited considerable experimental and theoretical interest. In situations where a symmetric H bond is possible in principle, it is frequently difficult to decide whether the proton is vibrating with a large amplitude about a single potential minimum or whether it is vibrating with a smaller amplitude but is also statistically disordered between two close sites, the potential energy barrier between the two sites being small.\(^{46,47}\) It now seems well established that the F–H–F bond is symmetrical in NaHF\(_2\) and KHF\(_2\), and that the O–H–O bond is symmetrical in HCrO\(_2\). Other examples are the intra-molecular H bonds in potassium hydrogen maleate, K\([\text{cis-CH=CHC(O)O-H-OC(O)}]\)^\(^+\) and its monochloro derivative; Numerous other examples of H bonding will be found in later chapters.

In summary, we can see that H bonding influences crystal structure by linking atoms or groups into larger structural units. These may be:

- finite groups: \(\text{HF}_2^-; [O_2\text{CO-\cdots COO}]^3^-\) in Na\(_3\)H(CO\(_3\))\(_2\).2H\(_2\)O dimers of carboxylic acids, etc.;
- infinite chains: HF, HCN, HCO\(_3^-\), HSO\(_4^-\), etc.;
- infinite layers: N\(_2\)H\(_6\)F\(_2\), B(OH)\(_3\), B\(_2\)O\(_3\)(OH)\(_3\), H\(_2\)SO\(_4\), etc.;
- three-dimensional nets: NH\(_4\)F, H\(_2\)O, H\(_2\)O\(_2\), Te(OH)\(_6\), H\(_2\)PO\(_4^-\) in KH\(_2\)PO\(_4\), etc.

H bonding also vitally influences the conformation and detailed structure of the polypeptide chains of protein molecules and the complementary intertwined polynucleotide chains which form the double helix in nucleic acids.\(^{56,58}\) Thus, proteins are built up from polypeptide chains of the type shown at the top of the next column.

These chains are coiled in a precise way which is determined to a large extent by N–H–O hydrogen bonds of length 279 ±

of developments of fundamental importance in biochemistry.\(^{(58)}\)

### 3.6.3 Strength of hydrogen bonds and theoretical description\(^{(59)}\)

Measurement of the properties of H-bonded systems over a range of temperatures leads to experimental values of \(\Delta G\), \(\Delta H\) and \(\Delta S\) for H-bond formation, and these data have been supplemented in recent years by increasingly reliable \textit{ab initio} quantum-mechanical calculations.\(^{(60)}\) Some typical values for the enthalpy of dissociation of H-bonded pairs in the gas phase are in Table 3.9.

The uncertainty in these values varies between \(\pm 1\) and \(\pm 6\) kJ mol\(^{-1}\). In general, H bonds of energy \(<25\) kJ mol\(^{-1}\) are classified as weak; those in the range \(25-40\) kJ mol\(^{-1}\) are medium; and those having \(\Delta H > 40\) kJ mol\(^{-1}\) are strong. Until recently, it was thought that the strongest H bond was that in the hydrogen difluoride ion \([\text{F-H-F}]^-\); this is difficult to determine experimentally and values in the range \(150-250\) kJ mol\(^{-1}\) have been reported. A recent theoretically computed value is \(169\) kJ mol\(^{-1}\) which agrees well with the value of \(163 \pm 4\) kJ mol\(^{-1}\) from ion cyclotron resonance studies.\(^{(61)}\) In fact, it now seems that the H bond between formic acid and the fluoride ion,

\begin{table}[h]

93.6.3 Strength of hydrogen bonds and theoretical description 63

[HC\(_2\)H\(\cdot\cdot\cdot\)F\(^-\)]\(^-\) is some 30 kJ mol\(^{-1}\) stronger than that calculated on the same basis for HF\(^2\)\(^-\).\(^{62}\)

Early discussions on the nature of the hydrogen bond tended to adopt an electrostatic approach in order to avoid the implication of a covalency greater than one for hydrogen. Indeed, such calculations can reproduce the experimental H-bond energies and dipole moments, but this is not a particularly severe test because of the parametric freedom in positioning the charges. However, the purely electrostatic theory is unable to account for the substantial increase in intensity of the stretching vibration \(v(A-H)\) on H bonding or for the lowered intensity of the bending mode \(\delta(A-H)\). More seriously, such a theory does not account for the absence of correlation between H-bond strength and dipole moment of the base, and it leaves the frequency shifts in the electronic transitions unexplained. Nonlinear A–H⋯B bonds would also be unexpected, though numerous examples of angles in the range 150–180° are known.\(^{66}\)

Valence-bond descriptions envisage up to five contributions to the total bond wave function,\(^{45}\) but these are now considered to be merely computational devices for approximating to the true wave function. Perturbation theory has also been employed and apportions the resultant bond energy between (1) the electrostatic energy of interaction between the fixed nuclei and the electron distribution of the component molecules, (2) Pauli exchange repulsion energy between electrons of like spin, (3) polarization energy resulting from the attraction between the polarizable charge cloud of one molecule and the permanent multipoles of the other molecule, (4) quantum-mechanical charge-transfer energy, and (5) dispersion energy, resulting from second-order induced dipole-induced dipole attraction. The results suggest that electrostatic effects predominate, particularly for weak bonds, but that covalency effects increase in importance as the strength of the bond increases. It is also possible to apportion the energy obtained from \textit{ab initio} SCF-MO calculations in this way.\(^{63}\)

For example, in one particular calculation for the water dimer HOH⋯OH\(_2\), the five energy terms enumerated above were calculated to be: \(E_{\text{elec stat}} = -26.5\), \(E_{\text{Pauli}} + 18\), \(E_{\text{polar}} - 2\), \(E_{\text{ch tr}} = 7.5\), \(E_{\text{disp}} = 0\) kJ mol\(^{-1}\). There was also a coupling interaction \(E_{\text{mix}} - 0.5\), making in all a total attractive force \(\Delta E_0 = E_{\text{dimer}} - E_{\text{monomers}} = -18.5\) kJ mol\(^{-1}\). To calculate the enthalpy change \(\Delta H_{298}\) as listed on p. 61, it is also necessary to consider the work of expansion and the various spectroscopic degrees of freedom:

\[
\Delta H_{298} = E_0 + \Delta(PV) + \Delta E_{\text{trans}} + \Delta E_{\text{vib}} + \Delta E_{\text{rot}}
\]

Such calculations can also give an indication of the influence of H-bond formation on the detailed electron distribution within the interacting components. There is general agreement that in the system X–A–H⋯B–Y as compared with the isolated species XAH and BY, there is a net gain of electron density by X, A and B and a net loss of electrons by H and Y. There is also a small transfer of electronic charge (~0.05 electrons) from BY to XAH in moderately strong H bonds (20–40 kJ mol\(^{-1}\)). In virtually all neutral dimers, the increase in the A–H bond length on H-bond formation is quite small (<5 pm), the one exception so far studied theoretically being CIH⋯NH\(_3\), where the proton position in the H bond is half-way between completely transferred to NH\(_3\) and completely fixed on HCl.

It follows from the preceding discussion that the unbranched H bond can be regarded as a 3-centre 4-electron bond A–H⋯B in which the 2 pairs of electrons involved are the bond pair in A–H and the lone pair on B. The degree of charge separation on bond formation will depend on the nature of the proton-donor group AH and the Lewis base B. The relation between this 3-centre bond formalism and the 3-centre bond descriptions frequently used for boranes, polyhalides and compounds of xenon is particularly instructive and is elaborated in

Figure 3.11 Schematic representation of the energy levels in various types of 3-centre bond. The B–H–B ("electron deficient") bond is non-linear, the ("electron excess") F–Xe–F bond is linear, and the A–H⋯B hydrogen bond can be either linear or non-linear depending on the compound.

Fig. 3.11. Numerous examples are also known in which hydrogen acts as a bridge between metallic elements in binary and more complex hydrides, and some of these will be mentioned in the following section which considers the general question of the hydrides of the elements.

3.7 Hydrides of the Elements

Hydrogen combines with many elements to form binary hydrides MH (or MₙHₙ). All the main-group elements except the noble gases and perhaps indium and thallium form hydrides, as do all the lanthanoids and actinoids that have been studied. Hydrides are also formed by the more electropositive transition elements, notably Sc, Y, La, Ac; Ti, Zr, Hf; and to a lesser extent V, Nb, Ta; Cr; Cu; and Zn. Hydrides of other transition elements are either non-existent or poorly characterized, with the spectacular exception of palladium which has been more studied than any other metal hydride system. The situation is summarized in Fig. 3.12; this indicates the idealized formulae of the known hydrides though many of the d-block and f-block elements form phases of variable compositions.

It has been customary to group the binary hydrides of the elements into various classes according to the presumed nature of their bonding: ionic, metallic, covalent, polymeric, and "intermediate" or "borderline". However, this is unsatisfactory because the nature of the bonding is but poorly understood in many cases and the classification obscures the important point that there is an almost continuous gradation in properties — and bond types(?) — between members of the various classes. It is also somewhat misleading in implying that the various bond types are mutually exclusive whereas it seems likely that more than one type of bonding is present in many cases. The situation is not unique to hydrides but is also well known for...
binary halides, oxides, sulfides, etc.: this serves to remind us that the various bond models represent grossly oversimplified limiting cases and that in most actual systems the position is more complex. For example, oxides might be classed as ionic (MgO), metallic (TiO, ReO₃), covalent (CO₂), polymeric (SiO₂), or as intermediate between these various classes, though any adequate bonding theory would recognize the arbitrary nature of these distinctions which merely emphasize particular features of the overall assembly of molecular orbitals and electron populations.

The metals in Groups 1 and 2 of the periodic table react directly with hydrogen to form white, crystalline, stoichiometric hydrides of formula MX and MX₂ respectively. The salt-like character of these compounds was recognized by G. N. Lewis in 1916 and he suggested that they contained the hydride ion H⁻. Shortly thereafter (1920) K. Moers showed that electrolysis of molten LiH (mp 692°C) gave the appropriate amount of hydrogen at the anode; the other hydrides tended to decompose before they could be melted. As expected, the ionic-bond model is most satisfactory for the later (larger) members of each group, and the tendency towards covalency becomes more marked for the smaller elements LiH, MgH₂, and particularly BeH₂, which is best described in terms of polymeric covalent bridge bonds. X-ray and neutron diffraction studies show that the alkali metal hydrides adopt the cubic NaCl structure (p. 242) whereas MgH₂ has the tetragonal TiO₂ (rutile type) structure (p. 961) and CaH₂, SrH₂ and BaH₂ adopt the orthorhombic PbCl₂-type structure (p. 382). The implied radius of the hydride ion H⁻ (1s²) varies considerably with the nature of the metal because of the ready deformability of the pair of electrons surrounding a single proton. Typical values are
given below and these can be compared with \( r(F^{-}) \sim 133 \text{ pm} \) and \( r(Cl^{-}) \sim 184 \text{ pm} \).

The closest M–M approach in these compounds is often less than for the metal itself: this should occasion no surprise since this is a common feature of many compounds in which there is substantial separation of charge. For example, the shortest Ca–Ca interatomic distance is 393 pm in calcium metal, 360 pm in CaH\(_2\), 380 pm in CaF\(_2\), and only 340 pm in CaO (why?).

The thermal stability of the alkali metal hydrides decreases from lithium to caesium, the temperature at which the reversible dissociation pressure of hydrogen reaches 10 mmHg being \( \sim 550^\circ \text{C} \) for LiH, \( \sim 210^\circ \text{C} \) for NaH and KH, and \( \sim 170^\circ \text{C} \) for RbH and CsH. The corresponding figures for the alkaline earth metal hydrides are CaH\(_2\) 885°C, SrH\(_2\) 585°C and BaH\(_2\) 230°C, though for MgH\(_2\) it is only 85°C. Chemical reactivity depends markedly on both the purity and the state of subdivision but increases from lithium to caesium and from calcium to barium with CaH\(_2\) being rather less reactive than LiH. The reaction of water with these latter two compounds forms a convenient portable source of hydrogen, but with NaH the reaction is more violent than with sodium itself. RbH and CsH actually ignite spontaneously in dry air.

Turning next to Group 3, Fig. 3.12 indicates that hydrides of limiting stoichiometry MH\(_2\) are also formed by Sc, Y, La, Ac and by most of the lanthanoids and actinoids. In the special case of EuH\(_2\) (Eu\(^{11} 4f^7\)) and YbH\(_2\) (Yb\(^{14}4f^{14}\)) the hydrides are isostructural with CaH\(_2\) and the ionic bonding model gives a reasonable description of the observed properties; however, YbH\(_2\) can absorb more hydrogen up to about YbH\(_{2.5}\). The other hydrides adopt the fluorite (CaF\(_2\)) crystal structure (p. 118) and the supernumerary valence electron is delocalized, thereby conferring considerable metallic conductivity. For example, LaH\(_2\) is a dark-coloured, brittle compound with a conductivity of about 10 ohm\(^{-1}\) cm\(^{-1}\) (\( \sim 1\% \) of that of La metal). Further uptake of hydrogen progressively diminishes this conductivity to \( < 10^{-1} \text{ ohm}^{-1}\text{ cm}^{-1} \) for the cubic phase LaH\(_3\) (cf. \( \sim 3 \times 10^{-5} \text{ ohm}^{-1}\text{ cm}^{-1} \) for YbH\(_2\)). The other Group 3 elements and the lanthanoids and actinoids are similar.

There is a lively controversy concerning the interpretation of these and other properties, and cogent arguments have been advanced both for the presence of hydride ions H\(^-\) and for the presence of protons H\(^+\) in the d-block and f-block hydride phases.\(^64\)\(^,\)\(^66\) These difficulties emphasize again the problems attending any classification based on presumed bond type, and a phenomenological approach which describes the observed properties is a sounder initial basis for discussion. Thus the predominantly ionic nature of a phase cannot safely be inferred either from crystal structure or from calculated lattice energies since many metallic alloys adopt the NaCl-type or CsCl-type structures (e.g. LaBi, \( \beta\)-brass) and enthalpy calculations are notoriously insensitive to bond type.

The hydrides of limiting composition MH\(_3\) have complex structures and there is evidence that the third hydrogen is sometimes less strongly bound in the crystal. For the earlier (larger) lanthanoids La, Ce, Pr and Nd, hydrogen enters octahedral sites and LnH\(_3\) has the cubic Li\(_3\)Bi structure.\(^57\) For Y and the smaller lanthanoids Sm, Gd, Tb, Dy, Ho, Er, Tm and Lu, as well as for the actinoids Np, Pu and Am, the hexagonal HoH\(_3\) structure is adopted. This is a rather complex structure based on an extended unit cell containing 6 Ho and 18 H atoms.\(^68\) The idealized structure has hcp Ho atoms with 12 tetrahedrally coordinated H atoms and 6 octahedrally coordinated H atoms; however, to make room for the bulky Ho atoms, close pairs of tetrahedral H atoms are slightly displaced and there is a more substantial movement of the “octahedral” H atoms towards the planes of the Ho atoms so that 2 of the H atoms are actually in the Ho planes and are trigonal 3-coordinate. The

\(^{68}\) M. MANSMANN and W. E. WALLACE J. de Physique 25, 454–9 (1964).
Hydrides of the elements 67

Hydrogen atoms are thus of three types having respectively 14, 11, and 9 H neighbours for the distorted trigonal, octahedral and tetrahedral sites. Each H atom has 3 H neighbours at either 210 or 217 or 224–299 pm respectively, and each H has 11 hydrogen neighbours, 9 at 210–229 pm and 2 somewhat further away at 248 pm. The 3-coordinate hydrogen is most unusual, the only other hydride in which it occurs being the complex cubic phase Th₄H₁₅.

Uranium forms two hydrides of stoichiometric composition UH₂. The normal β-form has a complex cubic structure and is the only one formed when the preparation is carried out above 200°C. Below this temperature increasing amounts of the slightly denser cubic α-form occur and this can be transformed to the β-phase by warming to 250°C. Both phases have ferromagnetic and metallic properties. Uranium hydride is commonly used as a starting material for the preparation of uranium compounds as it is finely powdered and extremely reactive. It is also used for purifying and regenerating hydrogen (or deuterium) gas.

The hydrides of Ti, Zr and Hf are characterized by considerable variability in composition and structure. When pure, the limiting phases MH₂ form massive, metallic crystals of fluorite structure (TiH₂) or body-centred tetragonal structure (ZrH₂, HfH₂, ThH₂), but there are also several hydrogen-deficient phases of variable composition and complex structure in which several M–H distances occur. These phases (and others based on Y, Ce and Nb) have been extensively investigated in recent years because of their potential applications as moderators, reflectors, or shield components for high-temperature, mobile nuclear reactors.

Other hydrides with interstitial or metallic properties are formed by V, Nb and Ta; they are, however, very much less stable than the compounds we have been considering and have extensive ranges of composition. Chromium also forms a hydride, CrH, though this must be prepared electrolytically rather than by direct reaction of the metal with hydrogen. It has the anti-NiAs structure (p. 555). Most other elements in this area of the periodic table have little or no affinity for hydrogen and this has given rise to the phrase “hydrogen gap”. The notable exception is the palladium–hydrogen system which is discussed on p. 1150.

The hydrides of the later main-group elements present few problems of classification and are best discussed during the detailed treatment of the individual elements. Many of these hydrides are covalent, molecular species, though association via H bonding sometimes occurs, as already noted (p. 53). Catenation flourishes in Group 14 and the complexities of the boron hydrides merit special attention (p. 151). The hydrides of aluminium, gallium, zinc (and beryllium) tend to be more extensively associated via M–H–M bonds, but their characterization and detailed structural elucidation has proved extremely difficult.

Two further important groups of hydride compounds should be mentioned and will receive detailed attention in later chapters. One is the group of complex metal hydrides of which notable examples are LiBH₄, NaBH₄, LiAlH₄, Al(BH₄)₃, etc. The other is the growing number of compounds in which the hydrogen atom is a monodentate or bidentate (bridging) ligand to a transition element: these date from the early 1930s when W. Hieber discovered [Fe(CO)₄H₂] and [Co(CO)₄H] and now cover an astonishing variety of structural types. The modest steric requirements of the H atom enable complexes such as [ReH₆]²⁻ to be synthesized, and bridged complexes such as the linear [Cr₂(CO)₁₀H]⁻ and bent [W₂(CO)₉H(NO)], are known. For η²-H₂ complexes see pp. 44–7. The role of hydrido complexes in homogeneous catalysis is also exciting considerable attention.

4

Lithium, Sodium, Potassium, Rubidium, Caesium and Francium

4.1 Introduction

The alkali metals form a homogeneous group of extremely reactive elements which illustrate well the similarities and trends to be expected from the periodic classification, as discussed in Chapter 2. Their physical and chemical properties are readily interpreted in terms of their simple electronic configuration, ns\(^1\), and for this reason they have been extensively studied by the full range of experimental and theoretical techniques. Compounds of sodium and potassium have been known from ancient times and both elements are essential for animal life. They are also major items of trade, commerce and chemical industry. Lithium was first recognized as a separate element at the beginning of the nineteenth century but did not assume major industrial importance until about 40 y ago. Rubidium and caesium are of considerable academic interest but so far have few industrial applications. Francium, the elusive element 87, has only fleeting existence in nature due to its very short radioactive half-life, and this delayed its discovery until 1939.

4.2 The Elements

4.2.1 Discovery and isolation

The spectacular success (in 1807) of Humphry Davy, then aged 29 y, in isolating metallic potassium by electrolysis of molten caustic potash (KOH) is too well known to need repeating in detail.\(^1\) Globules of molten sodium were similarly prepared by him a few days later from molten caustic soda. Earlier experiments with aqueous solutions had been unsuccessful because of the great reactivity of these new elements. The names chosen by Davy reflect the sources of the elements.

Lithium was recognized as a new alkali metal by J. A. Arfvedson in 1817 whilst he was working as a young assistant in J. J. Berzelius's laboratory. He noted that Li compounds were similar to those of Na and K but that the carbonate and hydroxide were much less soluble

in water. Lithium was first isolated from the sheet silicate mineral petalite, LiAlSi₄O₁₀, and Arfwedson also showed it was present in the pyroxene silicate spodumene, LiAlSi₂O₆, and in the mica lepidolite, which has an approximate composition K₂Li₃Al₄Si₇O₂₇(OH,F)₃. He chose the name lithium (Greek λιθος, stone) to contrast it with the vegetable origin of Davy's sodium and potassium. Davy isolated the metal in 1818 by electrolysis of molten Li₂O.

Rubidium was discovered as a minor constituent of lepidolite by R. W. Bunsen and G. R. Kirchhoff in 1861 only a few months after their discovery of caesium (1860) in mineral spa waters. These two elements were the first to be discovered by means of the spectroscope, which Bunsen and Kirchhoff had invented the previous year (1859); accordingly their names refer to the colour of the most prominent lines in their spectra (Latin rubidus, deepest red; caesius, sky blue).

Francium was first identified in 1939 by the elegant radiochemical work of Marguerite Perey who named the element in honour of her native country. It occurs in minute traces in nature as a result of the rare (1.38%) branching decay of $^{227}$Ac in the $^{235}$U series:

$$\begin{align*}
^{227}\text{Ac} & \xrightarrow{\alpha (1.38\%)} ^{223}\text{Fr} \xrightarrow{\beta^- 21.8 \text{ min}} ^{223}\text{Ra} \xrightarrow{\alpha 11.43 \text{ d}} \\
\text{t}_{1/2} & = 21.77 \text{ y} \quad \text{t}_{1/2} & = 21.8 \text{ min}
\end{align*}$$

Its terrestrial abundance has been estimated as $2 \times 10^{-18}$ ppm, which corresponds to a total of only 15 g in the top 1 km of the earth's crust. Other isotopes have since been produced by nuclear reactions but all have shorter half-lives than $^{223}$Fr, which decays by energetic $\beta^-$-emission, $\text{t}_{1/2} = 21.8$ min. Because of this intense radioactivity it is only possible to work with tracer amounts of the element.

**4.2.2 Terrestrial abundance and distribution**

Despite their chemical similarity, Li, Na and K are not closely associated in their occurrence, mainly because of differences in size (see Table on p. 75). Lithium tends to occur in ferromagnesian minerals where it partly replaces magnesium; it occurs to the extent of about 18 ppm by weight in crustal rocks, and this reflects its relatively low abundance in the cosmos (Chapter 1). It is about as abundant as gallium (19 ppm) and niobium (20 ppm). The most important mineral commercially is spodumene, LiAlSi₂O₆, and large deposits occur in the USA, Canada, Brazil, Argentina, the former USSR, Spain, China, Zimbabwe and the Congo. An indication of the industrial uses of lithium and its compounds is given in the Panel. World production of lithium compounds in 1994 corresponded to some 5700 tonnes of contained lithium (equivalent to 30000 tonnes of lithium carbonate) of which over 70% was in the USA.

Sodium, 22700 ppm (2.27%) is the seventh most abundant element in crustal rocks and the fifth most abundant metal, after Al, Fe, Ca and Mg. Potassium (18400 ppm) is the next most abundant element after sodium. Vast deposits of both Na and K salts occur in relatively pure form on all continents as a result of evaporation of ancient seas, and this process still continues today in the Great Salt Lake (Utah), the Dead Sea and elsewhere. Sodium occurs as rock-salt (NaCl) and as the carbonate (trona), nitrate (saltpetre), sulfate (mirabilite), borate (borax, kernite), etc. Potassium occurs principally as the simple chloride (sylvinite), as the double chloride KCl·MgCl₂·6H₂O (carnallite) and the anhydrous sulfate K₂Mg₂(SO₄)₃ (langbeinite). There are also unlimited supplies of NaCl in natural brines and oceanic waters (~30 kg m⁻³). Thus, it has been calculated that rock-salt equivalent to the NaCl in the oceans of the world would occupy 19 million cubic km (i.e. 50% more than the total volume of the North American continent above sea-level). Alternatively stated, a one-km square prism would stretch from the earth to the moon 47 times. Note also that, although Na and K are almost equally abundant in the crustal rocks of the earth, Na is some 30 times as abundant as K in the oceans. This is partly because K salts with the larger anions tend to be less soluble than the Na salts and, likewise, K is more strongly bound to...
Lithium and its Compounds (2-4)

The dramatic transformation of Li from a small-scale specialist commodity to a multikilotonne industry during the past three decades is due to the many valuable properties of its compounds. About 35 compounds of Li are currently available in bulk, and a similar number again can be obtained in developmental or research quantities. A major industrial use of Li is in the form of lithium stearate which is used as a thickener and gelling agent to transform oils into lubricating greases. These “all-purpose” greases combine high water resistance with good low-temperature properties (-20°C) and excellent high-temperature stability (>150°C); they are readily prepared from LiOH.H2O and tallow or other natural fats and have captured nearly half the total market for automotive greases in the USA.

Lithium carbonate is the most important industrial compound of lithium and is the starting point for the production of most other lithium compounds. It is also used as a flux in porcelain enamel formulations and in the production of special toughened glasses (by replacement of the larger Na ions): Li can either be incorporated within the glass itself or the preformed Na-glass can be dipped in a molten-salt bath containing Li ions to effect a surface cation exchange. In another application, the use of Li2CO3 by primary aluminium producers has risen sharply in recent years since it increases production capacity by 7-10% by lowering the mp of the cell content and permitting larger current flow; in addition, troublesome fluorine emissions are reduced by 25-50% and production costs are appreciably lowered. In 1987 the price for bulk quantities of Li2CO3 in the USA was $3.30 per kg.

The first commercial use of Li metal (in the 1920s) was as an alloying agent with lead to give toughened bearings; currently, it is used to produce high-strength, low-density aluminium alloys for aircraft construction. With magnesium it forms an extremely tough low-density alloy which is used for armour plate and for aerospace components (e.g. LA 141, d 1.35 g cm-3, contains 14% Li, 1% Al, 85% Mg). Other metallurgical applications employ LiCl as an invaluable brazing flux for Al automobile parts.

LiOH is used in the manufacture of lithium stearate greases (see above) and for CO2 absorption in closed environments such as space capsules (light weight) and submarines. LiH is used to generate hydrogen in military, meteorological, and other applications, and the use of LiD in thermonuclear weaponry and research has been mentioned (p. 18). Likewise, the important applications of LiAlH4, Li/NH3 and organolithium reagents in synthetic organic chemistry are well known, though these account for only a small percentage of the lithium produced. Other specialist uses include the growing market for ferroelectrics such as LiTaO3 to modulate laser beams (p. 57), and increasing use of thermoluminescent LiF in X-ray dosimetry.

Perhaps one of the most exciting new applications stems from the discovery in 1949 that small daily doses (1-2 g) of Li2CO3 taken orally provide an effective treatment for manic-depressive psychoses. The mode of action is not well understood but there appear to be no undesirable side effects. The dosage maintains the level of Li in the blood at about 1 mmol l-1 and its action may be related to the influence of Li on the Na/K balance and (or) the Mg/Ca balance since Li is related chemically to both pairs of elements.

Looking to the future, Li/FeS2 battery systems are emerging as a potentially viable energy storage system for off-peak electricity and as a non-polluting silent source of power for electric cars. The battery resembles the conventional lead-acid battery in having solid electrodes (Li/Si alloy, negative; FeS2, positive) and a liquid electrolyte (melted LiCl/KCl at 400°C). Other battery systems which have reached the prototype stage include the Li/S and Na/S cells (see p. 678).

The vital importance of NaCl in the heavy chemical industry is indicated in the Panel opposite, and information on potassium salts is given in the Panel on p. 73.

Rubidium (78 ppm, similar to Ni, Cu, Zn) and caesium (2.6 ppm, similar to Br, Hf, U) are much less abundant than Na and K and have only recently become available in quantity. No purely Rb-containing mineral is known and much of the commercially available material is obtained as a byproduct of lepidolite processing for Li. Caesium occurs as the hydrated aluminosilicate pollucite, Cs4Al2Si6O26.H2O, but the world’s only commercial source is at Bernic Lake,

the complex silicates and alumino silicates in the soils (ion exchange in clays). Again, K leached from rocks is preferentially absorbed and used by plants whereas Na can proceed to the sea. Potassium is an essential element for plant life and the growth of wild plants is often limited by the supply of K available to them.

---

§4.2.3 Production and uses of the metals

Production and Uses of Salt(5-7)

More NaCl is used for inorganic chemical manufacture than is any other material. It is approached only by phosphate rock, and world consumption of each exceeds 150 million tonnes annually, the figure for NaCl in 1982 being 168.7 million tonnes. Production is dominated by Europe (39%), North America (34%) and Asia (20%), whilst South America and Oceania have only 3% each and Africa 1%. Rock-salt occurs as vast subterraneean deposits often hundreds of metres thick and containing >90% NaCl. The Cheshire salt field (which is the principal UK source of NaCl) is typical, occupying an area of 60 km x 24 km and being some 400 m thick: this field alone corresponds to reserves of >10^11 tonnes. Similar deposits occur near Carlsbad New Mexico, in Saskatchewan Canada and in many other places. Production methods vary with locality and with the use to be made of the salt. For example, in the UK 82% is extracted as brine for direct use in the chemical industry and 18% is mined as rock-salt, mainly for use on roads; less than 1% is obtained by solar evaporation. By contrast, in the USA only 55% comes from brine, whereas 32% is mined as rock salt, 8% is obtained by vacuum pan evaporation, 4% by solar evaporation and 1% by the open pan process.

Major sections of the inorganic heavy chemicals industry are based on salt and, indeed, this compound was the very starting point of the chemical industry. Nicolas Leblanc (1742-1806), physician to the Duke of Orleans, devised a satisfactory process for making NaOH from NaCl in 1787 (Patent 1791) and this achieved enormous technological significance in Europe during most of the nineteenth century as the first industrial chemical process to be worked on a really large scale. It was, however, never important in the USA since it was initially cheaper to import from Europe and, by the time the US chemical industry began to develop in the last quarter of the century, the Leblanc process had been superseded by the electrolytic process. Thus in 1874 world production of NaOH was 525 000 tonnes of which 495 000 were by the Leblanc process; by 1902 production had risen to 1 800 000 tonnes, but only 150 000 tonnes of this was Leblanc. Despite its long history, there is still great scope for innovation and development in the chlor-alkali and related industries. For example, in recent years there has been a steady switch from mercury electrolysis cells to diaphragm and membrane cells for environmental and economic reasons.(7) Similarly, the ammonia-soda (Solvay) process for Na2CO3 is being phased out because of the difficulty of disposing of embarrassing byproducts such as NH4Cl and CaCl2, coupled with the increasing cost of NH3 and the possibility of direct mining for trona, Na2CO3.NaHC03.2H2O. The closely interlocking chemical processes based on salt are set out in the flow sheet (Fig. 4.1). The detailed balance of the processes differs somewhat in the various industrial nations but data for the usage of salt in the USA are typical: of the 34.8 million tonnes consumed in 1982, 48% was used for chlor-alkali production and Na2CO3, 24% for the salting of roads, 6% for food and food processing, 5% for animal feeds, 5% for various industries such as paper pulp, textiles, metal manufacturing and the rubber and oil industries, 2% for all other chemical manufacturing, and the remaining 10% for a wide variety of other purposes. Further discussion on the industrial production and uses of many of these chemicals (e.g. NaOH, Na2CO3, Na2SO4) is given on p. 89.

Current industrial prices are ~$5 per tonne for salt in brine and ~$55 per tonne for solid salt, depending on quality.

Manitoba and Cs (like Rb) is mainly obtained as a byproduct of the Li industry. The intense interest in Li for thermonuclear purposes since about 1958, coupled with its extensive use in automotive greases (p. 70), has consequently made Rb and Cs compounds much more available than formerly: annual production is in the region of 5 tonnes for each.

4.2.3 Production and uses of the metals

Most commercial Li ores have 1-3% Li and this is increased by flotation to 4-6%. Spodumene, LiAlSi2O6, is heated to ~1100° to convert the α-form into the less-dense, more friable β-form, which is then washed with H2SO4 at 250°C and water-leached to give Li2SO4.H2O. Successive treatment with Na2CO3 and HCl gives Li2CO3 (insol) and LiCl. Alternatively, the chloride can be obtained by calcining the washed ore with limestone (CaCO3) at 1000° followed by water leaching to give LiOH and then treatment with HCl. Recovery from natural brines is also extensively used in the USA (Searles Lake, California and Clayton Valley, Nevada).
Figure 4.1  Flow sheet on chemical processes based on salt.
§4.2.3

Production and uses of the metals

Production of Potassium Salts

Sylvite (KCl) and sylvinite (mixed NaCl, KCl) are the most important K minerals for chemical industry; camallite is also mined. Ocean waters contain only about 0.06% KCl, though this can rise to as high as 1.5% in some inland marshes and seas such as Searle’s Lake, the Great Salt Lake, or the Dead Sea, thereby making recovery economically feasible. Soluble minerals of K are generally referred to (incorrectly) as potash, and production figures are always expressed as the weight of K₂O equivalent. Massive evaporite beds of soluble K salts were first discovered at Stassfurt, Germany, in 1856 and were worked there for potash and rock-salt from 1861 until 1972. World production was 28.6 million tonnes K₂O equivalent in 1986 of which 35% was produced in the USSR and 24% Canada.

In the UK workable potash deposits are confined to the Cleveland–North Yorkshire bed which is ~11 m thick and has reserves of >500 million tonnes. Massive recovery is also possible from brines; e.g. Jordan has a huge plant capable of recovering up to a million tonnes pa from the Dead Sea and the annual production by this country and by Israel now matches that of the USA and France.

Potassium is a major essential element for plant growth and potassic fertilizers account for the overwhelming proportion of production (95%). Again KCl is dominant, accounting for more than 90% of the K used in fertilizers; K₂SO₄ is also used. KNO₃, though an excellent fertilizer, is now of only minor importance because of production costs. In addition to its dominant use in fertilizers, KCl is used mainly to manufacture KOH by electrolysis using the mercury and membrane processes (about 0.7 million tonnes of KOH worldwide in 1985). This in turn is used to make a variety of other compounds and materials such as those listed below (the figures referring to the percentage usage of KOH in the USA in 1984):

- K₂CO₃ 25%, liquid fertilizers 15%, soaps 10%, liquid detergents (K₄P₂O₇) 9%, synthetic rubber 5%, crop protection agents 3%. KMnO₄ 2%, other chemicals 26% and export 5%. The manufacture of metallic K is relatively minor, the world production in 1994 amounting only to about 500 tonnes. Prices in 1994 were $30–40 per kg for bulk K and $16–22 per kg for NaK (78% K).

The main industrial uses of potassium compounds other than KCl and KOH are:

- K₂CO₃ (from KOH and CO₂), used chiefly in high-quality decorative glassware, in optical lenses, colour TV tubes and fluorescent lamps; it is also used in china ware, textile dyes and pigments.
- KNO₃, a powerful oxidizing agent now used mainly in gunpowders and pyrotechnics, and in fertilizers.
- KMnO₄, an oxidizer, decolorizer, bleacher and purification agent; its major application is in the manufacture of saccharin.
- KO₂, used in breathing apparatus (p. 74).
- KClO₃, used in small amounts in matches and explosives (pp. 509, 862).
- KBr. used extensively in photography and as the usual source of bromine in organic syntheses; formerly used as a sedative.

It is interesting to note the effect of varying the alkali metal cation on the properties of various compounds and industrial materials. For example, a soap is an alkali metal salt formed by neutralizing a long-chain organic acid such as stearic acid, CH₃(CH₂)₁₇CO₂H, with MOH. Potassium soaps are soft and low melting, and are therefore used in liquid detergents. Sodium soaps have higher mps and are the basis for the familiar domestic “hard soaps” or bar soaps. Lithium soaps have still higher mps and are therefore used as thickening agents for high-temperature lubricating oils and greases — their job is to hold the oil in contact with the metal under conditions when the oil by itself would run off.

The metal is obtained by electrolysis of a fused mixture of 55% LiCl, 45% KCl at ~450°C, the first commercial production being by Metallgesellschaft AG, in Germany, 1923. Current world production of Li metal is about 1000 tonnes pa. Far greater tonnages of Li compounds are, of course, produced and their major commercial applications have already been noted (p. 70).

Sodium metal is produced commercially on the kilotonne scale by the electrolysis of a fused eutectic mixture of 40% NaCl, 60% CaCl₂ at ~580°C in a Downs cell (introduced by du Pont, Niagara Falls, 1921). Metallic Na and Ca are liberated at the cylindrical steel cathode and rise through a cooled collecting pipe which allows the calcium to solidify and fall back into the melt. Chlorine liberated at the central graphite anode is collected in a nickel dome and subsequently purified. Potassium cannot be produced in this way because it is too soluble in the molten chloride to float on top of the cell for collection and because it vaporizes readily.

---

10 Ref. 7 pp. 228–31.
at the operating temperatures, creating hazardous conditions. Superoxide formation is an added difficulty since this reacts explosively with K metal. Consequently, commercial production of K relies on reduction of molten KCl with metallic Na at 850°C. A similar process using Ca metal at 750°C under reduced pressure is used to produce metallic Rb and Cs.

Industrial uses of Na metal reflect its strong reducing properties. Much of the world production was used to make PbEt₄ (or PbMe₄) for gasoline antiknocks via the high-pressure reaction of alkyl chlorides with Na/Pb alloy, though this use is declining rapidly for environmental reasons. A further major use is to produce Ti, Zr, and other metals by reduction of their chlorides, and a smaller amount is used to make compounds such as NaH, NaOR and Na₂O₂. Sodium dispersions are also a valuable catalyst for the production of some artificial rubbers and elastomers. A growing use is as a heat-exchange liquid in fast breeder nuclear reactors where sodium’s low mp, low viscosity and low neutron absorption cross-section combine with its exceptionally high heat capacity and thermal conductivity to make it (and its alloys with K) the most-favoured material. The annual production of metallic Na in the USA fell steadily from 170,000 tonnes in 1974 to 86,000 tonnes in 1985 and is still falling. Potassium metal, being more difficult and expensive to produce, is manufactured on a much smaller scale. One of its main uses is to make the superoxide KO₂ by direct combustion; this compound is used in breathing masks as an auxiliary supply of O₂ in mines, submarines and space vehicles:

\[ 4\text{KO}_2 + 4\text{CO}_2 + 2\text{H}_2\text{O} \rightarrow 4\text{KHCO}_3 + 3\text{O}_2 \]

An indication of the relative cost of the alkali metals in bulk at 1980–82 prices (USA) is:

4.2.4 Properties of the alkali metals

The Group 1 elements are soft, low-melting metals which crystallize with bcc lattices. All are silvery-white except caesium which is golden yellow; in fact, caesium is one of only three metallic elements which are intensely coloured, the other two being copper and gold (see also pp. 112, 1177, 1232). Lithium is harder than sodium but softer than lead. Atomic properties are summarized in Table 4.1 and general physical properties are in Table 4.2. Further physical properties of the alkali metals, together with a review of the chemical properties and industrial applications of the metals in the molten state are in ref. 11.

Lithium has a variable atomic weight (p. 18) whereas sodium and caesium, being mononuclidic, have very precisely known and invariant atomic weights. Potassium and rubidium are both radioactive but the half-lives of their radioisotopes are so long that the atomic weight does not vary significantly from this cause. The large size and low ionization energies of the alkali metals compared with all other elements have already been noted (pp. 23–5) and this confers on the elements their characteristic properties. The group usually shows smooth trends in properties, and the weak bonding of the single valence electron leads to low mp, bp and density, and low heats of sublimation, vaporization and dissociation. Conversely, the elements have large atomic and ionic radii and extremely high thermal and electrical conductivity. Lithium is the smallest element in the group and has the highest ionization energy, mp and heat

of atomization; it also has the lowest density of any solid at room temperature.

All the alkali metals have characteristic flame colorations due to the ready excitation of the outermost electron, and this is the basis of their analytical determination by flame photometry or atomic absorption spectroscopy. The colours and principal emission (or absorption) wavelengths, \(\lambda\), are given below but it should be noted that these lines do not all refer to the same transition; for example, the Na D-line doublet at 589.0, 589.6 nm arises from the 3s\(^{1}\) – 3p\(^{1}\) transition in Na atoms formed by reduction of Na\(^{+}\) in the flame, whereas the red line for lithium is associated with the short-lived species LiOH.

The reduction potential for lithium appears at first sight to be anomalous and is one of the few properties that does not show a smooth trend with increasing atomic number in the group. This arises from the small size and very large hydration energy of the free gaseous lithium ion. The standard reduction potential \(E^+/V\) refers to the reaction \(\text{Li}^+(aq) + e^- \rightarrow \text{Li}(s)\) and is related to the free-energy change: \(\Delta G^o = -nFE^+\). The ionization energy \(I_M\), which is the enthalpy change of the gas-phase reaction \(\text{Li}(g) \rightarrow \text{Li}^+(g) + e^-\), is only one component of this, as can be seen from the following cycle:

\[
\begin{align*}
\text{Li}^+(aq) + e^- & \rightarrow \text{Li}(s) & E^+ = -\Delta G^o / nF \\
\Delta G^o = \Delta H^o - T\Delta S & & \Delta H = \Delta H_{\text{hydr}} \\
\text{Li}(g) + e^- & \rightarrow \text{Li}(s) & \Delta H = \Delta H_{\text{vap}} \\
\end{align*}
\]

Estimates of the heat of hydration of \(\text{Li}^+(g)\) give values near 520 kJ mol\(^{-1}\) compared with
405 kJ mol\(^{-1}\) for Na\(^+\)(g) and only 265 kJ mol\(^{-1}\) for Cs\(^+\)(g). This factor, although opposed by the much larger entropy change for the lithium electrode reaction (due to the more severe disruption of the water structure by the lithium ion), is sufficient to reverse the position of lithium and make it the most electropositive of the alkali metals (as measured by electrode potential) despite the fact that it is the most difficult element of the group to ionize in the gas phase.

### 4.2.5 Chemical reactivity and trends

The ease of involving the outermost \(ns^1\) electron in bonding, coupled with the very high second-stage ionization energy of the alkali metals, immediately explains both the great chemical reactivity of these elements and the fact that their oxidation state in compounds never exceeds +1. The metals have a high lustre when freshly cut but tarnish rapidly in air due to reaction with \(O_2\) and moisture. Reaction with the halogens is vigorous; even explosive in some cases. All the alkali metals react with hydrogen (p. 65) and with proton donors such as alcohols, gaseous ammonia and even alkynes. They also act as powerful reducing agents towards many oxides and halides and so can be used to prepare many metallic elements or their alloys.

The small size of lithium frequently confers special properties on its compounds and for this reason the element is sometimes termed "anomalous". For example, it is miscible with Na only above 380°C and is immiscible with molten K, Rb and Cs, whereas all other pairs of alkali metals are miscible with each other in all proportions. (The ternary alloy containing 12% Na, 47% K and 41% Cs has the lowest known mp, -78°C, of any metallic system.) Li shows many similarities to Mg. This so-called "diagonal relationship" stems from the similarity in ionic size of the two elements: \(r(\text{Li}^+)\) 76 pm, \(r(\text{Mg}^{2+})\) 72 pm, compared with \(r(\text{Na}^+)\) 102 pm. Thus, as first noted by Arfvedson in establishing lithium as a new element, LiOH and Li\(_2\)CO\(_3\) are much less soluble than the corresponding Na and K compounds and the carbonate (like MgCO\(_3\)) decomposes more readily on being heated. Similarly, LiF (like MgF\(_2\)) is much less soluble in water than any other alkali metal fluorides because of the large lattice energy associated with the small size of both the cation and the anion. By contrast, lithium salts of large, non-polarizable anions such as ClO\(_4^-\) are much more soluble than those of the other alkali metals, presumably because of the high energy of solvation of Li\(^+\). For the same reason many simple lithium salts are normally hydrated (p. 88) and the anhydrous salts are extremely hygroscopic: this great affinity for water forms the basis of the widespread use of LiCl and LiBr brines in dehumidifying and air-conditioning units. More subtly there is also a close structural relation between the hydrogen-bonded structures of LiClO\(_4\).3H\(_2\)O and Mg(ClO\(_4\))\(_2\).6H\(_2\)O in which the face-shared octahedral groups of [Li(H\(_2\)O)\(_6\)]\(^+\) are replaced alternately by half the number of discrete [Mg(H\(_2\)O)\(_6\)]\(^2+\) groups.\(^{13}\) Lithium sulfate, unlike the other alkali metal sulfates, does not form alums [M(H\(_2\)O)\(_6\)]\(^+\)[Al(H\(_2\)O)\(_6\)]\(^3+\) [SO\(_4\)]\(^2-\) because the hydrated lithium cation is too small to fill the appropriate site in the alum structure.

Lithium is unusual in reacting directly with \(N_2\) to form the nitride Li\(_3\)N; no other alkali metal has this property, which lithium shares with magnesium (which readily forms Mg\(_3\)N\(_2\)). On the basis of size, it would be expected that Li would be tetrahedrally coordinated by N but, as pointed out by A. F. Wells,\(^{13}\) this would require 12 tetrahedra to meet at a point which is a geometrical impossibility, 8 being the maximum number theoretically possible; accordingly Li\(_3\)N has a unique structure (see p. 92) in which one-third of the Li have 2 N atoms as nearest neighbours (at 194 pm) and the remainder have 3 N atoms as neighbours (at 213 pm); each N is surrounded by 2 Li at 194 pm and 6 more at 213 pm.

---

4.2.6 Solutions in liquid ammonia and other solvents

One of the most remarkable features of the alkali metals is their ready solubility in liquid ammonia to give bright blue, metastable solutions with unusual properties. Such solutions have been extensively studied since they were first observed by T. Weyl in 1863, and it is now known that similar solutions are formed by the heavier alkaline earth metals (Ca, Sr and Ba) and the divalent lanthanoids europium and ytterbium in liquid ammonia. Many amines share with ammonia this ability though to a much lesser extent. It is clear that solubility is favoured by low metal lattice energy, low ionization energies and high cation solvation energy. The most striking physical properties of the solutions are their colour, electrical conductivity and magnetic susceptibility. The solutions all have the same blue colour when dilute, suggesting the presence of a common coloured species, and they become bronze-coloured and metallic at higher concentrations. The conductivity of the dilute solutions is an order of magnitude higher than that of completely ionized salts in water; as the solutions become more concentrated the conductivity at first diminishes to a minimum value at about 0.04 M and then increases dramatically to approach values typical of liquid metals. Dilute solutions are paramagnetic with a susceptibility appropriate to the presence of 1 free electron per metal atom; this susceptibility diminishes with increase in concentration, the solutions becoming diamagnetic in the region of the conductivity minimum and then weakly paramagnetic again at still higher concentrations.

The interpretation of these remarkable properties has excited considerable interest: whilst there is still some uncertainty as to detail, it is now generally agreed that in dilute solution the alkali metals ionize to give a cation $M^+$ and a quasi-free electron which is distributed over a cavity in the solvent of radius 300–340 pm formed by displacement of 2–3 NH$_3$ molecules. This species has a broad absorption band extending into the infrared with a maximum at $\sim$1500 nm and it is the short wavelength tail of this band which gives rise to the deep-blue colour of the solutions. The cavity model also interprets the fact that dissolution occurs with considerable expansion of volume so that the solutions have densities that are appreciably lower than that of liquid ammonia itself. The variation of properties with concentration can best be explained in terms of three equilibria between five solute species $M, M_2, M^+, M^-$ and $e^-:

\begin{align*}
M_{am} &\rightleftharpoons M_{am}^+ + e_{am}^-; \quad K \sim 10^{-2} \text{ mol l}^{-1} \\
M_{am}^- &\rightleftharpoons M_{am}^- + e_{am}^-; \quad K \sim 10^{-3} \text{ mol l}^{-1} \\
(M_2)_{am} &\rightleftharpoons 2M_{am}^+; \quad K \sim 2 \times 10^{-4} \text{ mol l}^{-1}
\end{align*}

The subscript am indicates that the species are dissolved in liquid ammonia and may be solvated. At very low concentrations the first equilibrium predominates and the high ionic conductivity stems from the high mobility of the electron which is some 280 times that of the cation. The species $M_{am}$ can be thought of as an ion pair in which $M_{am}^+$ and $e_{am}^-$ are held together by coulombic forces. As the concentration is raised the second equilibrium begins to remove mobile electrons $e_{am}^-$ as the complex $M_{am}^-$ and the conductivity drops. Concurrently $M_{am}$ begins to dimerize to give $(M_2)_{am}$ in which the interaction between the 2 electrons is sufficiently strong to lead to spin-pairing and diamagnetism. At still higher concentrations the system behaves as a molten metal in which the metal cations are ammoniated. Saturated solutions are indeed extremely concentrated as indicated by the following table:

---

† Actually, the first observation was probably made by Sir Humphry Davy some 55 years earlier: an unpublished observation in his Notebook for November 1807 reads “When 8 grains of potassium were heated in ammoniacal gas it assumed a beautiful metallic appearance and gradually became of a pure blue colour”.

---

§4.2.6 Solutions in liquid ammonia and other solvents

77
The lower solubility of Li on a wt/wt basis reflects its lower atomic weight and, when compared on a molar basis, it is nearly 50% more soluble than Na (15.66 mol/kg NH₃ compared to 10.93 mol/kg NH₃). Note that it requires only 2.34 mol NH₃ (39.8 g) to dissolve 1 mol Cs (132.9 g).

Solutions of alkali metals in liquid ammonia are valuable as powerful and selective reducing agents. The solutions are themselves unstable with respect to amide formation:

\[ \text{M} + \text{NH₃} \rightarrow \text{MNH₂} + \frac{1}{2}\text{H₂} \]

However, under anhydrous conditions and in the absence of catalytic impurities such as transition metal ions, solutions can be stored for several days with only a few per cent decomposition. Some reductions occur without bond cleavage as in the formation of alkali metal superoxides and peroxide (p. 84).

Transition metal complexes can be reduced to unusually low oxidation states either with or without bond cleavage, e.g.:

\[ \text{K₂}[\text{Ni(CN)}₄] + 2\text{K} \xrightarrow{\text{NH₃}/-33^\circ} \text{K₄[Ni(CN)}₄]; \]

i.e. Ni(0)

\[ [\text{Pt(NH₃)}₄]\text{Br₂} + 2\text{K} \xrightarrow{\text{NH₃}/-33^\circ} [\text{Pt(NH₃)}₄] + 2\text{KBr}; \]

i.e. Pt(0)

\[ \text{Mn₂(CO)}₁₀ + 2\text{K} \xrightarrow{\text{NH₃}/-33^\circ} 2\text{K[Mn(CO)}₅]; \]

i.e. Mn(-1)

\[ \text{Fe(CO)}₅ + 2\text{Na} \xrightarrow{\text{NH₃}/-33^\circ} \text{Na₂[Fe(CO)}₄] + \text{CO}; \]

i.e. Fe(-2)

Salts of several heavy main-group elements can be reduced to form polyanions such as Na₄[Sn₉], Na₃[Sb₃] and Na₃[Sb₇] (p. 588).

Many protonic species react with liberation of hydrogen:

\[ \text{RC≡CH} + e^\text{am} \rightarrow \text{RC≡C}^- + \frac{1}{2}\text{H₂} \]

\[ \text{GeH₄} + e^\text{am} \rightarrow \text{GeH₃}^- + \frac{1}{2}\text{H₂} \]

\[ \text{NH₄}^+ + e^\text{am} \rightarrow \text{NH₃} + \frac{1}{2}\text{H₂} \]

\[ \text{AsH₃} + e^\text{am} \rightarrow \text{AsH₂}^- + \frac{1}{2}\text{H₂} \]

\[ \text{EtOH} + e^\text{am} \rightarrow \text{EtO}^- + \frac{1}{2}\text{H₂} \]

These and similar reactions have considerable synthetic utility. Other reactions which result in bond cleavage by the addition of one electron are:

\[ \text{R₂S} + e^\text{am} \rightarrow \text{RS}^- + \frac{1}{2}\text{R₂} \]

\[ \text{Et₃SnBr} + e^\text{am} \rightarrow \text{Et₃Sn}^- + \text{Br}^- \]

When a bond is broken by addition of 2 electrons, either 2 anions or a dianion is formed:

\[ \text{GeH₆} + 2e^\text{am} \rightarrow 2\text{GeH₃}^- \]

\[ \text{PhNHNH₂} + 2e^\text{am} \rightarrow \text{PhNH}^- + \text{NH₂}^- \]

\[ \text{PhN=O} + 2e^- \rightarrow \text{PhN}--\text{O}^- \]

\[ \text{S₈} + 2e^- \rightarrow \text{S₈}^{2^-} \]

Subsequent ammonolysis may also occur:

\[ \text{RCH=CH₂} + 2e^- \rightarrow \{\text{RCH}--\text{CH₂}^{2^-}\} \]

\[ \text{N₂O} + 2e^- \rightarrow \{\text{N₂} + \text{O}^{2^-}\} \]

\[ \text{NH₃} \rightarrow \text{N₂} + \text{OH}^- + \text{NH₂}^- \]
4.3 Compounds

4.3.1 Introduction: the ionic-bond model

The alkali metals form a complete range of compounds with all the common anions and have long been used to illustrate group similarities and trends. It has been customary to discuss the simple binary compounds in terms of the ionic bond model and there is little doubt that there is substantial separation of charge between the cationic and anionic components of the crystal lattice. On this model the ions are considered as hard, undeformable spheres carrying charges which are integral multiples of the electronic charge \( z_1 e^+ \). Corrections can be incorporated for zero-point energies, London dispersion energies, ligand-field stabilization energies and non-spherical ions (such as \( \text{NO}_3^- \), etc.). The attractive simplicity of this model, and its considerable success during the past 70 y in interpreting many of the properties of simple salts, should not, however, be allowed to obscure the growing realization of its inadequacy.\(^{(16)}\)

In particular, as already noted, success in calculating lattice energies and hence enthalpy of formation via the Born–Haber cycle, does not establish the correctness of the model but merely indicates that it is consistent with these particular observations. For example, the ionic model is quite successful in reproducing the enthalpy of formation of \( \text{BF}_3 \), \( \text{SiF}_4 \), \( \text{PF}_5 \) and even \( \text{SF}_6 \) on the assumption that they are assemblies of point charges at the known interatomic distance, \( \text{B}^3+(\text{F})_3 \), etc.,\(^{(20)}\) but this is not a sound reason...
for considering these molecular compounds as ionic. Likewise, the known lattice energy of lithium metal can be reproduced quite well by assuming that the observed bcc arrangement of atoms is made up from alternating ions Li$^+$ and Li$^-$ in the CsCl structure; the discrepancy is no worse than that obtained using the same model for AgCl (which has the NaCl structure). It appears that the ionic-bond model is self-compensating, and that the decrease in the hypothetical binding energy which accompanies the diminution of formal charges on the atoms is accompanied by an equivalent increase in binding energy which could be described as “covalent” (BF$_3$) or “metallic” (Li metal).

Indeed, the inherent improbability of the ionic bond model can be appreciated when it is realized that all simple cations have a positive charge and several vacant orbitals (and are therefore potentially electron pair acceptors) whereas all simple anions have a negative charge and several lone pairs of electrons (and are therefore potentially electron pair donors). The close juxtaposition of these electron-pair donor and acceptor species is thus likely to result in the transfer of at least some charge density by coordination, thereby introducing a substantial measure of covalency into the bonding of the alkali metal halides and related compounds. A more satisfactory procedure, at least conceptually, would be to describe crystalline salts and other solid compounds in terms of molecular orbitals. Quantitative calculations are difficult to carry out but the model allows flexibility in placing “partial ionic charges” on atoms by modifying orbital coefficients and populations, and it can also incorporate metallic behaviour by modifying the extent to which partly filled individual molecular orbitals are either separated by energy gaps or overlap.

The compounds which most nearly fit the classical conception of ionic bonding are the alkali metal halides. However, even here, one must ask to what extent it is reasonable to maintain that positively charged cations M$^+$ with favourably directed vacant p orbitals remain uncoordinated by the surrounding anionic ligands X$^-$ to form extended (bridged) complexes. Such interaction would be expected to increase from Cs$^+$ to Li$^+$ and from F$^-$ to I$^-$ (why?) and would place some electron density between the cation and anion. Some evidence on this comes from very precise electron density plots obtained by X-ray diffraction experiments on LiF, NaCl, KCl, MgO and CaF$_2$. Data for LiF are shown in Fig. 4.2a from which it is clear that the Li$^+$ ion is no longer spherical and that the electron density, while it falls to a low value between the ions, does not become zero. Even more significantly, as shown in Fig. 4.2b, the minimum does not occur at the position to be expected from the conventional ionic radii: whatever set of tabulated values is used the cation is always larger than expected and the anion smaller. This is consistent with a transfer of some electronic density from anion to cation since the smaller resultant positive charge on the cation exerts smaller coulombic attraction for the electrons and the ion expands. The opposite holds for the anion. These results also call into question the use of radius-ratio rules to calculate the coordination number of cations and leave undecided the numerical value of the ionic radii to be used (see also p. 66, hydrides). In fact, the radius-ratio rules are particularly unhelpful for the alkali halides, since they predict (incorrectly) that LiCl, LiBr and LiI should have tetrahedral coordination and that NaF, KF, KCl, RbF, RbCl, RbBr and CsF should all have the CsCl structure. It may be significant that adoption of the NaCl structure by all these compounds maximizes the p orbital overlap along the orthogonal x-, y- and z-directions, and so favours molecular orbital formation in these directions. Further information on the variation in apparent radius of the hydride, halide and other anions in compounds with the alkali metals and other cations is in ref. 23.

---

§4.3.1 The ionic-bond model

Figure 4.2 (a) Distribution of electron density ($\mu e/\text{pm}^3$) in the $xyo$ plane of LiF, and (b) variation of electron density along the Li–F direction near the minimum. The electron density rises to 17.99 $\mu e \text{pm}^{-3}$ at Li and to 115.63 $\mu e \text{pm}^{-3}$ at F. (The unit $\mu e \text{pm}^{-3}$ is numerically identical to $e \text{Å}^{-3}$.)

Deviations from the simple ionic model are expected to increase with increasing formal charge on the cation or anion and with increasing size and ease of distortion of the anion. Again, deviations tend to be greater for smaller cations and for those (such as Cu$^+$, Ag$^+$, etc.) which do not have an inert-gas configuration. The gradual transition from predominantly ionic to covalent is illustrated by the “isoelectronic” series:

NaF, MgF$_2$, AlF$_3$, SiF$_4$, PF$_5$, SF$_6$, IF$_7$, F$_2$

A similar transition towards metallic bonding is illustrated by the series:

NaCl, Na$_2$O, Na$_2$S, Na$_3$P, Na$_3$As, Na$_3$Sb, Na$_3$Bi, Na

Alkali metal alloys with gold have the CsCl structure and, whilst NaAu and KAu are essentially metallic, RbAu and CsAu have partial ionic bonding and are n-type semiconductors. These factors should constantly be borne in mind during the discussion of compounds in later chapters.

The extent to which charge is transferred back from the anion towards the cation in the alkali metal halides themselves is difficult to determine precisely. Calculations indicate that it is probably only a few percent for some salts such as NaCl, whereas for others (e.g. LiI) it may amount to more than 0.33 $e^-$ per atom. Direct experimental evidence on these matters is available for some other elements from techniques such as Mössbauer spectroscopy,$^{24}$ electron spin resonance spectroscopy,$^{25}$ and neutron scattering form factors.$^{26}$

---

4.3.2 Halides and hydrides

The alkali metal halides are all high-melting, colourless crystalline solids which can be conveniently prepared by reaction of the appropriate hydroxide (MOH) or carbonate (M_2CO_3) with aqueous hydrohalic acid (HX), followed by recrystallization. Vast quantities of NaCl and KCl are available in nature and can be purified if necessary by simple crystallization. The hydrides have already been discussed (p. 65).

Trends in the properties of MX have been much studied and typical examples are illustrated in Figs. 4.3 and 4.4. The mp and bp always follow the trend F > Cl > Br > I except perhaps for some of the Cs salts where the data are uncertain. Figure 4.3 also shows that the mp and bp of LiX are always below those of NaX and that (with the exception of the mp of KI) the values for NaX are the maximum for each series. Trends in enthalpy of formation ΔH°_f and lattice energy U_L are even more regular (Fig. 4.4) and can readily be interpreted in terms of the Born–Haber cycle, providing one assumes an invariant charge corresponding to loss or gain of one complete electron per ion, M^+X^-.

The Born–Haber cycle considers two possible routes to the formation of MX and equates the corresponding enthalpy changes by applying Hess’s law:

\[ \Delta H_f^\circ(MX) = S_M + \frac{1}{2}D_{X_2} + I_M - E_X - U_L \]

where \( S_M \) is the heat of sublimation of M(c) to a monatomic gas (Table 4.2), \( D_{X_2} \) is the dissociation energy of X_2(g) (Table 4.2), \( I_M \) is the ionization energy of M(g) (Table 4.2), and \( E_X \) the electron affinity of X(g) (Table 17.3, p. 800). The lattice energy \( U_L \) is given approximately by the expression

\[ U_L = \frac{N_0 A e^2}{4\pi \varepsilon_0 r_0} \left(1 - \frac{\rho}{r_0}\right) \]
where $N_0$ is the Avogadro constant, $A$ is a geometrical factor, the Madelung constant (which has the value of 1.7627 for the CsCl structure and 1.7476 for the NaCl structure), $r_0$ is the shortest internuclear distance between $M'$ and $X^-$ in the crystal, and $\rho$ is a measure of the close-range repulsion force which resists mutual interpenetration of the ions. It is clear that the sequence of lattice energies is determined primarily by $r_0$, so that the lattice energy is greatest for LiF and smallest for CsI, as shown in Fig. 4.4. In the Born–Haber expression for $\Delta H_f^\circ$ this factor predominates for the fluorides and there is a trend to smaller enthalpies of formation from LiF to CsF (Fig. 4.4). The same incipient trend is noted for the hydrides $MH$, though here the numerical values of $\Delta H_f^\circ$ are all much smaller than those for $MX$ because of the much higher heat of dissociation of $H_2$ compared to $X_2$. By contrast with the fluorides, the lattice energy for the larger halides is smaller and less dominant, and the resultant trend of $\Delta H_f^\circ$ is to larger values, thus reflecting the greater ease of subliming and ionizing the heavier alkali metals.

The Born–Haber cycle is also useful in examining the possibility of forming alkali–metal halides of stoichiometry $MX_2$. The dominant term will clearly be the very large second-stage ionization energy for the process $M^+(g) \rightarrow M^{2+}(g) + e^-$; this is 7297 kJ mol$^{-1}$ for Li but drops to 2255 kJ mol$^{-1}$ for Cs. The largest possible lattice energy to compensate for this would be obtained with the smallest halogen $F$ and (making plausible assumptions on lattice structure and ionic radius) calculations indicate that CsF$_2$ could indeed be formed exothermically from its elements:

$$\text{Cs}(s) + F_2(g) = \text{CsF}_2(s); \quad \Delta H_f^\circ \simeq -125 \text{ kJ mol}^{-1}$$

However, the compound cannot be prepared because of the much greater enthalpy of formation of CsF which makes CsF$_2$ unstable with respect to decomposition:

$$\text{Cs}(s) + \frac{1}{2}F_2(g) = \text{CsF}(s); \quad \Delta H_f^\circ = -530 \text{ kJ mol}^{-1}$$

whence

$$\text{CsF}_2(s) = \text{CsF}(s) + \frac{1}{2}F_2; \quad \Delta H_{\text{disprop}} \simeq -405 \text{ kJ mol}^{-1}$$

There is some evidence that Cs$^{3+}$ can be formed by cyclic voltammetry of Cs$^{+}$$[\text{OTeF}_5]^-$ in pure MeCN at the extremely high oxidizing potential of 3 V, and that Cs$^{3+}$ might be stabilized by 18-crown-6 and cryptand (see pp. 96 and 97 for nomenclature). However, the isolation of pure compounds containing Cs$^{3+}$ has so far not been reported.

Ternary alkali-metal halide oxides are known and have the expected structures. Thus Na$_2$ClO and the yellow K$_3$BrO have the anti-perovskite structure (p. 963) whereas Na$_4$Br$_2$O, Na$_4$I$_2$O and K$_4$Br$_2$O have the tetragonal anti-K$_2$NiF$_4$ structure.

The alkali metal halides, particularly NaCl and KCl, find extensive application in industry (pp. 71 and 73). The hydrides are frequently used as reducing agents, the product being a hydride or complex metal hydride depending on the conditions used, or the free element if the hydride is unstable. Illustrative examples using NaH are:

$$2\text{BF}_3 + 6\text{NaH} \rightarrow \text{B}_2\text{H}_6 + 6\text{NaF}$$

$$\text{BF}_3 + 4\text{NaH} \rightarrow \text{NaBH}_4 + 3\text{NaF}$$

$$\text{B}(_{\text{OMe}})\text{H}_3 + \text{NaH} \rightarrow \text{Na}[\text{BH}(_{\text{OMe}})\text{H}_3]$$

$$\text{B}(_{\text{OMe}})\text{H}_3 + 4\text{NaH} \rightarrow \text{NaBH}_4 + 3\text{NaOMe}$$

$$\text{AlBr}_3 + 4\text{NaH} \rightarrow \text{NaAlH}_4 + 3\text{NaBr}$$

$$\text{TiCl}_4 + 4\text{NaH} \rightarrow \text{Ti} + 4\text{NaCl} + 2\text{H}_2$$

Sulfur dioxide is uniquely reduced to dithionite (a process useful in bleaching paper pulp, p. 720). CO$_2$ gives the formate:

$$2\text{SO}_2(g) + 2\text{NaH} \rightarrow \text{Na}_2\text{S}_2\text{O}_4 + \text{H}_2$$

CO$_2(g) + \text{NaH} \rightarrow \text{HCO}_2\text{Na}$

Particularly reactive (pyrophoric) forms of LiH, NaH and KH can be prepared simply and in high yield by the direct hydrogenation of

hexane solutions of MBu" in the presence of tetramethylethylenediamine (tmeda) and these have proved extremely useful reagents for the metalation of organic compounds which have an active hydrogen site.\(^{(29)}\)

### 4.3.3 Oxides, peroxides, superoxides and suboxides

The alkali metals form a fascinating variety of binary compounds with oxygen, the most versatile being Cs which forms 9 compounds with stoichiometries ranging from Cs\(_7\)O to CsO\(_3\). When the metals are burned in a free supply of air the predominant product depends on the metal: Li forms the oxide Li\(_2\)O (plus some Li\(_2\)O\(_2\)), Na forms the peroxide Na\(_2\)O\(_2\) (plus some Na\(_2\)O) whilst K, Rb and Cs form the superoxide MO\(_2\). Under the appropriate conditions pure compounds M\(_2\)O, M\(_2\)O\(_2\) and MO\(_2\) can be prepared for all five metals.

The "normal" oxides M\(_2\)O (Li, Na, K, Rb) have the antifluorite structure as do many of the corresponding sulfides, selenides and tellurides. This structure is related to the CaF\(_2\) structure (p. 118) but with the sites occupied by the cations and anions interchanged so that M replaces F and O replaces Ca in the structure. Cs\(_2\)O has the anti-CdCl\(_2\) layer structure (p. 1211). There is a trend to increasing coloration with increasing atomic number, Li\(_2\)O and Na\(_2\)O being pure white, K\(_2\)O yellowish white, Rb\(_2\)O bright yellow and Cs\(_2\)O orange. The compounds are fairly stable towards heat, and thermal decomposition is not extensive below about 500\(^\circ\)C. Pure Li\(_2\)O is best prepared by thermal decomposition of Li\(_2\)O (see below) at 450\(^\circ\)C. Na\(_2\)O is obtained by reaction of Na\(_2\)O\(_2\), NaOH or preferably NaNO\(_2\) with the Na metal:

\[
\begin{align*}
\text{Na}_2\text{O}_2 + 2\text{Na} & \rightarrow 2\text{Na}_2\text{O} \\
\text{NaOH} + \text{Na} & \rightarrow \text{Na}_2\text{O} + \frac{1}{2}\text{H}_2 \\
\text{NaNO}_2 + 3\text{Na} & \rightarrow 2\text{Na}_2\text{O} + \frac{1}{2}\text{N}_2
\end{align*}
\]

Preparation of pure K\(_2\)O\(_2\), Rb\(_2\)O\(_2\) and Cs\(_2\)O\(_2\) by this route is difficult because of the ease with which they oxidize further to the superoxides MO\(_2\). Oxidation of the metals with NO has been used but the best method is the quantitative oxidation of the metals in liquid ammonia solution (p. 78). The peroxides can be regarded as salts of the dibasic acid H\(_2\)O\(_2\). Thus reaction with acids or water quantitatively liberates H\(_2\)O\(_2\):

\[
\begin{align*}
\text{M}_2\text{O}_2 + \text{H}_2\text{SO}_4 & \rightarrow \text{M}_2\text{SO}_4 + \text{H}_2\text{O}_2 \\
2\text{LiOOH} + \text{H}_2\text{O} & \xrightarrow{\text{heat}} \text{Li}_2\text{O}_2 + \text{H}_2\text{O}_2 + 2\text{H}_2\text{O}
\end{align*}
\]

It is a thermodynamically stable, white, crystalline solid which decomposes to Li\(_2\)O on being heated above 195\(^\circ\)C.

Na\(_2\)O\(_2\), is prepared as pale-yellow powder by first oxidizing Na to Na\(_2\)O in a limited supply of dry oxygen (air) and then reacting this further to give Na\(_2\)O\(_2\):

\[
2\text{Na} + \frac{1}{2}\text{O}_2 \xrightarrow{\text{heat}} \text{Na}_2\text{O} \xrightarrow{\text{heat}} \text{Na}_2\text{O}_2
\]

Preparation of pure K\(_2\)O\(_2\), Rb\(_2\)O\(_2\) and Cs\(_2\)O\(_2\) by this route is difficult because of the ease with which they oxidize further to the superoxides MO\(_2\). Oxidation of the metals with NO has been used but the best method is the quantitative oxidation of the metals in liquid ammonia solution (p. 78). The peroxides can be regarded as salts of the dibasic acid H\(_2\)O\(_2\). Thus reaction with acids or water quantitatively liberates H\(_2\)O\(_2\):

\[
\begin{align*}
\text{M}_2\text{O}_2 + \text{H}_2\text{SO}_4 & \rightarrow \text{M}_2\text{SO}_4 + \text{H}_2\text{O}_2 \\
\text{M}_2\text{O}_2 + \text{H}_2\text{O} & \rightarrow 2\text{MOH} + \text{H}_2\text{O}_2
\end{align*}
\]

Sodium peroxide finds widespread use industrially as a bleaching agent for fabrics, paper pulp, wood, etc., and as a powerful oxidant; it explodes with powdered aluminium or charcoal, reacts with sulfur with incandescence and ignites many organic liquids. Carbon monoxide forms the carbonate, and CO\(_2\) liberates oxygen (an important application in breathing apparatus for divers, firemen, and in submarines — space capsules use the lighter Li\(_2\)O\(_2\)):

\[
\text{Na}_2\text{O}_2 + \text{CO} \rightarrow \text{Na}_2\text{CO}_3
\]

§4.3.3 Oxides, peroxides, superoxides and suboxides

\[
\text{Na}_2\text{O}_2 + \text{CO}_2 \rightarrow \text{Na}_2\text{CO}_3 + \frac{1}{2}\text{O}_2
\]

In the absence of oxygen or oxidizable material, the peroxides (except Li$_2$O$_2$) are stable towards thermal decomposition up to quite high temperatures, e.g. Na$_2$O$_2 \sim 675°C$, Cs$_2$O$_2 \sim 590°C$.

The superoxides MO$_2$ contain the paramagnetic ion O$_2^-$ which is stable only in the presence of large cations such as K, Rb, Cs (and Sr, Ba, etc.). Li$_2$O$_2$ has only been prepared by matrix isolation experiments at 15 K and positive evidence for Na$_2$O$_2$ was first obtained by reaction of O$_2$ with Na dissolved in liquid NH$_3$; it can be obtained pure by reacting Na with O$_2$ at 450°C and 150 atm pressure. By contrast, the normal products of combustion of the heavier alkali metals in air are KO$_2$ (orange), mp 380°C, RbO$_2$ (dark brown), mp 412°C and CsO$_2$ (orange), mp 432°C. NaO$_2$ is trimorphic, having the marcasite structure (p. 680) at low temperatures, the pyrite structure (p. 680) between -77° and -50°C and a pseudo-NaCl structure above this, due to disordering of the O$_2^-$ ions by rotation. The heavier congeners adopt the tetragonal CaC$_2$ structure (p. 298) at room temperature and the pseudo-NaCl structure at high temperature.

Sesquioxides "M$_2$O$_3$" have been prepared as dark-coloured paramagnetic powders by careful thermal decomposition of MO$_2$ (K, Rb, Cs). They can also be obtained by oxidation of liquid ammonia solutions of the metals or by controlled oxidation of the peroxides, and are considered to be peroxide disuperoxides [(M$^{+4}$)$_4$(O$_2^{2-}$)(O$_2^-$)$_2$]. Indeed, pure Rb$_4$O$_6$, prepared by solid-state reaction between Rb$_2$O$_2$ and 2RbO$_2$, has recently been shown to be [Rb$_4$(O$_2^{2-}$)(O$_2^-$)$_2$] by single-crystal diffractometry, although the two types of diatomic anion could not be distinguished in the cubic unit cell even at -60°C; the compound is thermodynamically stable and melts at 461°C.(330)

Ozonides MO$_3$ have been prepared for Na, K, Rb and Cs by the reaction of O$_3$ on powdered anhydrous MOH at low temperature and extraction of the red MO$_3$ by liquid NH$_3$:

\[
3\text{MOH(c)} + 2\text{O}_3(\text{g}) \rightarrow 2\text{MO}_3(\text{c}) + \text{MOH.}\text{H}_2\text{O(c)} + \frac{1}{2}\text{O}_2(\text{g})
\]

Under similar conditions Li gives [Li(NH$_3$)$_4$]O$_3$ which decomposes on attempted removal of the coordinated NH$_3$, again emphasizing the important role of cation size in stabilizing catenated oxygen anions. Improved techniques involving the reaction of oxygen/ozone mixtures on the preformed peroxide, followed by extraction with liquid ammonia, now permit gram amounts of the pure crystalline ozonides of K, Rb and Cs to be prepared.(31) (See also p. 98, p. 610.) The ozonides, on standing, slowly decompose to oxygen and the superoxide MO$_2$, but on hydrolysis they appear to go directly to the hydroxide:

\[
\text{MO}_3 \rightarrow \text{MO}_2 + \frac{1}{2}\text{O}_2
\]

\[
4\text{MO}_3 + 2\text{H}_2\text{O} \rightarrow 4\text{MOH} + 5\text{O}_2
\]

In addition to the above oxides M$_2$O, M$_2$O$_2$, M$_4$O$_6$, MO$_2$ and MO$_3$ in which the alkali metal has the constant oxidation state +1, rubidium and caesium also form suboxides in which the formal oxidation state of the metal is considerably lower. Some of these intriguing compounds have been known since the turn of the century but only recently have their structures been elucidated by single crystal X-ray analysis.(32) Partial oxidation of Rb at low temperatures gives Rb$_9$O which decomposes above -7.3°C to give copper-coloured metallic crystals of Rb$_9$O$_2$:

\[
2\text{Rb}_6\text{O} \rightarrow \text{Rb}_9\text{O}_2 + 3\text{Rb}
\]

Rb$_9$O$_2$ inflames with H$_2$O and melts incongruently at 40.2°C to give 2Rb$_2$O + 5Rb. The structure of Rb$_9$O$_2$ comprises two ORb$_6$ octahedra sharing a common face (Fig. 4.5). It thus has the anti-[Tl$_2$Cl$_6$]$_{3-}$ structure. The Rb–Rb distance within this unit is only 352 pm (compared with 485 pm in Rb metal) and the nearest Rb–Rb distance

between groups is 511 pm. The Rb-O distance is ~249 pm, much less than the sum of the conventional ionic radii (289 pm) and the metallic character of the oxide comes from the excess of at least 5 electrons above that required for simple bookkeeping. Crystalline Rb\textsubscript{6}O has a unit cell containing 4 formula units, i.e. Rb\textsubscript{24}O\textsubscript{4}, and the structure consists of alternating layers of Rb\textsubscript{9}O\textsubscript{2} and close-packed metal atoms parallel to (001) to give the structural formula [(Rb\textsubscript{9}O\textsubscript{2})Rb\textsubscript{3}].

Caesium forms an even more extensive series of suboxides:\textsuperscript{(32)} Cs\textsubscript{7}O, bronze-coloured, mp +4.3°C; Cs\textsubscript{4}O, red-violet, decomposes >10.5°; Cs\textsubscript{11}O\textsubscript{3}, violet crystals, mp (incongruent) 52.5°C; and Cs\textsubscript{13+}O, a nonstoichiometric phase up to Cs\textsubscript{3}O, which decomposes at 166°C. Cs\textsubscript{7}O reacts vigorously with O\textsubscript{2} and H\textsubscript{2}O and the unit cell is found to be Cs\textsubscript{21}O\textsubscript{3}, i.e. [(Cs\textsubscript{11}O\textsubscript{3})Cs\textsubscript{10}]. The unit Cs\textsubscript{11}O\textsubscript{3} comprises 3 octahedral OC\textsubscript{6} groups each sharing 2 adjacent faces to form the trigonal group shown in Fig. 4.5b. These groups form chains along (001) and are also surrounded by the other Cs atoms. The Cs-Cs distance within the Cs\textsubscript{11}O\textsubscript{3} group is only 376 pm, whereas between groups it is 527 pm; this latter distance is also the shortest distance between Cs in a group and the other 10 Cs atoms, and is similar to the interatomic distance in Cs metal. The structures of the other 3 suboxides are more complex but it is salutary to realize that Cs forms at least 9 crystalline oxides whose structures can be rationalized in terms of general bonding systematics.

### 4.3.4 Hydroxides

Evaporation of aqueous solutions of LiOH under normal conditions produces the monohydrate, and this can be readily dehydrated by heating in an inert atmosphere or under reduced pressure. LiOH\cdot H\textsubscript{2}O has a crystal structure built up of double chains in which both Li and H\textsubscript{2}O have 4 nearest neighbours (Fig. 4.6a); Li is tetrahedrally coordinated by 2OH and 2H\textsubscript{2}O, and each tetrahedron shares an edge (2OH) and two corners (2H\textsubscript{2}O) to produce double chains which are held laterally by H bonds. Each H\textsubscript{2}O molecule is tetrahedrally coordinated by 2Li from the same chain and 2OH from other chains. Anhydrous LiOH has a layer lattice of edge-shared Li(OH)\textsubscript{4} tetrahedra (Fig. 4.6b) in which each Li in a plane is surrounded tetrahedrally by 4OH, and each OH has 4Li neighbours all lying on one side; neutron diffraction shows that the OH bonds are normal to the layer plane and there is no H bonding between layers.

Numerous hydrates have been prepared from aqueous solutions of the heavier alkali metal
hydroxides (e.g. NaOH\(_n\)H\(_2\)O, where \(n = 1, 2, 2.5, 3.5, 4, 5.25\) and 7) but little detailed structural information is available.\(^{33}\) The anhydrous compounds all show the influence of oriented OH groups on the structure,\(^{13}\) and there is evidence of weak O—H⋯O bonding for KOH and RbOH. Melting points are substantially lower than those of the halides, decreasing from 471°C for LiOH to 272°C for CsOH, and the mp of the hydrates is even lower, e.g. 2.5°C (incongr.) for CsOH.2H\(_2\)O and −5.5°C for the trihydrate.

The alkali metal hydroxides are the most basic of all hydroxides. They react with acids to form salts and with alcohols to form alkoxides. The alkoxides are oligomeric and the degree of polymerization can vary depending on the particular metal and the state of aggregation. The tert-butoxides, MOBu', (Bu' = OCMe\(_3\)) can be considered as an example. Crystalline (KOBu')\(_4\) has a cubane-like structure and the tetramer persists in tetrahydrofuran solution and in the gas phase.\(^{34,35}\) By contrast, (NaOBu')\(_4\) is exclusively tetrameric in thf, but is a mixture of hexamers and nonamers in the crystalline state and of hexamers and heptamers in the vapour phase. The lithium analogue is tetrameric in thf but is hexameric in benzene, toluene or cyclohexane and in the gas phase. The degree of polymerization can also be influenced by the nature of the organic residue. Thus X-ray crystallography shows that lithium 2,6-di-tert-butyl-4-methylphenolate is dimeric whereas the closely related phenolate \{LiOC\(_6\)H\(_2\)(CH\(_2\)NMe\(_2\))\(_2\)-2,6-Me-4\}\(_3\) provides the first example of a trimeric structure, with an essentially planar central Li\(_3\)O\(_3\) heterocyclic ring.\(^{36}\) The trimer, like the dimer, features unusually short Li—O and C\(_{ipso}\)—O bonds (186.5 and 130.1 pm, respectively) perhaps suggesting quasi-aromaticity of the Li\(_3\)O\(_3\) ring, the delocalized \(\pi\)-electrons originating from the lone pairs on the oxygen atoms.

The alkali metal hydroxides are also readily absorb CO\(_2\) and H\(_2\)S to form carbonates (or hydrogen carbonates) and sulfides (or hydrogen-sulfides), and are extensively used to remove mercaptans from petroleum products. Amphoteric oxides such as those of Al, Zn, Sn and Pb react with MOH to form aluminates, zincates, stannates and plumbates, and even SiO\(_2\) (and silicate glasses) are attacked.

Production and uses of LiOH have already been discussed (p. 70). Huge tonnages of NaOH and KOH are produced by electrolysis of brine (pp. 71, 73) and the enormous industrial importance of these chemicals has already been alluded to.

### 4.3.5 Oxoacid salts and other compounds

Many binary and pseudo-binary compounds of the alkali metals are more conveniently treated within the context of the chemistry of the other element and for this reason discussion is deferred to later chapters, e.g. borides (p. 145),

---

By contrast $\text{Li}_2\text{CO}_3$ is anhydrous and sparingly soluble (1.28 wt% at 25°C, i.e. 0.17 mol l$^{-1}$). The nitrate is also anhydrous but is hygroscopic and much more soluble (45.8 wt% at 25°C, i.e. 6.64 mol l$^{-1}$).

The heavier alkali metals form a wide variety of hydrated carbonates, hydrogencarbonates, sesquicarbonates and mixed-metal combinations of these, e.g. $\text{Na}_2\text{CO}_3\cdot\text{H}_2\text{O}$, $\text{Na}_2\text{CO}_3\cdot7\text{H}_2\text{O}$, $\text{Na}_2\text{CO}_3\cdot10\text{H}_2\text{O}$, $\text{Na}_2\text{CO}_3\cdot\text{NaHCO}_3\cdot2\text{H}_2\text{O}$, $\text{Na}_2\text{CO}_3\cdot3\text{NaHCO}_3$, $\text{NaKCO}_3\cdot\text{nH}_2\text{O}$, $\text{K}_2\text{CO}_3\cdot\text{NaHCO}_3\cdot2\text{H}_2\text{O}$, etc. These systems have been studied in great detail because of their industrial and geochemical significance (see Panel). Some solubility data are in Fig. 4.7, which indicates the considerable solubility of $\text{Rb}_2\text{CO}_3$ and $\text{Cs}_2\text{CO}_3$ and the lower solubility of the hydrogencarbonates. The various stoichiometries reflect differing ways of achieving charge balance, preferred coordination polyhedra, and H bonding. Thus $\text{Na}_2\text{CO}_3\cdot\text{H}_2\text{O}$ has two types of 6-coordinate Na, half being surrounded by 1H$_2$O plus 5 oxygen atoms from CO$_3$ groups and half by

---

Industrial Production and Uses of Sodium Carbonate, Hydroxide and Sulfate

Na₂CO₃ (soda ash) is interchangeable with NaOH in many of its applications (e.g. paper pulping, soap, detergents) and this gives a valuable flexibility to the chlor-alkali industry. About half the Na₂CO₃ produced is used in the glass industry. One developing application is in the reduction of sulfur pollution resulting from stack gases of power plants and other large furnaces: powdered Na₂CO₃ is injected with the fuel and reacts with SO₂ to give solids such as Na₂SO₃ which can be removed by filtration or precipitation. World production of Na₂CO₃ was 28.7 million tonnes in 1985: the five leading countries were the USA, the USSR, China, Bulgaria and the Federal Republic of Germany, and they accounted for over 70% of production. Most of this material was synthetic (Solvay), but the increasing use of natural carbonate (trona) is notable, particularly in the USA where it is now the sole source of Na₂CO₃, the last synthetic unit having been closed in 1985: reserves in the Green River, Wyoming, deposit alone exceed 10¹⁰ tonnes and occur in beds up to 3 m thick over an area of 2300 km². About one third of the world production is now from natural deposits.

Formerly Na₂CO₃ found extensive use as “washing soda” but this market has now disappeared due to the domestic use of detergents. The related compound NaHCO₃ is, however, still used, particularly because of its ready decomposition in the temperature range 50–100°C:

\[ 2\text{NaHCO}_3 \rightarrow \text{Na}_2\text{CO}_3 + \text{H}_2\text{O} + \text{CO}_2 \]

Production in the USA is ~350 000 tonnes annually of which 30% is used in baking-powder formulations, 20% in animal feedstuffs, 15% in chemicals manufacture, 11% in pharmaceuticals, 9% in fire extinguishers and the remaining 15% in the textile, leather and paper industries and in soaps, detergents and neutralizing agents.

Caustic soda (NaOH) is industry’s most important alkali. It is manufactured on a huge scale by the electrolysis of brine (p. 72) and annual production in the USA alone is over 10 million tonnes. Electrolysis is followed by concentration of the alkali in huge tandem evaporators such as those at PPG Industries’ Lake Charles plant. The evaporators, which are perhaps the world’s largest, are 41 m high and 12 m in diameter. About half the caustic produced is used directly in chemical production: a detailed breakdown of usage (USA, 1985) is: organic chemicals 30%, inorganic chemicals 20%, paper and pulp 20%, export 10%, soap and detergents 5%, oil industry 5%, textiles 4%, bauxite digestion 3% and miscellaneous 3%. Principal applications are in acid neutralization, the manufacture of phenol, resorcinol, β-naphthol, etc., and the production of sodium hypochlorite, phosphate, sulfide, aluminates, etc.

Salt cake (Na₂SO₄) is a byproduct of HCl manufacture using H₂SO₄ and is also the end-product of hundreds of industrial operations in which H₂SO₄ used for processing is neutralized by NaOH. For long it had few uses, but now it is the mainstay of the paper industry, being a key chemical in the kraft process for making brown wrapping paper and corrugated boxes: digestion of wood chips or saw-mill waste in very hot alkaline solutions of Na₂SO₄ dissolves the lignin (the brown resinous component of wood which cements the fibres together) and liberates the cellulose fibres as pulp which then goes to the paper-making screens. The remaining solution is evaporated until it can be burned, thereby producing steam for the plant and heat for the evaporation: the fused Na₂SO₄ and NaOH survive the flames and can be reused. Total world production of Na₂SO₄ (1985) was ~4.5 million tonnes (45% natural, 55% synthetic). Most of this (~70%) is used in the paper industry and smaller amounts are used in glass manufacture and detergents (~10% each). The hydrated form, Na₂SO₄⋅10H₂O, Glauber’s salt, is now less used than formerly. Further information on the industrial production and uses of Na₂CO₃, NaOH and Na₂SO₄ are given in Kirk-Othmer Encyclopedia of Chemical Technology, 4th edn., Vol. 1, 1991, pp. 1025–39 and Vol. 22, 1997, pp. 354–419.

2H₂O plus 4 oxygen atoms from CO₃ groups. The decahydrate has octahedral Na(H₂O)₆ groups associated in pairs by edge sharing to give [Na₂(H₂O)₁₀]. The hydrogen carbonate NaHCO₃ has infinite one-dimensional chains of HCO₃ formed by unsymmetrical O–H···O bonds (261 pm) which are held laterally by Na ions. The sesquicarbonates Na₃H(CO₃)₂⋅2H₂O have short, symmetrical O–H–O bonds (253 pm) which link the carbonate ions in pairs, and longer O–H···O bonds (275 pm) which link these pairs to water molecules. Similar phases are known for the other alkali metals.

Alkali metal nitrates can be prepared by direct reaction of aqueous nitric acid on the appropriate hydroxide or carbonate. LiNO₃ is used for scarlet flares and pyrotechnic displays. Large deposits of NaN₂O₃ (saltpetre) are found in Chile and were probably formed by bacterial decay of small marine organisms: the NH₃ initially produced

---

presumably oxidized to nitrous acid and nitric acid which would then react with dissolved NaCl. KNO₃ was formerly prepared by metathesis of NaNO₃ and KCl but is now obtained directly as part of the synthetic ammonia/nitrilic acid industry (p. 421).

Alkali metal nitrates are low-melting salts that decompose with evolution of oxygen above about 500°C, e.g.

\[ 2\text{NaNO}_3 \rightleftharpoons 2\text{NaNO}_2 + \text{O}_2; \]

\[ 2\text{NaNO}_3 \rightleftharpoons \text{Na}_2\text{O} + \text{N}_2 + \frac{5}{2}\text{O}_2 \]

Thermal stability increases with increasing atomic weight, as expected. Nitrates have been widely used as molten salt baths and heat transfer media, e.g. the 1:1 mixture LiNO₃:KNO₃ melts at 125°C and the ternary mixture of 40% NaNO₂, 7% NaNO₃ and 53% KNO₃ can be used from its mp 142° up to about 600°C.

The corresponding nitrites, MNO₂, can be prepared by thermal decomposition of MNO₃ as indicated above or by reaction of NO with the hydroxide:

\[ 4\text{NO} + 2\text{MOH} \longrightarrow 2\text{MNO}_2 + \text{N}_2\text{O} + \text{H}_2\text{O} \]

\[ 6\text{NO} + 4\text{MOH} \longrightarrow 4\text{MNO}_2 + \text{N}_2 + 2\text{H}_2\text{O} \]

Chemical reduction of nitrates has also been employed:

\[ \text{KNO}_3 + \text{Pb} \longrightarrow \text{KNO}_2 + \text{PbO} \]

\[ 2\text{RbNO}_3 + \text{C} \longrightarrow 2\text{RbNO}_2 + \text{CO}_2 \]

The commercial production of NaNO₂ is achieved by absorbing oxides of nitrogen in aqueous Na₂CO₃ solution:

\[ \text{Na}_2\text{CO}_3 + \text{NO} + \text{NO}_2 \longrightarrow 2\text{NaNO}_2 + \text{CO}_2 \]

Nitrites are white, crystalline hygroscopic salts that are very soluble in water. When heated in the absence of air they disproportionate:

\[ 5\text{NaNO}_2 \longrightarrow 3\text{NaNO}_3 + \text{Na}_2\text{O} + \text{N}_2 \]

NaNO₂, in addition to its use with nitrates in heat-transfer molten-salt baths, is much used in the production of azo dyes and other organo-nitrogen compounds, as a corrosion inhibitor and in curing meats.

Other oxoacid salts of the alkali metals are discussed in later chapters, e.g. borates (p. 205), silicates (p. 347), phosphites and phosphates (p. 510), sulfites, hydrogensulfates, thiosulfates, etc. (p. 706) selenites, selenates, tellurites and tellurates (p. 781), hypohalites, halites, halates and perhalates (p. 853), etc.

4.3.6 Coordination chemistry(38–42)

Exciting developments have occurred in the coordination chemistry of the alkali metals during the last few years that have completely rejuvenated what appeared to be a largely predictable and worked-out area of chemistry. Conventional beliefs had reinforced the predominant impression of very weak coordinating ability, and had rationalized this in terms of the relatively large size and low charge of the cations M⁺. On this view, stability of coordination complexes should diminish in the sequence Li > Na > K > Rb > Cs, and this is frequently observed, though the reverse sequence is also known for the formation constants of, for example, the weak complexes with sulfate, peroxosulfate, thiosulfate and the hexacyanoferrates in aqueous solutions.(39) It was also known that the alkali metal cations formed numerous hydrates, or aqua-complexes, as discussed in the preceding section, and there is a definite, though smaller tendency to form ammine complexes such as [Li(NH₃)₄]I. Other well-defined complexes include the extremely stable adducts LiX.5Ph₃PO, LiX.4Ph₃PO and NaX.5Ph₃PO, where X is a large anion such as I, NO₃, ClO₄, BPh₄, SbF₆, AuCl₄, etc.; these compounds melt in the range 200–315° and are stable to air and water (in which they are insoluble).

---

They probably all contain the tetrahedral ion [Li(OPPh₃)₄]⁺ which was established by X-ray crystallography for the compound Li₅PPh₃PO; the fifth molecule of Ph₃PO is uncoordinated.

In recent years this simple picture has been completely transformed and it is now recognized that the alkali metals have a rich and extremely varied coordination chemistry which frequently transcends even that of the transition metals. The efflorescence is due to several factors such as the emerging molecular chemistry of lithium in particular, the imaginative use of bulky ligands, the burgeoning numbers of metal amides, alkoxides, enolates and organometallic compounds, and the exploitation of multidentate crown and cryptand ligands. Some of these aspects will be dealt with more fully in subsequent subsections (4.3.7 and 4.3.8).

Lithium is now known in at least 20 coordination geometries with coordination numbers ranging from 1–12. Some illustrative examples are in Table 4.3 and in the accompanying Figs. 4.8 and 4.9 which will repay close attention. The bulky ligand bis(trimethylsilyl)methyl forms a derivative in which Li is 1-coordinate in the gas phase but which polymerizes in the crystalline form to give bent 2-coordinate Li (and 5-coordinate carbon). The related ligand tris(trimethylsilyl)methyl gives an anionic complex in which Li is linear 2-coordinate, and the

same stereochemistry is observed in the unique structure of Li₃N (Fig. 4.8a) which also features the highly unusual planar 6-coordination mode; the structure comprises hexagonal sheets of overall composition Li₂N stacked alternately with planes containing the 2-coordinate Li. The coordination number of N is 8 (hexagonal bipyramidal). Three-coordinate Li is known in planar, pyramidal and angular geometries, the latter two modes being illustrated in Fig. 4.8b, c and d. Numerous examples of 4-coordinate Li have already been mentioned. Five-coordinate Li can be trigonal bipyramidal as in [LiBr(phen)₂] and the aza cage cation shown in Fig. 4.8e, square pyramidal (Fig. 4.8f and g) or planar (Fig. 4.8h).

Table 4.3 indicates that octahedral coordination is a common mode for Li. Less usual is planar 6-fold coordination (Fig. 4.8a), pentagonal pyramidal coordination (Fig. 4.8i) or irregular 6-fold coordination (Fig. 4.9a). Examples of 7-fold coordination are in Fig. 4.9b and c. Lithium has cubic 8-fold coordination in the metallic form and in several of its alloys with metals of large radius. It is also 8-coordinate in the dilithionaphthalene complex shown in Fig. 4.9d; here the aromatic
hydrocarbon bonds to two lithium atoms in a bis-hexahapto bridging mode and each lithium is also coordinated by a chelating diamine. A much more complicated dimeric cluster compound, whose central \( (\text{Li}_6\text{Na}_2\text{Ni}_2) \) core is shown schematically in Fig. 4.9e, includes 9-coordinate lithium among its many fascinating structural features.

When Li metal is cold-worked it transforms from body-centred cubic to cubic close-packed in which each atom is surrounded by 12 others in twinned cuboctahedral coordination; below 78 K the stable crystalline modification is hexagonal close-packed in which each lithium atom has 12 nearest neighbours in the form of a cuboctahedron. This very high coordination
Figure 4.9 Structures of selected organolithium compounds illustrating coordination numbers ranging from 6 to 12. (a) The dilithio-bis(tetramethylethylendiamine)hexatriene complex; each Li is coordinated by the bridging bistetrahapto triene and by one chelating tmeda ligand. (b) The trimethylsilylcyclopentadienyllithium complex with tmeda. (c) The dilithopentalene-dimethoxyethane complex. (d) The dilithionaphthalene complex with tmeda. (e) The Li$_6$Na$_2$Ni$_2$ core in the cluster [(Na$_2$Ph(Et$_2$O)$_2$)(Ph$_2$Ni)$_2$N$_2$Li$_6$OEt$_4$(Et$_2$O)$_2$]$_2$ showing the four 9-coordinate Li atoms (1, 2, 5, 6), together with the 7-coordinate Li(4) and 6-coordinate Li(3) atoms. (f) Hexagonal-prismatic 12-fold coordination of Li in its $H$-indenofluorenide dimer.

Number is also found in the dimeric sandwich compound that Li forms with the extended planar hydrocarbon 7bH-indeno[1,2,3-jk]fluorene; in this case, as can be seen from Fig. 4.9f, the coordination geometry about the metal atoms is hexagonal prismatic.

Similar structural diversity has been established for the heavier alkali metals also but it is unnecessary to deal with this in detail. The structural chemistry of the organometallic compounds in particular, and of related complexes, has been well reviewed. 

41.42
Complexes with chelating organic reagents such as salicylaldehyde and \( \beta \)-diketonates were first prepared by N. V. Sidgwick and his students in 1925, and many more have since been characterized. Stability, as measured by equilibrium formation constants, is rather low and almost invariably decreases in the sequence \( \text{Li} > \text{Na} > \text{K} \). This situation changed dramatically in 1967 when C. J. Pedersen announced the synthesis of several macrocyclic polyethers which were shown to form stable complexes with alkali metal and other cations.\(^{(64)}\) The stability of the complexes was found to depend on the number and geometrical disposition of the ether oxygen atoms and in particular on the size and shape of potential coordination polyhedra relative to the size of the cation. For this reason stability could peak at any particular cation.

and, for $M^+$, this was often $K$ and sometimes $Na$ or $Rb$ rather than $Li$. Pedersen, who was awarded a Nobel Prize for these discoveries, coined the epithet “crown” for this class of macrocyclic polyethers because, as he said “the molecular structure looked like one and, with it, cations could be crowned and uncrowned without physical damage to either”. Typical examples of such “crown” ethers are given in Fig. 4.10, the numerical prefix indicating the number of atoms in the heterocycle and the suffix the number of ether oxygens. The aromatic rings can be substituted, replaced by naphthalene residues, or reduced to cyclohexyl derivatives. The “hole size” for coordination depends on the number of atoms in the ring and is compared with conventional ionic diameters in Table 4.4. The best complexing agents are rings of 15–24 atoms including 5 to eight oxygen atoms. Nitrogen and sulfur can also serve as the donor atoms in analogous macroheterocycles.

The X-ray crystal structures of many of these complexes have now been determined: representative examples are shown in Fig. 4.11 from which it is clear that, at least for the larger cations, coordinative saturation and bond directionality are far less significant factors than in many transition element complexes.

Further interest in these ligands stems from their use in biochemical modelling since they sometimes mimic the behaviour of naturally occurring, neutral, macrocyclic antibiotics such as valinomycin, monactin, nonactin, nigericin.

and enneatrin.\(^68,69\) They may also shed some light on the perplexing and remarkably efficient selectivity between Na and K in biological systems.\(^{68–70}\)

Another group of very effective ligands that have recently been employed to coordinate alkali metal cations are the macrobicyclic polydentate ligands that J.-M. Lehn has termed “cryptands”.\(^{71}\) e.g. \(\text{N}[(\text{CH}_2\text{CH}_2\text{O})_2\text{CH}_2\text{CH}_2]_3\text{N}\) (Fig. 4.13a, b). This forms a complex \([\text{Rb(crypt)}]\text{CNS}H_2O\) in which the ligand encapsulates the cation with a bicapped trigonal prismatic coordination polyhedron (Fig. 4.12c, d).

Such complexes are finding increasing use in solvent extraction, phase-transfer catalysis,\(^{72}\) the

---

stabilization of uncommon or reactive oxidation states and the promotion of otherwise improbable reactions. Extraordinarily pronounced selectivity in complexation can be achieved by suitably designed ligands, some of the more spectacular being $\text{K}^+ / \text{Na}^+ \sim 10^5$, $\text{Cu}^{2+} / \text{Zn}^{2+} \sim 10^8$, $\text{Cd}^{2+} / \text{Zn}^{2+} \sim 10^9$.

A growing application of cryptands and other macrocyclic polydentate ligands is in protecting sensitive anions from the polarizing and destabilizing effect of cationic charges, by encapsulating or crowning the cation and so preventing its close approach to the anion. For example, ozonides of K, Rb and Cs form stable solutions in typical organic solvents (such as $\text{CH}_2\text{Cl}_2$, tetrahydrofuran or MeCN) when the cation is coordinated by crown ethers or cryptands, thus enabling the previously unstudied solution chemistry of $\text{O}_3^-$ to be investigated at room temperature.\(^{73}\) Slow evaporation of ammonia solutions of such complexes yields red crystalline products and an X-ray structure of $[\text{Rb}({\eta}^6-18\text{-crown}-6)(\eta^2-\text{O}_3)(\text{NH}_3)]$ reveals 9-coordinate Rb, the chelating ozonide ion itself having O–O distances of 129 and 130 pm and an O–O–O angle of 117°.

§4.3.7 Imides, amides and related compounds

A particularly imaginative application of this concept has led to the isolation of compounds which contain monatomic alkali metal anions. For example, Na was reacted with cryptand in the presence of EtNH₂ to give the first example of a sodide salt of Na⁻.\(^{74}\)

\[
2\text{Na} + N((C₂H₄O)₂C₂H₄)₃N \xrightarrow{\text{EtNH₂}} \text{Na(cryptand)}⁺\text{Na}⁻
\]

The Na⁻ is 555 pm from the nearest N and 516 pm from the nearest O, indicating that it is a separate entity in the structure. Potas-
sides, rubidides and caesides have similarly been prepared.\(^{74}\) The same technique has been used to prepare solutions and even crys-
tals of electrides, in which trapped electrons can play the role of anion. Typical exam-
pl es are \([\text{K(cryptand)}]⁺\text{e}⁻\) and \([\text{Cs(18-crown-
6)}]⁺\text{e}⁻.\(^{74,75}\)

Macrocycles, though extremely effective as polydentate ligands, are not essential for the production of stable alkali metal complexes; additional conformational flexibility without loss of coordinating power can be achieved by synthesizing benzene derivatives with 2–6 pendant mercapto-polyether groups \(C₆H₆–ₙ\text{R}ₙ\), where R is \(-SC₂H₄OC₂H₄OMe, \text{--S(C}_₂\text{H}_₄\text{O})₃\text{Bu, etc. Such “octopus” ligands are more effective than crowns and often equally as effective as cryptands in sequester-
ing alkali metal cations.}\(^{76}\) Indeed, it is not even essential to invoke organic ligands at all since an inorganic cryptate which completely sur-
rounds Na has been identified in the heteropol-
tungstate \((\text{NH₄})₇\text{Na}[\text{NaW}_{21}\text{Sb}_{9}\text{O}_{86}].14\text{H₂O}; the compound was also found to have pronounced antiviral activity.\(^{77}\)

4.3.7 Imides, amides and related compounds \(^{(78,79)}\)

Before discussing the organometallic compounds of the alkali metals (which contain direct M–C bonds, Section 4.3.8) it is convenient to mention another important class of compounds: those which involve M–N bonds. In this way we shall resume the sequence of compounds which started with those having M–X bonds (i.e. halides, Section 4.3.2), through those with M–O bonds (oxides, hydroxides etc., Sections 4.3.3–4.3.5) to those with M–N and finally those with M–C bonds. As we shall see, several significant perceptions have emerged in this field during the past decade. For example, it is now generally agreed that in all these classes of compound the bond from the main group element to the alkali metal is predominantly ionic. Furthermore, structural studies of compounds with Li–N bonds in particular have led to the seminal concepts of ring-stacking and ring-laddering which, in turn, have permitted the rationalization of many otherwise puzzling structural features.

Lithium imides (imidolithiums) are air-sensitive compounds of general formula \((\text{RR'C}=\text{NLi})ₙ\). They can be prepared in high yield either by the addition of an organolithium compound across the triple bond of a nitrile (equation (1)) or by lithiation of a ketimine (equation (2)).

\[
\text{RLi} + \text{RC≡N} \rightarrow \text{RR'C≡NLi}
\]

\[
\text{R''Li} + \text{RR'C=NH} \rightarrow \text{RR'C=NLi} + \text{R'H}
\]

Lithium imides have proved to be useful reagents for the synthesis of imino derivatives of a wide variety of other elements, e.g. Be, B, Al, Si, P, Mo, W and Fe as in equation (3).

\[
\text{R''SiCl} + \text{RR'C=NLi} \rightarrow \text{RR'C=NSiR''₆} + \text{LiCl}
\]

When \(\text{R} \text{and R'}\) are both aryl groups the resulting lithium imides are amorphous, insoluble

Figure 4.13  (a) Schematic representation of the Li₆N₆ core cluster in hexameric lithium imides. (b) The X-ray structure of [Me₂N(Ph)C=NLi]₆ viewed from above showing the stacking of two 6-membered Li₃N₃ rings. (c) Each Li atom has two nearest-neighbour Li atoms in the adjacent ring at 248 pm, shown here joined by full lines; the mean Li-N distances (broken lines) are 198 pm within each ring and 206 pm between rings.°

(presumably polymeric) solids, but if only one or neither of R, R' is an aryl group, soluble crystalline hexamers are obtained. The skeletal structure of these hexamers comprises an Li₆N₆ cluster formed by the stacking of two slightly puckered heterocyclic Li₃N₃ rings so that the Li atoms in each ring are almost directly above or below the N atoms in the adjacent ring. This is illustrated schematically in Fig. 4.13a (cf. Fig. 4.8d for the analogous hexameric alkoxide structure). An alternative view, looking down onto the open 6-membered face of the stack, is shown in Fig. 4.13b for the case of [Me₂N(Ph)C=NLi]₆. Formation of such hexamers can be viewed as a stepwise process. Initially formed ion-pairs (monomers), Li⁺[N=CRR']⁻, with 1-coordinate Li⁺, associate at first to cyclic trimers, (LiN=CRR')₃, containing 2-coordinate Li⁺ centres. Such rings are essentially planar systems [the planarity of the (LiN)₃ ring itself extending outwards through the imido C up to

clusters of various sizes, but the details lie outside the scope of the present treatment.

In contrast to the planar (sp$^2$) nitrogen centres in lithium imides, lithium amides, $(RR'N)Li)_n$, feature tetrahedral (sp$^3$) nitrogen. The exocyclic R groups are thus above and below the $(LiN)_n$ plane and this prevents ring stacking. Rings of varying size are known, with $n = 2, 3$ or 4 depending on the nature of the substituents (Fig. 4.14a, b and c). In the important case of $n = 2$, the 4-membered $Li_2N_2$ heterocycles can associate further by edge fusion (rather than by face fusion) to form laddered structures as shown schematically in Fig. 4.14d. Specific examples of amidolithium heterocycles are $[(Me_3Si)_2NLi]_2$ (gas-phase), $[(PhCH_2)_2NLi]_3$ (Fig. 4.15a) and the tetramethylpiperidinatolithium tetramer $[Me_2C(CH_2)_3CMe_2NLi]_4$ (Fig. 4.15b). By contrast, lithiation of the cyclic amine pyrrolidine in the presence of the chelating ligand tetramethylethylenediamine (tmeda) affords the

![Figure 4.14 Schematic representation of (a) 4-membered, (b) 6-membered and (c) 8-membered $(LiN)_n$ heterocycles showing pendant groups on N lying both above and below the plane of the ring. (d) the laddered structure formed by lateral bonding of two $Li_2N_2$ units.](image)

![Figure 4.15 X-ray structure of (a) dibenzylamidolithium, $[(PhCH_2)_2NLi]_3$ and (b) tetramethylpiperidinatolithium, $[Me_2C(CH_2)_3CMe_2NLi]_4$.](image)

---

ladder complex \([\text{H}_2\text{C}(\text{CH}_2)_3\text{NLi})_2\text{tmeda}]_2\) (Fig. 4.16). Detailed examination of the interatomic distances in this structure clearly indicate that laddering is achieved by the lateral connection of the two outer Li$_2$N$_2$ rings. The Li–N bonds in all these compounds are considered to be predominantly ionic.

![Figure 4.16 X-ray structure of the laddered complex \([\text{H}_2\text{C}(\text{CH}_2)_3\text{NLi})_2\text{tmeda}]_2\) where tmeda is tetramethylethylenediamine.](image)

### 4.3.8 Organometallic compounds

Some structural aspects of the organometallic compounds of the alkali metals have already been briefly mentioned in Section 4.3.6. The diagonal relation of Li with Mg (p. 76), coupled with the known synthetic utility of Grignard reagents (pp. 132–5), suggests that Li, and perhaps the other alkali metals, might afford synthetically useful organometallic reagents. Such is found to be the case.\(^{86}\)

Organolithium compounds can readily be prepared from metallic Li and this is one of the major uses of the metal. Because of the great reactivity both of the reactants and the products, air and moisture must be rigorously excluded by use of an inert atmosphere. Lithium can be reacted directly with alkyl halides in light petroleum, cyclohexane, benzene or ether, the chlorides generally being preferred:

\[
2\text{Li} + \text{RX} \xrightarrow{\text{solvent}} \text{LiR} + \text{LiX}
\]

Reactivity and yields are greatly enhanced by the presence of 0.5–1% Na in the Li. The reaction is also generally available for the preparation of metal alkyls of the heavier Group 1 metals. Lithium aryls are best prepared by metal–halogen exchange using LiBu" and an aryl iodide, and transmetalation is the most convenient route to vinyl, allyl and other unsaturated derivatives:

\[
\text{LiBu}^\text{I} + \text{ArI} \xrightarrow{\text{ether}} \text{LiAr} + \text{Bu}^\text{I}
\]

\[
4\text{LiPh} + \text{Sn(CH=CH}_2)_4 \xrightarrow{\text{ether}} 4\text{LiCH=CH}_2 + \text{SnPh}_4
\]

The reaction between an excess of Li and an organomercury compound is a useful alternative when isolation of the product is required, rather than its direct use in further synthetic work:

\[
2\text{Li} + \text{HgR}_2 (\text{or HgAr}_2) \xrightarrow{\text{petrol or benzene}} 2\text{LiR} (\text{or LiAr}) + \text{Hg}
\]

Similar reactions are available for the other alkali metals. Metalation (metal–hydrogen exchange) and metal addition to alkenes provide further routes, e.g.

\[
\text{LiPh} + \text{Et}_2\text{O} \xrightarrow{\text{Et}_2\text{O}} \text{Li}[\text{O}] + \text{C}_6\text{H}_6
\]

\[
2\text{Na} + 3\text{C}_3\text{H}_6 \rightarrow 2\text{NaC}_3\text{H}_5 + \text{C}_3\text{H}_8
\]

\[
2\text{Na} + \text{Ph}_2\text{C}==\text{CPh}_2 \rightarrow \text{Ph}_2\text{C}==\text{CPh}_2
\]

\[
\text{Na} \quad \text{Na}
\]

Organometallic compounds

Organolithium compounds tend to be thermally unstable and most of them decompose to LiH and an alkene on standing at room temperature or above. Among the more stable compounds are the colourless, crystalline solids LiMe (decomp above 200°C), LiBu" and LiBu' (which shows little decomposition over a period of days at 100°C). Common lithium alkyls have unusual tetrameric or hexameric structures (see preceding sections). The physical properties of these oligomers are similar to those often associated with covalent compounds (e.g. moderately high volatility, high solubility in organic solvents and low electrical conductivity when fused). Despite this it is now generally agreed that the central (LiC), core is held together by predominantly ionic forces, though estimates of the precise extent of charge separation vary from about 55% to 95%. The resolution of this apparent paradox lies in the realization that continued polymerization of (LiR-) monomers into infinite ionic arrays, such as are found in the alkali-metal halides, is hindered by the bulky nature of the R groups. Furthermore, these organic groups, which are covalently bonded within themselves, almost completely surround the ionic core and so dominate the bulk physical properties. Such ionic/covalent oligomers have been termed "supramolecules".

The structure and bonding in lithium methyl have been particularly fully studied. The crystal structure consists of interconnected tetrameric units (LiMe), as shown in Fig. 4.17; the individual Li₄C₄ clusters consist of a tetrahedron

\[
2\text{Cs} + \text{CH}_2=\text{CH}_2 \rightarrow \text{CsCH}_2\text{CH}_2\text{Cs}
\]

In the presence of certain ethers such as Me₂O, MeOCH₂CH₂OMe or tetrahydrofuran, Na forms deep-green highly reactive paramagnetic adducts with polynuclear aromatic hydrocarbons such as naphthalene, phenanthrene, anthracene, etc.:

These compounds are in many ways analogous to the solutions of alkali metals in liquid ammonia (p. 77).

The most ionic of the organometallic derivatives of Group 1 elements are the acetylidic and dicarbides formed by the deprotonation of alkynes in liquid ammonia solutions:

\[
\text{Li} + \text{HC}≡\text{CH} \rightarrow \text{LiC}≡\text{CH} + \frac{1}{2}\text{H}_2
\]

\[
2\text{Li} + \text{HC}≡\text{CH} \rightarrow \text{Li}_2\text{C}_2 + \text{H}_2
\]

The largest industrial use of LiC₂H is in the production of vitamin A, where it effects ethynylolation of methyl vinyl ketone to produce a key tertiary carbinol intermediate. The acetylidic and dicarbides of the other alkali metals are prepared similarly. It is not always necessary to prepare this type of compound in liquid ammonia and, indeed, further substitution to give the bright red perlithiopropyne Li₄C₃ can be effected in hexane under reflux:(87)

\[
4\text{LiBu}^n + \text{CH}_3\text{C}=\text{CH} \rightarrow \text{Li}_3\text{CC}=\text{C}Li + 4\text{C}_4\text{H}_{10}
\]

Organolithium compounds tend to be thermally unstable and most of them decompose to LiH and an alkene on standing at room temperature or above. Among the more stable compounds are the colourless, crystalline solids LiMe (decomp above 200°C), LiBu" and LiBu' (which shows little decomposition over a period of days at 100°C). Common lithium alkyls have unusual tetrameric or hexameric structures (see preceding sections). The physical properties of these oligomers are similar to those often associated with covalent compounds (e.g. moderately high volatility, high solubility in organic solvents and low electrical conductivity when fused). Despite this it is now generally agreed that the central (LiC), core is held together by predominantly ionic forces, though estimates of the precise extent of charge separation vary from about 55% to 95%. The resolution of this apparent paradox lies in the realization that continued polymerization of (LiR-) monomers into infinite ionic arrays, such as are found in the alkali-metal halides, is hindered by the bulky nature of the R groups. Furthermore, these organic groups, which are covalently bonded within themselves, almost completely surround the ionic core and so dominate the bulk physical properties. Such ionic/covalent oligomers have been termed "supramolecules".

The structure and bonding in lithium methyl have been particularly fully studied. The crystal structure consists of interconnected tetrameric units (LiMe), as shown in Fig. 4.17; the individual Li₄C₄ clusters consist of a tetrahedron

The clusters are interconnected along cube diagonals via the bridging \( \text{CH}_3 \) groups and the intercluster Li–C distance (236 pm) is very similar to the Li–C distance within each cluster (231 pm). The carbon atoms are thus essentially 7-coordinate being bonded directly to 3H and 4Li. The Li–Li distance within the cluster is 268 pm, which is virtually identical with the value of 267.3 pm for the gaseous \( \text{Li}_2 \) molecule and substantially smaller than the value of 304 pm in Li metal (where each Li has 8 nearest neighbours). Each Li atom is therefore closely associated with three other Li atoms and three C atoms within its own cluster and with one C and three H atoms in an adjoining cluster. Detailed calculations show that the C–H–Li interactions make a substantial contribution to the overall bonding.\(^94\) Such “agostic” interactions were indeed first noted in lithium methyl long before their importance in transition metal organometallic compounds was recognized. The effect is most pronounced in \( (\text{LiEt})_4 \) where the \( \alpha \)-H on the ethyl group comes within 198 pm of its neighbouring Li atom;\(^99,91\) cf. 204.3 pm in solid LiH, which has the NaCl structure (pp. 65, 82).
Organometallic compounds

Higher alkyls of lithium adopt similar structures in which polyhedral clusters of metal atoms are bridged by alkyl groups located over the triangular faces of these clusters. For example, crystalline lithium t-buty1 is tetrameric and the structural units (LiBu')₄ persist in solution; by contrast lithium ethyl, which is tetrameric in the solid state, dissolves in hydrocarbons as the hexamer (LiEt)₆ which probably consists of octahedra of Li₆ with triply bridging -CH₂CH₃ groups above 6 of the 8 faces. As the atomic number of the alkali metal increases there is a gradual trend away from these oligomeric structures towards structures which are more typical of polarized ionic compounds. Thus, although NaMe is tetrameric like LiMe, NaEt adopts a layer structure in which the CH₂ groups have a trigonal pyramidal array of Na neighbours, and KMe adopts a NiAs-type structure (p. 679) in which each Me is surrounded by a trigonal prismatic array of K. The extent to which this is considered to be K⁺CH₃⁻ is a matter for discussion though it will be noted that CH₃⁻ is isoelectronic with the molecule NH₃.

The structure of the organometallic complex lithium tetr methylborate LiBMe₄ is discussed on pp. 127–8 alongside that of polymeric BeMe₂ with which it is isoelectronic.

Organometallic compounds of the alkali metals (particularly LiMe and LiBu") are valuable synthetic reagents and have been increasingly used in industrial and laboratory-scale organic syntheses during the past 20 y. [86,94,95]. The annual production of LiBu₄ alone has leapt from a few kilograms to about 1000 tonnes. Large scale applications are as a polymerization catalyst, alkylating agent and precursor to metalated organic reagents. Many of the synthetic reactions parallel those of Grignard reagents over which they sometimes have distinct advantages in terms of speed of reaction, freedom from complicating side reactions or convenience of handling. Reactions are those to be expected for carbanions, though free-radical mechanisms occasionally occur.

Halogens regenerate the parent alkyl (or aryl) halide and proton donors give the corresponding hydrocarbon:

\[
\begin{align*}
\text{LiR} + X_2 & \longrightarrow \text{LiX} + RX \\
\text{LiR} + H^+ & \longrightarrow \text{Li}^+ + \text{RH} \\
\text{LiR} + R'X & \longrightarrow \text{LiI} + RR'
\end{align*}
\]

C–C bonds can be formed by reaction with alkyl iodides or more usefully by reaction with metal carbonyls to give aldehydes and ketones: e.g. Ni(CO)₄ reacts with LiR to form an unstable acyl nickel carbonyl complex which can be attacked by electrophiles such as H⁺ or R'Br to give aldehydes or ketones by solvent-induced reductive elimination:

\[
\text{LiR} + [\text{Ni(CO)}]_4 \longrightarrow \text{Li}^+[\text{C-Ni(CO)}_3]^{-} + [\text{solvent}]\text{Ni(CO)}_3
\]

[Fe(CO)₅] reacts similarly. Aldehydes and ketones can also be obtained from N,N-disubstituted amides, and symmetrical ketones are formed by reaction with CO:

\[
\begin{align*}
\text{LiR} + \text{HCONMe}_2 & \longrightarrow \text{LiNMe}_2 + \text{RCHO} \\
\text{LiR} + \text{R'CONMe}_2 & \longrightarrow \text{LiNMe}_2 + \text{R'COR} \\
2\text{LiR} + 3\text{CO} & \longrightarrow 2\text{LiCO} + \text{R}_2\text{CO}
\end{align*}
\]

Thermal decomposition of LiR eliminates a β-hydrogen atom to give an olefin and LiH, a process of industrial importance for long-chain terminal alkenes. Alkenes can also be produced by treatment of ethers, the organometallic reacting here as a very strong base (proton acceptor):

\[
\text{LiR} + \text{HOR'} \longrightarrow \text{LiOR'} + \text{RH} + \overset{\text{C}}{\text{C}}
\]

Lithium aryls react as typical carbanions in non-polar solvents giving carboxylic acids with CO₂.

---

and tertiary carbinols with aryl ketones:

\[
\text{LiAr} + \text{CO}_2 \rightarrow \text{ArCO}_2\text{Li} \xrightarrow{\text{H}_2\text{O}} \text{LiOH} + \text{ArCO}_2\text{H}
\]

\[
\text{LiAr} + \text{Ar}_2\text{CO} \rightarrow [\text{Ar}_2\text{C(Ar)OLi}] \xrightarrow{\text{H}_2\text{O}} \text{LiOH} + \text{Ar}_2\text{C(Ar)OH}
\]

Organolithium reagents are also valuable in the synthesis of other organometallic compounds via metal–halogen exchange:

\[
3\text{LiR} + \text{BCl}_3 \rightarrow 3\text{LiCl} + \text{BR}_3
\]

\[
(4 - x)\text{LiR} + \text{SnCl}_4 \rightarrow (4 - x)\text{LiCl} + \text{SnCl}_x\text{R}_{4-x} \quad (1 \leq x \leq 4)
\]

\[
3\text{LiAr} + \text{P(OEt)}_3 \rightarrow 3\text{LiOEt} + \text{PAR}_3
\]

Similar reactions have been used to produce organo derivatives of As, Sb, Bi; Si, Ge and many other elements.
5

Beryllium, Magnesium, Calcium, Strontium, Barium and Radium

5.1 Introduction

The Group 2 or alkaline earth metals exemplify and continue the trends in properties noted for the alkali metals. No new principles are involved, but the ideas developed in the preceding chapter gain emphasis and clarity by their further application and extension. Indeed, there is an impressively close parallelism between the two groups as will become increasingly clear throughout the chapter.

The discovery of beryllium in 1798 followed an unusual train of events. The mineralogist R.-J. Haüy had observed the remarkable similarity in external crystalline structure, hardness and density of a beryl from Limoges and an emerald from Peru, and suggested to L.-N. Vauquelin that he should analyse them to see if they were chemically identical. As a result, Vauquelin showed that both minerals contained not only alumina and silica as had previously been known, but also a new earth, beryllia, which closely resembled alumina but gave no alums, apparently did not dissolve in an excess of KOH (perhaps because it had been fused?) and had a sweet rather than an astringent taste. Caution: beryllium compounds are now known to be extremely toxic, especially as dusts or smokes; it seems likely that this toxicity results from the ability of Be\(^{2+}\) to displace Mg\(^{2+}\) from Mg-activated enzymes due to its stronger coordinating ability.

Both beryl and emerald were found to be essentially \(\text{Be}_3\text{Al}_2\text{Si}_6\text{O}_{18}\), the only difference between them being that emerald also contains \(\sim 2\% \text{ Cr}\), the source of its green colour. The combining weight of Be was \(\sim 4.7\) but the similarity (diagonal relation) between Be and

---

\(\dagger\) A similar observation had been made (with less dramatic consequences) nearly 2000 years earlier by Pliny the Elder when he wrote: “Beryls, it is thought, are of the same nature as the smaragdus (emerald), or at least closely analogous” (Historia Naturalis, Book 37).
A led to considerable confusion concerning the valency and atomic weight of Be (2 × 4.7 or 3 × 4.7); this was not resolved until Mendeleev 70 y later stated that there was no room for a tervalent element of atomic weight 14 near nitrogen in his periodic table, but that a divalent element of atomic weight 9 would fit snugly between Li and B. Beryllium metal was first prepared by F. Wöhler in 1828 (the year he carried out his celebrated synthesis of urea from NH₄CNO); he suggested the name by allusion to the mineral (Latin beryllus from Greek βηρυλλος). The metal was independently isolated in the same year by A.-B. Bussy using the same method — reduction of BeCl₂ with metallic K. The first electrolytic preparation was by P. Lebeau in 1898 and the first commercial process (electrolysis of a fused mixture of BeF₂ and BaF₂) was devised by A. Stock and H. Goldschmidt in 1932. The close parallel with the development of Li technology (pp. 68–70) is notable.

Compounds of Mg and Ca, like those of their Group 1 neighbours Na and K, have been known from ancient times though nothing was known of their chemical nature until the seventeenth century. Magnesian stone (Greek Μαγνησία λιθος) was the name given to the soft white mineral steatite (otherwise called soapstone or talc) which was found in the Magnesia district of Thessally, whereas calcium derives from the Latin calcis — lime. The Romans used a mortar prepared from sand and lime (obtained by heating limestone, CaCO₃) because these lime mortars withstood the moist climate of Italy better than the Egyptian mortars based on partly dehydrated gypsum (CaSO₄·2H₂O); these had been used, for example, in the Great Pyramid of Gizeh, and all the plaster in Tutankhamun’s tomb was based on gypsum. The names of the elements themselves were coined by H. Davy in 1808 when he isolated Mg and Ca, along with Sr and Ba by an electrolytic method following work by J. J. Berzelius and M. M. Pontin: the moist earth (oxide) was mixed with one-third its weight of HgO on a Pt plate which served as anode; the cathode was a Pt wire dipping into a pool of Hg and electrolysis gave an amalgam from which the desired metal could be isolated by distilling off the Hg.

A mineral found in a lead mine near Strontian, Scotland, in 1787 was shown to be a compound of a new element by A. Crawford in 1790. This was confirmed by T. C. Hope the following year and he clearly distinguished the compounds of Ba, Sr and Ca, using amongst other things their characteristic flame colorations: Ba yellow-green, Sr bright red, Ca orange-red. Barium-containing minerals had been known since the seventeenth century but the complex process of unravelling the relation between them was not accomplished until the independent work of C. W. Scheele and J. G. Gahn between 1774 and 1779: heavy spar was found to be BaSO₄ and called barite or barytes (Greek βαρυτής, heavy), whence Scheele’s new base barya (BaO) from which Davy isolated barium in 1808.

Radium, the last element in the group, was isolated in trace amounts as the chloride by P. and M. Curie in 1898 after their historic processing of tonnes of pitchblende. It was named by Mme Curie in allusion to its radioactivity, a word also coined by her (Latin radius, a ray); the element itself was isolated electrolytically via an amalgam by M. Curie and A. Debierne in 1910 and its compounds give a carmine-red flame test.

5.2 The Elements

5.2.1 Terrestrial abundance and distribution

Beryllium, like its neighbours Li and B, is relatively un-abundant in the earth’s crust; it occurs to the extent of about 2 ppm and is thus similar to Sn (2.1 ppm), Eu (2.1 ppm) and As (1.8 ppm). However, its occurrence as surface deposits of beryl in pegmatite rocks (which are the last portions of granite domes to crystallize) makes it readily accessible. Crystals as large as 1 m on edge and weighing up to 60 tonnes have been reported. World reserves in commercial deposits are about 4 million tonnes of contained Be and mined production in 1985–86 was USA
223, USSR 76 and Brazil 37 tonnes of contained Be, which together accounted for 98% of world production. The cost of Be metal was $690/kg in 1987. By contrast, world supplies of magnesium are virtually limitless: it occurs to the extent of 0.13% in sea water, and electrolytic extraction at the present annual rate, if continued for a million years, would only reduce this to 0.12%.

Magnesium, like its heavier congeners Ca, Sr and Ba, occurs in crustal rocks mainly as the insoluble carbonates and sulfates, and (less accessibly) as silicates. Estimates of its total abundance depend sensitively on the geochemical model used, particularly on the relative weightings given to the various igneous and sedimentary rock types, and values ranging from 20,000 to 133,000 ppm are current.\(^3\) Perhaps the most acceptable value is 27,640 ppm (2.76%), which places Mg sixth in order of abundance by weight immediately following Ca (4.66%) and preceding Na (2.27%) and K (1.84%). Large land masses such as the Dolomites in Italy consist predominantly of the magnesium limestone mineral dolomite \([\text{MgCa(CO}_3]_2\), and there are substantial deposits of magnesite (MgCO\(_3\)), epsomite (MgSO\(_4\)\(\cdot\)7H\(_2\)O) and other evaporites such as carnallite (K\(_2\)MgCl\(_4\)\(\cdot\)6H\(_2\)O) and langbeinite [K\(_2\)Mg\(_2\)(SO\(_4\))\(_3\)]. Silicates are represented by the common basaltic mineral olivine \([(\text{Mg,Fe})_2\text{SiO}_4]\) and by soapstone (talc) [Mg\(_3\)Si\(_2\)O\(_{10}\)(OH\(_2\))], asbestos (chrysotile) [Mg\(_3\)Si\(_2\)O\(_5\)(OH\(_4\))], and micas. Spinel (MgAl\(_2\)O\(_4\)) is a metamorphic mineral and gemstone. It should also be remembered that the green leaves of plants, though not a commercial source of Mg, contain chlorophylls which are the Mg-porphine complexes primarily involved in photosynthesis.

Calcium, as noted above, is the fifth most abundant element in the earth's crust and hence the third most abundant metal after Al and Fe. Vast sedimentary deposits of CaCO\(_3\), which represent the fossilized remains of earlier marine life, occur over large parts of the earth's surface. The deposits are of two main types — rhombohedral calcite, which is the more common, and orthorhombic aragonite, which sometimes forms in more temperate seas. Representative minerals of the first type are limestone itself, dolomite, marble, chalk and iceland spar. Extensive beds of the aragonite form of CaCO\(_3\) make up the Bahamas, the Florida Keys and the Red Sea basin. Corals, sea shells and pearls are also mainly CaCO\(_3\). Other important minerals are gypsum (CaSO\(_4\)\(\cdot\)2H\(_2\)O), anhydrite (CaSO\(_4\)), fluorite (CaF\(_2\)); also blue john and fluorspar) and apatite [Ca\(_5\)(PO\(_4\))\(_3\)F].

Strontium (384 ppm) and barium (390 ppm) are respectively the fifteenth and fourteenth elements in order of abundance, being bracketed by S (340 ppm) and F (544 ppm). The most important mineral of Sr is celestite (SrSO\(_4\)), and strontianite (SrCO\(_3\)) is also mined. The largest producers are Mexico, Spain, Turkey and the UK, and the world production of these two minerals in 1985 was 10\(^5\) tonnes. The main uses of Sr compounds, especially SrCO\(_3\), are in the manufacture of special glasses for colour television and computer monitors (53%), for pyrotechnic displays (14%) and magnetic materials (11%). Strontium carbonate and sulfate are critical raw materials for the USA which is totally dependent on imports for supplies. The sulfate (barite) is also the most important mineral of Ba: it is mined commercially in over 40 countries throughout the world. Production in 1985 was 6.0 million tonnes, of which 44% was mined in the USA. The major use of BaSO\(_4\) (92%) is as a heavy mud slurry in well drilling; production of Ba chemicals accounts for only 7%.

Radium occurs only in association with uranium (Chapter 31); the observed ratio \(^{226}\text{Ra}/U\) is \(\sim 1\) mg per 3 kg, leading to a terrestrial abundance for Ra of \(\sim 10^{-6}\) ppm. As uranium ores normally contain only a few hundred ppm of U, it follows that about 10 tonnes of ore must be processed for 1 mg Ra. The total amount of Ra available worldwide is of the order of a few kilograms, but its use in cancer therapy has been superseded by the use of other isotopes, and the

annual production of separated Ra compounds is probably now only about 100 g. Chief suppliers are Belgium, Canada, Czechoslovakia, the UK, and the former Soviet Union. $^{226}\text{Ra}$ decays by $\alpha$-emission with a half-life of 1600 y, although 3 in every $10^{11}$ decays occur by $^{14}\text{C}$ emission ($^{226}\text{Ra} \rightarrow ^{212}\text{Pb} + ^{14}\text{C}$). This exceedingly rare form of radioactivity was discovered in 1984 in the rare naturally occurring radium isotope $^{223}\text{Ra}$ where about 1 in $10^9$ of the atoms decays by $^{14}\text{C}$ rather than $\alpha$-emission.\(^4\)

5.2.2 Production and uses of the metals \(^5\)

Beryllium is extracted from beryl by roasting the mineral with $\text{Na}_2\text{SiF}_6$ at 700–750°C, leaching the soluble fluoride with water and then precipitating $\text{Be(OH)}_2$ at about pH 12. The metal is usually prepared by reduction of $\text{BeF}_2$ (p. 116) with $\text{Mg}$ at about 1300°C or by electrolysis of fused mixtures of $\text{BeCl}_2$ and alkali metal chlorides. It is one of the lightest metals known and has one of the highest mps of the light metals. Its modulus of elasticity is one-third greater than that of steel. The largest use of Be is in high-strength alloys of Cu and Ni (see Panel below).

Magnesium is produced on a large scale (400 000 tonnes in 1985) either by electrolysis or silicothermal reduction. The major producers are the USA (43%), the former Soviet Union (26%), and Norway (17%). The electrolytic process uses either fused anhydrous $\text{MgCl}_2$ at 750°C or partly hydrated $\text{MgCl}_2$ from sea water at a slightly lower temperature. The silicothermal process uses calcined dolomite and ferrosilicon alloy under reduced pressure at 1150°C:

$$2(\text{MgO.CaO}) + \text{FeSi} \rightarrow 2\text{Mg} + \text{Ca}_2\text{SiO}_4 + \text{Fe}$$

Magnesium is industry’s lightest constructional metal, having a density less than two-thirds that of Al (see Panel on the next page). The price of the metal (99.8% purity) was $3.4/kg in 1994.

The other alkaline earth metals Ca, Sr and Ba are produced on a much smaller scale than Mg. Calcium is produced by electrolysis of fused $\text{CaCl}_2$ (obtained either as a byproduct of the Solvay process (p. 71) or by the action of $\text{HCl}$ or $\text{CaCO}_3$). It is less reactive than Sr or Ba, forming a protective oxide-nitride coating in air which enables it to be machined in a lathe or handled by other standard metallurgical techniques. Calcium metal is used mainly as an alloying agent to strengthen Al bearings, to control graphitic C in cast-iron and to remove Bi from Pb. Chemically it is used as a scavenger in the steel industry (O, S and P), as a getter for oxygen and nitrogen, to remove $\text{N}_2$ from argon and as a reducing agent in the production of other metals such as Cr, Zr, Th and U. Calcium also reacts directly with $\text{H}_2$ to give $\text{CaH}_2$, which is a useful source of $\text{H}_2$. World production of

---

**Uses of Beryllium Metal and Alloys**

The ability of Be to age-harden Cu was discovered by M. G. Corson in 1926 and it is now known that ~2% of Be increases the strength of Cu sixfold. In addition, the alloys (which also usually contain 0.25% Co) have good electrical conductivity, high strength, unusual wear resistance, and resistance to anelastic behaviour (hysteresis, damping, etc.): they are non-magnetic and corrosion resistant, and find numerous applications in critical moving parts of aero-engines, key components in precision instruments, control relays and electronics. They are also non-sparking and are thus of great use for hand tools in the petroleum industry. A nickel alloy containing 2% Be is used for high-temperature springs, clips, bellows and electrical connections. Another major use for Be is in nuclear reactors since it is one of the most effective neutron moderators and reflectors known. A small, but important, use of Be is as a window material in X-ray tubes: it transmits X-rays 17 times better than Al and 8 times better than Lindemann glass. A mixture of compounds of radium and beryllium has long been used as a convenient laboratory source of neutrons and, indeed, led to the discovery of the neutron by J. Chadwick in 1932. \(^9\)\text{Be}(\alpha,n)^{12}\text{C}$. 
Magnesium Metal and Alloys

The principal advantage of Mg as a structural metal is its low density (1.7 g cm\(^{-3}\) compared with 2.70 for Al and 7.80 for steel). For equal strength, the best Mg alloy weighs only a quarter as much as steel, and the best Al alloy weighs about one-third as much as steel. In addition, Mg has excellent machinability and it can be cast or fabricated by any of the standard metallurgical methods (rolling, extruding, drawing, forging, welding, brazing or riveting). Its major use therefore is as a lightweight construction metal, not only in aircraft but also in luggage, photographic and optical equipment, etc. It is also used for cathodic protection of other metals from corrosion, as an oxygen scavenger, and as a reducing agent in the production of Be, Ti, Zr, Hf and U. World production approaches 400 000 tonnes pa.

Magnesium alloys typically contain >90% Mg together with 2–9% Al, 1–3% Zn and 0.2–1% Mn. Greatly improved retention of strength at high temperature (up to 450°C) is achieved by alloying with rare-earth metals (e.g. Pr/Nd) or Th. These alloys can be used for automobile engine casings and for aeroplane fuselages and landing wheels. Other uses are in lightweight tread-plates, dock-boards, loading platforms, gravity conveyors and shovels.

Up to 5% Mg is added to most commercial Al to improve its mechanical properties, weldability and resistance to corrosion.

The metal is about 2500 tonnes pa of which >50% was in the USA (price $5.00–8.00/kg in 1991).

Metallic Sr and Ba are best prepared by high-temperature reduction of their oxides with Al in an evacuated retort or by small-scale electrolysis of fused chloride baths. They have limited use as getters, and a Ni–Ba alloy is used for spark-plug wire because of its high emissivity. Annual production of Ba metal is about 20–30 tonnes worldwide and the 1991 price about $80–140/kg depending on quality.

5.2.3 Properties of the elements

Table 5.1 lists some of the atomic properties of the Group 2 elements. Comparison with the data for Group 1 elements (p. 75) shows the substantial increase in the ionization energies; this is related to their smaller size and higher nuclear charge, and is particularly notable for Be. Indeed, the "ionic radius" of Be is purely a notional figure since no compounds are known in which uncoordinated Be has a 2+ charge. In aqueous solutions the reduction potential of

\(^{(c)}\) Four-coordinate.
Be is much less than that of its congeners, again indicating its lower electropositivity. By contrast, Ca, Sr, Ba and Ra have reduction potentials which are almost identical with those of the heavier alkali metals; Mg occupies an intermediate position.

Be and Mg are silvery white metals whereas Ca, Sr and Ba are pale yellow (as are the divalent rare earth metals Eu and Yb) although the colour is less intense than for Cs (p. 74). All the alkaline earth metals are lustrous and relatively soft, and their physical properties (Table 5.2), when compared with those of Group 1 metals, show that they have a substantially higher mp, bp, density and enthalpies of fusion and vaporization. This can be understood in terms of the size factor mentioned in the preceding paragraph and the fact that 2 valency electrons per atom are now available for bonding. Again, Be is notable in melting more than 1100° above Li and being nearly 3.5 times as dense; its enthalpy of fusion is more than 5 times that of Li. Beryllium resembles Al in being stable in moist air due to the formation of a protective oxide layer, and highly polished specimens retain their shine indefinitely. Magnesium also resists oxidation but the heavier metals tarnish readily. Beryllium, like Mg and the high-temperature form of Ca (>450°C), crystallizes in the hcp arrangement, and this confers a marked anisotropy on its properties; Sr is fcc, Ba and Ra are bcc like the alkali metals.

### 5.2.4 Chemical reactivity and trends

Beryllium metal is relatively unreactive at room temperature, particularly in its massive form. It does not react with water or steam even at red heat and does not oxidize in air below 600°C, though powdered Be burns brilliantly on ignition to give BeO and Be₃N₂. The halogens (X₂) react above about 600°C to give BeX₂ but the chalcogens (S, Se, Te) require even higher temperatures to form BeS, etc. Ammonia reacts above 1200°C to give Be₃N₂ and carbon forms BeC at 1700°C. In contrast with the other Group 2 metals, Be does not react directly with hydrogen, and BeH₂ must be prepared indirectly (p. 115). Cold, concentrated HNO₃ passivates Be but the metal dissolves readily in dilute aqueous acids (HCl, H₂SO₄, HNO₃) with evolution of hydrogen. Beryllium is sharply distinguished from the other alkaline earth metals in reacting with aqueous alkalies (NaOH, KOH) with evolution of hydrogen. It also dissolves rapidly in aqueous NH₄HF₂ (as does Be(OH)₂), a reaction of some technological importance in the preparation of anhydrous BeF₂ and purified Be:

\[ 2\text{NH}_4\text{HF}_2(aq) + \text{Be}(s) \rightarrow (\text{NH}_4)_2\text{BeF}_4 + \text{H}_2(g) \]

\[ (\text{NH}_4)_2\text{BeF}_4(s) \xrightarrow{280^\circ} \text{BeF}_2(s) + 2\text{NH}_4\text{F}(\text{subl}) \]

Magnesium is more electropositive than the amphoteric Be and reacts more readily with most of the non-metals. It ignites with the halogens, particularly when they are moist, to give MgX₂, and burns with dazzling brilliance in air to give MgO and Mg₃N₂. It also reacts directly with the other elements in Groups 15 and 16 (and Group 14) when heated and even forms MgH₂ with hydrogen at 570° and 200 atm. Steam produces MgO (or Mg(OH)₂) plus H₂, and ammonia reacts at elevated temperature to give Mg₃N₂. Methanol reacts at 200° to give Mg(OMe)₂ and ethanol (when activated

§5.3 Compounds

5.3.1 Introduction

The predominant divalence of the Group 2 metals can be interpreted in terms of their electronic configuration, ionization energies, and size (see Table 5.1). Further ionization to give simple salts of stoichiometry MX₃ is precluded by the magnitude of the energies involved, the third stage ionization being 14 849 kJ mol⁻¹ for Be, 7733 kJ mol⁻¹ for Mg and 4912 kJ mol⁻¹ for Ca; even for Ra the estimated value of 3281 kJ mol⁻¹ involves far more energy than could be recovered by additional bonding even if this were predominantly covalent. Reasons for the absence of univalent compounds MX are less obvious. The first-stage ionization energies for Ca, Sr, Ba and Ra are similar to that of Li (p. 75) though the larger size of the hypothetical univalent Group 2 ions, when compared to Li, would reduce the lattice energy somewhat (p. 82). By making plausible assumptions about the ionic radius and structure we can estimate the approximate enthalpy of formation of such compounds and they are predicted to be stable with respect to the constituent elements; their non-existence is related to the much higher enthalpy of formation of the conventional compounds MX₂, which leads to rapid and complete disproportionation. For example, the standard enthalpy of formation of hypothetical crystalline MgCl₂, assuming the NaCl structure, is $\Delta H_f = -125$ kJ mol⁻¹, which is substantially greater than for many known stable compounds and essentially the same as the experimentally observed value for AgCl: $\Delta H_f = -127$ kJ mol⁻¹. However, the corresponding (experimental) value for $\Delta H_f(MgCl₂)$ is $-642$ kJ mol⁻¹, whence an enthalpy of disproportionation of

$$\begin{align*}
2Mg(c) + Cl_2(g) &\rightarrow 2MgCl(c); \\
\Delta H_f = -642 \text{ kJ/(mol of MgCl}_2) \\
\end{align*}$$

$$\begin{align*}
2MgCl(c) &\rightarrow Mg(c) + MgCl_2(c); \\
\Delta H_{\text{disprop}} = -392 \text{ kJ/(2 mol of MgCl)} \\
\end{align*}$$

It is clear that, if synthetic routes could be devised which would mechanistically hinder disproportionation, such compounds might be preparable. Although univalent compounds of the Group 2 metals have not yet been isolated, there is some evidence for the formation of Mg¹ species during electrolysis with Mg electrodes. Thus H₂ is evolved at the anode when an aqueous solution of NaCl is electrolysed and the amount of Mg lost from the anode corresponds to an oxidation state of 1.3. Similarly, when aqueous Na₂SO₄ is electrolysed, the amount of H₂ evolved corresponds to the oxidation by water of Mg ions having an average oxidation state of 1.4:

$$Mg^{1.4+}(aq) + 0.6H_2O \rightarrow Mg^{2+}(aq) + 0.6OH^-(aq) + 0.3H_2(g)$$
On the basis of the discussion on pp. 79–81 the elements in Group 2 would be expected to deviate further from simple ionic bonding than do the alkali metals. The charge on $M^{2+}$ is higher and the radius for corresponding ions is smaller, thereby inducing more distortion of the surrounding anions. This is reflected in the decreased thermal stability of oxoacid salts such as nitrates, carbonates and sulfates. For example, the temperature at which the carbonate reaches a dissociation pressure of 1 atm $CO_2$ is: $BeCO_3 \ 250^\circ$, $MgCO_3 \ 540^\circ$, $CaCO_3 \ 900^\circ$, $SrCO_3 \ 1289^\circ$, $BaCO_3 \ 1360^\circ$. The tendency towards covalency is greatest with Be, and this element forms no compounds in which the bonding is predominantly ionic. For similar reasons Be (and to a lesser extent Mg) forms numerous stable coordination compounds; organometallic compounds are also well characterized, and these frequently involve multicentre (electron deficient) bonding similar to that found in analogous compounds of Li and B.

Many compounds of the Group 2 elements are much less soluble in water than their Group 1 counterparts. This is particularly true for the fluorides, carbonates and sulfates of the heavier members, and is related to their higher lattice energies. These solubility relations have had a profound influence on the mineralization of these elements as noted on p. 109. The ready solubility of $BeF_2$ (~20 000 times that of $CaF_2$) is presumably related to the very high solvation enthalpy of Be to give $[Be(H_2O)_4]^{2+}$.

Beryllium, because of its small size, almost invariably has a coordination number of 4. This is important in analytical chemistry since it ensures that edta, which coordinates strongly to Mg, Ca (and Al), does not chelate Be appreciably. BeO has the wurtzite (ZnS, p. 1209) structure whilst the other Be chalcogenides adopt the zinc blende modification. $BeF_2$ has the cristobalite (SiO$_2$, p. 342) structure and has only a very low electrical conductivity when fused. $Be_2C$ and $Be_2B$ have extended lattices of the antifluorite type with 4-coordinate Be and 8-coordinate C or B. $Be_2SiO_4$ has the phenacite structure (p. 347) in which both Be and Si are tetrahedrally coordinated, and $Li_2BeF_4$ has the same structure. $[Be(H_2O)_4]SO_4$ features a tetrahedral aquo-ion which is H bonded to the surrounding sulfate groups in such a way that $Be-O$ is 161 pm and the $O-H \cdots O$ are 262 and 268 pm. Further examples of tetrahedral coordination to Be are to be found in later sections. Other configurations, involving linear (two-fold) coordination (e.g. $BeBu_2^\circ$) or trigonal coordination [e.g. cyclic (Me$BeNMMe_2)_2$] are rare and most compounds which might appear to have such coordination (e.g. $BeMe_2$, $CsBeF_3$, etc.) achieve 4-coordination by polymerization. However $K_2BeO_2$, $Y_2BeO_4$ and one or two more complex structures do indeed contain trigonal planar ($BeO_3$) units with $Be-O$ ca. 155 pm, i.e. some 11 pm shorter than in tetrahedral ($BeO_4$). Likewise, $K_4BeE_2$ (E = P, As, Sb) feature linear anions $[E-Be-EI_4]$ iso-electronic with $BeCl_2$ molecules (p. 117). (See also p. 123). Six-coordination has been observed in $K_3Zr_6Cl_{15}Be$ and $Be_3Zr_6Cl_{18}Be$, in which the Be atom is encapsulated by and contributes two bonding elections to the octahedral $Zr_6$ cluster. (10) Trigonal-pyramidal

---

6-fold coordination of Be by H is found in Be(BH₄)₂ (p. 116).

The stereochemistry of Mg and the heavier alkaline earth metals is more flexible than that of Be and, in addition to occasional compounds which feature low coordination numbers (2, 3 and 4), there are many examples of 6, 8 and 12 coordination, some with 7, 9 or 10 coordination, and even some with coordination numbers as high as 22 or 24, as in SrCd₁₁, BaCd₁₁ and (Ca, Sr or Ba)Zn₁₃.¹¹ Strontium is 5-coordinate on the hemisolvate [Sr(OC₆H₄Bu:₂)(thf)₃]₁/₂thf which features a distorted trigonal bipyramidal structure with the two aryloxides in equatorial positions.¹¹a

5.3.2 Hydrides and halides

Many features of the structure, bonding and stability of the Group 2 hydrides have already been discussed (p. 65) and it is only necessary to add some comments on BeH₂, which is the most difficult of these compounds to prepare and the least stable. BeH₂ (contaminated with variable amounts of ether) was first prepared in 1951 by reduction of BeCl₂ with LiH and by the reaction of BeMe₂ with LiAlH₄. A purer sample can be made by pyrolysis of BeBu₁ at 210°C and the best product is obtained by displacing BH₃ from BeB₂H₅ using P₃Ph₃ in a sealed tube reaction at 180°C:

\[
\text{BeB}_2\text{H}_5 + 2\text{PPh}_3 \rightarrow 2\text{PPh}_3\text{BH}_3 + \text{BeH}_2
\]

BeH₂ is an amorphous white solid (d 0.65 g cm⁻³) which begins to evolve hydrogen when heated above 250°; it is moderately stable in air or water but is rapidly hydrolysed by acids, liberating H₂. A hexagonal crystalline form (d 0.78 g cm⁻³) has been prepared by compaction fusion at 6.2 kbar and 130° in the presence of ~1% Li as catalyst.¹² In all forms BeH₂ appears to be highly polymerized by means of BeH₃Be₃-centre bonds and its structure is probably similar to that of crystalline BeCl₂ and BeMe₂ (see below). A related compound is the volatile mixed hydride BeB₂H₈, which is readily prepared (in the absence of solvent) by the reaction of BeCl₂ with LiBH₄ in a sealed tube:

\[
\text{BeCl}_2 + 2\text{LiBH}_4 \xrightarrow{120°C} \text{BeB}_2\text{H}_8 + 2\text{LiCl}
\]

BeB₂H₈ inflames in air, reacts almost explosively with water and reacts with dry HCl even at low temperatures:

\[
\text{BeB}_2\text{H}_8 + 2\text{HCl} \rightarrow \text{BeCl}_2 + \text{B}_2\text{H}_6 + 2\text{H}_2
\]

The structure of this compound has proved particularly elusive and at least nine different structures have been proposed; it therefore affords an instructive example of the difficulties which attend the use of physical techniques for the structural determination of compounds in the gaseous, liquid or solution phases. In the gas phase it now seems likely that more than one species is present¹³ and the compound certainly shows fluxional behaviour which makes all the hydrogen atoms equivalent on the nmr time scale.¹⁴ A linear structure such as (a), with possible admixture of singly bridged B–H–B and triply bridged BeH₃B variants is now favoured, after a period in which triangular structures such as (b) had been vigorously canvassed. Even structure (c), which features planar 3-coordinate Be, had been advocated because it was thought to fit best much of the infrared and electron diffraction data and also accounted for the ready formation of adducts (d) with typical ligands such as Et₂O, thf, R₃N, R₃P, etc. In the solid state the structure has recently been established with some certainty by single-crystal X-ray analysis.¹⁵ BeB₂H₈ consists of helical polymers of BH₄⁻Be

Anhydrous beryllium halides cannot be obtained from reactions in aqueous solutions because of the formation of hydrates such as $[\text{Be}(\text{H}_2\text{O})_4]\text{F}_2$ and the subsequent hydrolysis which attends attempted dehydration. Thermal decomposition of $(\text{NH}_4)_2\text{BeF}_4$ is the best route for $\text{BeF}_2$, and $\text{BeCl}_2$ is conveniently made from the oxide

$$\text{BeO} + \text{C} + \text{Cl}_2 \xrightarrow{600-800^\circ} \text{BeCl}_2 + \text{CO}$$

$\text{BeCl}_2$ can also be prepared by direct high-temperature chlorination of metallic $\text{Be}$ or $\text{Be}_2\text{C}$, and these reactions are also used for the bromide and iodide. $\text{BeF}_2$ is a glassy material that is difficult to crystallize; it consists of a random network of 4-coordinate F-bridged $\text{Be}$ atoms similar to the structure of vitreous silica, $\text{SiO}_2$. Above 270°, $\text{BeF}_2$ spontaneously crystallizes to give the quartz modification (p. 342) and, like quartz, it exists in a low-temperature $\alpha$-form which transforms to the $\beta$-form at 227°; cristobalite and tridymite forms (p. 343) have also been prepared. The structural similarities between $\text{BeF}_2$ and $\text{SiO}_2$ extend to fluoroberyllates and silicates, and numerous parallels have been drawn: e.g. the phase diagram, compounds, and structures in the system $\text{NaF}-\text{BeF}_2$ resemble those for $\text{CaO}-\text{SiO}_2$; the system $\text{CaF}_2-\text{BeF}_2$ resembles $\text{ZrO}_2-\text{SiO}_2$; the compound $\text{KZnBe}_3\text{F}_9$ is isostructural with benitoite, $\text{BaTiSi}_3\text{O}_9$, etc.

$\text{BeCl}_2$ has an unusual chain structure (a) which can be cleaved by weak ligands such as $\text{Et}_2\text{O}$ to give 4-coordinate molecular complexes $\text{L}_2\text{BeCl}_2$ (b); stronger donors such as $\text{H}_2\text{O}$ or $\text{NH}_3$ lead
to ionic complexes $[\text{BeL}_4]^{2+}[\text{Cl}]^{-2}$ (c). In all these forms Be can be considered to use the $s$, $p_x$, $p_y$ and $p_z$ orbitals for bonding; the ClBeCl angle is substantially less than the tetrahedral angle of $109^\circ$ probably because this lessens the repulsive interaction between neighbouring Be atoms in the chain by keeping them further apart and also enables a wider angle than $71^\circ$ to be accommodated at each Cl atom, consistent with its predominant use of two p orbitals. The detailed interatomic distances and angles therefore differ significantly from those in the analogous chain structure BeMe$_2$ (p. 128), which is best described in terms of 3-centred "electron-deficient" bonding at the Me groups, leading to a BeCBe angle of $66^\circ$ and a much closer approach of neighbouring Be atoms (209 pm). In the vapour phase BeCl$_2$ tends to form a bridged sp$^2$ dimer (d) and dissociation to the linear (sp) monomer (e) is not complete below about $900^\circ$; in contrast, BeF$_2$ is monomeric and shows little tendency to dimerize in the gas phase.

The shapes of the monomeric molecules of the Group 2 halides (gas phase or matrix isolation) pose some interesting problems for those who are content with simple theories of bonding and molecular geometry. Thus, as expected on the basis of either sp hybridization or the VSEPR model, the dihalides of Be and Mg and the heavier halides of Ca and Sr are essentially linear. However, the other dihalides are appreciably bent, e.g. CaF$_2$ $\sim 145^\circ$, SrF$_2$ $\sim 120^\circ$, BaF$_2$ $\sim 108^\circ$; SrCl$_2$ $\sim 130^\circ$, BaCl$_2$ $\sim 115^\circ$; BaBr$_2$ $\sim 115^\circ$; BaI$_2$ $\sim 105^\circ$. The uncertainties on these bond angles are often quite large ($\pm 10^\circ$) and the molecules are rather flexible, but there seems little doubt that the equilibrium geometry is substantially non-linear. This has been interpreted in terms of sd (rather than sp) hybridization$^{(16)}$ or by a suitable \textit{ad hoc} modification of the VSEPR theory$^{(17)}$.

The \textit{crystal} structures of the halides of the heavier Group 2 elements also show some interesting trends (Table 5.3). For the fluorides, increasing size of the metal enables its

$^{(a)}$For description of these structures see: quartz (p. 342), rutile (p. 961), CdCl$_2$ (p. 1212), CdI$_2$ (p. 1212), PbCl$_2$ (p. 382); the fluorite, BeCl$_2$-chain and SrI$_2$ structures are described in this subsection.
The most important fluoride of the alkaline earth metals is CaF₂ since this mineral (fluorspar) is the only large-scale source of fluorine (p. 795). Annual world production now exceeds 5 million tonnes the principal suppliers (in 1984) being Mexico (15%), Mongolia (15%), China (14%), USSR (13%) and South Africa (7%). The largest consumer is the USA, though 85% of its needs must be imported. CaF₂ is a white, high-melting (1418°C) solid whose low solubility in water permits quantitative analytical precipitation. The other fluorides (except BeF₂) are also high-melting and rather insoluble. By contrast, the chlorides tend to be deliquescent and to have much lower mps (715–960°C); they readily form numerous hydrates and are soluble in alcohols. MgCl₂ is one of the most important salts of Mg industrially (p. 110) and its concentration in sea water is exceeded only by NaCl. CaCl₂ is also of great importance, as noted earlier; its production in the US is in the megatonne region and its 1990 price was: bulk $182/tonne, granules $360/tonne, i.e. 36 cents/kg. Its traditional uses include:

(a) brine for refrigeration plants (and for filling inflated tires of tractors and earth-moving equipment to increase traction);
(b) control of snow and ice on highways and pavements (sidewalks) — the CaCl₂–H₂O eutectic at 30 wt% CaCl₂ melts at −55°C (compared with NaCl–H₂O at −18°C);
(c) dust control on secondary roads, unpaved streets, and highway shoulders;
(d) freeze-proofing of coal and ores in shipping and stock piling;
(e) use in concrete mixes to give quicker initial set, higher early strength, and greater ultimate strength.

The bromides and iodides continue the trends to lower mps and higher solubilities. 

---

in water and their ready solubility in alcohols, ethers, etc., is also notable; indeed, MgBr₂ forms numerous crystalline solvates such as MgBr₂.₆ROH (R = Me, Et, Pr), MgBr₂.₆Me₂CO, MgBr₂.₃Et₂O, in addition to numerous ammines MgBr₂ₙNH₃ (ₙ = 2–6). The ability of Group 2 cations to form coordination complexes is clearly greater than that of Group 1 cations (p. 90).

Alkaline earth salts MHX, where M = Ca, Sr or Ba and X = Cl, Br or I can be prepared by fusing the hydride MH₂ with the appropriate halide MX₂ or by heating M + MX₂ in an atmosphere of H₂ at 900°. These hydride halides appear to have the PbClF layer lattice structure though the H atoms were not directly located. The analogous compounds of Mg have proved more elusive and the preceding preparative routes merely yield physical mixtures. However, MgClH and MgBrH can be prepared as solvated dimers by the reaction of specially activated MgH₂ with MgX₂ in thf:

\[
\text{MgR}_2 + \text{LiAlH}_4 \rightarrow \text{MgH}_2 + \text{LiAlH}_2\text{R}_2
\]

\[
\text{MgH}_2 + \text{MgX}_2 \rightarrow [\text{HMgX(thf)}]_2
\]

The chloride can be crystallized but the bromide disproportionates. On the basis of mol wt and infrared spectroscopic evidence the proposed structure is:

5.3.3 Oxides and hydroxides (¹⁹,²⁰)

The oxides MO are best obtained by calcining the carbonates (pp. 114 and 122); dehydration of the hydroxides at red heat offers an alternative route. BeO (like the other Be chalcogenides) has the wurtzite structure (p. 1210) and is an excellent refractory, combining a high mp (2507°C) with negligible vapour pressure below this temperature; it has good chemical stability and a very high thermal conductivity which is greater than that of any other non-metal and even exceeds that of some metals. The other oxides in the group all have the NaCl structure and this structure is also adopted by the chalcogenides (except MgTe which has the wurtzite structure). Lattice energies and mps are again very high: MgO mp 2832°, CaO 2627°, SrO 2665°, BaO 1913°C (all ± ca. 30°). The compounds are comparatively unreactive in bulk but their reactivity increases markedly with decrease in particle size and increase in atomic weight. Notable reactions (which reverse those used to prepare the oxides) are with CO₂ and with H₂O. MgO is extensively used as a refractory; like BeO it is unusual in being both an excellent thermal conductor and a good electrical insulator, thus finding widespread use as the insulating radiator in domestic heating ranges and similar appliances. CaO (lime) is produced on an enormous scale in many countries and, indeed, is one of the half-dozen largest tonnage industrial chemicals to be manufactured (see Panel on p. 120). Production in 1991 exceeded 16 million tonnes in the USA alone. Its major end uses (in descending tonnages) are as a flux in steel manufacture; in the production of Ca chemicals; in the treatment of municipal water supplies, industrial wastes and sewage; in mortars and cements; in the pulp and paper industries; and in non-ferrous metal production. Price for bulk quantities is ~$45 per tonne.

In addition to the oxides MO, peroxides MO₂ are known for the heavier alkaline earth metals and there is some evidence for yellow superoxides M(O₂)₂ of Ca, Sr and Ba; impure ozonides Ca(O₃)₂ and Ba(O₃)₂ have also been reported. (²¹) As with the alkali metals, stability

Industrial Uses of Limestone and Lime

Limestone rock is the commonest form of calcium carbonate, which also occurs as chalk, marble, corals, calcite, aragonite, etc., and (with Mg) as dolomite. Limestone and dolomite are widely used as building materials and road aggregate and both are quarried on a vast scale worldwide. CaCO₃ is also a major industrial chemical and is indispensable as the precursor of quick lime (CaO) and slaked lime, Ca(OH)₂. These chemicals are crucial to large sections of the chemical, metallurgical and construction industries, as noted below, and are produced on a scale exceeded by very few other materials. Thus, world production of lime exceeds 110 million tonnes, and even this is dwarfed by Portland cement (793 million tonnes in 1984) which is made by roasting limestone and sand with clay (p. 252).

Large quantities of lime are consumed in the steel industry where it is used as a flux to remove P, S, Si and to a lesser extent Mn. The basic oxygen steel process typically uses 75 kg lime per tonne of steel, or a rather larger quantity (100-300 kg) of dolomitic quick lime, which markedly extends the life of the refractory furnace linings. Lime is also used as a lubricant in steel wire drawing and in neutralizing waste sulfuric-acid-based pickling liquors. Another metallurgical application is in the production of Mg (p. 110): the ferro-silicon (Pidgeon) process (1) uses dolomitic lime and both of the Dow electrolytic methods (2), (3), also require lime.

\[
2(CaO, MgO) + Si/Fe \rightarrow 2Mg + Ca₂SiO₄/Fe \tag{1}
\]

\[
CaO.MgO + CaCl₂·MgCl₂(brine) + CO₂ \rightarrow 2CaCO₃ + 2MgCl₂ \text{ (then electrolysis)} \tag{2}
\]

\[
\text{Ca(OH)₂} + \text{MgCl₂ (seawater)} \rightarrow \text{Mg(OH)₂} + \text{CaCl₂}
\]

\[
\text{Mg(OH)₂} + 2\text{HCl} \rightarrow 2\text{H₂O} + \text{MgCl₂ (then electrolysis)} \tag{3}
\]

Lime is the largest tonnage chemical used in the treatment of potable and industrial water supplies. In conjunction with alum or iron salts it is used to coagulate suspended solids and remove turbidity. It is also used in water softening to remove temporary (bicarbonate) hardness. Typical reactions are:

\[
\text{Ca(HCO₃)₂} + \text{Ca(OH)₂} \rightarrow 2\text{CaCO₃}↓ + 2\text{H₂O}
\]

\[
\text{Mg(HCO₃)₂} + \text{Ca(OH)₂} \rightarrow \text{MgCO₃}↓ + \text{CaCO₃}↓ + 2\text{H₂O}
\]

\[
\text{MgCO₃} + \text{Ca(OH)₂} \rightarrow \text{Mg(OH)₂}↓ + \text{CaCO₃}↓ etc.
\]

The neutralization of acid waters (and industrial wastes) and the maintenance of optimum pH for the biological oxidation of sewage are further applications. Another major use of lime is in scrubbers to remove SO₂/H₂S from stack gases of fossil-fuel-powered generating stations and metallurgical smelters.

The chemical industry uses lime in the manufacture of calcium carbide (for acetylene, p. 297), cyanamide (p. 323), and numerous other chemicals. Glass manufacturing is also a major consumer, most common glasses having ~12% CaO in their formulation. The insecticide calcium arsenate, obtained by neutralizing arsenic acid with lime, is much used for controlling the cotton boll weevil, codling moth, tobacco worm, and Colorado potato beetle. Lime-sulfur sprays and Bordeaux mixtures [(CaSO₄/Ca(OH)₂)] are important fungicides.

The paper and pulp industries consume large quantities of Ca(OH)₂ and precipitated (as distinct from naturally occurring) CaCO₃. The largest application of lime in pulp manufacture is as a causticizing agent in sulfate (kraft) plants (p. 89). Here the waste Na₂CO₃ solution is reacted with lime to regenerate the caustic soda used in the process:

\[
\text{Na₂CO₃} + \text{CaO} + \text{H₂O} \rightarrow \text{CaCO₃} + 2\text{NaOH}
\]

About 95% of the CaCO₃ mud is dried and recalcined in rotary kilns to recover the CaO. Calcium hypochlorite bleaching liquor (p. 860) for paper pulp is obtained by reacting lime and Cl₂.

The manufacture of high quality paper involves the extensive use of specially precipitated CaCO₃. This is formed by calcining limestone and collecting the CO₂ and CaO separately; the latter is then hydrated and recarbonated to give the desired product. The type of crystals obtained, as well as their size and habit, depend on the temperature, pH, rate of mixing, concentration and presence of additives. The fine crystals (<45 µm) are often subsequently coated with fatty acids, resins and wetting agents to improve their flow properties. US prices (1991) range from 5-45 cents per kg depending on grade and the amounts consumed are immense, e.g. 5.9 million tonnes p.a. in the USA alone. CaCO₃ adds brightness, opacity, ink receptivity and smoothness to paper and, in higher concentration, counteracts the high gloss produced by kaolin additives and produces a matte or dull finish which is particularly popular for textbooks. Such papers may contain 5-50% by weight of precipitated CaCO₃. The compound is also used as a filler in rubbers, latex, wallpaints and enamels, and in plastics (~10% by weight) to improve their heat resistance, dimensional stability, stiffness, hardness and processability.

Panel continues

---

Domestic and pharmaceutical uses of precipitated CaCO₃ include its direct use as an antacid, a mild abrasive in toothpastes, a source of Ca enrichment in diets, a constituent of chewing gum and a filler in cosmetics.

In the dairy industry lime finds many uses. Lime water is often added to cream when separated from whole milk, in order to reduce its acidity prior to pasteurization and conversion to butter. The skimmed milk is then acidified to separate casein which is mixed with lime to produce calcium caseinate glue. Fermentation of the remaining skimmed milk (whey) followed by addition of lime yields calcium lactate which is used as a medicinal or to produce lactic acid on reacidification. Likewise the sugar industry relies heavily on lime: the crude sugar juice is reacted with lime to precipitate calcium sucrose which permits purification from phosphatic and organic impurities. Subsequent treatment with CO₂ produces insoluble CaCO₃ and purified soluble sucrose. The cycle is usually repeated several times; cane sugar normally requires \( \sim 3-5 \) kg lime per tonne but beet sugar requires 100 times this amount i.e. \( \sim \frac{1}{4} \) tonne lime per tonne of sugar.

Increases with electropositive character and size: no peroxide of Be is known; anhydrous MgO₂ can only be made in liquid NH₃ solution, aqueous reactions leading to various peroxide hydrates; CaO₂ can be obtained by dehydrating CaO₂.₈H₂O but not by direct oxidation, whereas SrO₂ can be synthesized directly at high oxygen pressures and BaO₂ forms readily in air at 500°C. Reactions with aqueous reagents are as expected, and the compounds can be used as oxidizing agents and bleaches:

\[
\begin{align*}
\text{CaO}_2(s) + \text{H}_2\text{SO}_4(aq) & \rightarrow \text{CaSO}_4(s) + \text{H}_2\text{O}_2(aq) \\
\text{Ca}(\text{O}_2)_2 + \text{H}_2\text{SO}_4(aq) & \rightarrow \text{CaSO}_4(s) + \text{H}_2\text{O}_2(aq) + \text{O}_2(g)
\end{align*}
\]

MgO₂ has the pyrite structure (p. 680) and the Ca, Sr and Ba analogues have the CaC₂ structure (p. 298).

The hydroxides of Group 2 elements show a smooth gradation in properties, with steadily increasing basicity, solubility, and heats of formation from the corresponding oxide. Be(OH)₂ is amphoteric and Mg(OH)₂ is a mild base which, as an aqueous suspension (milk of magnesia), is widely used as a digestive antacid. Note that, though mild, Mg(OH)₂ will neutralize 1.37 times as much acid as NaOH, weight for weight, and 2.85 times as much as NaHCO₃. Ca(OH)₂ and Sr(OH)₂ are moderately strong to strong bases and Ba(OH)₂ approaches the alkali hydroxides in strength.

Beryllium salts rapidly hydrolyse in water to give a series of hydroxo complexes of undetermined structure; the equilibria depend sensitively on initial concentration, pH, temperature, etc., and precipitation begins when the ratio \( \text{OH}^-/\text{Be}^{2+}(aq) > 1 \). Addition of further alkali redissolves the precipitate and the properties of the resultant solution are consistent (at least qualitatively) with the presence of isopolyanions of the type \([\text{HO}_2\text{Be}(\mu-\text{OH})_2]\text{Be(OH)}_2\text{H}^2-\). Further addition of alkali progressively polymerizes this chain anion by hydroxyl addition until ultimately the mononuclear beryllate anion \([\text{Be(OH)}_4]^{2-}\) is formed. The analogy with Zn(OH)₂ and Al(OH)₃ is clear.

The solubility of Be(OH)₂ in water is only \( \sim 3 \times 10^{-4} \text{ g l}^{-1} \) at room temperature, compared with \( \sim 3 \times 10^{-2} \text{ g l}^{-1} \) for Mg(OH)₂ and \( \sim 1.3 \text{ g l}^{-1} \) for Ca(OH)₂. Strontium and barium hydroxides have even greater solubilities (8 and 38 g l⁻¹ respectively at 20°C).

The crystal structures of M(OH)₂ also follow group trends. Be(OH)₂ crystallizes with 4-coordinate Be in the Zn(OH)₂ structure which can be considered as a diamond or cristobalite (SiO₂) lattice distorted by H bonding. Mg(OH)₂ (brucite) and Ca(OH)₂ have 6-coordinate cations in a CdI₂ layer lattice structure with OH bonds perpendicular to the layers and strong O–H···O bonding between them. Strontium is too large for the CdI₂ structure and Sr(OH)₂ features 7-coordinate Sr (3 + 4), the structure being built up of edge-sharing monocapped trigonal prisms with no H bonds. (The monohydrate has bicapped trigonal prismatic coordination about Sr.) The structure of Ba(OH)₂ is complex and has not yet been fully determined.
5.3.4 Oxoacid salts and coordination complexes

The chemical trends and geochemical significance of the oxoacid salts of the alkaline earth metals have already been mentioned (p. 109) and the immense industrial importance of the carbonates and sulfates in particular can hardly be overemphasized (see Panel on limestone and lime). A speciality use can also be noted: mother-of-pearl (nacre) is a material composed of thin plates of chalk (in the form of aragonite) stuck together with a protein glue. It is iridescent and highly decorative when polished and, despite being 95% chalk, is very strong.

Calcium sulfate usually occurs as the dihydrate (gypsum) though anhydrite (CaSO$_4$) is also mined. Alabaster is a compact, massive, finegrained form of CaSO$_4$.2H$_2$O resembling marble. When gypsum is calcined at 150–165°C it loses approximately three-quarters of its water of crystallization to give the hemihydrate CaSO$_4$.1/2H$_2$O, also known as plaster of Paris because it was originally obtained from gypsum quarried at Montmartre. Heating at higher temperatures yields various anhydrous forms:

\[
\begin{align*}
\text{CaSO}_4.2\text{H}_2\text{O} & \xrightarrow{\sim 150^\circ} \text{CaSO}_4.\frac{1}{2}\text{H}_2\text{O} & \xrightarrow{\sim 200^\circ} \\
\gamma-\text{CaSO}_4 & \xrightarrow{\sim 600^\circ} \beta-\text{CaSO}_4 & \xrightarrow{1100^\circ} \text{CaO} + \text{SO}_3
\end{align*}
\]

Gypsum, though not mined on the same scale as limestone, is nevertheless still a major industrial mineral. World production in 1990 was 97.7 million tonnes, the major producing countries being the USA (15.2%), Canada (8.4%), Iran (8.2%), China (8.2%), Japan (6.5%), Mexico (6.1%), Thailand (5.9%), France (5.8%) and Spain (5.1%); the remaining 30.6% (30 million tonnes) was distributed between over 20 other countries including the former Soviet Union (4.8%) and the UK (4.1%). A representative price in 1990 was $5.5 per tonne. In the USA about 28% of the gypsum used is uncalcined and most of this is for Portland cement (p. 252) or agricultural purposes. Of calcined gypsum, virtually all (95%) is used for prefabricated products, mainly wall board, and the rest is for industrial and building plasters. The hemihydrate expands slightly (0.2–0.3% linear) on rehydration with water and this is crucial to its use in mouldings and plasters; the expansion can be modified in the range 0.03–1.2% by the use of additives.

Other oxoacid salts and binary compounds are more conveniently discussed under the chemistry of the appropriate non-metals in later chapters.

Beryllium is unique in forming a series of stable, volatile, molecular oxide-carboxylates of general formula [OBe$_4$(RCO$_2$)$_6$], where R = H, Me, Et, Pr, Ph, etc. These white crystalline compounds, of which “basic beryllium acetate” (R = Me) is typical, are readily soluble in organic solvents, including alkanes, but are insoluble in water or the lower alcohols. They are best prepared simply by refluxing the hydroxide or oxide with the carboxylic acid; mixed oxide carboxylates can be prepared by reacting a given compound with another organic acid or acid chloride. The structure (Fig. 5.4) features a central O atom tetrahedrally surrounded by 4 Be. The 6 edges of the tetrahedron so formed are bridged by the 6 acetate groups in such a way that each Be is also tetrahedrally coordinated by 4 oxygens. [OBe$_4$(MeCO$_2$)$_6$] melts at 285° and boils at 330°; it is stable to heat and oxidation except under drastic conditions, is only slowly hydrolysed by hot water, but is decomposed rapidly by mineral acids to give an aqueous solution of the corresponding beryllium salt and free carboxylic acid. The basic nitrate [OBe$_4$(NO$_3$)$_6$] appears to have a similar structure with bridging nitrate groups. The compound is formed by first dissolving BeCl$_2$ in N$_2$O$_4$/ethyl-acetate to give the crystalline solvate [Be(NO$_3$)$_2$.2N$_2$O$_4$]; when heated to 50° this gives Be(NO$_3$)$_2$ which decomposes suddenly at 125°C into N$_2$O$_4$ and [OBe$_4$(NO$_3$)$_6$].

In addition to the oxide carboxylates, beryllium forms numerous chelating and bridged complexes with ligands such as the oxalate ion C$_2$O$_4^{2-}$, alkoxides, β-diketonates and 1,3-diketonates. These almost invariably feature 4-coordinate Be.
though severe steric crowding can reduce the coordination number to 3 or even 2; for example, the very volatile dimeric perfluoroalkoxide (a) was prepared in 1975 and the unique monomeric bis(2,6-di-t-butylphenoxy)beryllium (b) has been known since 1972.

Halide complexes are also well known but complexes with nitrogen-containing ligands are rare. An exception is the blue phthalocyanine complex formed by reaction of Be metal with phthalonitrile, 1,2-C₆H₄(CN)₂, and this affords an unusual example of planar 4-coordinate Be (Fig. 5.5). The complex readily picks up two molecules of H₂O to form an extremely stable dihydrate, perhaps by dislodging 2 adjacent Be–N bonds and forming 2 Be–O bonds at the preferred tetrahedral angle above and below the plane of the macrocycle.

Magnesium forms few halide complexes of the type MX₄²⁻, though [NEt₄]₂[MgCl₄] has been reported; examples of MXₙ⁻(n−2)⁻ for the heavier alkaline earths are lacking, though hydrates and
other solvates are well known. The first examples of monomeric six-coordinate (octahedral) complexes of strontium salts have recently been characterized, viz. trans-[SrI₂(hmpa)₄] and cis-[Sr(NCS)₂(hmpa)₄] where hmpa is (Me₂N)₃PO; they were made as colourless crystals by refluxing a mixture of NH₄I (or NH₄SCN) with metallic Sr and hmpa in toluene for 1 hour.\(^{(23)}\)

Oxygen chelates such as those of edta and polyphosphates are of importance in analytical chemistry and in removing Ca ions from hard water. There is no unique sequence of stabilities since these depend sensitively on a variety of factors: where geometrical considerations are not important the smaller ions tend to form the stronger complexes but in polydentate macrocycles steric factors can be crucial. Thus dicyclohexyl-18-crown-6 (p. 96) forms much stronger complexes with Sr and Ba than with Ca (or the alkali metals) as shown in Fig. 5.6.\(^{(24)}\) Structural data are also available and an example of a solvated 8-coordinate Ca complex [(benzo-15-crown-5)-Ca(NCS)₂.MeOH] is shown in Fig. 5.7. The coordination polyhedron is not regular: Ca lies above the mean plane of the 5 ether oxygens (mean Ca–O 253 pm) and is coordinated on the other side by a methanol molecule (Ca–O 239 pm) and two non-equivalent isothiocyanate

\(^{24}\) See refs. 38 and 66 of Chapter 4.
groups (Ca–N 244 pm) which make angles Ca–N–CS of 153° and 172° respectively.\(^{25}\) Cryptates (pp. 97–8) are also known and usually follow the stability sequence Mg < Ca < Sr < Ba.\(^{24}\) The first monomeric barium alkoxides, [Ba\(\text{O(CH}_2\text{CH}_2\text{O)}_n\text{Me})_2\] \((n = 2, 3)\), which incorporate coordinating polyether functions, were isolated in 1991; the compounds, which are unusual in being liquids at room temperature and which feature 6- and 8-coordinate Ba, respectively, were made by direct reaction of Ba metal with the oligoether alcohols in thf.\(^{26}\)

Preeminent in importance among the macrocyclic complexes of Group 2 elements are the chlorophylls, which are modified porphyrin complexes of Mg. These compounds are vital to the process of photosynthesis in green plants (see Panel). Magnesium and Ca are also intimately involved in biochemical processes in animals: Mg ions are required to trigger phosphate transfer enzymes, for nerve impulse transmissions and carbohydrate metabolism; Mg ions are also involved in muscle action, which is triggered by Ca ions. Ca is required for the formation of bones and teeth, maintaining heart rhythm, and in blood clotting.\(^{27a, f}\)

### Chlorophylls and Photosynthesis

Photosynthesis is the process by which green plants convert atmospheric \(\text{CO}_2\) into carbohydrates such as glucose. The overall chemical change can be expressed as

\[
6\text{CO}_2 + 6\text{H}_2\text{O} \xrightleftharpoons{hv} \text{C}_6\text{H}_12\text{O}_6 + 6\text{O}_2
\]

though this is a gross and somewhat misleading over-simplification. The process is initiated in the photoreceptors of the green magnesium-containing pigments which have the generic name chlorophyll (Greek: \(\chi\lambda\omega\rho\delta\varsigma\), \(\text{chloros}\) green; \(\phi\dot{\omega}\lambda\lambda\omicron\nu\), \(\text{phyllon}\) leaf), but many of the subsequent steps can proceed in the dark. The overall process is endothermic (\(\Delta H^\circ \approx 469\) kJ per mole of \(\text{CO}_2\)) and involves more than one type of chlorophyll. It also involves a manganese complex of unknown composition, various iron-containing cytochromes and ferredoxin (p. 1102), and a copper containing plastocyanin.

Photosynthesis is essentially the conversion of radiant electromagnetic energy (light) into chemical energy in the form of adenosine triphosphate (ATP) and reduced nicotinamide adenine dinucleotide phosphate (NADP). This energy eventually permits the fixation of \(\text{CO}_2\) into carbohydrates, with the liberation of \(\text{O}_2\). As such, the process is the basis for the nutrition of all living things and also provides mankind with fuel (wood, coal, petroleum), fibres (cellulose) and innumerable useful chemical compounds. About 90–95% of the dry weight of crops is derived from the \(\text{CO}_2/\text{H}_2\text{O}\) fixed from the air during photosynthesis — only about 5–10% comes from minerals and nitrogen taken from the soil. The detailed sequence of events is still not fully understood but tremendous advances were made from 1948 onwards by use of the then newly available radioactive \(^{14}\text{CO}_2\) and paper chromatography. With these tools and classical organic chemistry M. Calvin and his group were able to probe the biosynthetic pathways and thus laid the basis for our present understanding of the complex series of reactions. Calvin was awarded the 1961 Nobel Prize in Chemistry “for his research on the carbon dioxide assimilation in plants".\(^{28}\)

Panel continues
Chlorophylls are complexes of Mg with macrocyclic ligands derived from the parent tetapyrrole molecule porphin (structure 1). They are thus related to the porphyrin (substituted porphin) complexes which occur in haem proteins\(^5\) such as haemoglobin, myoglobin and the cytochromes (p. 1101). [The word haem and the prefix haemo derive directly from the Greek word ῥύμα, blood, whereas porphyrins derive their name from the characteristic purple-red coloration which these alkaloids give when acidified (Greek πορφυρός, porphyros purple).] The haem group is illustrated in structure 2. When the C=C double bond in the pyrrole-ring IV of porphin is trans hydrogenated and when a cyclopentanone ring is formed between ring III and the adjacent (γ) methine bridge then the chlorin macrocycle (structure 3) is produced, and this is the basis for the various chlorophylls. Chlorophyll \(\alpha\) (Chl \(\alpha\)) is shown in structure 4; this is the most common of the chlorophylls and is found in all \(O_2\)-evolving organisms. It was synthesized with complete chiral integrity by R. B. Woodward and his group in 1960 — an achievement of remarkable virtuosity. Variants of chlorophyll are:

Chlorophyll \(b\), in which the 3-Me group is replaced by \(-\text{CHO}\); this occurs in higher plants and green algae, the ratio CHl \(b\)/Chl \(\alpha\) being \(\sim 1:3\).

Chlorophyll \(c\), in which position 7 is substituted by acrylic acid, \(-\text{CH}==\text{CHCO}_2\text{H}\); it occurs in diatoms and brown algae.

Chlorophyll \(d\), in which 2-vinyl is replaced by \(-\text{CHO}\).

---

\(^5\)The first time that these two apparently very different but actually closely related coloured materials, chlorophyll and haemoglobin, were connected was in an extraordinarily percipient poem written in 1612 by the English poet John Donne who mused: Why grass is green or why our blood is red/Are mysteries that none have reached unto.
It is important to note that the chlorin macrocycle is "ruffled" rather than completely planar and the Mg atom is ~30–50 pm above the plane of the 4 N atoms. In fact the Mg is not 4-coordinate but carries one (or sometimes two) other ligands, notably water molecules, which play a crucial role in interconnecting the basic chlorophyll units into stacks by H bonding to the cyclopentanone ring V of an adjacent chlorophyll molecule (see structure 5).

The function of the chlorophyll in the chloroplast is to absorb photons in the red part of the visible spectrum (near 680–700 nm) and to pass this energy of excitation on to other chemical intermediates in the complex reaction scheme. At least two photosystems are involved: the initiating photosystem II (P680) which absorbs at 680 nm and the subsequent photosystem I (P700). The detailed redox processes occurring, and the enzyme-catalysed synthetic pathways (dark reactions) in so far as they have yet been elucidated, are described in biochemical texts and fall outside our present scope. The Mg ion apparently serves several purposes: (a) it keeps the macrocycles fairly rigid so that energy is not so readily dissipated by thermal vibrations; (b) it coordinates the H2O molecules which mediate in the H bonding between adjacent molecules in the stack; and (c) it thereby enhances the rate at which the short-lived singlet excited state formed initially by absorption of a photon by the macrocycle is transformed to the corresponding longer-lived triplet state which is involved in the redox chain (since this involves the H bonded system between several individual chlorophyll units over a distance of some 1500–2000 pm). However, it is by no means clear why, of all metals, Mg is uniquely suited for this purpose.

### 5.3.5 Organometallic compounds (29–31)

Compounds containing M–C bonds are well established for Be and Mg but, as with the alkali metals, reactivity within the group increases with increasing electropositivity, and relatively few organometallic compounds of Ca, Sr or Ba have been isolated.

**Beryllium** (30)

Beryllium dialkyls (BeR₂, R = Me, Et, Pr⁻, Pr', Bu etc.) can be made by reacting lithium alkyls or Grignard reagents with BeCl₂ in ether solution, but the products are difficult to free from ether and, when pure compounds rather than solutions are required, a better route is by heating Be metal with the appropriate mercury dialkyl:

\[
\text{BeCl}_2 + 2\text{LiMe} \xrightarrow{\text{Et}_2\text{O}} \text{BeMe}_2.n\text{Et}_2\text{O} + 2\text{LiCl}
\]

\[
\text{BeCl}_2 + 2\text{MeMgCl} \xrightarrow{\text{Et}_2\text{O}} \text{BeMe}_2.n\text{Et}_2\text{O} + 2\text{MgCl}_2
\]

\[
\text{Be} + \text{HgMe}_2 \xrightarrow{110^\circ} \text{BeMe}_2 + \text{Hg}
\]

BePh₂ (mp 245°) can be prepared similarly, using LiPh or HgPh₂; an excess of the former reagent yields Li[BePh₃]. Beryllium dialkyls are colourless solids or viscous liquids which are spontaneously flammable in air and explosively hydrolysed by water. BeMe₂ (like MgMe₂, p. 131) has been shown by X-ray analysis to have a chain structure analogous to that found in BeCl₂ (p. 116) though the bonding is probably best described in terms of 2-electron 3-centre bridge bonds involving -CH₃ groups rather than that adopted by bridging Cl atoms which each form two 2-electron 2-centre bonds involving a CH₃ group. As with polymeric BeCl₂, addition of strong ligands results in depolymerization and the eventual formation of monomeric adducts, e.g. [BeMe₂(PMe₃)₂], [BeMe₂(Me₂NCH₂CH₂NMe₂)], etc. Pyrolysis eliminates alkenes and leads to mixed hydrido species of variable composition (see also p. 115).

---

Alkylberyllium hydrides of more precise stoichiometry can be prepared by reducing $\text{BeBr}_2$ with $\text{LiH}$ in the presence of $\text{BeR}_2$, e.g.:

$$\text{BeMe}_2 + \text{BeBr}_2 + 2\text{LiH} \rightarrow \text{Et}_2\text{O} \rightarrow \text{BeMe}_2 + 2\text{LiBr}$$

The coordinated ether molecules can be replaced by tertiary amines. Use of $\text{NaH}$ in the absence of halide produces the related compound $\text{Na}_2[\text{Me}_2\text{BeH}_2\text{BeMe}_2]$; the corresponding ethyl derivative crystallizes with 1 mole of $\text{Et}_2\text{O}$ per Na but this can readily be removed under reduced pressure. The crystal structure of the etherate is shown in Fig. 5.9(32) and is important in illustrating once more (cf. p. 103) how misleading it can be to differentiate too sharply between different kinds of bonding in solids, for example: ionic $[\text{Na(OEt}_2])_2^+\text{[Et}_2\text{BeH}_2\text{BeEt}_2]^{2-}$ or polymeric $[\text{Et}_2\text{ONaHBeEt}_2]_n$. Thus in the structure shown in Fig. 5.9 each Be is surrounded tetrahedrally by 2 Et and 2 bridging H to form a subunit.

In addition, each H is coordinated tetrahedrally by 2 Be and 2 Na, and each Na is directly bonded to 1 Et$_2$O. Be–C is 180 pm and Be–H is 140 pm, close to expected values; Na–H is 240 pm, equal to that in NaH. The distance Na–Na is 362 pm which is less than in Na metal (372 pm) but greater than in NaH (345 pm), where each Na is surrounded by 6 H; Be–Be is 220 pm as in Be metal. It is therefore misleading to consider the structure as being built up from the isolated ions $[\text{Na(OEt}_2])_2^+$ and $[\text{Et}_2\text{BeH}_2\text{BeEt}_2]^{2-}$ and it is perhaps better to regard it as a chain polymer $[\text{Et}_2\text{ONaHBeEt}_2]_n$ which in plane projection can be written as:

[Diagram of chain structure of BeMe$_2$ showing the acute angle at the bridging methyl group; the Be–Be distance is 209 pm and the distance between the 2 C atoms across the bridge is 315 pm. (b) Pictorial representation of the 3 approximately sp$^3$ orbitals used to form one 3-centre bridge bond; this description of the bonding is consistent with the acute bridging angle at C and the close approach of adjacent Be atoms noted in (a).]

---

Alkylberyllium alkoxides (RBeOR') can be prepared from BeR₂ by a variety of routes such as alcoholysis with R'OH, addition to carbonyls, cleavage of peroxides R'OOR' or redistribution with the appropriate dialkoxide Be(OR')₂, e.g.:

\[ 4\text{BeMe}_2 + 4\text{Bu'OH} \rightarrow 4\text{MeBeOBu'}_4 \]

\[ 2\text{BeMe}_2 + 2\text{Be(Obu')}_2 \rightarrow \text{(MeBeOBu')}_4 \]

\[ 4\text{BeMe}_2 + 2\text{Bu'OObu'} + 4\text{BeMe}_2 + 4\text{Me}_2\text{C} \rightarrow \text{(MeBeOBu')}_4 \]

Ring opening of ethylene oxide has also been used:

\[ 4\text{BeMe}_2 + 4\text{CH}_2 \rightarrow \text{(MeBeOPr')}_4 \]

The compounds are frequently tetrameric and probably have the "cubane-like" structure established for the zinc analogue (MeZnOMe)_₄. The methylberyllium alkoxides (MeBeOR')₄ are reactive, low-melting solids (mp for R' = Me 25°, Et 30°, Pr' 40°, Bu' 136°, Bu' 93°). Bulky substituents may reduce the degree of oligomerization, e.g. trimeric (EtBeOCEt₃)₃, and reaction with coordinating solvents or strong ligands can also lead to depolymerization, e.g. dimeric (MeBeOBu',py)₂ and monomeric PhBeOMe₂Et₂O:

Reaction of beryllium dialkyls with an excess of alcohol yields the alkoxides Be(OR)₂. The methoxide and ethoxide are insoluble and
probably polymeric, whereas the \( \text{t-butoxide} \) (\( \text{mp 112}^\circ \)) is readily soluble as a trimer in benzene or hexane; the proposed structure:

![Diagram](image)

involves both 3- and 4-coordinate \( \text{Be} \) and is consistent with the observation of 2 proton nmr signals at \( \tau \) 8.60 and 8.75 with intensities in the ratio 2:1. (A precisely analogous structure has been established by X-ray diffraction analysis for the "isoelectronic" linear trimer \([\text{Be(NMe}_2]_3\)\].\(^{33}\))

Beryllium forms a series of cyclopentadienyl complexes \([\text{Be}(\eta^5-C_5H_5)Y]\) with \( Y = \text{H, Cl, Br, Me, } -\text{C} = \text{CH} \) and \( \text{BH}_4 \), all of which show the expected \( C_{5v} \) symmetry (Fig. 5.10a). If the \textit{pentahapto}-cyclopentadienyl group (p. 937) contributes 5 electrons to the bonding, then these are all 8-electron \( \text{Be} \) complexes consistent with the octet rule for elements of the first short period.\(^{34}\) The bis(cyclopentadienyl) compound (\( \text{mp 59}^\circ \)), first prepared by E. O. Fischer and H. P. Hofmann in 1959, is also known but does not adopt the ferrocene-type structure (p. 937) presumably because this would require 12 electrons in the valence shell of \( \text{Be} \). Instead, the complex has \( C_2 \) symmetry and is, in fact, \([\text{Be}(\eta^1-C_5H_5)(\eta^5-C_5H_5)]\)\(^{35}\), as shown in Fig. 5.10b.\(^{35}\) The \( \sigma \)-bonded \( \text{Be-C} \) distance is significantly shorter than the five other \( \text{Be-C} \) distances and there is some alternation of \( \text{C-C} \) distances in the \( \sigma \)-bonded cyclopentadienyl group. All \( \text{H} \) atoms are coplanar with the rings except for the one adjacent to the \( \text{Be-C}_\sigma \) bond. For free molecules in the gas phase it seems unlikely that the two cyclopentadienyl rings are coplanar, and the most recent calculations\(^{36}\) suggest a dihedral angle between the rings of 117° with \( \text{Be-C}_{\sigma} 172 \text{pm, Be-C}_{\pi} 187 \text{pm, and the angle Be-C}_{\sigma}-\text{H} 108^\circ \).

---

**Figure 5.10** Cyclopentadienyl derivatives of beryllium showing (a) the \( C_{5v} \) structure of \([\text{Be}(\eta^5-C_5H_5)Y]\) and (b) the structure of crystalline \([\text{Be}(\eta^1-C_5H_5)(\eta^5-C_5H_5)]\) at \(-120^\circ \) (see text).
Pentamethylcyclopentadienyl derivatives are also known, e.g., \( [(\eta^5-C_5H_5)BeCl] \); this reacts with LiPBu\(_3\) in Et\(_2\)O at \(-78^\circ\) to give colourless crystals of \( [(\eta^5-C_5Me_5)BePBu_2] \) in high yield.\(^{37}\) Here the dibutylphosphido group is acting as a 1-electron ligand to Be to form a covalent bond of length 208.3 pm almost perpendicular to the \( C_5 \) plane: angle \( P-Be-C_5(\text{centroid}) \) 168.3°. Interestingly, the \( Be-C_5(\text{centroid}) \) distance (148 pm) is notably shorter than that found in \( [(\eta^5-C_5H_5BeMe)] \) (190.7 pm), implying stronger bonding in the pentamethyl derivative. Because the Be nucleus has a spin of \( 3/2 \), the \(^{31}\)P(\( ^1\)H) nmr signal consists of a 1:1:1:1 quartet with a coupling constant \( J_{\text{Be-P}} \) of 50.0 Hz; this is an order of magnitude greater than for Lewis-base (2-electron) tertiary phosphine adducts of Be.

**Magnesium**\(^{31}\)

Magnesium dialkyls and diaryls, though well established, have been relatively little studied by comparison with the vast amount of work which has been published on the Grignard reagents RMgX. The dialkyls (and diaryls) can be conveniently made by the reaction of LiR (LiAr) on Grignard reagents, or by the reaction of HgR\(_2\) (HgAr\(_2\)) on Mg metal (sometimes in the presence of ether). On an industrial scale, alkenes can be reacted at 100° under pressure with MgH\(_2\) or with Mg in the presence of H\(_2\):

\[
\text{LiR} + \text{RMgX} \xrightarrow{\text{Et}_2\text{O}} \text{MgR}_2 + \text{LiX}
\]

\[
\text{HgR}_2 + \text{Mg} \xrightarrow{\text{Et}_2\text{O}, \text{pressure}} \text{MgR}_2 + \text{Hg}
\]

\[
2\text{C}_2\text{H}_4 + \text{H}_2 + \text{Mg} \xrightarrow{\text{100°}} \text{MgEt}_2
\]

A suitable laboratory method is to shift the Schlenk equilibrium in a Grignard solution (p. 132) by adding dioxan to precipitate the complex MgX\(_2\).diox; this enables MgR\(_2\) to be isolated by careful removal of solvent under reduced pressure:

\[
2\text{RMgX} \xrightarrow{\text{C}_2\text{H}_4, \text{H}_2, \text{Mg}} \text{MgR}_2 + \text{MgX}_2 \xrightarrow{\text{C}_2\text{H}_4\text{O}_2} \text{MgR}_2 + \text{MgX}_2\cdot\text{C}_4\text{H}_8\text{O}_2
\]

MgMe\(_2\) is a white involatile polymeric solid which is insoluble in hydrocarbons and only slightly soluble in ether. Its structure is very similar to that of BeMe\(_2\) (p. 128) the corresponding dimensions for MgMe\(_2\) being: Mg–C 224 pm, Mg–C–Mg 75°, C–Mg–C 105°, Mg⋯Mg 272 pm and C⋯C (across the bridge) 357 pm. Precisely analogous bridging Me groups are found in dimeric Al\(_2\)Me\(_6\) (p. 259) and in the monomeric compound Mg(AlMe\(_3\))\(_2\) which can be formed by direct reaction of MgMe\(_2\) and Al\(_2\)Me\(_6\):

\[
\text{MgEt}_2 \text{ and higher homologues are very similar to MgMe}_2 \text{ except that they decompose at a lower temperature (175–200° instead of ~250°C) to give the corresponding alkene and MgH}_2 \text{ in a reaction which reverses their preparation. MgPh}_2 \text{ is similar: it is insoluble in benzene dissolves in ether to give the monomeric complex MgPh}_2\cdot2\text{Et}_2\text{O and pyrolyses at 280° to give Ph}_2 \text{ and Mg metal. Like BePh}_2 \text{ it reacts with an excess of LiPh to give the colourless complex Li[MGPh}_3].

The first organosilylmagnesium compound \([\text{Mg(SiMe}_3)_2]_{1}(\cdot\text{CH}_2\text{OME})_2\) was isolated in 1977,\(^{38}\) it was obtained as colourless, spontaneously flammable crystals by reaction of bis(trimethylsilyl)mercury with Mg powder in

More recently\(^{39}\) the bulkier bis[tris(trimethylsilyl)methyl] derivative, [Mg\(\{C(SiMe_3)_3\}^2\), was obtained as an unsolvated crystalline monomer; this was the first example of 2-coordinate (linear) Mg in the solid state, though this geometry had been established earlier by electron diffraction in the gas phase for bis(neopentyl)magnesium.\(^{40}\)

Grignard reagents are the most important organometallic compounds of Mg and are probably the most extensively used of all organometallic reagents because of their easy preparation and synthetic versatility. Despite this, their constitution in solution has been a source of considerable uncertainty until recent times.\(^{41}\) It now seems well established that solutions of Grignard reagents can contain a variety of chemical species interlinked by mobile equilibria whose position depends critically on at least five factors: (i) the steric and electronic nature of the alkyl (or aryl) group R, (ii) the nature of the halogen X (size, electron-donor power, etc.), (iii) the nature of the solvent (Et\(_2\)O, thf, benzene, etc.), (iv) the concentration and (v) the temperature. The species present may also depend on the presence of trace impurities such as H\(_2\)O or O\(_2\). Neglecting solvation in the first instance, the general scheme of equilibria can be set out as shown below. Thus "monomeric" (solvated) RMgX can disproportionate to MgR\(_2\) and MgX\(_2\) by the Schlenk equilibrium or can dimerize to RMgX\(_2\)MgR. Both the monomer and the dimer can ionize, and reassociation can give the alternative dimer R\(_2\)MgX\(_2\)Mg. Note that only halogen atoms X are involved in the bridging of these species.

Evidence for these species and the associated equilibria comes from a variety of techniques such as vibration spectroscopy, nmr spectroscopy, molecular-weight determinations, radioisotopic exchange using \(^{28}\)Mg, electrical conductivity, etc. In some cases equilibria can be displaced by crystallization or by the addition of complexing agents such as dioxan (p. 131) or NEt\(_3\). The crystal structures of several pertinent adducts have recently been determined (Fig. 5.11). None call for special comment except the curious solvated dimer [EtMg\(_2\)Cl\(_3\)(OC\(_4\)H\(_8\))\(_3\)]\(_2\) which features both 5-coordinate trigonal bipyramidal and 6-coordinate octahedral Mg groups; note also that, whilst 4 of the Cl atoms each bridge 2 Mg atoms, the remaining 2 Cl atoms are triply bridging.

\(^{41}\) E. C. Ashby, Qt. Rev. 21, 259-85 (1967).
Organometallic compounds

The order of reactivity of RX is I > Br > Cl and alkyl > aryl. The mechanism has been much studied but is not fully understood.\(^\text{42}\) The fluorides RMgF (R = Me, Et, Bu, Ph) can be prepared by reacting MgR\(_2\) with mild fluorinating agents such as BF\(_3\)OEt\(_2\), Bu\(_3\)SnF or SiF\(_4\).\(^\text{43}\) The scope of Grignard reagents in syntheses has been greatly extended by a recently developed method for preparing very reactive Mg (by reduction of MgX\(_2\) with K in the presence of KI).\(^\text{44}\) Grignard reagents have a wide range of application in the synthesis of alcohols, aldehydes, ketones, carboxylic acids, esters and amides, and are probably the most versatile reagents for constructing C–C bonds by carbanion (or occasionally\(^\text{45}\) free-radical) mechanisms. Standard Grignard methods are also available for constructing C–N, C–O, C–S (Se, Te) and C–X bonds (see Panel on pp. 134–5).

A related class of compounds are the alkylmagnesium alkoxides: these can be prepared by reaction of MgR\(_2\) with an alcohol or ketone or by reaction of Mg metal with the appropriate alcohol and alkyl chloride in methylcyclohexane solvent, e.g.:

\[
4\text{MgEt}_2 + 4\text{Bu}^+\text{OH} \rightarrow (\text{EtMgOBU}^+)\text{Cl}_4 + 4\text{C}_2\text{H}_6
\]

\[
2\text{MgMe}_2 + 2\text{Ph}_2\text{CO} \rightarrow \text{MeMgOCMePh}_2\text{Et}_2\text{O})\text{Cl}_4
\]

\[
6\text{Mg} + 6\text{Bu}^+\text{Cl} + 3\text{Pr}^+\text{OH} \rightarrow (\text{Bu}^+\text{MgOPr})_3 + 3\text{MgCl}_2 + 3\text{C}_4\text{H}_{10}
\]

---

Synthetic Uses of Grignard Reagents

Victor Grignard (1871–1935) showed in 1900 that Mg reacts with alkyl halides in dry ether at room temperature to give ether-soluble organomagnesium compounds; the use of these reagents to synthesize acids, alcohols, and hydrocarbons formed the substance of his doctorate thesis at the University of Lyon in 1901, and further studies on the synthetic utility of Grignard reagents won him the Nobel Prize for Chemistry in 1912. The range of applications is now enormous and some indication of the extraordinary versatility of organomagnesium compounds can be gauged from the following brief summary.

Standard procedures convert RMgX into ROH, RCH2OH, RCH2CH2OH and an almost unlimited range of secondary and tertiary alcohols:

\[
\begin{align*}
RMgX + O_2 & \rightarrow ROOMgX \rightarrow 2ROMgX \xrightarrow{\text{acid}} 2ROH \\
RMgX + HCHO & \rightarrow RCH_2OMgX \rightarrow RCH_2OH \\
RMgX + CH_2=CH_2 & \rightarrow RCH_2CH_2OMgX \xrightarrow{\text{acid}} RCH_2CH_2OH \\
RMgX + R'CHO & \rightarrow RR'CHOMgX \xrightarrow{\text{acid}} RR'CHOH \\
RMgX + R'C\text{COR}' & \rightarrow RR'R''COMgX \xrightarrow{\text{acid}} RR'R''\text{COH}
\end{align*}
\]

Aldehydes and carboxylic acids having 1 C atom more than R, as well as ketones, amides and esters can be prepared similarly, the reaction always proceeding in the direction predicted for potential carbanion attack on the unsaturated C atom:

\[
\begin{align*}
RMgX + HC(OEt)_3 & \xrightarrow{\text{acid}} RCH(OEt)_2 \xrightarrow{\text{acid}} RCHO \\
RMgX + CO_2 & \xrightarrow{\text{acid}} RCO_2MgX \xrightarrow{\text{acid}} RCO_2H \\
RMgX + R'CN & \rightarrow [RR'C=NMgX] \xrightarrow{\text{acid}} RR'C=O \\
RMgX + R'NCO & \rightarrow [RCNR'(OMgX)] \xrightarrow{\text{acid}} RC(O)NHR' \\
RMgX + EtOCCOCI & \rightarrow [RC(OEt)Cl(OMgX)] \xrightarrow{\text{acid}} RCO_2Et
\end{align*}
\]

Grignard reagents are rapidly hydrolysed by water or acid to give the parent hydrocarbon, RH, but this reaction is rarely of synthetic importance. Hydrocarbons can also be synthesized by nucleophilic displacement of halide ion from a reactive alkyl halide, e.g.

\[
\text{MeMgCl} + C=CHCH_2Cl \rightarrow C=CHCH_2Me + MgCl_2
\]

However, other products may be formed simultaneously by a free-radical process, especially in the presence of catalytic amounts of CoCl₂ or CuCl:

\[
\begin{align*}
2C=CHCH_2Cl + \text{MeMgCl} & \text{CoCl}_2 \rightarrow C=CHCH_2CH=CHC \\\n2C=C & \xrightarrow{\text{CuCl/thf}} C=C
\end{align*}
\]

Panel continues
Similarly, aromatic Grignard reagents undergo free-radical self-coupling reactions when treated with $\text{MCl}_2$ ($M=\text{Cr, Mn, Fe, Co, Ni}$), e.g.:

$$2\text{PhMgBr} + \text{CrCl}_2 \rightarrow 2''\text{MgBrCl}'' + \text{Ph}_2\text{Cr}$$

Ph$_2$ + Cr $\xrightarrow{\text{heat}}$ Ph$_2$Cr

Alkenes can be synthesized from aldehydes or ketones using the Grignard reagent derived from CH$_2$Br$_2$:

$$\text{CH}_2(\text{MgBr})_2 + \text{RR'C} = \text{O} \rightarrow \text{RR'C} = \text{CH}_2 + \text{MgO} + \text{MgBr}_2$$

The formation of C–N bonds can be achieved by using chloramine or O-methylhydroxylamine to yield primary amines; aryl diazonium salts yield azo-compounds:

$$\text{R MgX} + \text{ClNH}_2 \rightarrow \text{RNH}_2 + ''\text{MgClX}''$$
$$\text{R MgX} + \text{MeONH}_2 \rightarrow \text{RNH}_2 + \text{MeOMgX}$$
$$\text{R MgX} + [\text{ArN}_2]\text{X} \rightarrow \text{RN} = \text{NAr} + \text{MgX}_2$$

Carbon-oxygen bonds can be made using the synthetically uninteresting conversion of RMgX into ROH (shown as the first reaction listed above); direct acid hydrolysis of the peroxy compound ROOMgX yields the hydroperoxide ROOH. Carbon-sulfur bonds can be constructed using S$_8$ to make thiols or thioethers, and similar reactions are known for Se and Te:

$$\text{RMgX} + \text{S}_8 \rightarrow \text{RS}_2\text{MgX} \rightarrow \text{RSMgX}$$

$$\text{RSMgX} \rightarrow \text{RSH} + \text{MgX}_2$$
$$\text{RSMgX} \rightarrow \text{R}_2\text{S} + \text{MgX}_2 + \text{Mg}$$

Formation of C–X bonds is not normally a problem but the Grignard route can occasionally be useful when normal halogen exchange fails. Thus iodination of Me$_3$CCH$_2$Cl cannot be achieved by reaction with NaI or similar reagents but direct iodination of the corresponding Grignard effects a smooth conversion:

$$\text{Me}_3\text{CCH}_2\text{MgCl} + \text{I}_2 \rightarrow \text{Me}_3\text{CCH}_2\text{I} + ''\text{MgClI}''$$

Further examples of the ingenious use of Grignard reagents will be found in many books on synthetic organic chemistry and much recent work in this area was reviewed in a special edition of Bull. Soc. Chim. France, 1972, 2127-86, which commemorated the centenary of Victor Grignard's birth.
As with the Grignard reagents, the structure and degree of association of the product depend on the bulk of the organic groups, the coordinating ability of the solvent, etc. This is well illustrated by MeMgOR \((R = Pr'', Pr', Bu', CMePh_2)\) in thf, Et_2O and benzene: the strongly coordinating solvent thf favours solvated dimers (A) but prevents the formation both of oligomers (B) involving the relatively weak Me bridges and of cubane structures (C) involving the relatively weak triply bonding oxygen bridges.

By contrast, in the more weakly coordinating solvent Et_2O, Me bridges and \(\mu_3-OR\) bridges can form, leading to linear oligomers and cubanes, provided OR is not too bulky. Thus when \(R = CMePh_2\), oligomerization and cubane formation are blocked and MeMgOCCMePh_2 exists only as a solvated dimer even in Et_2O. In benzene, \(R = Bu'\) and \(Pr'\) form cubane tetramers but \(Pr''\) can form an oligomer of 7–9 monomer units. The sensitive dependence of the structure of a compound on solvation energy, lattice energy and the relative coordinating abilities of its component atoms and groups will be a recurring theme in many subsequent chapters.

Dicyclopentadienylmagnesium \([\text{Mg}(\eta^5-\text{C}_5\text{H}_5)_2]\), mp 176\(^\circ\), can be made in good yield by direct reaction of Mg and cyclopentadiene at 500–600\(^\circ\); it is very reactive towards air, moisture, \(\text{CO}_2\) and \(\text{CS}_2\), and reacts with transition-metal halides to give transition-element cyclopentadienyls. It has the staggered \((D_{5d})\) "sandwich" structure (cf. ferrocene p. 1109) with Mg–C 230 pm and C–C 139 pm. The bonding is thought to be intermediate between ionic and covalent but the actual extent of the charge separation between the central atom and the rings is still being discussed.

Calcium, strontium and barium\(^{31,48}\)

Organometallic compounds of Ca, Sr and Ba are far more reactive than those of Mg and have been much less studied until recently. For example, although about 50,000 papers have been published on organomagnesium compounds and reagents, less than 1% of this number have appeared for the heavier triad of elements. Many of the differences in reactivity can be traced to the larger radii of the cations (Ca\(^{2+}\) 100, Sr\(^{2+}\) 118, Ba\(^{2+}\) 135 pm) when compared to Mg\(^{2+}\) (72 pm) — i.e. the lower (charge/size) ratio enhances still further the ionic character of the bonding and thus increases the kinetic lability of the ligands. Coordinative unsaturation also plays a rôle and, indeed, the organometallic behaviour of the heavier alkali metals often resembles

---

\(^{47}\) W. BUNDER and E. WEISS, \([\text{Mg}(\eta^5-\text{C}_5\text{H}_5)_2]\). J. Organometall. Chem. 92, 1–6 (1975).

\(^{48}\) T. P. HANUSA, Polyhedron 9, 1345–62 (1990)
that of the similarly-sized divalent lanthanide elements (Yb$^{2+}$ 102, Eu$^{2+}$ 117, Sm$^{2+}$ 122 pm) rather than that of Mg. In these circumstances it became clear that stability would be enhanced by the use of bulky ligands. Early work showed that the reactive compounds MR$_2$ (M = Ca, Sr, Ba; R = Me, Et, allyl, Ph, PhCH$_2$, etc.) can be prepared using HgR$_2$ under appropriate conditions, often at low temperature. Compounds of the type RCaI (R = Bu, Ph, tolyl) have also been known for some time and can now be isolated as crystals.

Calcium (and Sr) dicyclopentadienyl can be made by direct reaction of the metal with either [Hg(C$_5$H$_5$)$_2$] or with cyclo-C$_5$H$_6$ itself; cyclopentadiene also reacts with CaC$_2$ in liquid NH$_3$ to form [Ca(C$_5$H$_5$)$_2$] and HC≡CH. The barium analogue [Ba(C$_5$H$_5$)$_2$] is best made (though still in small yield) by treating cyclo-C$_5$H$_6$ with BaH$_2$. The structure of [Ca(C$_5$H$_5$)$_2$] is unique.$^{49}$ Each Ca is surrounded by 4 planar cyclopentadienyl rings and the overall structure involves a complex sharing of rings which bridge the various Ca atoms. The coordination geometry about a given Ca atom is shown in Fig. 5.12:

![Figure 5.12 Coordination geometry about Ca in polymeric [Ca(C$_5$H$_5$)$_2$] showing 2×$\eta^5$-, $\eta^3$- and $\eta^1$- bonding (see text).](image)

Figure 5.12 Coordination geometry about Ca in polymeric [Ca(C$_5$H$_5$)$_2$] showing 2×$\eta^5$-, $\eta^3$- and $\eta^1$- bonding (see text).

two of the rings (A, C) are $\eta^5$, with all Ca–C distances 275 pm. A third ring (B) is $\eta^3$ with one Ca–C distance 270, two at 279, and two longer distances at 295 pm. These three polyhaptic rings (A, B, C) are arranged so that their centroids are disposed approximately trigonally about the Ca atom. The fourth ring (A') is $\eta^1$, with only 1 Ca–C within bonding distance (310 pm) and this bond is approximately perpendicular to the plane formed by the centroids of the other 3 rings. The structure is the first example in which $\eta^5$, $\eta^3$- and $\eta^1$-C$_5$H$_5$ groups are all present. Indeed, the structure is even more complex than this implies because of the ring-bridging between adjacent Ca atoms; for example ring A (and A') is simultaneously bonded $\eta^5$ to 1 Ca (248 pm from the ring centre) and $\eta^1$ to another on the opposite side of the ring, whereas ring C is equally associated in pentahapto mode with 2 Ca atoms each 260 pm from the plane of the ring.

Replacement of the ligand C$_5$H$_5$ by the bulkier C$_5$Me$_5$ results in improved solubility, volatility and kinetic stability of the compound, and all three complexes [M($\eta^5$-C$_5$Me$_5$)$_2$] have been prepared in >65% yield by the reaction of NaC$_5$Me$_5$ (or KC$_5$Me$_5$) with the appropriate diiodide, Ml$_2$, in diethyl ether or thf, followed by removal of the coordinated ether (or thf) by refluxing the product in toluene. [Ca(C$_5$Me$_5$)$_2$(thf)$_2$] has also been prepared in 48% yield by the reaction of C$_5$HMe$_5$ and Ca(NH$_3$)$_2$ in liquid ammonia. The greater tractability of these complexes enabled the first (gas-phase) molecular structures of organo-Sr and organo-Ba compounds to be determined.$^{50}$ and also the first organo-Ba crystal structure.$^{51}$ Group comparisons show that the angle subtended by the two C$_5$Me$_5$ ring centroids at the metal atom in the gas phase is almost the same (to within 1 esd) for the three metals (154 ± 4°) but that this drops to 131.0° for crystalline [Ba(C$_5$Me$_5$)$_2$]. A theoretical rationalization for these angles, especially in the gas phase, is not obvious.$^{48}$

---

Figure 5.13  (a) Structure of \([\text{Ba}(\eta^5-C_5\text{Me}_5)_2]_2(\mu-1,4-C_6\text{H}_4\text{N}_2)]\) in which the pyrazine ligand bridges two bent \([\text{BaCp}^*]_2\) units to give a centrosymmetric adduct with an essentially linear disposition of the four atoms \(\text{BaNNBa}\). (b) The polymeric dioxane-bridged structure of \([\text{trans-Sr(NR}_2]^*(p-1,4\text{C}_4\text{H}_4\text{O})]\) showing the 4-coordinate square-planar stereochemistry of the Sr atoms. (c) The 5-coordinate trigonal-bipyramidal structure of \([\text{Ca(OAr)}_2(\text{thf})_3]\) \((\text{Ar}=\text{C}_6\text{H}_2-2,6-\text{Bu}_2-4-\text{Me})\) showing one equatorial and two axial thf ligands.

Attempts to prepare the mono(cyclopentadienyl) derivatives are sometimes frustrated by a Schlenk-type equilibrium (see p. 132), but judicious choice of ligands, solvent etc. occasionally permits the isolation of such compounds, e.g. the centrosymmetric halogen-bridged dimer \([\{(\eta^5-C_5\text{Me}_5)\text{Ca}(\mu-1)(\text{thf})_2\}_2]\) which crystallizes from toluene solution. The complex is isostructural with the dimeric organosamarium(II) analogue.\(^{52}\)

Other interesting structures of organometallic and related complexes of the heavier Group 2 metals include those of the centrosymmetric pyrazine adduct \([\text{Ba}(\eta^5-C_5\text{Me}_5)_2]_2(\mu-1,4-C_4\text{H}_4\text{N}_2)]\), (Fig. 5.13a)\(^{48}\), the square-planar Sr complex \([\text{trans-Sr(NR}_2]^*(\mu-1,4-C_4\text{H}_4\text{O})]\) \((\text{R} = \text{SiMe}_3)\), Fig. 5.13b\(^{53}\) and the 5-coordinate trigonal-bipyramidal Ca complex \([\text{Ca(OAr)}_2^*(\text{thf})_3]\) \((\text{Ar}=\text{C}_6\text{H}_2-2,6-\text{Bu}_2-4-\text{Me})\), Fig. 5.13c.\(^{54}\)

6
Boron

6.1 Introduction

Boron is a unique and exciting element. Over the years it has proved a constant challenge and stimulus not only to preparative chemists and theoreticians, but also to industrial chemists and technologists. It is the only non-metal in Group 13 of the periodic table and shows many similarities to its neighbour, carbon, and its diagonal relative, silicon. Thus, like C and Si, it shows a marked propensity to form covalent, molecular compounds, but it differs sharply from them in having one less valence electron than the number of valence orbitals, a situation sometimes referred to as "electron deficiency". This has a dominant effect on its chemistry.

Borax was known in the ancient world where it was used to prepare glazes and hard (borosilicate) glasses. Sporadic investigations during the eighteenth century led ultimately to the isolation of very impure boron by H. Davy and by J. L. Gay Lussac and L. J. Thénard in 1808, but it was not until 1892 that H. Moissan obtained samples of 95–98% purity by reducing B₂O₃ with Mg.

High-purity boron (>99%) is a product of this century, and the various crystalline forms have been obtained only during the last few decades mainly because of the highly refractory nature of the element and its rapid reaction at high temperatures with nitrogen, oxygen and most metals. The name boron was proposed by Davy to indicate the source of the element and its similarity to carbon, i.e. bor(ax + carb)on.

Boron is comparatively un abundant in the universe (p. 14); it occurs to the extent of about 9 ppm in crustal rocks and is therefore rather less abundant than lithium (18 ppm) or lead (13 ppm) but is similar to praseodymium (9.1 ppm) and thorium (8.1 ppm). It occurs almost invariably as borate minerals or as borosilicates. Commercially valuable deposits are rare, but where they do occur, as in California or Turkey, they can be vast (see Panel). Isolated deposits are also worked in the former Soviet Union, Tibet and Argentina.

The structural complexity of borate minerals (p. 205) is surpassed only by that of silicate minerals (p. 347). Even more complex are the structures of the metal borides and the various allotropic modifications of boron itself. These factors, together with the unique structural and bonding problems of the boron hydrides, dictate that boron should be treated in a separate chapter.
Borate Minerals

The world’s major deposits of borate minerals occur in areas of former volcanic activity and appear to be associated with the waters from former hot springs. The primary mineral that first crystallized was normally ulexite, NaCa[BSO₆(OH)₄]·5H₂O, but this was frequently mixed with lesser amounts of borax, Na₂[B₂O₅(OH)₄]·8H₂O (p. 206). Exposure and subsequent weathering (e.g. in the Mojave Desert, California) resulted in leaching by surface waters, leaving a residue of the less-soluble mineral colemanite, Ca[B₂O₅(OH)₃]·H₂O (p. 206). The leached (secondary) borax sometimes reaccumulated and sometimes underwent other changes to form other secondary minerals such as the commercially important kernite, Na₂[B₂O₅(OH)₄]·2H₂O. at Boron, California: This is the world’s largest single source of borates and comprises a deposit 6.5 km long, 1.5 km wide and 25–50 m thick containing material that averages 75% of hydrated d tâm tetraborates (borax and kernite). World reserves (expressed as B₂O₃ content) exceed 315 million tonnes (Turkey 45%, USA 21%, Kazakhstan 17%, China 8.6%, Argentina 7.3%). Annual world production of borates was 2.67 million tonnes in 1990. Production in Turkey has expanded dramatically in the last two decades and now exceeds that of the USA, the 1990 production figures being 1.20 and 1.09 Mt respectively. Smaller producers (10¹ t) are: “Russia” 175, Chile 132, China 27, Argentina 26 and Peru 18. The 1991 bulk price per tonne of borax in USA was $264 for technical grade and $2222 for refined granules.

The main chemical products produced from these minerals are (a) boron oxides, boric acid and borates, (b) esters of boric acid, (c) refractory boron compounds (borides, etc.), (d) boron halides, (e) boranes and carbaboranes and (f) organoboranes. The main industrial and domestic uses of boron compounds in Europe (USA in parentheses) are:

<table>

</table>

The uses in the glass and ceramics industries reflect the diagonal relation between boron and silicon and the similarity of vitreous borate and silicate networks (pp. 203, 206 and 347). In the UK and continental Europe (but not in the USA or Japan) sodium perborate (p. 206) is a major constituent of washing powders since it hydrolyses to H₂O₂ and acts as a bleaching agent in very hot water (~90°C); in the USA domestic washing machines rarely operate above 70°C, at which temperature perborates are ineffective as bleaches.

Details of other uses of boron compounds are noted at appropriate places in the text.

The general group trends, and a comparison with the chemistry of the metallic elements of Group 13 (Al, Ga, In and Tl), will be deferred until the next chapter.

6.2 Boron

6.2.1 Isolation and purification of the element

There are four main methods of isolating boron from its compounds:

(i) Reduction by metals at high temperature, e.g. the strongly exothermic reaction

\[ \text{B}_2\text{O}_3 + 3\text{Mg} \longrightarrow 2\text{B} + 3\text{MgO} \]

(Moissan boron, 95–98% pure)

Other electropositive elements have been used (e.g. Li, Na, K, Be, Ca, Al, Fe), but the product is generally amorphous and contaminated with refractory impurities such as metal borides. Massive crystalline boron (96%) has been prepared by reacting BCl₃ with zinc in a flow system at 900°C.

(ii) Electrolytic reduction of fused borates or tetrafluoroborates, e.g. KBF₄ in molten KCl/KF at 800°C. The process is comparatively cheap but yields only powdered boron of 95% purity.

(iii) Reduction of volatile boron compounds by H₂, e.g. the reaction of BBr₃ + H₂ on a heated

---

tantalum metal filament. This method, which was introduced in 1922 and can now be operated on the kilogram scale, is undoubtedly the most effective general preparation for high purity boron (>99.9%). Crystallinity improves with increasing temperature, amorphous products being obtained below 1000°C, α- and β-rhombohedral modifications between 1000–1200°C and tetragonal crystals above this. BCl₃ can be substituted for BBr₃ but B₁₃ is unsatisfactory because it is expensive and too difficult to purify sufficiently. Free energy calculations indicate that BF₃ would require impractically high temperatures (>2000°C).

(iv) Thermal decomposition of boron hydrides and halides. Boranes decompose to amorphous boron when heated at temperatures up to 900°C and crystalline products can be obtained by thermal decomposition of B₁₃. Indeed, the first recognized sample of α-rhombohedral B was prepared (in 1960) by decomposition of B₁₃ on Ta at 800–1000°C, and this is still an excellent exclusive preparation of this allotrope.

6.2.2 Structure of crystalline boron

Boron is unique among the elements in the structural complexity of its allotropic modifications; this reflects the variety of ways in which boron seeks to solve the problem of having fewer electrons than atomic orbitals available for bonding. Elements in this situation usually adopt metallic bonding, but the small size and high ionization energies of B (p. 222) result in covalent rather than metallic bonding. The structural unit which dominates the various allotropes of B is the B₁₂ icosahedron (Fig. 6.1), and this also occurs in several metal boride structures and in certain boron hydride derivatives. Because of the fivefold rotation symmetry at the individual B atoms, the B₁₂ icosahedra pack rather inefficiently and there

---

---

Figure 6.1 The icosahedron and some of its symmetry elements. (a) An icosahedron has 12 vertices and 20 triangular faces defined by 30 edges. (b) The preferred pentagonal pyramidal coordination polyhedron for 6-coordinate boron in icosahedral structures; as it is not possible to generate an infinite threedimensional lattice on the basis of fivefold symmetry, various distortions, translations and voids occur in the actual crystal structures. (c) The distortion angle θ, which varies from 0° to 25°, for various boron atoms in crystalline boron and metal borides.
are regularly spaced voids which are large enough to accommodate additional boron (or metal) atoms. Even in the densest form of boron, the \( \alpha \)-rhombohedral modification, the percentage of space occupied by atoms is only 37\% (compared with 74\% for closest packing of spheres).

The \( \alpha \)-rhombohedral form of boron is the simplest allotropic modification and consists of nearly regular \( \text{B}_{12} \) icosahedra in slightly deformed cubic close packing. The rhombohedral unit cell (Fig. 6.2) has \( a_0 = 505.7 \text{ pm} \), \( \alpha = 58.06^\circ \) (60\° for regular ccp) and contains 12 B atoms. It is important to remember that in Fig. 6.2, as in most other structural diagrams in this chapter, the lines merely define the geometry of the clusters of boron atoms; they do not usually represent 2-centre 2-electron bonds between pairs of atoms. In terms of the MO theory to be discussed on p. 157, the 36 valence electrons of each \( \text{B}_{12} \) unit are distributed as follows: 26 electrons just fill the 13 available bonding MOs within the icosahedron and 6 electrons share with 6 other electrons from 6 neighbouring icosahedra in adjacent planes to

**Figure 6.2** Basal plane of \( \alpha \)-rhombohedral boron showing close-packed arrangement of \( \text{B}_{12} \) icosahedra. The B–B distances within each icosahedron vary regularly between 173–179 pm. Dotted lines show the 3-centre bonds between the 6 equatorial boron atoms in each icosahedron to 6 other icosahedra in the same sheet at 202.5 pm. The sheets are stacked so that each icosahedron is bonded by six 2-centre B–B bonds at 171 pm (directed rhombohedrally, 3 above and 3 below the icosahedron). \( \text{B}_{12} \) units in the layer above are centred over 1 and those in the layer below are centred under 2.

**Figure 6.3** (a) The \( \text{B}_{84} \) unit in \( \beta \)-rhombohedral boron comprising a central \( \text{B}_{12} \) icosahedron and 12 outwardly directed pentagonal pyramids of boron atoms. The 12 outer icosahedra are completed by linking with the \( \text{B}_{10} \) subunits as described in the text. The central icosahedron (●) is almost exactly regular with B–B 176.7 pm. The shortest B–B distances (162–172 pm) are between the central icosahedron and the apices of the 12 surrounding pentagonal pyramids (○). The B–B distances within the 12\( \text{B}_6 \) pentagonal pyramids (half-icosahedra) are somewhat longer (185 pm) and the longest B–B distances (188–192 pm) occur within the hexagonal rings surrounding the 3-fold symmetry axes of the \( \text{B}_{84} \) polyhedron. Note that if the 24 "internal" B atoms (● and ○) are removed from the \( \text{B}_{84} \) unit then a \( \text{B}_{60} \) unit (b) remains which has precisely the fullerene structure subsequently found some 25 years later for \( \text{C}_{60} \) (p. 279).
Figure 6.4 Crystal structure of α-tetragonal boron. This was originally thought to be B\textsubscript{50} (4B\textsubscript{12} + 2B) but is now known to be either B\textsubscript{50}C\textsubscript{2} or B\textsubscript{50}N\textsubscript{2} in which the 2C (or 2N) occupy the 2(b) positions; the remaining 2B are distributed statistically at other "vacant" sites in the lattice. Note that this reformulation solves three problems which attended the description of the α-tetragonal phase as a crystalline modification of pure B:

1. The lattice parameters showed considerable variation from one crystal to another with average values \(a\) 875 pm, \(c\) 506 pm; this is now thought to arise from variable composition depending on the precise preparative conditions used.
2. The interatomic distances involving the single 4-coordinate atoms at 2(b) were only 160 pm; this is unusually short for B–B but reasonable for B–C or B–N distances.
3. The structure requires 160 valence electrons per unit cell computed as follows: internal bonding within the 4 icosahedra (4 × 26 = 104); external bonds for the 4 icosahedra (4 × 12 = 48); bonds shared by the atoms in 2(b) positions (2 × 4 = 8). However, 50 B atoms have only 150 valence electrons and even with the maximum possible excess of boron in the unit cell (0.75 B) this rises to only 152 electrons. The required extra 8 or 10 electrons are now supplied by 2C or 2N though the detailed description of the bonding is more intricate than this simple numerology implies.

The thermodynamically most stable polymorph of boron is the β-rhombohedral modification which has a much more complex structure with 105 B atoms in the unit cell \((a_0\) 1014.5 pm, \(α\) 65.28°). The basic unit can be thought of as a central B\textsubscript{12} icosahedron surrounded by an icosahedron of icosahedra; this can be visualized as 12 of the B\textsubscript{7} units in Fig. 6.1b arranged so that the apex atoms form the central B\textsubscript{12} surrounded by 12 radially disposed pentagonal dishes to give the B\textsubscript{84} unit shown in Fig. 6.3a. The 12 half-icosahedra are then completed by means of 2 complicated B\textsubscript{10} subunits per unit cell, each comprising a central 9-coordinate B atom surrounded by 9 B atoms in the form of 4 fused pentagonal rings. This arrangement corresponds to 104 B \((84 + 10 + 10)\) and there is, finally, a 6-coordinate B atom at the centre of symmetry between 2 adjacent B\textsubscript{10} condensed units, bringing the total to 105 B atoms in the unit cell.

The first crystalline polymorph of B to be prepared (1943) was termed α-tetragonal boron and was found to have 50 B atoms in the unit cell \((4B\textsubscript{12} + 2B)\) (Fig. 6.4). Paradoxically, however, more recent work (1974) suggests that this phase never forms in the absence of carbon or nitrogen as impurity and that it is, in reality, B\textsubscript{50}C\textsubscript{2} or B\textsubscript{50}N\textsubscript{2} depending on the preparative conditions; yields are increased considerably when the BB\textsubscript{3}/H\textsubscript{2} mixture is purposely doped with a few per cent of CH\textsubscript{4}, CHBr\textsubscript{3} or N\textsubscript{2}. The
work illustrates the great difficulties attending preparative and structural studies in this area. The crystal structures of other boron polymorphs, particularly the \( \beta \)-tетragonal phase with 192 B atoms in the unit cell \((a 1012, c 1414 \text{ pm})\), are even more complex and have so far defied elucidation despite extensive work by many investigators.\(^3\)

### 6.2.3 Atomic and physical properties of boron

Boron has 2 stable naturally occurring isotopes and the variability of their concentration (particularly the difference between borates from California (low in \(^{10}\)B) and Turkey (high in \(^{11}\)B)) prevents the atomic weight of boron being quoted more precisely than 10.811(7) (p. 17). Each isotope has a nuclear spin (Table 6.1) and this has proved particularly valuable in nmr spectroscopy, especially for \(^{11}\)B.\(^4\) The great difference in neutron absorption cross-section of the 2 isotopes is also notable, and this has led to the development of viable separation processes on an industrial scale. The commercial availability of the separated isotopes has greatly assisted the solution of structural and mechanistic problems in boron chemistry and has led to the development of boron-10 neutron capture therapy for the treatment of certain types of brain tumour (see p. 179).

Boron is the fifth element in the periodic table and its ground-state electronic configuration is \([\text{He}]2s^22p^1\). The first 3 ionization energies are 800.6, 2427.1 and 3659.7 kJ mol\(^{-1}\), all substantially larger than for the other elements in Group 13. (The values for this and other properties of B are compared with those for Al, Ga, In and Tl on p. 222). The electronegativity (p. 25) of B is 2.0, which is close to the values for H (2.1) Si (1.8) and Ge (1.8) but somewhat less than the value for C (2.5). The implied reversal of the polarity of B–H and C–H bonds is an important factor in discussing hydroboration (p. 166) and other reactions.

The determination of precise physical properties for elemental boron is bedevilled by the twin difficulties of complex polymorphism and contamination by irremovable impurities. Boron is an extremely hard refractory solid of high mp, low density and very low electrical conductivity. Crystalline forms are dark red in transmitted light and powdered forms are black. The most stable (\( \beta \)-rhombohedral) modification has mp 2092°C (exceeded only by C among the non-metals), bp \(~4000^\circ\text{C}\), \(d\) 2.35 g cm\(^{-3}\) (\(\alpha\)-rhombohedral form 2.45 g cm\(^{-3}\)), \(\Delta H_{\text{sublimation}}\) 570 kJ per mol of B, electrical conductivity at room temperature \(1.5 \times 10^{-6} \text{ ohm}^{-1} \text{ cm}^{-1}\).

#### 6.2.4 Chemical properties

It has been argued\(^1\) that the inorganic chemistry of boron is more diverse and complex than that of any other element in the periodic table. Indeed, it is only during the last three decades that the enormous range of structural types has begun to

\(^b\)1 barn = \(10^{-28} \text{ m}^2\) in SI; the cross-section for natural boron (~20% \(^{10}\)B) is ~767 barns.
be elucidated and the subtle types of bonding appreciated. The chemical nature of boron is influenced primarily by its small size and high ionization energy, and these factors, coupled with the similarity in electronegativity of B, C and H, lead to an extensive and unusual type of covalent (molecular) chemistry. The electronic configuration $2s^22p^1$ is reflected in a predominant tervalence, and bond energies involving B are such that there is no tendency to form univalent compounds of the type which increasingly occur in the chemistry of Al, Ga, In and Tl. However, the availability of only 3 electrons to contribute to covalent bonding involving the 4 orbitals $s$, $p_x$, $p_y$ and $p_z$ confers a further range of properties on B leading to electron-pair acceptor behaviour (Lewis acidity) and multicentre bonding (p. 157). The high affinity for oxygen is another dominant characteristic which forms the basis of the extensive chemistry of borates and related oxo complexes (p. 203). Finally, the small size of B enables many interstitial alloy-type metal borides to be prepared, and the range of these is considerably extended by the propensity of B to form branched and unbranched chains, planar networks, and three-dimensional arrays of great intrinsic stability which act as host frameworks to house metal atoms in various stoichiometric proportions.

It is thus possible to distinguish five types of boron compound, each having its own chemical systematics which can be rationalized in terms of the type of bonding involved, and each resulting in highly individualistic structures and chemical reactions:

(i) metal borides ranging from $M_3B$ to $MB_{66}$ (or even $MB_{110}$) (see below);
(ii) boron hydrides and their derivatives including carbaboranes and polyhedral borane-metal complexes (p. 151);
(iii) boron trihalides and their adducts and derivatives (p. 195);
(iv) oxo compounds including polyborates, borosilicates, peroxoborates, etc. (p. 203);
(v) organoboron compounds and B–N compounds (B–N being isoelectronic with C–C) (p. 207).

The chemical reactivity of boron itself obviously depends markedly on the purity, crystallinity, state of subdivision and temperature. Boron reacts with $F_2$ at room temperature and is superficially attacked by $O_2$ but is otherwise inert. At higher temperatures boron reacts directly with all the non-metals except H, Ge, Te and the noble gases. It also reacts readily and directly with almost all metals at elevated temperatures, the few exceptions being the heavier members of groups 11–15 (Ag, Au; Cd, Hg; Ga, In, Tl; Sn, Pb; Sb, Bi).

The general chemical inertness of boron at lower temperatures can be gauged by the fact that it resists attack by boiling concentrated aqueous NaOH or by fused NaOH up to 500°C, though it is dissolved by fused Na$_2$CO$_3$/NaN$O_3$ mixtures at 900°C. A 2:1 mixture of hot concentrated $H_2SO_4/HNO_3$ is also effective for dissolving elemental boron for analysis but non-oxidizing acids do not react.

### 6.3 Borides

#### 6.3.1 Introduction

The borides comprise a group of over 200 binary compounds which show an amazing diversity of stoichiometries and structural types; e.g. $M_3B$, $M_4B$, $M_3B$, $M_3B_2$, $M_7B_3$, $M_2B$, $M_5B_3$, $M_3B_2$, $M_{11}B_8$, $MB$, $M_{10}B_{11}$, $M_3B_4$, $M_2B_3$, $M_3B_5$, $MB_2$, $M_2B_5$, $MB_3$, $MB_4$, $MB_6$, $M_3B_{13}$, $MB_{10}$, $MB_{12}$, $MB_{15}$, $MB_{18}$ and $MB_{66}$. There are also numerous nonstoichiometric phases of variable composition and many ternary and more complex phases in which more than one metal combines with boron. The rapid advance in our understanding of these compounds during the past few decades has been based mainly on X-ray diffraction analysis and the work has been stimulated not only by the inherent academic challenge implied by the existence of these unusual compounds but also by the extensive industrial interest generated by their unique combination of desirable physical and chemical properties (see Panel).
Properties and Uses of Borides

Metal-rich borides are extremely hard, chemically inert, involatile, refractory materials with mps and electrical conductivities which often exceed those of the parent metals. Thus the highly conducting diborides of Zr, Hf, Nb and Ta all have mps > 3000°C and TiB₂ (mp 2980°C) has a conductivity 5 times greater than that of Ti metal. Borides are normally prepared as powders but can be fabricated into the desired form by standard techniques of powder metallurgy and ceramic technology. TiB₂, ZrB₂ and CrB₂ find application as turbine blades, combustion chamber liners, rocket nozzles and ablation shields. Ability to withstand attack by molten metals, slags and salts have commended borides or boride-coated metals as high-temperature reactor vessels, vaporizing boats, crucibles, pump impellers and thermocouple sheaths. Inertness to chemical attack at high temperatures, coupled with excellent electrical conductivity, suggest application as electrodes in industrial processes.

Nuclear applications turn on the very high absorption cross-section of ¹⁰B for thermal neutrons (p. 144) and the fact that this property is retained for high-energy neutrons (10⁴–10⁶ eV) more effectively than for any other nuclide. Another advantage of ¹⁰B is that the products of the (n,α) reaction are the stable, non-radioactive elements Li and He. Accordingly, metal borides and boron carbide have been used extensively as neutron shields and control rods since the beginning of the nuclear power industry. More dramatically, following the disaster at Chernobyl in the early hours of 26 April 1986, some 40 tonnes of boron carbide particles were dumped from helicopters onto the stricken reactor to prevent further runaway fission occurring. (In addition there were 800 tonnes of dolomite to provide a CO₂ gas blanket, 1800 t of clay and sand to quench the fires and filter radionuclides, plus 2400 t of lead to absorb heat by melting and to provide a liquid layer that would in time solidify and seal the top of the core of the vault.)

The principal non-nuclear industrial use of boron carbide is as an abrasive grit or powder for polishing or grinding; it is also used on brake and clutch linings. In addition, there is much current interest in its use as light-weight protective armour, and tests have indicated that boron carbide and beryllium borides offer the best choice; applications are in bullet-proof protective clothing and in protective armour for aircraft. More elegantly, boron carbide can now be produced in fibre form by reacting BCl₃/H₂ with carbon yarn at 1600–1900°C:

\[4\text{BCl}_3 + 6\text{H}_2 + \text{C(fibres)} \rightarrow \text{B}_4\text{C(fibres)} + 12\text{HCl}\]

Fibre curling can be eliminated by heat treatment under tension near the mp, and the resulting fibres have a tensile strength of \(3.5 \times 10^5\) psi (1 psi = 6895 N m⁻²) and an elastic modulus of \(50 \times 10^6\) psi at a density of 2.35 g cm⁻³; the form was 1 ply, 720 filament yarn with a filament diameter of 11–12 μm. The fibres are inert to hot acid and alkali, resistant to Cl₂ up to 700°C and air up to 800°C.

Boron itself has been used for over two decades in filament form in various composites; BCl₃/H₂ is reacted at 1300°C on the surface of a continuously moving tungsten fibre 12 μm in diameter. US production capacity is about 20 tonnes pa and the price in about $800/kg. The primary use so far has been in military aircraft and space shuttles, but boron fibre composites are also being studied as reinforcement materials for commercial aircraft. At the domestic level they are finding increasing application in golf shafts, tennis rackets and bicycle frames.

6.3.2 Preparation and stoichiometry

Eight general methods are available for the synthesis of borides, the first four being appropriate for small-scale laboratory preparations and the remaining four for commercial production on a scale ranging from kilogram amounts to tonne quantities. Because high temperatures are involved and the products are involatile, borides are not easy to prepare pure and subsequent purification is often difficult; precise stoichiometry is also sometimes hard to achieve because of differential volatility or high activation energies. The methods are:

(i) Direct combination of the elements: this is probably the most widely used technique, e.g.

\[\text{Cr} + n\text{B} \xrightarrow{1150^\circ} \text{CrB}_n\]

(ii) Reduction of metal oxide with B (rather wasteful of expensive elemental B), e.g.

\[\text{Sc}_2\text{O}_3 + 7\text{B} \xrightarrow{1800^\circ} 2\text{ScB}_2 + 3\text{BO}\]

(iii) Co-reduction of volatile mixed halides with H₂ using a metal filament, hot tube or plasma torch, e.g.

\[2\text{TiCl}_4 + 4\text{BCl}_3 + 10\text{H}_2 \xrightarrow{1300^\circ} 2\text{TiB}_2 + 20\text{HCl}\]
Reduction of BCl₃ (or BX₃) with a metal (sometimes assisted by H₂), e.g.

\[ nBX₃ + (x + 1)M \rightarrow MB_n + xMX_{3n/x} \]

\[ BCl₃ + W \xrightarrow{H₂/1200°} WB + Cl₂ + HCl \]

Electrolytic deposition from fused salts: this is particularly effective for MB₆ (M = alkaline earth or rare earth metal) and for the borides of Mo, W, Fe, Co and Ni. The metal oxide and B₂O₃ or borax are dissolved in a suitable, molten salt bath and electrolysed at 700–1000° using a graphite anode; the boride is deposited on the cathode which can be graphite or steel.

Co-reduction of oxides with carbon at temperatures up to 2000°, e.g.

\[ V₂O₅ + B₂O₃ + 8C \xrightarrow{1500°} 2VB + 8CO \]

Reduction of metal oxide (or M + B₂O₃) with boron carbide, e.g.

\[ Eu₂O₃ + 3B₄C \xrightarrow{1600°} 2EuB₆ + 3CO \]

\[ 7Ti + B₂O₃ + 3B₄C \xrightarrow{2000°} 7TiB₂ + 3CO \]

Boron carbide (p. 149) is a most useful and economic source of B and will react with most metals or their oxides. It is produced in tonnage quantities by direct reduction of B₂O₃ with C at 1600°: a C resistor is embedded in a mixture of B₂O₃ and C, and a heavy electric current passed.

Co-reduction of mixed oxides with metals (Mg or Al) in a thermite-type reaction — this usually gives contaminated products including ternary borides, e.g. Mo₇Al₆B₇. Alternatively, alkali metals or Ca can be used as reductants, e.g.

\[ TiO₂ + B₂O₃ \xrightarrow{molten Na} TiB₂ \]

The various stoichiometries are not equally common, as can be seen from Fig. 6.5; the most frequently occurring are M₂B, MB, MB₂, MB₄ and MB₆, and these five classes account for 75% of the compounds. At the other extreme Ru₁₁B₈ is the only known example of this stoichiometry. Metal-rich borides tend to be formed by the transition elements whereas the boron-rich borides are characteristic of the more electropositive elements in Groups 1–3, the lanthanides and the actinides. Only the diborides MB₂ are common to both classes.

![Figure 6.5](https://example.com/figure6_5.png)

**Figure 6.5** Frequency of occurrence of various stoichiometries among boride phases: (a) field of borides of d elements, and (b) field of borides of s, p and f elements.

### 6.3.3 Structures of borides

The structures of metal-rich borides can be systematized by the schematic arrangements shown in Fig. 6.6, which illustrates the increasing tendency of B atoms to catenate as their concentration in the boride phase increases; the B atoms are often at the centres of trigonal prisms of metal atoms (Fig. 6.7) and the various stoichiometries are accommodated as follows:

---

Idealized patterns of boron catenation in metal-rich borides. Examples of the structures (a)–(f) are given in the text. Boron atoms are often surrounded by trigonal prisms of M atoms as shown in Fig. 6.7.

Idealized boron environment in metal-rich borides (see text): (a) isolated B atoms in M₃B and M₇B₃; (b) pairs of B atoms in Cr₅B₃ and M₁B₂; (c) zigzag chains of B atoms in Ni₃B₄ and MB; (d) branched chains in Ru₁₁B₈; and (e), (f) double chains and plane nets in M₃B₄, MB₂ and M₂B₃.

(a) isolated B atoms: Mn₄B; M₃B (Tc, Re, Co, Ni, Pd); Pd₃B₂; M₂B₃ (Tc, Re, Ru, Rh); M₂B (Ta, Mo, W, Mn, Fe, Co, Ni);

(b) isolated pairs B₂: M₃B₂ (V, Nb, Ta);

(c) zigzag chains of B atoms: Cr, Mn, Ni; MB (Ti, Hf); V, Nb, Ta; Cr, Mo, W; Mn, Fe, Co, Ni;

(d) branched chains of B atoms: Ru₁₁B₈;

(e) double chains of B atoms: M₃B₄ (V, Nb, Ta; Cr, Mn);

(f) plane (or puckered) nets: MB₂ (Mg, Al; Sc, Y; Ti, Zr, Hf; V, Nb, Ta; Cr, Mo, W; Mn, Tc, Re; Ru, Os; U, Pu); M₂B₅ (Ti; Mo, W).

It will be noted from Fig. 6.6 that structures with isolated B atoms can have widely differing interatomic B–B distances, but all other classes involve appreciable bonding between B atoms, and the B–B distances remain almost invariant despite the extensive variation in the size of the metal atoms.
The structures of boron-rich borides (e.g. MB₄, MB₆, MB₁₀, MB₁₂, MB₆₆) are even more effectively dominated by inter-B bonding, and the structures comprise three-dimensional networks of B atoms and clusters in which the metal atoms occupy specific voids or otherwise vacant sites. The structures are often exceedingly complicated (for the reasons given in Section 6.2.2): for example, the cubic unit cell of YB₆₆ has a₀ 2344 pm and contains 1584 B and 24 Y atoms; the basic structural unit is the 13-icosahedron unit of 156 B atoms found in β-rhombohedral B (p. 142); there are 8 such units (1248 B) in the unit cell and the remaining 336 B atoms are statistically distributed in channels formed by the packing of the 13-icosahedron units.

Another compound which is even more closely related to β-rhombohedral boron is boron carbide, “B₄C”; this is now more correctly written as B₁₃C₂, but the phase can vary over wide composition ranges which approach the stoichiometry B₁₂C₃. The structure is best thought of in terms of B₈₄ polyhedra (p. 142) but these are now interconnected simply by linear C–B–C units instead of the larger B₁₀–B–B₁₀ units in β-rhombohedral B. The result is a more compact packing of the 13-icosahedron units so generated and this is reflected in the unit cell dimensions (a 517.5 pm, α 65.74°). A notable feature of the structure (Fig. 6.8) is the presence of regular hexagonal planar rings B₄C₂ (shaded). Stringent tests had to be applied to distinguish confidently between B and C atoms in this structure and to establish that it was indeed B₁₂ CBC and not B₁₂C₃ as had previously been thought. [This view has recently been challenged as a result of a ¹³C nmr study using magic-angle spinning, which suggests that the carbon is present only as C₃ chains and that the structure is in fact still best represented as B₁₂C₃ (or B₁₂²⁻C₃²⁺).] It is salutary to recall that boron carbide, which was first made by H. Moissan in 1899 and which has been manufactured in tonne amounts for several decades, still waits definitive structural characterization. On one view the wide variation in stoichiometry from “B₆.₅C” to “B₄C” is due to progressive vacancies in the CBC chain (B₁₂C₂ ≡ B₆C) and/or progressive substitution of one C for B in the icosahedron [(B₁₁C)CBC ≡ B₄C)]. Related phases are B₁₂PBP and B₁₂X₂ (X = P, As, O, S). See also p. 288 for BₙC₆₀₋ₙ (n = 1–6).

By contrast with the many complex structures formally related to β-rhombohedral boron, the structures of the large and important groups of cubic borides MB₁₂ and MB₆ are comparatively simple. MB₁₂ is formed by many large electropositive metals (e.g. Sc, Y, Zr, lanthanides and actinides) and has an “NaCl-type” fcc structure in which M atoms alternate with B₁₂ cubo-octahedral clusters (Fig. 6.9). (Note that the B₁₂ cluster is not an icosahedron.) Similarly, the cubic hexaborides MB₆ consist of a simple CsCl-type lattice in which the halogen is replaced by B₆ octahedra (Fig. 6.10); these B₆ octahedra are linked together in all 6 orthogonal directions to give a rigid but open framework which can accommodate large,
electropositive metal atoms at the corners of the interpenetrating cubic sublattice. The rigidity of the B framework is shown by the very small linear coefficient of thermal expansion of hexaborides \((6-8 \times 10^{-6} \text{ deg}^{-1})\) and by the narrow range of lattice constants of these phases which vary by only 4% \((410-427 \text{ pm})\), whereas the diameters of the constituent metal atoms vary by 25% \((355-445 \text{ pm})\). Bonding theory for isolated groups such as \(\text{B}_6\text{H}_6^{2-}\) \((p. 160)\) requires the transfer of 2 electrons to the borane cluster to fill all the bonding MOs; however, complete transfer of 2e per \(\text{B}_6\) unit is not required in a three-dimensional crystal lattice and calculations for \(\text{MB}_6\) \((\text{Ca, Sr, Ba})\) indicate the transfer of only 0.9–1.0e.\(^8\) This also explains why metal-deficit phases \(\text{M}_{1-x}\text{B}_6\) remain stable and why the alkali metals \((\text{Na, K})\) can form hexaborides. The \(\text{M}^{II}\text{B}_6\) hexaborides \((\text{Ca, Sr, Ba, Eu, Yb})\) are semiconductors but \(\text{M}^{III}\text{B}_6\) and \(\text{M}^{IV}\text{B}_6\) \((\text{M}^{III} = \text{Y, La, lanthanides}; \text{M}^{IV} = \text{Th})\) have a high metallic conductivity at room temperature \(10^4 - 10^5 \text{ ohm}^{-1} \text{ cm}^{-1}\).

The “radius” of the 24-coordinate metal site in \(\text{MB}_6\) is too large \((215-225 \text{ pm})\) to be comfortably occupied by the later (smaller) lanthanide elements \(\text{Ho, Er, Tm and Lu}\), and these form \(\text{MB}_4\) instead, where the metal site has a radius of 185–200 pm. The structure of \(\text{MB}_4\) (also formed by \(\text{Ca, Y, Mo and W}\)) consists of a tetragonal lattice formed by chains of \(\text{B}_6\) octahedra linked along the c-axis and joined laterally by pairs of \(\text{B}_2\) atoms in the \(xy\) plane so as to form a 3D skeleton with tunnels along the c-axis that are filled by metal atoms (Fig. 6.11). The pairs of boron atoms are thus surrounded by trigonal prisms of

---

metal atoms and the structure represents a transition between the puckered layer structures of MB₂ and the cubic MB₆.

Figure 6.11 Structure of ThB₄.

The structure and properties of many borides emphasize again the inadequacy of describing bonding in inorganic compounds as either ionic, covalent or metallic. For example, in conventional terminology LaB₆ would be described as a rigid, covalently bonded network of B₆ clusters having multicentred bonding within each cluster and 2-centre covalent B–B bonds between the clusters; this requires the transfer of up to 2 electrons from the metal to the boron sublattice and so could be said also to involve ionic bonding (La²⁺B₆²⁻) in addition to the covalent inter-boron bonding. Finally, the third valency electron on La is delocalized in a conduction band of the crystal (mainly metal based) and the electrical conductivity of the boride is actually greater than that of La metal itself so that this aspect of the bonding could be called metallic. The resulting description of the bonding is an ad hoc mixture of four oversimplified limiting models and should more logically be replaced by a generalized MO approach. It will also be clear from the preceding paragraphs that a classification of borides according to the periodic table does not result in the usual change in stoichiometry from one group to the next; instead, a classification in terms of the type of boron network and the size and electropositivity of the other atoms is frequently more helpful and revealing of periodic trends.

6.4 Boranes (Boron Hydrides)(1,9)

6.4.1 Introduction

Borane chemistry began in 1912 with A. Stock’s classic investigations, and the numerous compounds prepared by his group during the following 20 y proved to be the forerunners of an amazingly diverse and complex new area of chemistry. During the past few decades the chemistry of boranes and the related carboranes (p. 181) has been one of the major growth areas in inorganic chemistry, and interest continues unabated. The importance of boranes stems from three factors: first, the completely unsuspected structural principles involved; secondly, the growing need to extend covalent MO bond theory considerably to cope with the unusual stoichiometries; and finally, the emergence of a versatile and extremely extensive reaction chemistry which parallels but is quite distinct from that of organic and organometallic chemistry. This efflorescence of activity culminated (in the centenary year of Stock’s birth) in the award of the 1976 Nobel Prize for Chemistry to W. N. Lipscomb (Harvard) “for his studies of boranes which have illuminated problems of chemical bonding”.

Over 50 neutral boranes, BₙHₘ, and an even larger number of borane anions BₙHₘ⁻ have been characterized; these can be classified

---

according to structure and stoichiometry into 5 series though examples of neutral or unsubstituted boranes themselves are not known for all 5 classes:

closo-boranes (from Greek κλοσόδοξος, clovos, a cage) have complete, closed polyhedral clusters of $n$ boron atoms;
nido-boranes (from Latin nidus, a nest) have non-closed structures in which the $B_n$ cluster occupies $n$ corners of an $(n+1)$-cornered polyhedron;
arachno-boranes (from Greek ἀράχνη, arachne, a spider’s web) have even more open clusters in which the B atoms occupy $n$ contiguous corners of an $(n+2)$-cornered polyhedron;
hypho-boranes (from Greek ὑφέ, hyphe, a net) have the most open clusters in which the B atoms occupy $n$ corners of an $(n+3)$-cornered polyhedron;

Examples of these various series are listed below and illustrated in the accompanying structural diagrams. Their interrelations are further discussed in connection with carborane structures 51–81.

**Closo-boranes:**
$B_nH_n^{2-}$ ($n = 6–12$) see structures 1–7. The neutral boranes $B_nH_{n+2}$ are not known.

**Nido-boranes:**
$B_nH_{n+4}$, e.g. $B_2H_6$ (8), $B_5H_9$ (9), $B_6H_{10}$ (10), $B_{10}H_{14}$ (11); $B_8H_{12}$ also has this formula but has a rather more open structure (12) which can be visualized as being formed from $B_{10}H_{14}$ by removal of B(9) and B(10).

$B_nH_{n+3}$– formed by removal of 1 bridge proton from $B_nH_{n+4}$, e.g. $B_3H_8$–, $B_{10}H_{13}$–; other anions in this series such as $B_4H_7$– and $B_5H_{12}$– are known though the parent boranes have proved too fugitive to isolate; $BH_4$– can be thought of as formed by addition of $H^-$ to $BH_3$.

$$B_nH_{n+2}^{2-}, \text{ e.g. } B_{10}H_{12}^{2-}, B_{11}H_{13}^{2-}.$$ 

**Arachno-boranes:**
$B_nH_{n+6}$, e.g. $B_9H_{10}$ (13), $B_3H_{11}$ (14), $B_6H_{12}$ (15), $B_8H_{14}$ (16), $n$-$B_9H_{15}$ (17), $i$-$B_9H_{15}$.

$B_nH_{n+5}$–, e.g. $B_2H_7$– (18), $B_3H_8$– (19), $B_5H_{10}$–, $B_9H_{14}$– (20), $B_{10}H_{15}$–.

$B_nH_{n+4}$–, e.g. $B_{10}H_{14}$– (21).

**Hypho-boranes:**
$B_nH_{n+8}$. No neutral borane has yet been definitely established in this series but the known compounds $B_9H_{16}$ and $B_{10}H_{18}$ may prove to be hypho-boranes and several adducts are known to have hypho-structures (pp. 171–2).

**Conjuncto-boranes:**
$B_nH_m$. At least five different structure types of interconnected borane clusters have been identified; they have the following features:

(a) fusion by sharing a single common B atom, e.g. $B_{15}H_{23}$ (22);

(b) formation of a direct 2-centre $B$–$B$ bond between 2 clusters, e.g. $B_8H_{18}$, i.e. ($B_4H_9$)$_2$ (23), $B_{10}H_{16}$, i.e. ($B_5H_8$)$_2$ (3 isomers) (24), $B_{20}H_{26}$, i.e. ($B_{10}H_9$)$_2$ (11 possible isomers of which most have been prepared and separated), (e.g. 25a, b, c); anions in this subgroup are represented by the 3 isomers of $B_{20}H_{18}$–, i.e. ($B_{10}H_9^{2-}$)$_2$ (26);

(c) fusion of 2 clusters via 2 B atoms at a common edge, e.g. $B_{13}H_{19}$ (27), $B_{14}H_{18}$ (28), $B_{14}H_{20}$ (29), $B_{16}H_{20}$ (30), $n$-$B_{18}H_{22}$ (31), $i$-$B_{13}H_{22}$ (32);

(d) fusion of two clusters via 3 B atoms at a common face: no neutral borane or borane anion is yet known with this conformation but the solvated complex ($MeCN)_2B_{20}H_{16}.MeCN$ has this structure (33);

(e) more extensive fusion involving 4 B atoms in various configurations, e.g. $B_{20}H_{16}$ (34), $B_{20}H_{18}^{2-}$ (35).
Boranes: Introduction

(1) The $\text{B}_9\text{H}_{12}^{2-}$ anion. The relationship to the structure of the $\text{B}_9$ network in $\text{GaB}_9$ and the boron cluster in $\text{B}_9\text{H}_9$ should be noted.

(2) Probable $D_{5h}$ pentagonal bipyramidal structure of the anion $\text{B}_9\text{H}_{12}^{2-}$ in solution.

(3) The $D_{5h}$ configuration of the boron atoms in $\text{B}_9\text{H}_{12}^{2-}$ showing the two structurally non-equivalent sets of 4 boron atoms.

(4) Structure of the boron cluster in $\text{B}_9\text{H}_{12}^{2-}$ (interatomic distances ± 1.5 pm). The four unique BH distances are 107, 110, 127 and 144 ± 1.5 pm.

(5) $\text{B}_9\text{H}_{12}^{2-}$ decaborane trihydroborate ($\text{B}_9\text{H}_{12}^{2-}$).

(6) $\text{B}_{10}\text{H}_{16}^{2-}$.

(7) Position of boron atoms and numbering system in the icosahedral borane anion $\text{B}_{12}\text{H}_{16}^{2-}$.

The hydrogen atoms, which are attached radially to each boron atom, are omitted for clarity. There are six B-B distances of 175.3 pm and 24 of 178 pm.
86.4.1 Boranes: Introduction

The 1,1'-isomer comprises two pentaborane(9) groups linked in eclipsed configuration via the apex boron atoms to give overall $D_4h$ symmetry; the B-B bond distances are 174 pm for the linking bond, 176 pm for the slant edge of the pyramids, and 171 pm for the basal boron atoms.
(26) Proposed structures for the three isomers of $[\text{B}_{10}\text{H}_{16}]^{4-}$; terminal hydrogen atoms omitted for clarity. (See also p. 180)

(27) $\text{B}_{13}\text{H}_{19}$

(28) Proposed structure of $\text{B}_{14}\text{H}_{18}$, omitting terminal hydrogen atoms for clarity

(29) $\text{B}_{14}\text{H}_{18}$
Terminal hydrogen atoms have been omitted for clarity

(30) $\text{B}_{16}\text{H}_{20}$

(31) $\nu\text{B}_{13}\text{H}_{12}$ (centrosymmetric)

(32) Plane projection of the structure of $\nu\text{B}_{14}\text{H}_{18}$. The two decaborane units are fused at the S(7') and 6(6') positions to give a non-centrosymmetric structure with $C_3$ symmetry
Boranes are usually named\(^{(12)}\) by indicating the number of B atoms with a latin prefix and the number of H atoms by an arabic number in parentheses, e.g. $\text{B}_3\text{H}_9$, pentaborane(9); $\text{B}_5\text{H}_{11}$, pentaborane(11). Names for anions end in “ate” rather than “ane” and specify both the number of H and B atoms and the charge, e.g. $\text{B}_3\text{H}_8^-$ octahydrooctaborate(1−). Further information can be provided by the optional inclusion of the italicized descriptors closo-, nido-, arachno-, hypho- and conjuncto-, e.g.:

$\text{B}_{10}\text{H}_{10}^{2-}$ : decahydro-closo-decaborate(2−)  
[structure (5)]

$\text{B}_{10}\text{H}_{14}$ : nido-decaborane(14) [structure (11)]

$\text{B}_{10}\text{H}_{14}^{2-}$ : tetradecahydro-arachno-decaborate(2−) [structure (21)]

$\text{B}_{10}\text{H}_{16}$ : 1,1′-conjuncto-decaborane(16)  
[structure (24a)]

[i.e. 1,1′-bi(nido-pentaboranyl)]

The detailed numbering schemes are necessarily somewhat complicated but, in all other respects, standard nomenclature practices are followed.\(^{(12)}\)

Derivatives of the boranes include not only simple substituted compounds in which H has been replaced by halogen, OH, alkyl or aryl groups, etc., but also the much more diverse and numerous class of compounds in which one or more B atom in the cluster is replaced by another main-group element such as C, P or S, or by a wide range of metal atoms or coordinated metal groups. These will be considered in later sections.

### 6.4.2 Bonding and topology

The definitive structural chemistry of the boranes began in 1948 with the X-ray crystallographic determination of the structure of decaborane(14); this showed the presence of 4 bridging H atoms and an icosahedral fragment of 10 B atoms. This was rapidly followed in 1951 by the unequivocal demonstration of the H-bridged structure of diborane(6) and by the determination of the structure of pentaborane(9). Satisfactory theories of bonding in boranes date from the introduction of the concept of the 3-centre 2-electron $\text{B}−\text{H}−\text{B}$ bond by H. C. Longuet-Higgins in 1949; he also extended the principle of 3-centre bonding and multicentre bonding to the higher boranes. These ideas have been extensively developed and
refined by W. N. Lipscomb and his group during the past four decades.\(^{13}\)

In simple covalent bonding theory molecular orbitals (MOs) are formed by the linear combination of atomic orbitals (LCAO); for example, two AOs can combine to give one bonding and one antibonding MO and the orbital of lower energy will be occupied by a pair of electrons. This is a special case of a more general situation in which a number of AOs are combined together by the LCAO method to construct an equal number of MOs of differing energies, some of which will be bonding, some possibly nonbonding and some antibonding. In this way 2-centre, 3-centre, and multicentre orbitals can be envisaged. The three criteria that determine whether particular AOs can combine to form MOs are that the AOs must (a) be similar in energy, (b) have appreciable spatial overlap, and (c) have appropriate symmetry. In borane chemistry two types of 3-centre bond find considerable application: B–H–B bridge bonds (Fig. 6.12) and central 3-centre BBB bonds (Fig. 6.13). Open 3-centre B–B–B bonds are not now thought to occur in boranes and their anions though they are still useful in describing the bonding in carbaboranes and other heteroatom clusters (p. 194). The relation between the 3-centre bond formation for B–H–B, where the bond angle at H is around 90° and the 3-centre bond formation for approximately linear H bonds A–H–..–B is given on pp. 63–4.

Localized 3-centre bond formalism can readily be used to rationalize the structure and bonding in most of the non-closo-boranes. This is illustrated for some typical nido- and arachno-boranes in the following plane-projection diagrams which use an obvious symbolism for normal 2-centre bonds: B–B \(\bullet\)–\(\circ\), B–H, \(\circ\)–\(\bullet\), (t = terminal), central 3-centre bonds \(\circ\)–\(\bullet\)–\(\circ\) and B–H\(_{\mu}\)–B bridge bonds \(\circ\)–\(\bullet\)–\(\circ\). It is particularly important

Each terminal BH$_2$ group and each (bridging) H$_n$ contributes 1 electron to the bridging; these 4 electrons just fill the two B–H–B bonds.

Each of the 4 B and 4H$_n$ contribute 1 electron to the B–H–B bonds, i.e. 4 pairs of electrons for the 4 (3-centre) bonds. The 2 "hinge" BH$_4$ groups each have 1 remaining electron and 1 orbital which interact to give the 2-centre B–B bond.

In B$_3$H$_9$ the bonding can be thought of as involving the structure shown and 3 other equivalent structures in which successive pairs of adjacent basal B atoms are combined with the apex B in a 3-centre bond.

number of valence electrons for a borane of formula B$_n$H$_m$ is $(3n + m)$ and the number of bonds shown in the structure should be just half this. It follows, too, that the number of electron-pair bonds in the molecule is $n$ plus the sum of the individual styx numbers (e.g. 13 for B$_5$H$_{11}$, 14 for B$_6$H$_{10}$) and this constitutes a further check.† An appropriate number of additional electrons should be added for anionic species.

For closo-boranes and for the larger open-cluster boranes it becomes increasingly difficult to write a simple satisfactory localized orbital structure, and a full MO treatment is required. Intermediate cases, such as B$_5$H$_9$, require several "resonance hybrids" in the localized orbital formation and, by the time B$_{10}$H$_{14}$ is considered there are 24 resonance hybrids, even assuming that no open 3-centre B–B–B bonds occur. The best single compromise structure in this case is the (4620) arrangement shown at the foot of the page, but the open 3-centre B–B–B bonds can be avoided if "fractional" central 3-centre bonds replace the B–B and B–B–B bonds in pairs:

† Further checks, which can readily be verified from the equations of balance, are (a) the number of atoms in a neutral borane molecule $= 2(s + t + y + x)$, and (b) there are as many framework electrons as there are atoms in a neutral borane B$_n$H$_m$ since each BH$_4$ group supplies 2 electrons and each of the $(m - n)$ "extra" H atoms supplies 1 electron, making $n + m$ in all.
MO Description of Bonding in \( \text{closo-B}_6\text{H}_6^{2-} \)

Closo \( \text{B}_6\text{H}_6^{2-} \) (structure 1) has a regular octahedral cluster of 6 B atoms surrounded by a larger octahedron of 6 radially disposed H atoms. Framework MOs for the \( \text{B}_6 \) cluster are constructed (LCAO) using the \( 2s, 2p_x, 2p_y \) and \( 2p_z \) boron AOs. The symmetry of the octahedron suggests the use of sp hybrids directed radially outwards and inwards from each \( \text{B} \) along the cartesian axes (see figure) and 2 pure p orbitals at right angles to these (i.e. oriented tangentially to the \( \text{B}_6 \) octahedron). These sets of AOs are combined, with due regard to symmetry, to give 24 MOs as follows: the 24 AOs on the 6 \( \text{B} \) combine to give 24 MOs of which 7 (i.e. \( n + 1 \)) are bonding framework MOs, 6 are used to form \( \text{B}-\text{H} \) bonds, and the remaining 11 are antibonding.

![Symmetry of orbitals on the \( \text{B}_6 \) octahedron.](image)

(a) Six outward-pointing (sp) orbitals used for \( \sigma \) bonding to 6 \( \text{H} \). (b) Six inward-pointing (sp) orbitals used to form the \( a_{1g} \) framework bonding molecular orbital. (c) Components for one of the \( t_{1u} \) framework bonding molecular orbitals — the other two molecular orbitals are in the \( yz \) and \( xz \) planes. (d) Components for one of the \( t_{2g} \) framework bonding molecular orbitals — the other two molecular orbitals are in the \( yz \) and \( xz \) planes.

The diagrams also indicate why neutral \( \text{closo-} \text{N}_6\text{H}_6^{2+} \) are unknown since the 2 anionic charges are effectively located in the low-lying inwardly directed \( a_{1g} \) orbital which has no overlap with protons outside the cluster (e.g. above the edges or faces of the \( \text{B}_6 \) octahedron). Replacement of the 6 \( \text{H} \) by 6 further \( \text{B} \) builds up the basic three-dimensional network of hexaborides \( \text{M}_6 \) (p. 150) just as replacement of the 4 \( \text{H} \) in \( \text{CH}_4 \) begins to build up the diamond lattice.

The diagrams, with minor modification, also describe the bonding in isoelectronic species such as \( \text{closo-CB}_3\text{H}_6^{-} \), \( 1,2\text{-closo-C}_2\text{B}_4\text{H}_6^- \), \( 1,6\text{-closo-C}_2\text{B}_4\text{H}_6^- \), etc. (pp. 181–2). Similar though more complex, diagrams can be derived for all \( \text{closo-B}_n\text{H}_n^{2-} \) \( (n = 6-12) \); these have the common feature of a low lying \( a_{1g} \) orbital and \( n \) other framework bonding MOs: in each case, therefore \( (n + 1) \) pairs of electrons are required to fill these orbitals as indicated in Wade's rules (p. 161). It is a triumph for MO theory that the existence of \( \text{B}_6\text{H}_6^{2-} \) and \( \text{B}_{12}\text{H}_{12}^{2-} \) were predicted by H. C. Longuet-Higgins in 1954–5,(14) a decade before \( \text{B}_6\text{H}_6^{2-} \) was first synthesized and some 5 y before the (accidental) preparation of \( \text{B}_{10}\text{H}_{10}^{2-} \) and \( \text{B}_{12}\text{H}_{12}^{2-} \) were reported.(15,16)

\[ \text{MO Approach to the bonding in \( \text{closo-B}_6\text{H}_6^{2-} \) (structure 1, p. 153) is shown in the Panel. It is a general feature of \( \text{closo-B}_n\text{H}_n^{2-} \) anions that there are no \( \text{B}-\text{H}-\text{B} \) or \( \text{BH}_2 \) groups and the \( 4n \) boron atomic orbitals are always} \]
distributed as follows:

\[ n \] in the \( n(B-H_t) \) bonding orbitals  

\( (n + 1) \) in framework bonding MOs  

\( (2n - 1) \) in nonbonding and antibonding framework MOs

As each B atom contributes 1 electron to its B–H\(_t\) bond and 2 electrons to the framework MOs, the \( (n + 1) \) framework bonding MOs are just filled by the \( 2n \) electrons from \( n \) B atoms and the 2 electrons from the anionic charge. Further, it is possible (conceptually) to remove a BH\(_t\) group and replace it by 2 electrons to compensate for the 2 electrons contributed by the BH\(_t\) group to the MOs. Electroneutrality can then be achieved by adding the appropriate number of protons; this does not alter the number of electrons in the system and hence all bonding MOs remain just filled.

\[
\text{B}_6\text{H}_9^- \xrightarrow{-\text{BH} + 2e^-} \{\text{B}_3\text{H}_5^4-\} \rightarrow 4\text{H}^+ \
\text{B}_3\text{H}_9 \quad (\text{structure 9, p. 154})
\]

\[
\text{B}_6\text{H}_9^- \xrightarrow{-2\text{BH} + 4e^-} \{\text{B}_4\text{H}_9^6-\} \rightarrow 6\text{H}^+ \
\text{B}_4\text{H}_{10} \quad (\text{structure 13})
\]

The structural interrelationship of all the various closo-, nido- and arachno-boranes thus becomes evident; a further example is shown at the foot of the page.

These relationships were codified in 1971 by K. Wade in a set of rules which have been extremely helpful not only in rationalizing known structures, but also in suggesting the probable structures of new species.\(^{(17)}\) Wade’s rules can be stated in extended form as follows:

- **closo-borane anions** have the formula \( \text{B}_n\text{H}_n^{2-} \); the B atoms occupy all \( n \) corners of an \( n \)-cornered triangulated polyhedron, and the structures require \( (n + 1) \) pairs of framework bonding electrons;

- **nido-boranes** have the formula \( \text{B}_n\text{H}_{n+4} \) with B atoms at \( n \) corners of an \( (n + 1) \) cornered polyhedron; they require \( (n + 2) \) pairs of framework-bonding electrons;

- **arachno-boranes**: \( \text{B}_n\text{H}_{n+6} \), \( n \) corners of an \( (n + 2) \) cornered polyhedron, requiring \( (n + 3) \) pairs of framework-bonding electrons;

- **hypho-boranes**: \( \text{B}_n\text{H}_{n+8} \): \( n \) corners of an \( (n + 3) \) cornered polyhedron, requiring \( (n + 4) \) pairs of framework-bonding electrons.

The rules can readily be extended to isoelectronic anions and carbaboranes \( (\text{BH}=\text{B}'=\text{C}) \) and also to metalloboranes (p. 174), metallocarbaboranes (p. 194) and even to metal clusters themselves, though they become less reliable the further one moves away from boron in atomic size, ionization energy, electronegativity, etc.

More sophisticated and refined calculations lead to orbital populations and electron charge distributions within the borane molecules and to predictions concerning the sites of electrophilic and nucleophilic attack. In general, the highest electron charge density (and the preferred site of electrophilic attack) occurs at apical B atoms which are furthest removed from open faces; conversely the lowest electron charge density (and the preferred site of nucleophilic attack) occurs on B atoms involved in B–H–B bonding. The consistency of this correlation implies that the electron distribution in the activated complex formed during reaction must follow a similar sequence to that in the ground state. Bridge H atoms tend to be more acidic than terminal H atoms and are the ones first lost during the formation of anions in acid-base reactions.

6.4.3 Preparation and properties of boranes

Earlier methods for preparing the boron hydrides were tedious and inefficient but have now been superseded by modern high-yield routes. The first great advance was to replace the reaction between protonic hydrogen and negative boride clusters by the reaction of hydridic species such as LiH or LiAlH₄ with boron halides or alkoxides which contain more positive boron centres. Subsequently, S. G. Shore and his group developed a systematic synthesis by using the Lewis acid properties of BX₃ (X = F, Cl, Br) to abstract H⁻ from the now readily available borane anions such as BH₄⁻, B₃H₈⁻ etc. For example:

\[
\begin{align*}
BX₃ + BH₄⁻ & \rightarrow HBX₃⁻ + (BH₃) \rightarrow 1/2B₂H₆ \\
BX₃ + B₃H₈⁻ & \rightarrow HBX₃⁻ + [B₃H₁]⁻ \rightarrow 1/2B₄H₁₀ + 1/2"B₂H₄" \text{ polymer} \\
BX₃ + B₄H₉⁻ & \rightarrow HBX₃⁻ + [B₄H₈]⁻ \rightarrow 1/2B₂H₁₁ + 1/2"B₂H₅" \text{ polymer} \\
BX₃ + B₄H₁₄⁻ & \rightarrow HBX₃⁻ + [B₄H₁₃]⁻ \rightarrow 1/2B₁₀H₁₄ + 1/2"B₈H₁₀" \text{ polymer} + 1/2H₂ \\
\end{align*}
\]

The perception by R. Schaeffer that nido-B₉H₁₀ (structure 10, pp. 154, 159) could act as a Lewis base towards reactive (vacant orbital) borane radicals has led to several new conjuncto-boranes, e.g.:

\[
\begin{align*}
B₆H₁₀ + 1/2B₂H₆ & \rightarrow [B₇H₁₁] \\
B₆H₁₀ & \rightarrow B₁₃H₁₉ + H₂ \\
B₆H₁₀ + B₈H₁₂ & \rightarrow B₁₄H₂₂ \\
B₆H₁₀ + iso-B₉H₁₅ & \rightarrow B₁₃H₂₃(22) + H₂ \\
\end{align*}
\]

A useful route to B–B bonded conjuncto-boranes involves the photolysis of parent nido-boranes. Thus, ultraviolet irradiation of B₅H₉ (9) yields the three isomers of conjuncto-B₁₀H₁₆ (24) and similar treatment of B₁₀H₁₄ (11) yields a mixture of 1,2'− and 2,2'−B₁₀H₁₃₋₂ (25a). High-yield catalytic routes to specific B–B coupled conjuncto-boranes (using PtBr₂) have been developed by L. G. Sneddon and his group, e.g. B₅H₉ gave 1,2'−(B₃H₈)₂ (24), B₄H₁₀ gave 1,1−(B₄H₉)₂ (i.e. conjuncto-B₈H₁₈, of which the 2,2'-isomer is shown in 23), and a mixture of B₄H₁₀ and B₅H₉ yielded 1,2'−(B₄H₉)(B₃H₈), i.e. conjuncto-B₁₀H₁₇. When applied to a mixture of B₂H₆ and B₅H₉ in decane at room temperature, the method gave the first authenticated neutral heptaborane, B₁₀H₁₃, in which one of the bridging H atoms in diborane has been replaced by a basal B atom of the B₅ unit, i.e. 1,2−µ(2-B₅H₈)B₂H₅.

The synthesis of closo-borane dianions B₉H₇⁻ (1–7) relies principally on thermolysis reactions of boranes in the presence of either BH₄⁻ or amino-borane adducts. The yields

---

are very sensitive to conditions (solvent, pressure and temperature) and mixtures are often obtained. A more recent variant is the thermolysis of Et₄NBH₄ at 175–190°C for about 12 hours, which yields a mixture of closo-B₉H₉²⁻, B₁₀H₁₀²⁻, B₁₂H₁₂²⁻ and nido-B₁₁H₁₄⁻. The smaller closo-dianions (n = 6, 7, 8) can then be obtained (in smaller yield) by the oxidative (air) degradation of B₉H₉⁻ salts in the presence of EtOH, thf or 1,2-dimethoxyethane.

Boranes are colourless, diamagnetic, molecular compounds of moderate to low thermal stability. The lower members are gases at room temperature but with increasing molecular weight they become volatile liquids or solids (Table 6.2); bps are approximately the same as those of hydrocarbons of similar molecular weight. The boranes are all endothermic and their free energies of formation ΔGᵣ are also positive; however, their thermodynamic instability results from the exceptionally strong interatomic bonds in both elemental B and H₂ rather than any weakness of the B–H bond. In this the boranes resemble the hydrocarbons. Likewise, the remarkable chemical reactivity of the boranes and their ready thermolytic interconversion (p. 164) should not be taken to imply that the bonds holding the boranes together are inherently weak. Indeed, the opposite is the case; the B–B and B–H bonds are among the strongest 2-electron bonds known, and the great reactivity of the boranes is to be sought rather in the availability of alternative structures and vacant orbitals of similar energies. Some comparative data are in Table 6.3(22) which shows that the bond enthalpies E for the 2-centre B–B bond in boranes and for the C–C bond in C₂H₆ are essentially identical and that the value for the 3-centre 2-electron BBB bond in boranes is very similar to that for the B–C bond in BMe₃.

Boranes are extremely reactive compounds and several are spontaneously flammable in air. *Arachno*-boranes tend to be more reactive (and less stable to thermal decomposition) than *nido*-boranes and reactivity also diminishes with increasing mol wt. *Closo*-borane anions are exceptionally stable and their general chemical behaviour has suggested the term “three-dimensional aromaticity”.

Boron hydrides have proved to be extremely versatile chemical reagents but the very diversity of their reactions makes a general classification unduly cumbersome. For this reason, the range of behaviour will be illustrated by typical examples taken from the chemistry of the boranes and their anions, arranged approximately according to the size of the borane cluster being discussed. Nearly all boranes are highly toxic when inhaled or absorbed through the skin though they can be safely and conveniently handled with relatively minor precautions.

---

6.4.4 The chemistry of small boranes and their anions (B₁–B₄)

Diborane occupies a special place because all the other boranes can be prepared from it (directly or indirectly); it is also one of the most studied and synthetically useful reagents in the whole of chemistry.\(^{(1,23)}\) B₂H₆ gas can most conveniently be prepared in small quantities by the reaction of I₂ on NaBH₄ in diglyme \([\text{MeOCH}_2\text{CH}_2\text{O}]\), or by the reaction of a solid tetrahydroborate with an anhydrous acid:

\[
\begin{align*}
2\text{NaBH}_4 + \text{I}_2 &\xrightarrow{\text{diglyme} \quad (98\% \text{ yield})} \text{B}_2\text{H}_6 + 2\text{NaI} + \text{H}_2 \\
2\text{NaBH}_4(c) + 2\text{H}_3\text{PO}_4(l) &\xrightarrow{(70\% \text{ yield})} \text{B}_2\text{H}_6(g) + 2\text{NaH}_2\text{PO}_4(c) + 2\text{H}_2(g)
\end{align*}
\]

When B₂H₆ is to be used as a reaction intermediate without the need for isolation or purification, the best procedure is to add Et₂OBF₃ to NaBH₄ in a polyether such as diglyme:

\[
\begin{align*}
3\text{NaBH}_4 + 4\text{Et}_2\text{OBF}_3 &\xrightarrow{\text{diglyme} \quad 25\°} 2\text{B}_2\text{H}_6(g) + 3\text{NaBF}_4 + 4\text{Et}_2\text{O}
\end{align*}
\]

On an industrial scale gaseous BF₃ can be reduced directly with NaH at 180° and the product trapped out as it is formed to prevent subsequent pyrolysis:

\[
\begin{align*}
2\text{BF}_3(g) + 6\text{NaH(c)} &\xrightarrow{180\°} \text{B}_2\text{H}_6(g) + 6\text{NaF(c)}
\end{align*}
\]

Some 200 tonnes per annum of B₂H₆ is produced commercially, worldwide. Care should be taken in all these reactions because B₂H₆ is spontaneously flammable; its heat of combustion \((-\Delta H^\circ)\) is higher per unit weight of fuel than for any other substance except H₂, BeH₂ and Be(BH₄)₂: \[\text{B}_2\text{H}_6(g) = 2165 \text{kJ mol}^{-1} = 78.2 \text{kJ g}^{-1}.\]

The pyrolysis of gaseous B₂H₆ in sealed vessels at temperatures above 100° is exceedingly complex and has only recently been fully elucidated.\(^{(24−27)}\) The initiating step is the unimolecular equilibrium dissociation of B₂H₆ to give 2[BH₃], and the {BH₃} then reacts with further B₂H₆ to give {B₃H₇} plus H₂ in a concerted rate-controlling reaction via a {B₃H₉} transition state. This explains the observed 1.5-order of the kinetics and also successfully interprets all other aspects of the initial reaction:

\[
\begin{align*}
\text{B}_2\text{H}_6 &\xrightarrow{} 2\{\text{BH}_3\} \\
\{\text{BH}_3\} + \text{B}_2\text{H}_6 &\xrightarrow{} \{\text{B}_3\text{H}_7\} + \text{H}_2
\end{align*}
\]

In these and subsequent reactions, unstable intermediates that have but transitory existence are placed in curly brackets, {}.

The first stable intermediate, B₄H₁₀, is then formed followed by B₅H₁₁:

\[
\begin{align*}
\{\text{BH}_3\} + \{\text{B}_3\text{H}_7\} &\xrightarrow{} \text{B}_4\text{H}_{10} \\
\text{B}_2\text{H}_6 + \{\text{B}_3\text{H}_7\} &\xrightarrow{} \{\text{BH}_3\} + \text{B}_4\text{H}_{10} \\
&\xrightarrow{} \text{B}_5\text{H}_{11} + \text{H}_2
\end{align*}
\]

A complex series of further steps gives B₅H₉, B₆H₁₀, B₆H₁₂, and higher boranes, culminating in B₁₀H₁₄ as the most stable end product, together with polymeric materials BH₄ and a trace of conjuncto-icosaboranes B₂₀H₂₆.

Careful control of temperature, pressure and reaction time enables the yield of the various intermediate boranes to be optimized. For example, B₃H₁₀ is best prepared by storing B₂H₆ under pressure at 25° for 10 days; this gives a 15% yield and quantitative conversion according to the

\[\text{B}_2\text{H}_6 + 2\text{BH}_3 \rightarrow \text{B}_3\text{H}_{10} + \text{H}_2.\]

---

§6.4.4 The chemistry of small boranes (B₁−B₄) 165

overall reaction:

$$2\text{B}_2\text{H}_6 \rightarrow \text{B}_4\text{H}_{10} + \text{H}_2$$

B₅H₁₁ can be prepared in 70% yield by the reaction of B₂H₆ and B₄H₁₀ in a carefully dimensioned hot/cold reactor at +120°/−30°:

$$2\text{B}_4\text{H}_{10} + \text{B}_2\text{H}_6 \longrightarrow 2\text{B}_5\text{H}_{11} + 2\text{H}_2$$

Alternative high-yield syntheses of these various boranes via hydride-ion abstraction from borane anions by BBr₃ and other Lewis acids have recently been devised (28) (see p. 162).

From the foregoing it is clear that BH₃ is a fugitive reaction species: it exists only at exceedingly low concentrations but can be isolated and studied using matrix isolation techniques. Thus it can be generated by thermal dissociation of loosely bound 1:1 adducts with Lewis bases, such as PF₃.BH₃, and its reactions studied. The relative stability of the adducts L.BH₃ has been determined from thermochemical and spectroscopic data and leads to the following unusual sequence:

$$\text{PF}_3 < \text{CO} < \text{Et}_2\text{O} < \text{Me}_2\text{O} < \text{C}_4\text{H}_8\text{O} < \text{C}_4\text{H}_8\text{S} < \text{Et}_2\text{S} < \text{Me}_2\text{S} < \text{py} < \text{Me}_3\text{N} < \text{H}^-$$

Note that both PF₃ and CO form isolable although weak adducts, and that organic sulfide adducts are more stable than those of ethers, thereby showing that BH₃ has some class b acceptor ("soft acid") characteristics despite the absence of low-lying d orbitals on boron (see p. 909). The ligand H⁻ is a special case since it gives the symmetrical tetrahedral ion BH₄⁻, isoelectronic with CH₄ and NH₄⁺. Many other complexes of BH₃ with N, P, As, O, S etc. donor atoms are also known and they are readily formed by symmetrical homolytic (cleavage of the bridge bonds in B₂H₆). Occasionally, however, unsymmetrical (heterolytic) cleavage products result, perhaps partly as a result of steric effects, e.g. NH₃, MeNH₂ and Me₂NH give unsymmetrical cleavage products whereas Me₃N gives the symmetrical cleavage product, Me₃N.BH₃ (see scheme below).

In addition to pyrolysis and cleavage reactions, B₂H₆ undergoes a wide variety of substitution, redistribution, and solvolytic reactions of which the following are representative. Gaseous HCl yields B₂H₅Cl₁ whereas Cl₂ (and F₂) give BX₃ directly even at low temperatures and high dilution. Methylation with PbMe₄ yields B₂H₅Me, but comproportionation with BMe₃ affords MeₙB₂H₆₋ₙ (n = 1–4), the two BHB bridge bonds remaining intact. Hydrolysis gives the stoichiometric amount of B(OH)₃. The related alcoholysis reaction was much used in earlier times as a convenient means of total analysis.

28 T. P. FEHLNER, Chap. 4 in ref. 9, pp. 175–96.

29 S. G. SHORE, Chap. 3 in ref. 9, pp. 79–174.
since the volatile B(OMe)3 could readily be distilled off and determined while the number of moles of H2 evolved equaled the number of H atoms in the borane molecule:

\[ \text{B}_2\text{H}_6 + 6\text{MeOH} \rightarrow 2\text{B(OMe)}_3 + 6\text{H}_2 \]

This works well for all nido- and arachnaboranes but not for the closo-dianions, which are much less reactive. Reactions of B2H6 with NH3 are complex and, depending on the conditions, yield aminodiborane, H2B(μ-H)(μ-NH2)BH2, or the dianmoniate of diborane, [BH2(NH3)2]-[BH4] (p. 165); at higher temperatures the benzene analogue borazine, (HNBH)3, results (see p. 210).

The remarkably facile addition of B2H6 to alkenes and alkynes in ether solvents at room temperatures was discovered by H. C. Brown and B. C. Subba Rao in 1956:

\[ 3\text{RCH}═\text{CH}_2 + \frac{1}{2}\text{B}_2\text{H}_6 \rightarrow \text{B(CH}_2\text{CH}_2\text{R)}_3 \]

This reaction, now termed hydroboration, has opened up the quantitative preparation of organoboranes and these, in turn, have proved to be of outstanding synthetic utility.\(^\text{30,31}\) It was for his development of this field that H. C. Brown (Purdue) was awarded the 1979 Nobel Prize in Chemistry. Hydroboration is regiospecific, the boron showing preferential attachment to the least substituted C atom (anti-Markovnikov). This finds ready interpretation in terms of electronic factors and relative bond polarities (p. 144); steric factors also work in the same direction. The addition is stereospecific cis (syn). Recent extensions of the methodology have encompassed the significant development of generalized chiral syntheses.\(^\text{32}\)

Diborane reacts slowly over a period of days with metals such as Na, K, Ca or their amalgams and more rapidly in the presence of ether:

\[ 2\text{B}_2\text{H}_6 + 2\text{Na} \rightarrow \text{NaBH}_4 + \text{NaB}_3\text{H}_8 \]

B3H8- prepared in this way was the first polyborane anion (1955); it is now more conveniently made by the reaction

\[ \text{B}_2\text{H}_6 + \text{NaBH}_4 \xrightarrow{\text{diglyme}} 100\text{o}^\circ \text{NaB}_3\text{H}_8 + \text{H}_2 \]

Alternatively, BH3.thf can be reduced by alkali metal amalgams (M = K, Rb, Cs) to give good yields of solvent-free products:\(^\text{33}\)

\[ 2\text{M/Hg} + 4\text{BH}_3.thf \rightarrow \text{MBH}_4 + \text{MB}_3\text{H}_8 \]

Tetrahydroborates, M(BH4)_x, were first identified in 1940 (M = Li, Be, Al) and since then have been widely exploited as versatile nucleophilic reducing agents which attack centres of low electron density (cf. electrophiles such as B2H6 and LBH3 which attack electron-rich centres). The most stable are the alkali derivatives MBH4: LiBH4 decomposes above ~380° but the others (Na–Cs) are stable up to ~600°. MBH4 are readily soluble in water and many other coordinating solvents such as liquid ammonia, amines, ethers (LiBH4) and polyethers (NaBb). They can be prepared by direct reaction of MH with either B2H6 or BX3 at room temperature though the choice of solvent is often crucial, e.g.:

\[ 2\text{LiH} + \text{B}_2\text{H}_6 \xrightarrow{\text{Et}_2\text{O}} 2\text{LiBH}_4 \]

\[ 2\text{NaH} + \text{B}_2\text{H}_6 \xrightarrow{\text{diglyme}} 2\text{NaBH}_4 \]

\[ 4\text{LiH} + \text{Et}_2\text{OBF}_3 \xrightarrow{} \text{LiBH}_4 + 3\text{LiF} + \text{Et}_2\text{O} \]

\[ 4\text{NaH} + \text{BCl}_3 \xrightarrow{\text{Al}_2\text{Et}_6} \text{NaBH}_4 + 3\text{NaCl} \]

These laboratory-scale syntheses are clearly unsuitable for large-scale industrial production;

---

\(^{31}\) D. J. Pasto, Solution reactions of borane and substituted boranes, Chap. 5 in ref. 7, pp. 197–222.

here the preferred route, introduced in the early 1960s is the Bayer process which uses borax (or ulexite), quartz, Na and H$_2$ under moderate pressure at 450–500°C.\(^{(34)}\)

$$\text{(Na}_2\text{B}_4\text{O}_7 + 7\text{SiO}_2) + 16\text{Na} + 8\text{H}_2 \rightarrow 4\text{NaBH}_4 + 7\text{Na}_2\text{SiO}_3$$

The resulting mixture is extracted under pressure with liquid NH$_3$ and the product obtained as a 98% pure powder (or pellets) by evaporation. An alternative route is:

$$\text{B(OMe)}_3 + 4\text{NaH} \xrightarrow{250–270^\circ} \text{NaBH}_4 + 3\text{NaOMe}$$

The resulting mixture is hydrolysed with water and the aqueous phase extracted with Pr$_3$NH$_2$.

Worldwide production of NaBH$_4$ is now about 3000 tonnes per annum (1990) and the price for powdered NaBH$_4$ in 1991 was $48.39/kg.

Reaction of MBH$_4$ with electronegative elements is also often crucially dependent on the solvent and on the temperature and stoichiometry of reagents. Thus LiBH$_4$ reacts with S at $-50^\circ$ in the presence of Et$_2$O to give Li[BH$_3$SH], whereas at room temperature the main products are Li$_3$S, Li[B$_2$S$_2$H$_6$], and H$_2$; at 200°C in the absence of solvent LiBH$_4$ reacts with S to give LiBS$_2$ and either H$_2$ or H$_2$S depending on whether S is in excess. Similarly, MBH$_4$ react with I$_2$ in cyclohexane at room temperature to give Bi$_3$, HI and MI, whereas in diglyme B$_2$H$_6$ is formed quantitatively (p. 164).

The product of reaction of BH$_4^-$ with element halides depends on the electropositivity of the element. Halides of the electropositive elements tend to form the corresponding M(BH$_4$)$_x$, e.g. M = Be, Mg, Ca, Sr, Ba; Zn, Cd; Al, Ga, Ti$^\text{IV}$; lanthanides; Ti, Zr, Hf and U$^\text{IV}$. Halides of the less electropositive elements tend to give the hydride or a hydrido-complex since the BH$_4$ derivative is either unstable or non-existent: thus SiCl$_4$ gives SiH$_4$; PCl$_3$ and PCl$_5$ give PH$_3$; Ph$_2$AsCl gives Ph$_2$AsH; [Fe(η$^5$-C$_5$H$_5$)(CO)$_2$Cl] gives [Fe(η$^5$-C$_5$H$_5$)(CO)$_2$H], etc.

A particularly interesting reaction (and one of considerable commercial value in the BOROL process for the in situ bleaching of wood pulp) is the production of dithionite, S$_2$O$_4^{2-}$, from SO$_2$:

$$\text{NaBH}_4 + 8\text{NaOH} + 8\text{SO}_2 \rightarrow 90\% \text{ yield} \rightarrow \text{4Na}_2\text{S}_2\text{O}_4 + \text{NaBO}_2 + 6\text{H}_2\text{O}$$

In reactions with organic compounds, LiBH$_4$ is a stronger (less selective) reducing agent than NaBH$_4$ and can be used, for example, to reduce esters to alcohols. NaBH$_4$ reduces ketones, acid chlorides and aldehydes under mild conditions but leaves other functions (such as –CN, −NO$_2$, esters) untouched; it can be used as a solution in alcohols, ethers, dimethylsulfoxide, or even aqueous alkali (pH > 10). Perhaps the classic example of its selectivity is shown below where an aldehyde group is hydrogenated in high yield without any attack on the nitro group, the bromine atom, the olefinic bond, or the thiophene ring:

\[
\begin{align*}
\text{O}_2\text{N} & \quad \begin{array}{c}
\text{S} \\
\text{Br}
\end{array} \\
\text{CH} & \quad \begin{array}{c}
\text{C} \\
\text{C} \quad \text{-CHO}
\end{array}
\end{align*}
\xrightarrow{\text{NaBH}_4/\text{EtOH}}
\begin{align*}
\text{O}_2\text{N} & \quad \begin{array}{c}
\text{S} \\
\text{Br}
\end{array} \\
\text{CH} & \quad \begin{array}{c}
\text{C} \\
\text{C} \quad \text{-CH}_2\text{OH}
\end{array}
\end{align*}
\]

Industrial interest in LiBH$_4$, and particularly NaBH$_4$, stems not only from their use as versatile reducing agents for organic functional groups and their use in the bleaching of wood pulp, but also for their application in the electroless (chemical) plating of metals. Traditionally, either sodium hypophosphite, Na$_3$H$_2$PO$_3$, or formaldehyd have been used (as in the silvering of glass), but NaBH$_4$ was introduced on an industrial scale in the early 1960s, notably for the deposition of Ni on metal or non-metallic substrates; this gives corrosion-resistant, hard, protective coatings, and is also useful for metallizing plastics prior to
further electroplating or for depositing contacts in electronics. Chemical plating also achieves a uniform thickness of deposit independent of the geometric shape, however complicated.

The BH$_4^-$ ion is essentially non-coordinating in its alkali metal salts. However, despite the fact that it is isoelectronic with methane, BH$_4^-$ has been found to act as a versatile ligand, forming many coordination compounds by means of 3-centre B–H→M bonds to somewhat less electropositive metals.\(^{35,37}\) Indeed, BH$_4^-$ affords a rare example of a ligand that can act in at least 6 coordination modes: $\eta^1$, $\eta^2$, $\eta^3$, $\mu(\eta^2,\eta^3)$, $\mu(\eta^3)$ and $\mu(\eta^4)$. Such complexes are usually readily prepared by reacting the corresponding (or closely related) halides with BH$_4^-$ in what are essentially ligand replacement reactions. Some examples follow:

$\eta^1$: [Cu($\eta^1$-BH$_4$)(PMePh$_2$)$_3$] (see Fig. 6.14a); [Cu($\eta^1$-BH$_4$)(MeC(CH$_2$PPh$_2$)$_3$)]; [FeH($\eta^1$-BH$_4$)-

---

---

Figure 6.14 Examples of the various coordination modes of BH$_4^-$ (continued on facing page).
§6.4.4 The chemistry of small boranes (B₁−B₄)

![Figure 6.14 continued]

(e) [Co(μ₃-BH₄)₂(μ-Ph₂P(CH₂)₃PPh₂)]₂

(f) [Ce(μ-η⁴-BH₄)(η⁴-C₃H₃Bu₂)]₂

Many complexes have more than one coordination mode of BH₄⁻ featured in their structure, e.g. [U₄⁺(η²-BH₄)(η⁴-BH₄)₂(dmpe)₂]. Likewise, whereas [M(BH₄)₄] are monomeric 12-coordinate complexes for M = Zr, Hf, Np, Pu, they are polymeric for M = Th, Pa, U: the coordination number rises to 14 and each metal centre is coordinated by two η³-BH₄⁻ and four bridging η²-BH₄⁻ groups. It is clear that among the factors which determine the mode adopted are the size of the metal atom and the steric requirements of the co-ligands. Many of the complexes are fluxional on an nmr timescale in solution; indeed, this property of fluxionality, which has been increasingly recognized to occur in many inorganic and organometallic systems, was first observed (1955) on the tris-bidentate complex [Al(η²-BH₄)₃].

The B₃H₈⁻ ion (p. 166) is a triangular cluster of C₃ (∉ C2ᵥ) symmetry (see Fig. 6.15a); the bridging H₆ atoms are essentially in the B₃ plane with H₆ above and below. While it has been conventional to represent the cluster bonding in terms of two BHB and one B–B bond (Fig. 6.15b), recent high-level computations(40) suggest the presence of a 3-centre BBB bond, as depicted approximately in Fig. 6.15c.

The arachno-anion B₃H₈⁻ is the only binary triboron species that is stable at room temperature and above. It can be viewed as a ligand-stabilized {B₃H₇} group, i.e. (L₃B₃H₇), in which the ligand is H⁺ (cf. B₄H₄⁻). However, the ion is completely fluxional in solution, all three boron atoms (and all eight protons) being equivalent on an nmr timescale. The B₃H₈⁻ anion has an

---

extensive reaction chemistry both as a reducing agent and as a source of arachno-$\text{B}_4\text{H}_{10}$ (p. 162). Conversely, unsymmetrical (heterolytic) cleavage of $\text{B}_4\text{H}_{10}$ with ligands, L, such as NH$_3$ yield $[\text{L}_2\text{BH}_2]^+[\text{B}_3\text{H}_8]^-$. The $\text{B}_3\text{H}_8^-$ ion is also a versatile ligand and forms bidentate and even tridentate complexes with many metal centres.$^{(41)}$ The octahedrally coordinated 18-electron manganese(I) complex $[\text{Mn}(\eta^3-\text{B}_3\text{H}_8)(\text{CO})_4]$ is a particularly instructive example. As can be seen from Fig. 6.16a it has a cluster structure that is clearly related to that of $\text{B}_4\text{H}_{10}$ (13). When heated to 180°C or irradiated with ultraviolet light the complex loses one of the four CO ligands and this enables a further B–H group to coordinate to give the trihapto complex fac-$[\text{Mn}(\eta^3-\text{B}_3\text{H}_8)(\text{CO})_3]$ (Fig. 6.16b). Treatment of this product with an excess of CO under moderate pressure regenerates the original dihapto species by a simple ligand replacement reaction.$^{(42)}$

6.4.5 Intermediate-sized Boranes and their Anions ($\text{B}_5$–$\text{B}_9$)

Pentaborane(9), nido-$\text{B}_5\text{H}_9$, is by far the most studied borane in this group. It can be prepared by passing a 1:5 mixture of $\text{B}_2\text{H}_6$ and H$_2$ at subatmospheric pressure through a furnace at 250°C with a residence time of 3 s (or at 225° with a 15 s residence time); there is a 70% yield and 30% conversion. Alternatively $\text{B}_3\text{H}_8$ can be pyrolysed for 2.5 days in a static hot/cold reactor at 180°/–80°. $\text{B}_3\text{H}_9$ is a colourless, volatile liquid, bp 60.0°C; it is thermally stable but chemically very reactive and spontaneously flammable in air. Its structure is essentially a square-based pyramid of B atoms each of which carries a terminal H atom and there are 4 bridging H atoms around the base (structure 9, p. 154). The slant edge of the pyramid, B(1)–B(2), is 168 pm and the basal interboron distances, B(2)–B(3) etc, are 178 pm; other key dimensions are B–H$_1$ 122 pm, B–H$_{\mu}$ 135 pm and B–H$_{\mu}$–B 83°. Calculations suggest that B(1) has a slightly higher electron density than the basal borons and that H$_{\mu}$ is slightly more positive than H$_1$. Apex-substituted derivatives 1-X$\text{B}_5\text{H}_8$ can
readily be prepared by electrophilic substitution (e.g. halogenation or Friedel-Crafts alkylation with RX or alkenes), whereas base-substituted derivatives 2-XB₅H₈ result when nucleophilic reaction is induced by amines or ethers, or when 1-XB₅H₈ is isomerized in the presence of a Lewis base such as hexamethylenetetramine or an ether:

\[
B₅H₉ + I₂/AlX₃ \rightarrow 1-IB₅H₈ \xrightarrow{\text{base}} (CH₂)₈N₄ \rightarrow 2-IB₅H₈
\]

SbF₅ \rightarrow 2-FB₅H₈

Further derivatives can be obtained by metathesis, e.g.

\[
2-ClB₅H₈ + NaMn(CO)₅ \rightarrow 2-\{(CO)₃Mn\}B₅H₈ \text{ (also Re)}
\]

B₅H₉ reacts with Lewis bases (electron-pair donors) to form adducts, some of which have now been recognized as belonging to the new series of hypho-borane derivatives BₓHₓ₋₈ (p. 152). Thus PMe₃ gives the adduct [B₅H₉(PMe₃)₂] which is formally analogous to [B₅H₁₁]²⁻ and the (unknown) borane B₅H₁₃. [B₅H₉(PMe₃)₂] has a very open structure in the form of a shallow pyramid with the ligands attached at positions 1 and 2 and with major rearrangement of the H atoms (Fig. 6.17a). Chelating phosphine ligands such as (Ph₂P)₂CH₂ and (Ph₂PCH₂)₂ have similar structures but [B₅H₉(Me₂NCH₂CH₂NMe₂)] undergoes a much more severe distortion in which the ligand chelates a single boron atom, B(2), which is joined to the rest of the molecule by a single bond to the apex B(1) (Fig. 6.17b). With NH₃ as ligand (at −78°) complete excision of one B atom occurs by “unsymmetrical cleavage” to give [(NH₃)₂B₄H₄]⁺[B₄H₇]⁻.

B₅H₉ also acts as a weak Brønsted acid and, from proton competition reactions with other boranes and borane anions, it has been established that acidity increases with increasing size of the borane cluster and that arachno-boranes are more acidic than nido-boranes:

\[
\text{nido : } B₅H₉ < B₆H₁₀ < B₁₀H₁₄ < B₁₆H₂₀ < B₁₈H₂₂
\]
\[
\text{arachno : } B₄H₁₀ < B₅H₁₁ < B₆H₁₂ \text{ and }
\]
\[
B₄H₁₀ > B₆H₁₀
\]

Accordingly, B₅H₉ can be deprotonated at low temperatures by loss of Hₓ⁺ to give B₅H₈⁻ providing a sufficiently strong base such as a lithium alkyl or alkali metal hydride is used. Bridge-substituted derivatives of B₅H₉ can then be obtained by reacting MB₅H₈ with chloro compounds such as R₂PCl, Me₃SiCl, Me₃GeCl,

---

Figure 6.17 Structure of hypho-borane derivatives: (a) [B₅H₉(PMe₃)₂] — the distances B(1)-B(2) and B(2)-B(3) are as in B₅H₉ (p. 170) but B(3)···B(4) is 295 pm (cf. B···B 297 pm in B₅H₁₁, structure 14, p. 154), and (b) [B₂H₆(Me₂NCH₂CH₂NMe₂)] — the distances B(2)···B(3) and B(2)···B(5) are 273 and 272 pm respectively.

or even Me₂BCl to give compounds in which the 3-centre B-H-B bond has been replaced by a 3-centre bond between the 2 B atoms and P, Si, Ge or B respectively. Many metal-halide coordination complexes react similarly, and the products can be considered as adducts in which the B₃H₉⁻ anion is acting formally as a 2-electron ligand via a 3-centre B-M-B bond.\(^{44,45}\) Thus [Cu_{1}(B₅H₈)(PPh₃)₂] (Fig. 6.18a) is readily formed by the low-temperature reaction of KB₅H₉ with [CuCl(PPh₃)₃] and analogous 16-electron complexes have been prepared for many of the later transition elements, e.g. [Cd(B₅H₈)Cl(PPh₃)], [Ag(B₅H₈)(PPh₃)₂] and [M^{II}(B₅H₈)XL₂], where M^{II} = Ni, Pd, Pt; X = Cl, Br, I; L₂ = a diphosphine or related ligand. By contrast, [Ir(CO)(PPh₃)₂] reacts by oxidative insertion of Ir and consequent cluster expansion to give \([\text{Ir(B}_5\text{H}_8)(\text{CO})(\text{PPh}_3)_2]\) which, though superficially of similar formula, has the structure of an irida-nido-hexaborane (Fig. 6.18b).\(^{46}\) In this, the \([\text{Ir(CO)(PPh}_3)_2]\) moiety replaces a basal BH₆H₄ unit in B₆H₁₀ (structure 10, p. 154).

Cluster-expansion and cluster-degradation reactions are a feature of many polyhedral borane species. Examples of cluster-expansion are:\(^{11,47}\)

\[
\text{LiB}_5\text{H}_8 + \frac{1}{2}\text{B}_2\text{H}_6 \xrightarrow{\text{Et}_3\text{O}^+/-78^\circ} \text{LiB}_6\text{H}_{11} \quad \text{(fast)}
\]

\[
\text{HCl} \quad \text{B}_6\text{H}_{12}
\]

\[
\text{Me}_2\text{O}^+/-78^\circ \xrightarrow{} \text{[LiB}_7\text{H}_{14}] \quad \text{(slow)}
\]

\[
\text{B}_6\text{H}_{10} + \text{LiBH}_4
\]

\[
1.8\text{B}_5\text{H}_9 + \text{MH} \xrightarrow{\text{thrt.}} \text{MB}_9\text{H}_{14} + \text{H}_2 \quad \text{plus minor products (M=Na, K)}
\]

Cluster degradation has already been mentioned in connection with the unsymmetrical cleavage reaction (p. 165) and other examples are:

\[
\text{KB}_9\text{H}_{14} + 0.4\text{B}_2\text{H}_9 \xrightarrow{\text{glyme/85°, 20h}} \text{KB}_{11}\text{H}_{14} + 1.8\text{H}_2
\]

Replacement of a \{BH\} unit in \(\text{B}_5\text{H}_9\) by an “isoelectronic” organometallic group such as \{Fe(CO)_3\} or \{Co(η^3-C_5\text{H}_5)\} can also occur, and this illustrates the close interrelation between metalloboranes, metal–metal cluster compounds, and organometallic complexes in general (see Panel).

The structures of several other nido- and arachno- \(\text{B}_5\text{–B}_9\) boranes are given on page 154 but a detailed discussion of their chemistry is beyond the scope of this treatment. Further information is in refs. 9, 11, 27, 51 and 52.

### 6.4.6 Chemistry of nido-decaborane, \(\text{B}_{10}\text{H}_{14}\)

Decaborane is the most studied of all the polyhedral boranes and at one time (mid-1950s) was manufactured on a multitonne scale in the USA as a potential high-energy fuel. It is now obtainable in research quantities by the pyrolysis of \(\text{B}_2\text{H}_6\) at 100–200°C in the presence of catalytic amounts of Lewis bases such as \(\text{Me}_2\text{O}\). \(\text{B}_{10}\text{H}_{14}\) is a colourless, volatile, crystalline solid (see Table 6.2, p. 163) which...
Metalloboranes, Metal Clusters and Organometallic Complexes

Copyrolysis of $\text{B}_2\text{H}_9$ and $[\text{Fe(CO)}_3]$ in a hot/cold reactor at 220°/20° for 3 days gives an orange liquid (mp 5°C) of formula $[1\cdot\text{Fe(CO)}_3]_2\text{B}_2\text{H}_8$ having the structure shown in (a). The isoelectronic complex $[1\cdot\text{Co}(\eta^5\cdot\text{C}_5\text{H}_5)]\text{B}_2\text{H}_8$ (structure b) can be obtained as yellow crystals by pyrolysis at 200° of the corresponding basal derivative $[2\cdot\text{Co}(\eta^5\cdot\text{C}_5\text{H}_5)]\text{B}_2\text{H}_8$ (structure c) which is obtained as red crystals from the reaction of NaB$_2$H$_8$ and CoCl$_2$ with NaC$_5$H$_5$ in thf at -20°. The course of these reactions is obscure and other products are also obtained.

As $[\text{BH}_2]$ is isoelectronic with [CH], these metalloborane clusters are isoelectronic with the cyclobutadiene adduct $[\text{Fe}(\eta^4\cdot\text{C}_4\text{H}_4)(\text{CO})_3]$, see (d). (e) and (f). Likewise $[\text{Fe(CO)}_3]$ or $[\text{Co}(\eta^5\cdot\text{C}_5\text{H}_5)]$ can replace a $\text{BH}$ group in $\text{B}_2\text{H}_9$ and two descriptions of the bonding are given in (g) and (h): the Fe atom supplies 2 electrons and 3 atomic orbitals to the cluster (as does BH), thereby enabling it to form 2 Fe–B σ bonds and to accept a pair of electrons from adjacent B atoms to form a 3-centre BMB bond. In this description the Fe atom is formally octahedral Fe$^{10}$ (d$^6$). Alternatively, diagram (h) emphasizes the relation between $[1\cdot\text{Fe(CO)}_3]_2\text{B}_2\text{H}_8$ and $[\text{Fe(CO)}_3(\eta^5\cdot\text{C}_5\text{H}_5)]$ or $[\text{Fe(CO)}_3]$: the Fe atom accepts 2 pairs of electrons to form two 3-centre BMB bonds and is formally Fe$^{10}$ with a trigonal bipyramidal arrangement of bonds.

It is possible to replace more than one $\text{BH}$ group in $\text{B}_2\text{H}_9$ by a metal centre, e.g. in the dimetalla species $[1,2\cdot(\text{Fe(CO)}_3)_2]_2\text{B}_2\text{H}_7$ [50] it is also notable that the iron carbonyl cluster compound $[\text{Fe}_5(\text{CO})_{13}\text{C}]$ (p. 1108) features the same square-pyramidal cluster in which 5 $\text{Fe(CO)}_3$ groups have replaced the five $\text{BH}$ groups in $\text{B}_2\text{H}_9$, and the C atom (in the centre of the base) replaces the 4 bridging H atoms by supplying the 4 electrons required to complete the bonding.

Many other equivalent groups can be envisaged and the formalism permits a unified approach to possible synthetic routes and to probable structures of a wide variety of compounds. [17,51–53]

---

is insoluble in $H_2O$ but readily soluble in a wide range of organic solvents. Its structure (36) can be regarded as derived from the 11 B atom cluster $B_{11}H_{11}^{2-}$ (p. 153) by replacing the unique BH group with 2 electrons and appropriate addition of $4H_\mu$. MO-calculations give the sequence of electron charge densities at the various B atoms as 2, 4 > 1, 3 > 5, 7, 8, 10 > 6, 9 though the total range of deviation from charge neutrality is less than ±0.1 electron per B atom. The chemistry of $B_{10}H_{14}$ can be conveniently discussed under the headings (a) proton abstraction, (b) electron addition, (c) adduct formation, (d) cluster rearrangements, cluster expansions, and cluster degradation reactions, and (e) metalloborane and other heteroborane compounds.

$B_{10}H_{14}$ can be titrated in aqueous/alcoholic media as a monobasic acid, $pK_a$ 2.70:

$$B_{10}H_{14} + OH^- \rightleftharpoons B_{10}H_{13} + H_2O$$

Proton abstraction can also be effected by other strong bases such as $H^-$, $OMe^-$, $NH_2^-$, etc. The $B_{10}H_{13}^-$ ion is formed by loss of a bridge proton, as expected, and this results in a considerable shortening of the $B(5)-B(6)$ distance from 179 pm in $B_{10}H_{14}$ to 165 pm in $B_{10}H_{13}^-$ (structures 36, 37). Under more forcing conditions with NaH a second $H_\mu$ can be removed to give $Na_2B_{10}H_{12}$; the probable structure of $B_{10}H_{12}^{2-}$ is (38) and the anion acts as a formal bidentate (tetrahapto) ligand to many metals (p. 177).

Electron addition to $B_{10}H_{14}$ can be achieved by direct reaction with alkali metals in ethers, benzene or liquid $NH_3$:

$$B_{10}H_{14} + 2Na \rightarrow Na_2B_{10}H_{14}$$

A more convenient preparation of the $B_{10}H_{14}^{2-}$ anion uses the reaction of aqueous $BH_4^-$ in alkaline solution:

$$B_{10}H_{14} + BH_4^- \rightarrow \{BH_3\} - \{BH_3\} - \rightarrow B_{10}H_{15}^{2-} + H^+$$

Structure (39) conforms to the predicted (2632) topology (p. 158) and shows that the 2 added electrons have relieved the electron deficiency to the extent that the 2 $B-H-B$ groups have been
converted to B–H₄ with the consequent appearance of 2BH₂ groups in the structure. Calculations show that this conversion of a nido- to an arachno-cluster reverses the sequence of electron charge density at the 2, 4 and 6, 9 positions so that for B₁₀H₁₄⁻ the sequence is 6, 9 > 1, 3 > 5, 7, 8, 10 > 2, 4; this is paralleled by changes in the chemistry. B₁₀H₁₄⁻ can formally be regarded as B₁₀H₁₂L₂ for the special case of L = H⁻. Compounds of intermediate stoichiometry B₁₀H₁₄⁻L⁻ are formed when B₁₀H₁₄ is deprotonated in the presence of the ligand L:

\[ \text{B}_{10} \text{H}_{14}^+ + 2 \text{MeCN} \rightarrow \text{B}_{10} \text{H}_{12}^+ (\text{MeCN})_2 + \text{H}_2 \]

\[ \text{B}_{10} \text{H}_{12}^+ + 2 \text{L}^+ \rightarrow \text{B}_{10} \text{H}_{12}^+ \text{L}_2 + 2 \text{L}^- \]

Ligands L, L' can be drawn from virtually the full range of inorganic and organic neutral and anionic ligands and, indeed, the reaction severely limits the range of donor solvents in which B₁₀H₁₄ can be dissolved. The approximate sequence of stability is:

\[ \text{SR}_2 < \text{RCN} < \text{AsR}_3 < \text{RCONMe}_2 < \text{P(OR)}_3 < \text{py} \approx \text{NET}_3 \approx \text{PPH}_3 \]

The stability of the phosphine adducts is notable as is the fact that thioethers readily form such adducts whereas ethers do not. Bis-ligand adducts of moderate stability play an important role in activating decaborane for several types of reaction to be considered in more detail in subsequent paragraphs, e.g.:

Substitution: B₁₀H₁₂(SR₂)₂ + HX \( \xrightarrow{\text{C}_4 \text{H}_6/20^\circ} \) 6-(5-)XB₁₀H₁₃ (X = F, Cl, Br, I)

Cluster rearrangement: arachno-B₁₀H₁₂(NET₃)₂ \( \rightarrow \) [NET₃H]⁺⁺[closo-B₁₀H₁₀]⁻⁻²⁻

Cluster addition: arachno-B₁₀H₁₂(SR₂)⁺⁺ \( \rightarrow \) closo-B₁₀H₁₀(CR)⁺⁺ \( \rightarrow \) closo-B₁₀H₁₀(CR)₂⁺⁺ + 2SR₂ + H₂

Cluster degradation: B₁₀H₁₂L₂ + 3ROH \( \rightarrow \)

\[ \text{B}_9 \text{H}_₃ \text{L} + \text{B(OR)}_3 + \text{L} + \text{H}_2 \]

In this last reaction it is the coordinated B atom at position 9 that is solvolytically cleaved from the cluster.

Electrophilic substitution of B₁₀H₁₄ follows the sequence of electron densities in the ground-state molecule. Thus halogenation in the presence of AlCl₃ leads to 1- and 2-monosubstituted derivatives and to 2,4-disubstitution. Similarly, Friedel–Crafts alkylations with RX/AlCl₃ (or FeCl₃) yield mixtures such as 2-MeB₁₀H₁₃, 2,4- and 1,2-Me₂B₁₀H₁₂, 1,2,3- and 1,2,4-Me₃B₁₀H₁₁, and 1,2,3,4-Me₄B₁₀H₁₀. By contrast, nucleophilic substitution (like the adduct formation with Lewis bases) occurs preferentially at the 6 (9) position; e.g., LiMe produces 6-MeB₁₀H₁₃ as the main product with smaller amounts of 5-Me₂B₁₀H₁₃, 6,5(8)-Me₂B₁₀H₁₂ and 6,9-Me₂B₁₀H₁₂.

B₁₀H₁₄ undergoes numerous cluster-addition reactions in which B or other atoms become incorporated in an expanded cluster. Thus in a reaction which differs from that on p. 175 BH₄⁻ adds to B₁₀H₁₄ with elimination of H₂ to form initially the nido-B₁₁H₁₄⁻ anion (structure 41, p. 178) and then the closo-B₁₂H₁₂⁻²⁻:

\[ \text{B}_{10} \text{H}_{14} + \text{LiBH}_4 \rightarrow \text{LiB}_{11} \text{H}_{14} + 2 \text{H}_2 \]

\[ \text{B}_{10} \text{H}_{14} + 2 \text{LiBH}_4 \rightarrow \text{Li}_2 \text{B}_{12} \text{H}_{12} + 5 \text{H}_2 \]

A more convenient high-yield synthesis of B₁₂H₁₂⁻²⁻ is by the direct reaction of amine-boranes with B₁₀H₁₄ in the absence of solvents:

\[ \text{B}_{10} \text{H}_{14} + 2 \text{Et}_3 \text{NH}_3 \rightarrow [\text{NET}_3]^+ [\text{B}_{12} \text{H}_{12}]^{2+} + 3 \text{H}_2 \]

Heteroatom cluster addition reactions are exemplified by the following:

\[ \text{B}_{10} \text{H}_{14} + \text{Me}_3 \text{NAI}_3 \rightarrow \text{Et}_3 \text{O} \]

\[ \text{B}_{10} \text{H}_{14} + 2 \text{TiMe}_3 \rightarrow \text{Et}_3 \text{O} \]

\[ [\text{TiMe}_2]^+[\text{B}_{10} \text{H}_{12} \text{TiMe}_2]^- \]
The Concept of Boranes as Ligands

Boranes are usually regarded as being electron-deficient, in the sense that they have an insufficient number of electrons to form classical 2-centre 2-electron bonds between each contiguous pair of atoms. However, in the mid-1960s several groups began to realize that, far from being deficient in electrons, many boranes and their anions could act as very effective polyhapto ligands: that is, they could form donor–acceptor complexes (coordination compounds, Chap. 19) in which the borane cluster itself was acting as the electron donor or ligand. The application of this astonishing idea has extended enormously the range of boron hydride compounds which can be made. Many aspects have already been alluded to in the preceding pages and these are briefly summarized in this Panel.

Boranes can act as ligands either by forming 3-centre, 2-electron B–H–M bonds (analogous to BHB bonds) or by forming direct B–M bonds (n = 1–6, analogous to B–B, BBB etc bonds). All hapticities from n1–n6 and occasionally beyond are known. The various coordination modes of BH3− and B2H5− were discussed on pp. 168–71: these involve the conversion of B–Hn bonds to B–H–M bonds. Likewise, the use of B2H6− as an n2-ligand was described on pp. 172–3, this involves the notional donation to a metal centre of the electron pair in a B–B bond, thus forming a BMB 3-centre bond. B2H6− can also act as a notional n1-donor by replacement of a terminal H atom in B2H6 with a ligand.

It is clear that some boranes are amphoteric Lewis acid/bases—that is they can act either as electron-pair donors as above or as electron-pair acceptors (e.g. in L.BH3 and L.B3H7). It follows that a borane donor could conceivably ligate to a borane acceptor to form a borane–borane complex. In this sense B2H6 itself could be regarded either as a coordination complex of BH3− with the notional cation BH4+, or as the mutual coordination of two monodentate [BH3] units. Replacement of these donors with stronger ligands such as NH3 or NMe3 would then result in either unsymmetrical or symmetrical cleavage of B2H6 as discussed on p. 165. Likewise, B2H10 could be regarded either as a complex between n2-B2H6− and [BH4+] or as a mutual coordination between [B2H7] and [BH4]; reaction with stronger ligands, L, would then yield either [L2B2H7]− or LB3H7 and L.BH3 by ligand displacement reactions (pp. 169–70).

The neutral nido-borane B2H10 (structure 10) has a basal B–B bond (see p. 159) and this enables it to act as a ligand by displacing ethene from Zeise’s salt (p. 930).

\[ K[Pt(n^2-C_2H_2)Cl_3] + 2B_2H_{10} \rightarrow \text{trans-[Pt(n^2-B_2H_{10})Cl_2]} + C_2H_4 + KCl \]

Similarly, reaction of B2H10 with Fe2(CO)9 (p. 1104) at room temperature results in the smooth elimination of Fe(CO)5 to form [Fe(n^2-B_2H_{10})(CO)_4] as a stable, volatile yellow solid. Use of these electron-donor properties of B2H10 towards reactive (vacant orbital) borane radicals resulted in the preparation of several new conjuncto-boranes, e.g. B13H19, B14H12 and B15H23 (p. 162).

Another important concept is the notion of stabilization by means of coordination. A classic example is the stabilization of the fugitive species cyclobutadiene, [C4H4] by coordination to [Fe(CO)5] (p. 936). As the C atom is isoelectronic with BH, so [C4H4] is isoelectronic with the borane fragment [B4H8] which is similarly stabilized by coordination to [Fe(CO)5] or the isoelectronic [Co(n^2-C_2H_2)] (see Panel on p. 174). Indeed it is a general feature of metallaborane chemistry that such clusters are often much more stable than are the parent boranes themselves.

As a result of the systematic application of coordination-chemistry principles, dozens of previously unsuspected structure types have been synthesized in which polyhedral boranes or their anions can be considered to act as ligands which donate electron density to metal centres, thereby forming novel metallaborane clusters. Some 40 metals have been found to act as acceptors in this way (see also p. 178). The ideas have been particularly helpful in emphasizing the close interconnection between several previously separated branches of chemistry, notably boron hydride cluster chemistry, metallaborane and metallocarborane chemistry (pp. 189–95), organometallic chemistry and metal–metal cluster chemistry. All are now seen to be parts of a coherent whole.

It is also noteworthy that Alfred Stock, who is universally acclaimed as the discoverer of the boron hydrides (1912,140) was also the first to propose the use of the term “ligand” in a lecture in Berlin on 27 November 1916. Both events essentially predate the formulation by G. N. Lewis of the electronic theory of valency (1916). It is therefore felicitous that, albeit some 20 years after Stock’s death in 1946, two such apparently disparate aspects of his work should be connected in the emerging concept of “boranes as ligands”.

55 A. Stock, Berichte 50, 170 (1917).
The structure of the highly reactive anion \([\text{AlB}_{10}\text{H}_{14}]^-\) is thought to be similar to \(\text{nido-B}_{11}\text{H}_{14}^-\) with one facial B atom replaced by Al. The metal alkyls react somewhat differently to give extremely stable metalloborane anions which can be thought of as complexes of the bidentate ligand \(\text{B}_{10}\text{H}_{12}^-\) (structures 42, 43). Many other complexes \([\text{M(}\text{B}_{10}\text{H}_{12})_2]^-\) and \([\text{L}_2\text{M(}\text{B}_{10}\text{H}_{12})]\) are known with similar structures except that, where \(\text{M = Ni, Pd, Pt}\), the coordination about the metal is essentially square-planar rather than pseudotetrahedral as for Zn, Cd and Hg. Such compounds were among the first examples to be recognized of the novel and extremely fruitful perception that “electron-deficient” boranes and their anions can, in fact, act as powerful stabilizing electron-donor ligands (see Panel on p. 177).

6.4.7 Chemistry of \(\text{closo-B}_n\text{H}_n^{2-}\) \(^{(1,56,57)}\)

The structures of these anions have been indicated on p. 153. Preparative reactions are often mechanistically obscure but thermolysis under controlled conditions is the dominant procedure (pp. 162–3). Many of the product \(\text{closo-boranes}\) are not degraded even when heated to 600°C. Salts of \(\text{B}_{12}\text{H}_{12}^{2-}\) and \(\text{B}_{10}\text{H}_{10}^{2-}\) are particularly stable and their reaction chemistry has been extensively studied. As expected from their charge, they are extremely stable towards nucleophiles but moderately susceptible to electrophilic attack. For \(\text{B}_{10}\text{H}_{10}^{2-}\) the apex positions 1,10 are substituted preferentially to by Al. The metal alkyls react somewhat differently to give extremely stable metalloborane anions which can be thought of as complexes of the bidentate ligand \(\text{B}_{10}\text{H}_{12}^-\) (structures 42, 43). Many other complexes \([\text{M(}\text{B}_{10}\text{H}_{12})_2]^-\) and \([\text{L}_2\text{M(}\text{B}_{10}\text{H}_{12})]\) are known with similar structures except that, where \(\text{M = Ni, Pd, Pt}\), the coordination about the metal is essentially square-planar rather than pseudotetrahedral as for Zn, Cd and Hg. Such compounds were among the first examples to be recognized of the novel and extremely fruitful perception that “electron-deficient” boranes and their anions can, in fact, act as powerful stabilizing electron-donor ligands (see Panel on p. 177).

\[ \text{B}_{10}\text{H}_{14} + 2\text{ZnR}_2 + \text{Et}_3\text{O} \rightarrow [\text{B}_{10}\text{H}_{12}\text{Zn(}\text{Et}_2\text{O})_2]\]

\[ \text{H}_2\text{O/Me}_4\text{NCl} \rightarrow [\text{NMe}_4]^+ \cdot 2[\text{Zn(}\text{B}_{10}\text{H}_{12})_2]^- \]

Oxidation of \(\text{closo-B}_{10}\text{H}_{10}^{2-}\) with aqueous solutions of Fe\(^{III}\) or Ce\(^{IV}\) (or electrochemically) yields \(\text{conjuncto-B}_{20}\text{H}_{18}^{2-}\) (44) which can be photoisomerized to \(\text{neo-B}_{20}\text{H}_{18}^{2-}\) (45). If the oxidation is carried out at 0° with Ce\(^{IV}\),
§6.4.7 Chemistry of \( \text{closo-}^7\text{B}_n\text{H}_n^{2-} \)

Boron-10 Neutron Capture Therapy\(^{58,59}\)

Every year more than 600,000 people throughout the world contract brain tumours and about 1700 die from this cause every day. Treatment by surgical excision is usually impossible because of the site of the malignant growth and the lack of a distinct boundary (gliomas). Likewise, conventional radiotherapy (X-rays, \( \gamma \)-rays etc.) from outside the skull is rarely effective. An ingenious approach to this problem which has given encouraging results so far is impregnation of the tumour with a suitable boron compound, followed by irradiation with thermal neutrons which readily pass harmlessly through normal tissue but are strongly absorbed by the isotope \( ^{10}\text{B} \). As can be seen from Table 6.1 (p. 144) \( ^{10}\text{B} \) is 767,000 times more effective than \( ^{11}\text{B} \) and, in fact, has one of the highest neutron absorption cross-sections for any nuclide. The strategy is thus to synthesize cluster compounds enriched in \( ^{10}\text{B} \), thereby enhancing the neutron absorption cross-section of the boron nearly five-fold, and then to attach these clusters to the cells comprising the brain tumour. A single injection of, say, \( \text{Na}_2[^{10}\text{B}_{12}\text{H}_{11}\text{SH}] \) usually suffices. Treatment with thermal neutrons from a nuclear reactor then releases huge amounts of energy right within the tumour tissue (and nowhere else) as a result of the nuclear reaction:

\[
\text{^{10}B} + ^{1}n \rightarrow \text{^{11}B}^* \rightarrow \text{^2He} + ^{3}\text{Li} + \gamma
\]

The recoiling \( \alpha \)-particle (\( ^{4}\text{He} \)) and lithium nucleus (\( ^{3}\text{Li} \)) between them carry 2.4 MeV of energy and this is shed within just a few \( \mu \text{m} \), the \( \alpha \)-particle travelling about 9 \( \mu \text{m} \) and the \( \text{Li} \) nucleus about 5.5 \( \mu \text{m} \) in the opposite direction. The radiation damage is thus confined within the cancerous tissue alone.

This is a very active area of research which involves collaboration between synthetic inorganic chemists, biochemists, neurosurgeons, nuclear physicists and reactor engineers, and there is considerable scope for advance in all of these areas.\(^{58,60,61}\)

or in a two-phase system with \( \text{Fe}^{III} \) using very concentrated solutions of \( \text{B}_{10}\text{H}_{10}^{2-} \), the intermediate H-bridged species \( \text{B}_{20}\text{H}_{19}^{3-} \)\(^{(46)} \) can be isolated. Reduction of \( \text{conjuncto-B}_{20}\text{H}_{18}^{2-} \) with \( \text{Na}/\text{NH}_3 \) yields the equatorial–equatorial (ee) isomer of \( \text{conjuncto-B}_{20}\text{H}_{18}^{4-} \)\(^{(47)} \), and this can be successively converted by acid catalyst to the ae isomer\(^{(49)} \) and, finally, to the aa isomer\(^{(48)} \). Careful protonation of this aa isomer yields the elusive anion \( [\text{aa-B}_{20}\text{H}_{19}]^{3-} \) in which the \( \text{conjuncto} \) \( \text{B–B} \) bond in structure \( (48) \) is replaced by an unsupported \( \text{B–H}_{\mu} \)-\( \text{B} \) bond (angle 91(3)°, \( \text{B–H}_{\mu} \) 136(5) pm, \( \text{B}_a \cdots \text{B}_3 \) 193.6 pm), though the two \( \text{closo} \) clusters still share a common axis through their \( \text{B}(1)\text{–B}(10) \) vertices.\(^{(61a)} \) An extensive derivative chemistry of these various species has been developed. Another important (though mechanistically obscure) reaction of \( \text{conjuncto-B}_{20}\text{H}_{18}^{2-} \) is its degradation in high yield to \( n\text{-B}_{18}\text{H}_{22} \) by passage of an enhanolic solution through an acidic ion exchange resin; \( i\text{-B}_{18}\text{H}_{22} \) is also formed as a minor product. The relation of these 2 edge-fused decaborane clusters to the \( \text{B}_{20} \) species is illustrated in structures \( (31) \) and \( (32) \) (p. 156).

When salts of \( \text{closo-B}_{10}\text{H}_{10}^{2-} \) and \( \text{closo-B}_{12}\text{H}_{12}^{2-} \) are passed through an acid ion exchange resin, hydrates of the strong acids \( \text{H}_2\text{B}_n\text{H}_n \) are obtained. For example, \( [\text{NEt}_4]^+^2-\text{[B}_{10}\text{H}_{10}]^{2-} \) gives \( \text{H}_2\text{B}_{10}\text{H}_{10}^4\text{H}_2\text{O} \) which, on careful dehydration, yields the dihydrate, \( [\text{H}_3\text{O}]^+^2\text{[B}_{10}\text{H}_{10}]^{2-} \). Repeated low-pressure evaporation of benzene solutions of this acid at room temperature results in reductive cluster opening to give the \( \text{nido-decaborane} \) derivative \( [6,6’-(\text{B}_{10}\text{H}_{13})_2\text{O}] \) in good yield, probably via \( \text{nido-6-B}_{15}\text{H}_{13}(\text{OH}) \).\(^{(62)} \) The structure of the readily sublimable \( \text{bis(nido-decaboranyl)} \) oxide.

---

Structures of the 3 isomers of conjuncto-\(\text{B}_{20}\text{H}_{18}^{2-}\). 

(B\(_{10}\text{H}_{13}\)\(_2\))\(_2\)O, prepared by other routes, had previously been established by X-ray diffraction analysis\(^{63}\) and by nmr spectroscopy.\(^{64}\) Another interesting derivative is \([\text{closo}-1,10\text{-B}_{10}\text{H}_{6}(\text{N}_2)_2]\) in which the apical H atoms in \(\text{B}_{10}\text{H}_{10}^{2-}\) have been replaced by end-on dinitrogen ligands (see pp. 414–6): the B–N distance is 149.9 pm and the N–N distance is 109.1 pm\(^{65}\) (cf 109.8 pm in gaseous \(\text{N}_2\)). The isoelectronic ligand CO fulfils the same function in \([\text{closo}-1,10\text{-B}_{10}\text{H}_{8}(\text{CO})_2]\).\(^{66,67}\) The closely related stable, volatile, icosahedral molecule \([\text{closo}-1,12\text{-B}_{12}\text{H}_{10}(\text{CO})_2]\) can be prepared by the reaction of \(\text{H}_2\text{B}_{12}\text{H}_{12}.4\text{H}_2\text{O}\) with CO at 130°C and 800–1000 atm. pressure in the presence of dicobaltoctacarbonyl as catalyst.\(^{67}\) In the absence of this catalyst, approximately equal amounts of the 1,7- and 1,12-isomers are formed.

§6.5 Carboranes

Carboranes burst onto the chemical scene in 1962–3 when classified work that had been done in the USA during the late 1950s was cleared for publication. The succeeding 30 y has seen a tremendous burgeoning of activity, as a result of which the carboranes and the related metallocarboranes (p. 189) now occupy a strategic position in the chemistry of the elements, since they overlap and give coherence to several other large areas including the chemistry of polyhedral boranes, transition-metal complexes, metal-cluster compounds and organometallic chemistry. The field has become so vast that it is only possible to give a few illustrative examples of the many thousands of known compounds, and to indicate the general structural features and reactivity. The vast majority of carboranes (>95%) have two C atoms in the cluster, reflecting their ready formation from alkynes (see below). A few have one C atom and there are a growing number incorporating three or even four C atoms as cluster vertices.

Carboranes (or more correctly carbaboranes) are compounds having as the basic structural unit a number of C and B atoms arranged on the vertices of a triangulated polyhedron. Their structures are closely related to those of the isoelectronic boranes (p. 161) \([\text{BH} \equiv \text{B} \equiv \text{C}]; \text{BH}_2 \equiv \text{BH} \equiv \text{B-L} \equiv \text{CH}\). For example, \text{nido-}\text{B}_8\text{H}_{10} \,(\text{structures} \, 10, \, 50) \text{provides the basic cluster structure for the 4 carboranes CB}_3\text{H}_9 \,(51), \text{C}_2\text{B}_4\text{H}_8 \,(52), \text{C}_3\text{B}_3\text{H}_7 \,(53) \text{and C}_4\text{B}_2\text{H}_6 \,(54), each successive replacement of a basal B atom by C being compensated by the removal of one H}_\mu. \text{Carboranes have the general formula} \[(\text{CH})_a(\text{BH})_m\text{H}_b\]\]^− \text{with} \, a \text{CH units and} \, m \text{BH units at the polyhedral vertices, plus} \, b \text{“extra” H atoms which are either bridging (H}_\mu \text{) or endo (i.e. tangential to the surface of the polyhedron as distinct from the axial H}_1 \text{atoms specified in the CH and BH groups; H}_\text{endo} \text{occur in BH}_2 \text{groups which are thus more precisely specified as BH}_1\text{H}_\text{endo}. \text{It follows that the number of electrons available for skeletal bonding is} \, 3e \text{from each CH unit,} \, 2e \text{from each BH unit,} \, 1e \text{from each H}_\mu \text{or H}_\text{endo}, \text{and} \, ce \text{from the anionic charge. Hence:}

\[
total \text{number of skeletal bonding electron pairs} = \frac{1}{2}(3a + 2m + b + c) = n + \frac{1}{2}(a + b + c),\]

where \(n(= a + m)\) is the number of occupied vertices of the polyhedron. 

\text{closo-structures have} \,(n + 1) \text{pairs of skeletal bonding electrons (i.e.} \, a + b + c = 2). 
\text{nido-structures have} \,(n + 2) \text{pairs of skeletal bonding electrons (i.e.} \, a + b + c = 4). 
\text{arachno-structures have} \,(n + 3) \text{pairs of skeletal bonding electrons (i.e.} \, a + b + c = 6). 

If \(a = 0\) the compound is a borane or borane anion rather than a carborane. If \(b = 0\) there are no H}_\mu \text{or H}_\text{endo}; this is the case for all closo-carboranes except for the unique octahedral

---

69 H. BEALL, Chap. 9 in ref. 9, pp. 302–47. T. ONAK, Chap. 10 in ref. 9, pp. 349–82.
monocarbaborane, 1-CB₅H₇, which has a triply bridging H₆ over one B₃ face of the octahedron. If c = 0 the compound is a neutral carborane molecule rather than an anion.

Nomenclature follows the well-established oxa-aza convention of organic chemistry. Numbering begins with the apex atom of lowest coordination and successive rings or belts of polyhedral vertex atoms are numbered in a clockwise direction with C atoms being given the lowest possible numbers within these rules.†

Closo-carboranes are the most numerous and the most stable of the carboranes. They are colourless volatile liquids or solids (depending on mol wt.) and can be prepared from an alkyn and a borane by pyrolysis, or by reaction in a silent electric discharge. This route, which generally gives mixtures, is particularly useful for small closo-carboranes (n = 5–7) and for some intermediate closo-carboranes (n = 8–11), e.g.

\[
\text{nido-}B_5H_9 \xrightarrow{\text{C}_2\text{H}_2} \text{closo-1,5-}C_2B_3H_5 \quad (55) \quad 500°-600° \quad (56)
\]

\[+ \text{closo-1,6-}C_2B_4H_6 + \text{closo-2,4-}C_2B_3H_7 \quad (57) \quad (58)\]

Milder conditions provide a route to nido-carboranes, e.g.:

\[
\text{nido-}B_5H_9 \xrightarrow{\text{C}_2\text{H}_2} \text{nido-2,3-}C_2B_4H_8 \quad (59) \quad 200°
\]

Pyrolysis of nido- or arachno-carboranes or their reaction in a silent electric discharge also leads to closo-species either by loss of H₂ or disproportionation:

\[
\text{C}_2\text{B}_n\text{H}_{n+4} \rightarrow \text{C}_2\text{B}_n\text{H}_{n+2} + \text{H}_2
\]

\[2\text{C}_2\text{B}_n\text{H}_{n+4} \rightarrow \text{C}_2\text{B}_{n-1}\text{H}_{n+1} + \text{C}_2\text{B}_{n+1}\text{H}_{n+3} + 2\text{H}_2\]

For example, pyrolysis of the previously mentioned nido-2,3-C₂B₄H₈ gives the 3 closo-species shown above, whereas under the milder conditions of photolytic closure the less-stable isomer closo-1,2-C₂B₄H₆ is obtained. Pyrolysis of alkyl boranes at 500–600° is a related route which is particularly useful to monocarbaboranes though the yields are often low, e.g.:

\[
1,2-\text{Me}_2\text{-}nido-\text{B}_5\text{H}_7 \rightarrow \text{closo-1,5-}C_2B_3H_5 \quad (60) \quad (56)
\]

\[+ \text{closo-1-CB}_5H_7 + \text{nido-2-CB}_5H_9 \quad (61) \quad (62)
\]

\[+ 3-\text{Me-nido-2-CB}_5H_8 \quad (63)\]
Cluster expansion reactions with diborane provide an alternative route to intermediate closo-carboranes, e.g.:

\[
\text{closo-1,7-C}_2\text{B}_6\text{H}_8 + \frac{1}{2}\text{B}_2\text{H}_6 \rightarrow \text{closo-1,6-C}_2\text{B}_7\text{H}_9 + \text{H}_2
\]

Conversely, cluster degradation reactions lead to more open structures, e.g.:

\[
\text{achno-1,3-C}_2\text{B}_7\text{H}_{12} - \text{B(OH)}_3 \rightarrow \text{closo-1,6-C}_2\text{B}_8\text{H}_{10} + \text{H}_2
\]

Other convenient routes to carboranes, selected from the growing number of recently reported syntheses, are as follows. Monocarbon carboranes can be prepared in good yield by the transition-metal catalysed hydroboration of alkenes followed by thermal rearrangement of the intermediate product, e.g.\(^{(72)}\)

\[
\text{B}_3\text{H}_9 + \left(\text{MeC} \equiv \text{CMe}\right)\text{Co}_2(\text{CO})_6 \rightarrow 75^\circ
\]

\[
\left[\text{nido-B}_5\text{H}_9-2-(\text{CMe} \equiv \text{CHMe})\right] \rightarrow 355^\circ
\]

\[
\left[\text{nido-2-CB}_3\text{B}_7\text{H}_7-2-\text{Me}-3\text{(or 4)-Et}\right] (\text{see structure 51}).
\]

The two isomers are each obtained in about 30% yield. Again, the Me\(_2\)S-promoted reaction of nido-B\(_{10}\)H\(_{14}\) with bis(trimethylsilyl) ethyne, Me\(_3\)SiC\(\equiv\)CSiMe\(_3\), results in monocarbon insertion by internal hydroboration and SiMe\(_3\) group migration to give \([\text{nido-7-CH}_2\text{B}_9\text{H}_{11}-7-((\text{Me}_3\text{Si})_2\text{CH})-9-(\text{Me}_2\text{S})]\) structure (68) in 28% yield.\(^{(73)}\) New dicarbaboranes can be obtained from preformed nido-dicarbaboranes either by reducing them to give the corresponding achno species\(^{(74)}\) or by a capping reaction to give a closo-dicarbaborane,\(^{(75)}\) e.g.

\[
\text{nido-C}_2\text{B}_8\text{H}_{12} + \text{Et}_3\text{NBH}_3 \rightarrow \text{closo-2,3-C}_2\text{B}_3\text{H}_3 + 2\text{H}_2 + \text{NEt}_3
\]

A convenient route to three-carbon carboranes is the hydroboration of an alkyne with a preformed dicarbaborane. For example,\(^{(76)}\) reaction of ethyne (or propyne) with achno-4,5-C\(_2\)B\(_7\)H\(_{13}\) (70) in hexane at 120°C gives a mixture of tri- and tetra-carbaboranes, e.g. (71), (72), (73), (74) in modest yield. Access to other

tetracarbaboranes was greatly facilitated by the discovery of oxidative fusion reactions in 1974; these involve the construction of large clusters by metal-promoted face-to-face fusion of smaller clusters.\(^{(71)}\) For example, bridge-deprotonation of 2,3-R\(_2\)C\(_2\)B\(_4\)H\(_6\) (see structure 52) with alkali metal hydride, followed by treatment with FeCl\(_2\) and exposure to O\(_2\) yields the desired product R\(_4\)C\(_4\)B\(_8\)H\(_8\) (75) (see Scheme above). The starting material is available in multigram amounts via the room-temperature reaction of B\(_5\)H\(_9\) with alkynes in the presence of NEt\(_3\):  

\[
\text{B}_5\text{H}_9 + \text{R}_2\text{C}_2 + \text{NEt}_3 \rightarrow 2,3-\text{R}_2\text{C}_2\text{B}_4\text{H}_6 \quad (52)
\]

Metal-promoted alkyne-insertion reactions afford another good method (see structure 12 for cluster geometry and numbering):\(^{(77)}\)  

\[
2,3-\text{Et}_2\text{C}_2\text{B}_4\text{H}_6 \quad (52) + \text{NaH} + \text{MeC=CM}e \\
+ \text{NiCl}_2 \quad \text{thf} \rightarrow 4,5,7,8-\text{Me}_2\text{Et}_2\text{C}_4\text{B}_4\text{H}_4
\]

Some Further Generalizations Concerning Carboranes

1. Carbon tends to adopt the position of lowest coordination number on the polyhedron and to keep as far from other C atoms as possible (i.e. the most stable isomer has the greatest number of B–C connections).

2. Boron–boron distances in the cluster increase with increasing coordination number (as expected). Average B–B distances are: 5-coordinate B 170 pm, 6-coordinate B 177 pm, 7-coordinate B 186 pm.

3. Carbon is somewhat smaller than B and interatomic distances involving C are correspondingly shorter. Thus B–C and C–C distances are about 165 pm and 145 pm, respectively, for 5-coordinate C; the corresponding values for 6-coordinate C are 172 pm and 165 pm.

4. Negative electronic charge on B is computed to decrease in the sequence: 
   B (not bonded to C) > B (bonded to 1C) > B (bonded to 2C).

Within each group the B with lower coordination number has a greater negative charge than those with higher coordination.

5. CH groups tend to be more positive than BH groups with the same coordination number (despite the higher electronegativity of C). This presumably arises because each C contributes 3e for bonding within the cluster whereas each B contributes only 2e.

6. In nido- and arachno-carboranes Ht is more acidic than Ht and is the one removed on deprotonation with NaH.

In general nido- (and arachno-) carboranes are less stable thermally than are the corresponding closo-compounds and they are less stable to aerial oxidation and other reactions, due to their more open structure and the presence of labile H atoms in the open face. Most closo-carboranes are stable to at least 400° though they may undergo rearrangement to more stable isomers in which the distance between the C atoms is increased. Some other structural and bonding generalizations are summarized in the Panel. Note, however, that kinetic control during synthesis may result in the isolation of a thermodynamically less favoured structure, with contiguous C atoms, while electronic factors in carboranes with as many as four C atoms may result in distortions or other deviations from the structures predicted on the basis of the simple application of electron counting rules.\(^\text{71}\)

The three isomeric icosahedral carboranes (76–78) are unique both in their ease of preparation and their great stability in air, and consequently their chemistry has been the most fully studied. The 1,2-isomer in particular is available on the multikilogram scale. It is best prepared in bulk by the direct reaction of ethyne with decaborane in the presence of a Lewis base, preferably Et2S:

\[
\text{nido-} \text{B}_{10}\text{H}_{14} + 2\text{SEt}_2 \rightarrow \text{B}_{10}\text{H}_{12}(\text{SEt}_2)_2 + \text{H}_2
\]

\[
\text{B}_{10}\text{H}_{12}(\text{SEt}_2)_2 + \text{C}_2\text{H}_2 \rightarrow \text{closo-1,2-} \text{C}_2\text{B}_{10}\text{H}_{12} + 2\text{SEt}_2 + \text{H}_2
\]

The 1,7-isomer is obtained in 90% yield by heating the 1,2-isomer in the gas phase at 470°C.
for several hours (or in quantitative yield by flash pyrolysis at 600° for 30 s). The 1,12-isomer is most efficiently prepared (20% yield) by heating the 1,7-isomer for a few seconds at 700°C. The mechanism of these isomerizations has been the subject of considerable speculation but definitive experiments are hard to devise. The "diamond-square-diamond" mechanism has been proposed (Fig. 6.19) for the 1,2 1,7 isomerization, but the 1,12 isomer cannot be generated by this mechanism. Moreover, the activation energy required to pass through the cubo-octahedral transition state is likely to be rather high. An alternative proposal, which could, in principle, lead to both the 1,7 and the 1,12 isomers, is the successive concerted rotation of the 3 atoms on a triangular face, and a third possible mechanism involves the concerted basal twisting of two parallel pentagonal pyramids comprising the icosahedron. Vertex extrusion to a capping position, followed by reinsertion at an adjacent site in the cluster has also been suggested. It is extremely difficult to devise experiments to test these mechanisms, but where this has been achieved (as in the case of the disubstituted derivative of (58), closo-5-Me-6-Cl-2,4-C2B9H12, for example) the results rule out triangular face rotation and are consistent with a "diamond-square-diamond" mechanisms. It is conceivable that for other clusters the various mechanisms operate in different temperature ranges or that two (or more) mechanisms are active simultaneously. For recent definitive work on closo-C2B10H12 see refs. 79 and 80.

An entirely different form of isomerism, which is attracting increasing attention, is described in the Panel opposite.

An extensive derivative chemistry of the icosahedral carboranes has been developed, especially for 1,2-C2B10H12. Terminal H atoms attached to B undergo facile electrophilic substitution and the sequence of reactivity follows the sequence of negative charge density on the BH₄ group:(81)

\[
\text{closo-1,2-C}_2\text{B}_{10}\text{H}_{12} : \\
(8, 10 \approx 9, 12) > 4, 5, 7, 11 > 3, 6
\]

\[
\text{closo-1,7-C}_2\text{B}_{10}\text{H}_{12} : \\
9, 10 > 4, 6, 8, 11 > 5, 12 > 2, 3
\]

Similar reactions occur for other closo-carboranes, e.g.:

\[
\text{1,6-C}_2\text{B}_7\text{H}_9 + \text{Br}_2/\text{AlCl}_3 \rightarrow \text{8-Br-1,6-C}_2\text{B}_7\text{H}_8 + \text{HBr}
\]

\[
\text{1,10-C}_2\text{B}_8\text{H}_{10} + 8\text{Cl}_2/\text{CCl}_4 \rightarrow \text{1,10-(CH)}_2\text{B}_6\text{Cl}_8 + 8\text{HCl}
\]

It is noteworthy that, despite the greater electronegativity of C, the CH group tends to be more

---

---

Figure 6.19 The interconversion of 1,2- and 1,7-disubstituted icosahedral species via a proposed cubooctahedral intermediate formed during four "diamond-square-diamond" rearrangements.
"Classical-Nonclassical" Valence Isomerism

A novel and far-reaching type of isomerism concerns the possibility of valence isomerism between "nonclassical" (electron-deficient) clusters and "classical" organoboron structures. Thus, \( n \)-vertexed nido-boranes, \( B_nH_{4n-4} \), have cluster structures with \( 4H \); cf. (9), (10), (11) — whereas the precisely isoelectronic \( n \)-vertexed nido-tetracarbaboranes, \( C_4B_{n-4}H_n \), have no bridging H atoms and can, in principle, adopt either a cluster borane structure or one of several classical organic structures. For example, derivatives of \( C_4B_3H_4 \) could adopt either the nido-2,3,4,5-tetracarbabexaborane structure (a) — i.e. (54) — or the 1,4-dibora-2,5-cyclohexadiene structure (b). As might be expected, the 3-coordinate B atoms in (b) are stabilized by \( \pi \)-donor substituents (e.g. \( R = \text{F}, \text{OMe} \)) whereas when \( R = \text{alkyl} \), rearrangement to the nido-carbaborane (a) occurs.\(^{82} \) The novel diborafulvene isomer (c) has also been synthesized in good yield\(^{83,84} \) and two other isomers, (d) and (e) have been stabilized as ligands in Ru- and Rh-complexes.

\[ \text{Similar possibilities arise for 10-atom clusters. Thus, dimerization of the closo-C}_2\text{B}_3 \text{ cluster 1,5-Me}_2\text{C}_2\text{B}_3\text{Et}_3 (56) by means of K metal then I}_2 \text{ in thf yields the "classical" adamantane derivative Me}_2\text{C}_6\text{B}_6\text{Et}_6 (f); when this is heated to 160\(^\circ \text{C} \) the nido-tetracarbadeccaborane cluster (g) is obtained rapidly and quantitatively.}^{84} \text{It will be noted that in (f) all four C atoms are 4-coordinate and all six B atoms are 3-coordinate, whereas in (g) the three C atoms in the C}_3 \text{ triangular face are 5-coordinate while the boron atoms are variously 4, 5 or 6 coordinate.} \]

positive than the BH groups and does not normally react under these conditions.

The weakly acidic CH$_3$ group can be deprotonated by strong nucleophiles such as LiBu or RMgX; the resulting metalated carboranes LiCCHB$_{10}$H$_{10}$ and (LiCl)$_2$B$_{10}$H$_{10}$ can then be used to prepare a full range of C-substituted derivatives -R, -X, -SiMe$_3$, -COOH, -COCl, -CONHR, etc. The possibility of synthesizing extensive covalent C-C or siloxane networks with pendant carborane clusters is obvious and the excellent thermal stability of such polymers has already been exploited in several industrial applications.

Although closo-carboranes are stable to high temperatures and to most common reagents, M. F. Hawthorne showed (1964) that they can be specifically degraded to nido-carborane anions by the reaction of strong bases in the presence of protic solvents, e.g.:

\[
1,2$\text{C}_2\text{B}_{10}\text{H}_{12} + \text{EtO}^- + 2\text{EtOH} \rightarrow 7,8$\text{C}_2\text{B}_9\text{H}_{12}^- + \text{B}($\text{OEt}$)$_3 + \text{H}_2
\]

\[
1,7$\text{C}_2\text{B}_{10}\text{H}_{12} + \text{EtO}^- + 2\text{EtOH} \rightarrow 7,9$\text{C}_2\text{B}_9\text{H}_{12}^- + \text{B}($\text{OEt}$)$_3 + \text{H}_2
\]

Figure 6.20 indicates that, in both cases, the BH vertex removed is the one adjacent to the two CH vertices: since the C atoms tend to remove electronic charge preferentially from contiguous B atoms, the reaction can be described as a nucleophilic attack by EtO$^-$ on the most positive (most electron deficient) B atom in the

Figure 6.20 Degradation of closo-carboranes to the corresponding debor-nido-carborane anions.

Figure 6.21 Relation between C$_2$B$_9$H$_{11}^{2-}$ and C$_5$H$_5^-$. In this formalism the closo-carboranes C$_2$B$_{10}$H$_{12}$ are considered as a coordination complex between the pentahapto 6-electron donor C$_2$B$_9$H$_{11}^{2-}$ and the acceptor BH$_2^+$ (which has 3 vacant orbitals). The closo-structure can be regained by capping the open pentagonal face with an equivalent metal acceptor that has 3 vacant orbitals.
cluster. Deprotonation of the monoanions by NaH removes the bridge proton to give the nido-dianions 7,8-\(\text{C}_2\text{B}_9\text{H}_{11}^2\) (80) and 7,9-\(\text{C}_2\text{B}_9\text{H}_{11}^2\) (81). It was the perceptive recognition that the open pentagonal faces of these dianions were structurally and electronically equivalent to the pentahapto cyclopentadienide anion (\(\eta^5\text{-C}_5\text{H}_5\)) (Fig. 6.21) that led to the discovery of the metallocarboranes and the development of some of the most intriguing and far-reaching reactions of the carboranes. These are considered in the next section.

### 6.6 Metallocarboranes

There are now at least a dozen synthetic routes to metallocarboranes including (i) coordination using nido-carborane anions as ligands, (ii) polyhedral expansion reactions, (iii) polyhedral contraction reactions, (iv) polyhedral subrogation and (v) thermal metal transfer reactions. These first five routes were all devised by M. F. Hawthorne and his group in the period 1965–74 and have since been extensively exploited and extended by several groups. Examples of each will be given before mentioning some of the more recent routes that have been developed. It is worth noting that the carborane dianions (80) and (81) are both more effective as ligands than is \(\eta^5\text{-C}_5\text{H}_5\), perhaps because of the more favourable angles of the orbitals, the lower electronegativity of boron and the higher formal anionic charge. Thus, the carboranes form stable sandwich complexes with Cu\(\text{II}\), Al\(\text{II}\) and Si\(\text{IV}\), for example, whereas cyclopentadienyl does not.\(^{90,91}\)

(i) **Coordination using nido-carborane anions as ligands (1965).** Reaction of \(\text{C}_2\text{B}_9\text{H}_{11}^2\) with FeCl\(_2\) in tetrahydrofuran (thf) with rigorous exclusion of moisture and air gives the pink, diamagnetic bis-sandwich-type complex of Fe(II) (structure 82) which can be reversibly oxidized to the corresponding red Fe(III) complex:

\[
2\text{C}_2\text{B}_9\text{H}_{11}^2 + \text{Fe}^{2+} \rightarrow \text{Fe}^{3+}(\eta^5\text{-C}_2\text{B}_9\text{H}_{11})_2^2- \quad (82)
\]

When the reaction is carried out in the presence of NaC\(_5\)H\(_5\) the purple mixed sandwich complex (83) is obtained:

\[
\text{C}_2\text{B}_9\text{H}_{11}^2 + \text{C}_5\text{H}_5^- + \text{Fe}^{2+} \rightarrow \text{Fe}^{3+}(\eta^5\text{-C}_2\text{B}_9\text{H}_{11})_2^2- + \text{e}^- 
\]

(ii) **Polyhedral expansion (1970).** This entails the 2-electron reduction of a closo-carborane with a strong reducing agent such as sodium naphthalide in thf followed by reaction with a transition-metal reagent:

\[
\text{C}_2\text{B}_9\text{H}_{11}^2 - + \text{Mo(CO)}_6 \rightarrow \text{Mo(CO)}_3(\eta^5\text{-C}_2\text{B}_9\text{H}_{11})^2- + 3\text{CO}
\]

The reaction is general and has been applied to many transition metals as well as lanthanides and actinides.\(^{92}\) Variants use metal carbylons and other complexes to supply the capping unit, e.g.

\[
\text{C}_2\text{B}_9\text{H}_{11}^2 - + \text{Mo(CO)}_6 \rightarrow \text{Mo(CO)}_3(\eta^5\text{-C}_2\text{B}_9\text{H}_{11})^2- + 3\text{CO}
\]

\[
\text{M}^{m+} + [\text{M}(\text{C}_2\text{B}_9\text{H}_{11})]^7 - \rightarrow [\text{M}(\text{C}_2\text{B}_9\text{H}_{11})]^7 - (m-4)+
\]

The reaction, which is quite general for closo-carboranes, involves the reductive opening of an \(n\)-vertex closo-cluster followed by metal
insertion to give an \((n+1)\)-vertex closo-cluster. Numerous variants are possible including the insertion of a second metal centre into an existing metallocarborane, e.g.:

\[
\text{closo-1,7-C}_2\text{B}_6\text{H}_8 \rightarrow \text{CoCl}_2 + \text{NaC}_5\text{H}_5 \rightarrow [\text{Co}(\text{C}_5\text{H}_5)\text{C}_2\text{B}_6\text{H}_8]^{2e^-/\text{thf}} \rightarrow [\text{Co}(\text{C}_5\text{H}_5)\text{C}_2\text{B}_6\text{H}_8] \quad (84)
\]

The structure of the bimetallic 10-vertex cluster was shown by X-ray diffraction to be (84). When the icosahedral carborane 1,2-\(\text{C}_2\text{B}_{10}\text{H}_{12}\) was used, the reaction led to the first supraicosahedral metallocarboranes with 13- and 14-vertex polyhedral structures (85)-(89). Facile isomerism of the 13-vertex monometallodicarbaboranes was observed as indicated in the scheme above (in which \(\bullet = \text{CH}\) and \(\circ = \text{BH}\)).

(iii) Polyhedral contraction (1972). This involves the clean removal of one BH group from a closo-metallocarborane by nucleophilic base degradation, followed by oxidative closure of the resulting nido-metallocarborane complex to a closo-species with one vertex less than the original, e.g.:

\[
\begin{align*}
[3-\{\text{Co}(\eta^5-\text{C}_5\text{H}_5)\}(1,2-\text{C}_2\text{B}_9\text{H}_{11})]^{1-} & \rightarrow \text{EtO}^- \rightarrow [\text{Co}(\eta^5-\text{C}_5\text{H}_5)\{2,4-\text{C}_2\text{B}_8\text{H}_{10}\}]^{1-} \quad (91)
\end{align*}
\]

Polyhedral contraction is not so general a method of preparing metallocarboranes as is polyhedral expansion since some metallocarboranes degrade completely under these conditions.

(iv) Polyhedral subrogation (1973). Replacement of a BH vertex by a metal vertex without changing the number of vertices in the cluster is termed polyhedral subrogation. It is an offshoot of the polyhedral contraction route in that degradative removal of the BH unit is followed by reaction with a transition metal ion rather than
with an oxidizing agent, e.g.:

$$\text{[Co(\eta^5-C_5H_5)(C_2B_{10}H_{12})]} \xrightarrow{\text{(1) OH}^-} \text{[Co(\eta^5-C_5H_5)]}_2(C_2B_9H_{11})$$

The method is clearly of potential use in preparing mixed metal clusters, e.g. (Co + Ni) or (Co + Fe), and can be extended to prepare more complicated cluster arrays as depicted below, the subrogated B atom being indicated as a shaded circle in (92).

(\text{v) Thermal metal transfer (1974).} This method is less general and often less specific than the coordination of nido-anions or polyhedral expansion; it involves the pyrolysis of pre-existing metallocarboranes and consequent cluster expansion or disproportionation similar to that of the closo-carboranes themselves (p. 182). Mixtures of products are usually obtained, e.g.:

$$\text{[(C_3H_5)_2Co]^+[(2,3-C_2B_9H_{10})_2Co]^-} \xrightarrow{525^\circ \text{(hot tube)}} \text{[C}_3\text{H}_5\text{C}_2\text{Co}_3\text{C}_2\text{B}_9\text{H}_{10}]$$

A related technique (R. N. Grimes, 1973) is direct metal insertion by gas-phase reactions at elevated temperatures; typical reactions are shown in the scheme (p. 192). The reaction with $\text{[Co(\eta^5-C_5H_5)(CO)\text{}_2]}$ also gave the 7-vertex closo-bimetallocarborane (101) which can be considered as a rare example of a triple-decker sandwich compound; another isomer (102) can be made by base degradation of $\text{[(Co(\eta^5-C_5H_5))(C_2B_4H_6)]}$ followed by deprotonation and subrogation with a second $\text{[Co(\eta^5-C_5H_5)]}$ unit. (85) It will be noted that the central planar formal $\text{C}_2\text{B}_3\text{H}_6^{-}$ unit is isoelectronic with $\text{C}_5\text{H}_5^{-}$.

A particularly elegant route to metallacarboranes is the direct oxidative insertion of a metal centre into a closo-carborane cluster: the reaction uses zero-valent derivatives of Ni, Pd and Pt in a concerted process which involves a nett transfer of electrons from the nucleophilic metal centre to the cage: (93)

$$\text{M}^{0}\text{L}_{x+y} + \text{C}_2\text{B}_n\text{H}_{n+2} \xrightarrow{-30^\circ} \text{[M}^{1+}\text{L}_x\text{(C}_2\text{B}_n\text{H}_{n+2})]\} + y\text{L}$$

where $\text{L} = \text{PR}_3, \text{C}_8\text{H}_{12}, \text{RNC}, \text{etc.}$. A typical reaction is

$$\text{[Pt(PEt}_3\text{)_3]} + 2,3-\text{Me}_2-2,3-\text{C}_2\text{B}_9\text{H}_9 \xrightarrow{-30^\circ \text{ petro}} \text{[1-\{Pt(PEt}_3\text{)_2]-2,4-(MeC)_2B_9H_9]} + \text{PEt}_3$$

Many novel cluster compounds have now been prepared in this way, including mixed metal clusters. Further routes involve the oxidative fusion of dicarbon metallacarborane anions to give dimetal tetracarbon clusters such as (103) and (104); the insertion of isonitriles into metallaborane clusters to give monocarbon metallacarboranes such as (105); and the reaction of small nido-carboranes with alane adducts such as Et₃AlH₃ to give the *commo* species (106).

---

Numerous other aluminacarborane structural types have also recently been synthesized by a variety of routes and, indeed, the burgeoning field of metallocarborane chemistry now encompasses the whole Periodic Table with an almost bewildering display of exotic and unprecedented structural types.

The electron-counting rules outlined for boranes (p. 161) and carboranes (p. 181) can readily be extended to the metallocarboranes (see Panel on next page). For bis-complexes of 1,2-C\(_2\)B\(_{10}\)H\(_{11}\)\(^{2-}\) which can be regarded as a 6-electron penta-hapto ligand, it has been found that “electron-sufficient” (18-electron) systems such as those involving d\(^6\) metal centres (e.g. Fe\(^{II}\), Co\(^{III}\) or Ni\(^{IV}\)) have symmetrical structures with the metal atom equidistant from the 2 C and 3 B atoms in the pentagonal face. The same is true for “electron-deficient” systems such as those involving d\(^2\) Ti\(^{II}\) (14-electron), d\(^3\) Cr\(^{III}\) (15-electron), etc., though here the metal-cluster bonds are somewhat longer. With “electron excess” complexes such as [Ni\(^{II}\)(C\(_2\)B\(_{10}\)H\(_{11}\))\(_2\)]\(^{2-}\) and the corresponding complexes of Pd\(^{II}\), Cu\(^{III}\) and Au\(^{III}\) (20 electrons), so-called “slipped-sandwich” structures (107) are observed in which the metal atom is significantly closer to the 3 B atoms than to the 2 C atoms. This has been thought by some to indicate \(\pi\)-allylic bonding to the 3 B but is more likely to arise from an occupation of orbitals that are antibonding with respect to both the metal and the cluster thereby leading to an opening of the 12-vertex closo-structure to a pseudo-nido structure in which the 12 atoms of the cluster occupy 12 vertices of a 13-vertex polyhedron. A similar type of distortion accompanies the use of metal centres with increasing numbers of electron-pairs on the metal and it seems that these electrons may also, at least in part, contribute to the framework electron count with consequent cluster opening.

97 H. M. Colquhoun, T. J. Greenhough and M. G. H. Wallbridge, J. Chem. Soc., Chem. Commun., 737–8 (1977); see also H. M. Colquhoun, T. J. Greenhough...
Electron-counting Rules for Metallocarboranes and Other Heteroboranes

As indicated on pp. 161 and 174 each framework atom (except H) uses 3 atomic orbitals (AOs) in cluster bonding. For B, C, and other first-row elements this leaves one remaining AO to bond exopolyhedrally to \(-\text{H}, -\text{X}, -\text{R}, \text{etc.}\). In contrast, transition elements have a total of 9 valence AOs (five d, one s, three p). Hence, after contributing 3 AOs to the cluster, they have 6 remaining AOs which can be used for bonding to external ligands and for storage of nonbonding electrons. In \emph{close}-clusters the \((n + 1)\) MOs require \((2n + 2)\) electrons from the B, C and M vertex atoms. In its simplest form the electron counting scheme invokes only the total number of framework MOs and electrons, and requires no assumptions as to orbital hybridization or formal oxidation state. For example, the neutral moiety \([\text{Fe(CO)}_3]\) has 8 Fe electrons and 9 Fe AOs: since 3 AOs are involved in bonding to 3 CO and 3 AOs are used in cluster bonding, there remain 3 AOs which can accommodate 6 (nonbonding) Fe electrons, leaving 2 Fe electrons to be used in cluster bonding. Neutral \([\text{Fe(CO)}_3]\) is thus precisely equivalent to \([\text{BH}]\), as distinct from \([\text{CH}]\), which provides 3 electrons for the cluster. Other groups such as \([\text{Co(}\eta^5\text{-C}_5\text{H}_5])\) and \([\text{Ni(CO)}_3]\) are clearly equivalent to \([\text{Fe(CO)}_3]\).

An alternative scheme that is qualitatively equivalent is to assign formal oxidation states to the metal moiety and to consider the bonding as coordination from a carborane ligand, e.g. \([\text{Fe(CO)}_3]^{2+}\eta^3\)-bonded to a cyclocarborane ring as in \([\text{C}_2\text{B}_9\text{H}_{11}]^{2-}\). This is acceptable when the anionic ligand is well characterized as an independent entity, as in the case just cited, but for many metallocarboranes the “ligands” are not known as free species and the presumed anionic charge and metal oxidation state become somewhat arbitrary. It is therefore recommended that the metalloborane cluster be treated as a single covalently bonded structure with no artificial separation between the metal and the rest of the cluster; electron counting can then be done unambiguously on the basis of neutral atoms and attached groups.

To the structural generalizations on carboranes (p. 185) can be added the rule that, in metallocarboranes, the M atom tends to adopt a vertex with high coordination number: M occupancy of a low CN vertex is not precluded, particularly in kinetically controlled syntheses, but isomerization to more stable configurations usually results in the migration of M to high CN vertices.

Other main-group atoms besides C can occur in heteroborane clusters and the electron-counting rules can readily be extended to them.\(^{(17)}\) Thus, whereas each \([\text{BH}]\) contributes 2 e and \([\text{CH}]\) contributes 3 e to the cluster, so \([\text{NH}]\) or \([\text{PH}]\) contributes 4 e, \([\text{SH}]\) contributes 5 e, \([\text{S}]\) contributes 4 e, etc. For example, the following 10-vertex thiaboranes (and their isoelectronic equivalents) are known: \emph{closo}-1-SB\(_9\)H\(_9\) \((\text{B}_{10}\text{H}_{10}^{2-})\), \emph{nido}-6-SB\(_9\)H\(_{11}\) \((\text{B}_{10}\text{H}_{12}^{-})\) and \emph{arachno}-6-SB\(_9\)H\(_{12}^{-}\) \((\text{B}_{10}\text{H}_{14}^{2-})\). Similarly, the structures of 12-, 11- and 9-vertex thiaboranes parallel those of boranes and carbaboranes with the same skeletal electron count, the S atom in each case contributing 4 electrons to the framework plus an exo-polyhedral lone-pair.

cluster is noted for complexes of 1,2-C\(_2\)B\(_9\)H\(_{11}\)\(^{2-}\) with Re\(^{1+}\) \((d^6)\), Au\(^{11+}\) \((d^8)\), Hg\(^{II}\) \((d^{10})\) and Tl\(^{I}\) \((d^{19}2s^2)\) as shown in structures (108)–(111). Thus the Re\(^1\) \((d^6)\) complex (108) is a symmetrically bonded 12-vertex cluster with Re–B 234 pm and Re–C 231 pm. The Au\(^{11}\) \((d^8)\) complex (109) has the metal appreciably closer to the 3 B atoms (221 pm) than to the 2 C atoms (278 pm). With the Hg\(^{II}\) \((d^{10})\) complex (110) this distortion is even more pronounced and the metal is pseudo-\(\sigma\)-bonded to 1 B atom at 220 pm; there is some additional though weak interaction with the other 2 B (252 pm) but the two Hg···C distances (290 pm) are essentially nonbonding. Finally, the Tl\(^{I}\) \((d^{10}s^2)\) complex (111), whilst having the Tl atom more symmetrically located above the open face, has Tl–cluster distances that exceed considerably the expected covalent Tl–B distance of ~236 pm; the shortest Tl–B distance is 266 pm and there are two other Tl–B at 274 pm and two Tl–C at 292 pm: the species can thus be regarded formally as being closer to an ion pair \([\text{Tl}^+\text{(C}_2\text{B}_9\text{H}_{11})^2^-]\).

In general, metallocarboranes are much less reactive (more stable) than the corresponding metalloenes and they tend to stabilize higher oxidation states of the later transition metals, e.g. \([\text{Cu}^{II}(1,2\text{-C}_2\text{B}_9\text{H}_{11})_2]^2^-\) and \([\text{Cu}^{III}(1,2\text{-C}_2\text{B}_9\text{H}_{11})_2]^2^-\) are known whereas cuprocene...
86.7.1 Boron trihalides

[Bu^{1'}(\eta^5-C_5H_5)_2] is not. Likewise, Fe^{III} and Ni^{IV} carborane derivatives are extremely stable. Conversely, metallocarboranes tend to stabilize lower oxidation states of early transition elements and complexes are well established for Ti^{II}, Zr^{II}, Hf^{II}, V^{II}, Cr^{II} and Mn^{II}; these do not react with H_2, N_2, CO or PPh_3 as do cyclopentadienyl derivatives of these elements.

The chemistry of metallocarboranes of all cluster sizes is still rapidly developing and further unusual reactions and novel structures are continually appearing. Furthermore, as Si, Ge, Sn (and Pb) are in the same periodic group as C, heteroboranes containing these elements are to be expected (see p. 394). Likewise, as CC is isoelectronic with BN, the dicarbaboranes such as C_2B_{10}H_{12} can be paralleled by NB_2H_{12} etc. Numerous azaboranes and their metalla-derivatives are known (see p. 211) as indeed are clusters incorporating P, As, Sb (and Bi) (p. 212). The incorporation of the more electronegative element O has proved to be a greater challenge but several examples are now known. Sulfur provides an extensive thia- and polythia-borane chemistry (p. 214) and this is paralleled, although to a lesser extent, by Se and Te derivatives (p. 215). Detailed discussion of these burgeoning areas of borane cluster chemistry fall outside this present treatment but the general references cited on the above mentioned pages provide a useful introduction into this important new area of chemistry.

6.7 Boron Halides

Boron forms numerous binary halides of which the monomeric trihalides BX_3 are the most stable and most extensively studied. They can be regarded as the first members of a homologous series B_nH_{n+2}. The second members B_2X_4 are also known for all 4 halogens but only F forms more highly catenated species containing BX_2 groups: B_3F_7, B_4F_6.L, B_8F_{12} (p. 201). Chlorine forms a series of neutral closo-polyhedral compounds B_nCl_n (n = 4, 8–12) and several similar compounds are known for Br (n = 7–10) and I (e.g. B_9I_9). There are also numerous involatile subhalides, particularly of Br and I, but these are of uncertain stoichiometry and undetermined structure.

6.7.1 Boron trihalides

The boron trihalides are volatile, highly reactive, monomeric molecular compounds which show no detectable tendency to dimerize (except perhaps in Kr matrix-isolation experiments at 20K). In
this they resemble organoboranes, BR₃, but differ sharply from diborane, B₂H₆, and the aluminium halides and alkyls, Al₂X₆, Al₂R₆ (p. 259). Some physical properties are listed in Table 6.4; mps and volatilities parallel those of the parent halogens, BF₃ and BCl₃ being gases at room temperature, BBr₃ a volatile liquid, and BI₃ a solid. All four compounds have trigonal planar molecules of D₃h symmetry with angle X–B–X 120° (Fig. 6.22a). The interatomic distances B–X are substantially less than those expected for single bonds and this has been interpreted in terms of appreciable pₓ–pₓ interaction (Fig. 6.22b). However, there is disagreement as to whether the extent of this π bonding increases or diminishes with increasing atomic number of the halogen; this probably reflects the differing criteria used (extent of orbital overlap, percentage π-bond character, amount of π-charge transfer from X to B, π-bond energy, or reorganization energy in going from planar BX₃ to tetrahedral LBX₃, etc.).

For example, it is quite possible for the extent of π-charge transfer from X to B to increase in the sequence F < Cl < Br < I but for the actual magnitude of the π-bond energy to be in the reverse sequence BF₃ > BCl₃ > BBr₃ > BI₃ because of the much greater bond energy of the lighter homologues. Indeed, the mean B–F bond energy in BF₃ is 646 kJ mol⁻¹, which makes it the strongest known "single" bond; if x% of this were due to π bonding, then even if 2.4x% of the B–I bond energy were due to π bonding, the π-bond energy in BI₃ would be less than that in BF₃ in absolute magnitude. The point is one of some importance since the chemistry of the trihalides is dominated by interactions involving this orbital.

BF₃ is used extensively as a catalyst in various industrial processes (p. 199) and can be prepared on a large scale by the fluorination of boric oxide or borates with fluor spar and concentrated H₂SO₄:

\[ \text{6CaF}_2 + \text{Na}_2\text{B}_4\text{O}_7 + 8\text{H}_2\text{SO}_4 \rightarrow 2\text{NaHSO}_4 + 6\text{CaSO}_4 + 7\text{H}_2\text{O} + 4\text{BF}_3 \]
Better yields are obtained in the more modern two-stage process:

$$\text{Na}_2\text{B}_4\text{O}_7 + 12\text{HF} \rightarrow 6\text{H}_2\text{O} \rightarrow [\text{Na}_2\text{O}(\text{BF}_3)_4] + 2\text{NaHSO}_4 + \text{H}_2\text{O} + 4\text{BF}_3$$

On the laboratory scale, pure BF$_3$ is best made by thermal decomposition of a diazonium tetrafluoroborate (e.g. PhN$_2$BF$_4$ $\rightarrow$ PhF + N$_2$ + BF$_3$). BCl$_3$ and BB$_3$ are prepared on an industrial scale by direct halogenation of the oxide in the presence of C, e.g.:

$$\text{B}_2\text{O}_3 + 3\text{C} + 3\text{Cl}_2 \rightarrow 500^\circ\text{C} \rightarrow 6\text{CO} + 2\text{BCl}_3$$

Laboratory samples of the pure compounds can be made by halogen exchange between BF$_3$ and Al$_2$X$_6$. Bl$_3$ is made in good yield by treating LiBH$_4$ (or NaBH$_4$) with elemental I$_2$ at 125$^\circ$ (or 200$^\circ$). Both BB$_3$ and BIl$_3$ tend to decompose with liberation of free halogen when exposed to light or heat; they can be purified by treatment with Hg or Zn/Hg.

Simple BX$_3$ undergo rapid scrambling or redistribution reactions on being mixed and the mixed halides BX$_2$Y and BXY$_2$ have been identified by vibrational spectroscopy, mass spectrometry, or nmr spectroscopy using $^{11}$B or $^{19}$F. A good example of this last technique is shown in Fig. 6.23, where not only the species BF$_3$-nX$_n$($n = 0$, 1, 2) were observed but also the trihalogeno species BFClBr.$^{99}$ The equilibrium concentration of the various species are always approximately random (equilibrium constants between 0.5 and 2.0) but it is not possible to isolate individual mixed halides because the equilibrium is too rapidly attained from either direction ($<1$ s). The related systems RBX$_2$/R'BY$_2$ (and ArBX$_2$/Ar'BY$_2$) also exchange X and Y but not R (or Ar). The scrambling mechanism probably involves a 4-centre transition state. Consistent with this, complexes such as Me$_2$OBX$_3$ or Me$_2$NBX$_3$ do not scramble at room temperature, or even above, in the absence of free BX$_3$.$^{100}$ (cf. the stability of CFCI$_3$, CF$_2$Cl$_2$, etc.) and species that are

Factors Affecting the Stability of Donor–Acceptor Complexes

For a given ligand, stability of the adduct LBX₃ usually increases in the sequence BF₃ < BCl₃ < BBr₃ < BI₃, probably because the loss of π bonding on reorganization from planar to tetrahedral geometry (p. 196) is not fully compensated for by the expected electronegativity effect. However, if the ligand has an H atom directly bonded to the donor atom, the resulting complex is susceptible to protonolysis of the B–X bond, e.g.:

\[
\text{ROH} + \text{BX₃} \rightarrow \text{[ROH.BX₃]} \rightarrow \text{ROBX} + \text{HX}
\]

In such cases the great strength of the B–F bond ensures that the BF₃ complex is more stable than the others. For example, BF₃ forms stable complexes with H₂O, MeOH, Me₂NH, etc., whereas BCl₃ reacts rapidly to give B(OH)₃, B(OMe)₃, and B(NMe₂)₃, with BBr₃ and BI₃ such protolytic reactions are sometimes of explosive violence. Even ethers may be cleaved by BCl₃ to give RCl and ROBCl₂, etc.

For a given BX₃, the stability of the complex depends on (a) the chemical nature of the donor atom, (b) the presence of polar substituents on the ligand, (c) steric effects, (d) the stoichiometric ratio of ligand to acceptor, and (e) the state of aggregation. Thus the majority of adducts have as the donor atom N, P, As; O, S; or the halide and hydride ions X⁻. BX₃ (but not BH₃) can be classified as type-a acceptors, forming stronger complexes with N, O and F ligands than with P, S and Cl. However, complexes are not limited to these traditional main-group donor atoms, and, following the work of D. F. Shriver (1963), many complexes have been characterized in which the donor atom is a transition metal, e.g. [(C₅H₅)₂H₂W⁺BF₃], [(Ph₃P)₂(PCIC)(PH₃)⁺BF₃], [(Ph₃P)(CO)CIR⁺(BF₃)⁺], [(Ph₃P)₂(PCIC)²], etc. Displacement studies on several such complexes indicate that BF₃ is a weaker acceptor than BCl₃.

The influence of polar substituents on the ligand follows the expected sequence for electronegative groups, e.g. electron donor properties decrease in the order NMe₃ > NMe₂Cl > NMeCl > NC₃. Steric effects can also limit the electron-donor strength. For example, whereas pyridine, C₅H₅N, is a weaker base (proton acceptor) than 2-MeC₅H₄N and 2,6-Me₂C₅H₃N, the reverse is true when BF₃ is the acceptor due to steric crowding of the α-Me groups which prevent the close approach of BF₃ to the donor atom. Steric effects also predominate in determining the decreasing stability of BF₃ etherates in the sequence C₅H₅O(Ph) > C₅H₅O > C₂H₅O > Pr₂O.

The influences of stoichiometry and state of aggregation are more subtle. At first sight it is not obvious why BF₃, with 1 vacant orbital should form not only BF₃.H₂O but also the more stable BF₃.2H₂O; similarly, the 1:2 complexes with ROH and RCOOH are always more stable than the 1:1 complexes. The second mole of ligand is held by hydrogen bonding in the solid, e.g. BF₃.OH₂...OH; however, above the mp 6.2°C the compound melts and the act of coordinate-bond formation causes sufficient change in the electron distribution within the ligand that ionization ensues and the compound is virtually completely ionized as a molten salt

The greater stability of the 1:2 complex is thus seen to be related to the formation of H₂O⁺, ROH₂⁺, etc., and the lower stability of the 1:1 complexes HBF₃OH, HBF₃OR, is paralleled by the instability of some other anhydrous oxo acids, e.g. H₂CO₃. The mp of the hydrate is essentially the transition temperature between an H-bonded molecular solid and an ionically dissociated liquid. A transition in the opposite sense occurs when crystalline [PCl₄]⁺[PCl₆]⁻ melts to give molecular PCl₅ (p. 498) and several other examples are known. The fact that coordination can substantially modify the type of bonding should occasion no surprise: the classic example (first observed by J. Priestley in 1774) was the reaction NH₃(g) + HCl(g) → NH₄Cl(s).

expected to form stronger π bonds than BX₃ (such as R₂NBX₂) exchange much more slowly (days or weeks).

The boron trihalides form a great many molecular addition compounds with molecules

(ligands) possessing a lone-pair of electrons (Lewis base). Such adducts have assumed considerable importance since it is possible to investigate in detail the process of making and breaking one bond, and to study the effect this has on the rest of the molecule (see Panel). The tetrahalogeno borates $\text{BX}_4^-$ are a special case in which the ligand is $\text{X}^-$; they are isoelectronic with $\text{BH}_4^-$ (p. 165) and with $\text{CH}_4$ and $\text{CX}_4$. Salts of $\text{BF}_4^-$ are readily formed by adding a suitable metal fluoride to $\text{BF}_3$ either in the absence of solvent or in such nonaqueous solvents as HF, $\text{BrF}_3$, $\text{AsF}_3$ or $\text{SO}_2$. The alkali metal salts $\text{MBF}_4$ are stable to hydrolysis in aqueous solutions. Some molecular fluorides such as $\text{NO}_2\text{F}$ and $\text{RCOF}$ react similarly. There is a significant lengthening of the $\text{B}–\text{F}$ bond from 130 pm in $\text{BF}_3$ to 145 pm in $\text{BF}_4^-$. The other tetrahalogenoborates, $\text{BX}_4^-$, are less stable but may be prepared using large counter cations, e.g. Rb, Cs, pyridinium, tetraalkylammonium, tropenium, triphenylcarbonium, etc. The $\text{BF}_4^-$ anion is a very weakly coordinating ligand, indeed one of the weakest; however, unstable complexes are known in which it acts as an $\eta^1$-ligand and, in the case of $[\text{Ag(lut)}_2(\text{BF}_4)]$ it acts as a bis(bidentate) bridging ligand $[\mu_4-\eta^2,\eta^2-\text{BF}_4]^{-}$ to form a polymeric chain of 6-coordinate Ag centres [lut = lutidene, i.e. 2,6-dimethylpyridine].

The importance of the trihalides as industrial chemicals stems partly from their use in preparing crystalline boron (p. 141) but mainly from their ability to catalyse a wide variety of organic reactions. $\text{BF}_3$ is the most widely used but $\text{BCl}_3$ is employed in special cases. Thus, $\text{BF}_3$ is manufactured on the multikilotonne scale whereas the production of $\text{BCl}_3$ (USA, 1990) was 250 tonnes and $\text{BBr}_3$ was about 23 tonnes. $\text{BF}_3$ is shipped in steel cylinders containing 2.7 or 28 kg at a pressure of 10–12 atm, or in tube trailers containing about 5.5 tonnes. Prices for $\text{BF}_3$ are in the range $4.00–5.00/kg depending on purity and quantity; corresponding prices (USA, 1991) for $\text{BCl}_3$ and $\text{BBr}_3$ were $8.50–16.75/kg and $81.50/kg, respectively.

Many of the reactions of $\text{BF}_3$ are of the Friedel–Crafts type though they are perhaps not strictly catalytic since $\text{BF}_3$ is required in essentially equimolar quantities with the reactant. The mechanism is not always fully understood but it is generally agreed that in most cases ionic intermediates are produced by or promoted by the formation of a $\text{BX}_3$ complex; electrophilic attack of the substrate by the cation so produced completes the process. For example, in the Friedel–Crafts-type alkylation of aromatic hydrocarbons:

$$\text{RX} + \text{BF}_3 \rightleftharpoons [\text{R}^+][\text{BF}_3\text{X}^-]$$

$$[\text{R}^+] + \text{PhH} \rightleftharpoons \text{PhR} + [\text{H}^+]$$

$$[\text{H}^+] + [\text{BF}_3\text{X}^-] \rightleftharpoons \text{BF}_3 + \text{HX}$$

Similarly, ketones are prepared via acyl carbocation ions:

$$\text{RCOOMe} + \text{BF}_3 \rightleftharpoons [\text{RCO}^+][\text{BF}_3(\text{OMe})^-]$$

$$[\text{RCO}^+] + \text{PhH} \rightleftharpoons \text{PhCOR} + [\text{H}^+]$$

$$[\text{H}^+] + [\text{BF}_3(\text{OMe})^-] \rightleftharpoons \text{MeOH.BF}_3$$

Evidence for many of these ions has been extensively documented.

$$\text{ROH} + \text{BF}_3 \rightleftharpoons [\text{H}^+] + [\text{BF}_3(\text{OR})^-]$$

$$[\text{H}^+] + \text{ROH} \rightleftharpoons [\text{ROH}_2^+]$$

$$\text{BF}_3 \rightleftharpoons [\text{R}^+] + \text{H}_2\text{OBF}_3$$

$$[\text{R}^+] + \text{ROH} \rightarrow \text{R}_2\text{O} + [\text{H}^+]$$

A similar mechanism has been proposed for the esterification of carboxylic acids:

$$[\text{H}^+] + \text{RCOOH} \rightleftharpoons [\text{RCOOH}_2^+]$$

$$\text{BF}_3 \rightleftharpoons [\text{RCO}^+] + \text{H}_2\text{OBF}_3$$

$$[\text{RCO}^+] + \text{R}'\text{OH} \rightarrow \text{RCOOR}' + [\text{H}^+]$$
Nitration and sulfonation of aromatic compounds probably occur via the formation of the nitryl and sulfonyl cations:

\[
\text{HONO}_2 + \text{BF}_3 \rightleftharpoons [\text{NO}_2^+] + [\text{BF}_3(\text{OH})^-]
\]
\[
\text{HOSO}_3\text{H} + \text{BF}_3 \rightleftharpoons [\text{SO}_2\text{H}^+] + [\text{BF}_3(\text{OH})^-]
\]

Polymerization of alkenes and the isomerization of alkanes and alkenes occur in the presence of a cocatalyst such as H\(_2\)O, whereas the cracking of hydrocarbons is best performed with HF as cocatalyst. These latter reactions are of major commercial importance in the petrochemicals industry.

### 6.7.2 Lower halides of boron

B\(_2\)F\(_4\) (mp \(-56^\circ\)C, bp \(-34^\circ\)C) has a planar (\(D_{2d}\)) structure with a rather long B–B bond; in this it resembles both the oxalate ion C\(_2\)O\(_4^{2-}\) and N\(_2\)O\(_4\) with which it is precisely isoelectronic. Crystalline B\(_2\)Cl\(_4\) (mp \(-92.6^\circ\)C) has the same structure, but in the gas phase (bp \(65.5^\circ\)) it adopts the staggered \(D_{2d}\) configuration (see below) with hindered rotation about the B–B bond (\(\Delta E_f = 7.7\) kJ mol\(^{-1}\)). The structure of gaseous B\(_2\)Br\(_4\) is also \(D_{2d}\) with B–B 169 pm and \(\Delta E_f = 12.8\) kJ mol\(^{-1}\). B\(_2\)I\(_4\) is presumably similar.

B\(_2\)Cl\(_4\) was the first compound in this series to be prepared and is the most studied; it is best made by subjecting BCl\(_3\) vapour to an electrical discharge between mercury or copper electrodes:

\[
2\text{BCl}_3 + 2\text{Hg} \rightarrow \text{B}_2\text{Cl}_4 + \text{Hg}_2\text{Cl}_2
\]

The reaction probably proceeds by formation of a \{BCl\} intermediate which then inserts into a B–Cl bond of BCl\(_3\) to give the product directly.

Another route is via the more stable B\(_2\)(NMe\(_2\))\(_4\) (see reaction scheme). Thermal stabilities of these compounds parallel the expected sequence of \(p\pi–p\pi\) bonding between the substituent and B:

\[
\text{B}_2(\text{NMe}_2)_4 > \text{B}_2(\text{OMe})_4 > \text{B}_2(\text{OH})_4
\]

> B\(_2\)F\(_4\) > B\(_2\)Cl\(_4\) > B\(_2\)Br\(_4\)

The halides are much less stable than the corresponding BX\(_3\), the most stable member B\(_2\)F\(_4\) decomposing at the rate of about 8% per day at room temperature. B\(_2\)Br\(_4\) disproportionates so rapidly at room temperature that it is difficult to purify:

\[
n\text{B}_2\text{X}_4 \rightarrow n\text{BX}_3 + (\text{BX})_n
\]

The compounds B\(_2\)X\(_4\) are spontaneously flammable in air and react with H\(_2\) to give BH\(_2\)X\(_2\), B\(_2\)H\(_6\) and related hydrohalides; they form adducts with Lewis bases (B\(_2\)Cl\(_4\)L\(_2\) more stable than B\(_2\)F\(_4\)L\(_2\)) and add across C–C multiple bonds, e.g.

\[
\text{C}_2\text{H}_2 + \text{B}_2\text{Cl}_4 \rightarrow \text{C} \equiv \text{C} \quad \text{Cl}_2\text{B} \quad \text{Cl}_2\text{B} \quad \text{B}_2\text{Cl}_4
\]

Other reactions of B\(_2\)Cl\(_4\) are shown in the scheme and many of these also occur with B\(_2\)F\(_4\).

When BF\(_3\) is passed over crystalline B at 1850°C and pressures of less than 1 mmHg, the reactive gas BF is obtained in high yield and can
be condensed out at $-196^\circ$. Cocondensation with BF$_3$ yields B$_2$F$_4$ then B$_3$F$_5$ (i.e. F$_2$B–B(F)–BF$_2$). However, this latter compound is unstable and it disproportionates above $-50^\circ$ according to

$$4(BF_2)_2BF \rightarrow 2B_2F_4 + B_2F_{12} \quad (112)$$

The yellow compound B$_8$F$_{12}$ appears to have a diborane-like structure (112) and this readily undergoes symmetrical cleavage with a variety of ligands such as CO, PF$_3$, PCl$_3$, PH$_3$, AsH$_3$ and SMe$_2$ to give adducts LB(BF$_2$)$_2$ which are stable at room temperature in the absence of air or moisture.

Thermolysis of B$_2$Cl$_4$ and B$_2$Br$_4$ at moderate temperatures gives a series of closo-halogenoboranes B$_n$X$_n$ where $n = 4$, 8–12 for Cl, and $n = 7–10$ for Br. Other preparative routes include the high-yield halogenation of B$_9$H$_{10}^{-}$ to B$_9$X$_n^{-}$ using N-chlorosuccinimide, N-bromosuccinimide or I$_2$. The redox sequences B$_9$X$_n^{-}$ have also been established, the radical anions B$_9$X$_n^{-}$ being isolated as air-stable coloured salts.

B$_4$Cl$_4$, a pale-yellow-green solid, has a regular closo-tetrahedral structure (Fig. 6.24a); it is hyperelectron deficient when compared with the closo-boranes B$_n$H$_n^{-}$ (pp. 153, 160) and the

Molecular structures of (a) tetrahedral $B_4C_{14}$, (b) dodecahedral $B_8Cl_8$, and (c) tricapped trigonal pyramidal $B_9Cl_9$ and $B_9Br_9$. In $B_8Cl_8$ note that the shortest B–B distances are between two 5-coordinate B atoms, e.g. $B(1)-B(2)$ 168 pm; the longest are between two 6-coordinate B atoms, e.g. $B(4)-B(6)$ 201 pm and intermediate distances are between one 5- and one 6-coordinate B atom. A similar trend occurs in $B_9Cl_9$.

Bonding has been discussed in terms of localized 3-centre bonds above the 4 tetrahedral faces supplemented by $p_x$ interaction with $p$ orbitals of suitable symmetry on the 4 Cl atoms: the 8 electrons available for framework bonding from the 4 $\{BCl\}$ groups fill 4 bonding MOs of class $A_1$ and $T_2$ and there are 2 additional bonding MOs of class $E$ which have correct symmetry to mix with the Cl $p_x$ orbitals. $B_8Cl_8$ (variously described as dark red, dark purple or green-black crystals) has an irregular dodecahedral (bisphenoid) arrangement of the $closo$-$B_8$ cluster (Fig. 6.24b) with 14 B–B distances in the range 168–184 pm and 4 substantially longer B–B distances at 193–205 pm. $B_9Br_9$ is a particularly stable compound; it forms as dark-red crystals together with other subbromides ($n = 7–10$) when gaseous $BBr_3$ is subjected to a silent electric discharge in the presence of Cu wool, and can be purified by sublimation under conditions (200°C) which rapidly decompose the other products. $B_9Br_9$ is isostructural with $B_9Cl_9$ (yellow-orange) (Fig. 6.24c). The photoelectron spectra and bonding in $B_4C_{14}$, $B_8Cl_8$ and $B_9Cl_9$ have been described in detail.\(^\text{109}\)

Many mixed halides $B_nBr_{n-x}Cl_x$ ($n = 9, 10, 11$) have been identified by mass spectrometry and other techniques, but their separation as pure compounds has so far not been achieved. Chemical reactions of $B_nX_n$ resemble those of $B_2X_4$ except that alkenes do not cleave the B–B bonds in the $closo$-species. Thus, $B_4C_{14}$ reacts with LiEt to give the yellow liquids $B_4C_{13}Et$ and $B_4C_{12}Et_2$, whereas LiBu$^+$ afforded $B_4Bu^+_{14}$ as a glassy solid, mp 45°C.\(^\text{110}\) By contrast, reaction with $Me_3SnH$ yields $arachno$-$B_4H_{10}$ and LiBH$_4$ yields a mixture of $nido$-$B_3H_9$ and $nido$-$B_3H_{10}$, while $B_2H_6$ gave $nido$-$B_6H_{10}$Cl$_4$ and a mixture of $nido$-$B_{10}H_{10}Cl_{14-n}$ ($n = 8–12$).\(^\text{111}\)

---

6.8 Boron–Oxygen Compounds

Boron (like silicon) invariably occurs in nature as oxo compounds and is never found as the element or even directly bonded to any other element than oxygen. The structural chemistry of B–O compounds is characterized by an extraordinary complexity and diversity which rivals those of the borides (p. 145) and boranes (p. 151). In addition, vast numbers of predominantly organic compounds containing B–O are known.

6.8.1 Boron oxides and oxoacids

The principal oxide of boron is boric oxide, B\textsubscript{2}O\textsubscript{3} (mp 450°, bp (extrap) 2250°C). It is one of the most difficult substances to crystallize and, indeed, was known only in the vitreous state until 1937. It is generally prepared by careful dehydration of boric acid B(OH)\textsubscript{3}. The normal crystalline form (d 2.56 g cm\textsuperscript{-3}) consists of a 3D network of trigonal BO\textsubscript{3} groups joined through their O atoms, but there is also a dense form (d 3.11 g cm\textsuperscript{-3}) formed under a pressure of 35 kbar at 525°C and built up from irregular interconnected BO\textsubscript{4} tetrahedra. In the vitreous state (d \approx 1.83 g cm\textsuperscript{-3}) B\textsubscript{2}O\textsubscript{3} probably consists of a network of partially ordered trigonal BO\textsubscript{3} units in which the 6-membered (BO)\textsubscript{3} ring predominates; at higher temperatures the structure becomes increasingly disordered and above 450°C polar —B═O groups are formed. Fused B\textsubscript{2}O\textsubscript{3} readily dissolves many metal oxides to give characteristically coloured borate glasses. Its major application is in the glass industry where borosilicate glasses (e.g. Pyrex) are extensively used because of their small coefficient of thermal expansion and their easy workability. US production of B\textsubscript{2}O\textsubscript{3} exceeds 25 000 tonnes pa and the price (1990) was $2780–2950 per tonne for 99% grade.

Orthoboric acid, B(OH)\textsubscript{3}, is the normal end product of hydrolysis of most boron compounds and is usually made (\approx 160 000 tonnes pa) by acidification of aqueous solutions of borax. Price depends on quality, being $805 per tonne for technical grade and about twice that for refined material (1990). It forms flaky, white, transparent crystals in which a planar array of BO\textsubscript{3} units is joined by unsymmetrical H bonds as shown in Fig. 6.25. In contrast to the short O—H•••O distance of 272 pm within the plane, the distance between consecutive layers in the crystal is 318 pm, thus accounting for the pronounced basal cleavage of the waxy, plate-like crystals, and their low density (1.48 g cm\textsuperscript{-3}). B(OH)\textsubscript{3} is a very weak monobasic acid and acts exclusively by hydroxyl-ion acceptance rather than proton donation:

\[ \text{B(OH)}_3 + 2\text{H}_2\text{O} \rightleftharpoons \text{H}_3\text{O}^+ + \text{B(OH)}_4^-; \]

\[ pK = 9.25 \]

Figure 6.25 Layer structure of B(OH)\textsubscript{3}. Interatomic distances are B—O 136 pm, O—H 97 pm, O—H•••O 272 pm. Angles at B are 120° and at O 126° and 114°. The H bond is almost linear.

Its acidity is considerably enhanced by chelation with polyhydric alcohols (e.g. glycerol, mannitol) and this forms the basis of its use in analytical chemistry; e.g. with mannitol pK drops to 5.15.
indicating an increase in the acid equilibrium constant by a factor of more than $10^4$;\(^{(113)}\)

$$\text{B(OH)}_3 + 2 \text{C} - \text{C} \quad \longrightarrow \quad \text{H}_3\text{O}^+ +$$

$$\text{B(OH)}_3 \quad \text{O} \quad \text{O} \quad \text{C}$$

$$+ 2\text{H}_2\text{O}$$

\(\text{B(OH)}_3\) also acts as a strong acid in anhydrous \(\text{H}_2\text{SO}_4\):

$$\text{B(OH)}_3 + 6\text{H}_2\text{SO}_4 \longrightarrow 3\text{H}_3\text{O}^+ + 2\text{HSO}_4^- + [\text{B(HSO}_4)_4^-]$$

Other reactions include esterification with ROH/\(\text{H}_2\text{SO}_4\) to give B(OR)\(_3\), and coordination of this with NaH in tlf to give the powerful reducing agent Na[BH(OR)\(_3\)]. Reaction with \(\text{H}_2\text{O}_2\) gives peroxoboric acid solutions which probably contain the monoperoxoborate anion \([\text{B(OH)}_3\text{OOH}]^-\). A complete series of fluoroboric acids is also known in aqueous solution and several have been isolated as pure compounds:

$$\text{H[B(OH)}_4], \text{H[BF(OH)}_3], \text{H[BF}_2(\text{OH)}_2], \text{H[BF}_2\text{OH}], \text{HBF}_4$$

The hypohalito analogues \([\text{B(OH)}_3(\text{OX})]^-\) (X=Cl, Br) have recently been characterized in aqueous solutions of \(\text{B(OH)}_3\) containing NaOX; the stability constants \(\log \beta'\) at 25\(^\circ\)C being 2.25(1) and 1.83(4), respectively,\(^{(114)}\) compared with 5.39(7) for \(\text{B(OH)}_4^-\).

6.8.2 Borates\(^{112,115}\)

The phase relations, stoichiometry and structural chemistry of the metal borates have been extensively studied because of their geochemical implications and technological importance. Borates are known in which the structural unit is mononuclear (1 B atom), bi-, tri-, tetra- or pentanuclear, or in which there are polydimensional networks including glasses. The main structural principles underlying the bonding in crystalline metal borates are as follows:\(^{116}\)

1. Boron can link either three oxygens to form a triangle or four oxygens to form a tetrahedron.
2. Polynuclear anions are formed by corner-sharing only of boron-oxygen triangles and tetrahedra in such a manner that a compact insular group results.
3. In the hydrated borates, protonatable oxygen atoms will be protonated in the following sequence: available protons are first assigned to free \(O^2-\) ions to convert these to free \(OH^-\) ions; additional protons are assigned to tetrahedral oxygens in the borate ion, and then to triangular oxygens in the borate ion, and finally any remaining protons are assigned to free \(OH^-\) ions to form \(H_2O\) molecules.

Examples of minerals and compounds containing monomeric triangular, \(BO_3\) units (structure 113) are the rare-earth orthoborates \(M^{III}BO_3\) and the minerals \(CaSn^{IV}(BO_3)_2\) and \(Mg_3(BO_3)_2\).

Binuclear trigonal planar units (114) are found in the pyroborates \(Mg_2B_2O_5\), \(Co^{II}_2B_2O_5\) and \(Fe^{II}_2B_2O_5\). Trinuclear cyclic units (115) occur in the metaborates \(NaB_02\) and \(KBO_2\), which should therefore be written as \(M_3B_3O_6\) (cf. metaboric acid, p. 204). Polynuclear linkage of \(BO_3\) units into infinite chains of stoichiometry \(BO_2\) (116) occurs in \(Ca(BO_2)_2\), and three-dimensional linkage of planar \(BO_3\) units occurs in the borosilicate mineral tourmaline and in glassy \(B_2O_3\) (p. 203).

Monomeric tetrahedral \(BO_4\) units (117) are found in the zircon-type compound \(Ta^VBO_4\) and in the minerals \((Ta,Nb)BO_4\) and \(Ca_2H_4BAs^V_0_8\). The related tetrahedral unit \([B(OH)_4]^–\) (118) occurs in \(Na_2[B(OH)_4]Cl\) and \(Cu^{II}[B(OH)_4]Cl\).

Binuclear tetrahedral units (119) have been found
in Mg[B₂O(OH)₆] and a cyclic binuclear tetrahedral structure (120) characterizes the peroxyanion [B₂(O₂)₂(OH)₄]²⁻ in “sodium perborate” NaB₆O₃.₄H₂O, i.e. Na₂[B₂(O₂)₂(OH)₄].₆H₂O. A more complex polynuclear structure comprising sheets of tetrahedrally coordinated BO₃(OH) units occurs in the borosilicate mineral CaB(OH)SiO₄ and the fully three-dimensional polynuclear structure is found in BPO₄ (cf. the isoelectronic SiO₂), BaSO₄ and the minerals NaBSi₃O₅ and Zn₄B₆O₁₃.

The final degree of structural complexity occurs when the polynuclear assemblages contain both planar BO₃ and tetrahedral BO₄ units joined by sharing common O atoms. The structure of monoclinic HBO₂ affords an example (p. 204). A structure in which the ring has but one BO₄ unit is the spiroanion [B₅O₆(OH)₄]⁻ (structure 121) which occurs in hydrated potassium pentaborate KB₅O₆.₄H₂O, i.e. K[B₅O₆(OH)₄].₂H₂O. The anhydrous pentaborate KB₅O₈ has the same structural unit but dehydration of the OH groups link the spiroanions of structure (121) sideways into ribbon-like helical chains. The mineral CaB₃O₅(OH)₅.₅H₂O has 2 BO₄ units in the 6-membered heterocycle (122) and related chain elements [B₃O₄(OH)₃]²⁻ linked by a common oxygen atom are found in the important mineral colemanite Ca₂B₆O₁₁.₅H₂O, i.e. [CaB₃O₄(OH)₅].₅H₂O. It is clear from these examples that, without structural data, the stoichiometry of these borate minerals gives little indication of their constitution. A further illustration is afforded by borax which is normally formulated Na₂B₄O₇.₁₀H₂O, but which contains tetranuclear units [B₄O₅(OH)₄]²⁻ formed by fusing 2 B₃O₃ rings which each contain 2 BO₄ (shared) and 1 BO₃ unit (123); borax should therefore be written as Na₂[B₄O₅(OH)₄].₈H₂O.

There is wide variation of B–O distances in these various structures the values increasing, as expected, with increase in coordination:

The extent to which B₃O₅ rings catenate into more complex structures or hydrolyse into smaller units such as [B(OH)₄]⁻ clearly depends sensitively on the activity (concentration) of water in the system, on the stoichiometric ratio of metal ions to boron and on the temperature (TΔS).
Many metal borates find important industrial applications (p. 140) and annual world production exceeds 2.9 million tonnes: Turkey 1.2, USA 1.1, Argentina 0.26, the former Soviet Union 0.18, Chile 0.13 Mt. Main uses are in glass-fibre and cellular insulation, the manufacture of borosilicate glasses and enamels, and as fire retardants. Sodium perborate (for detergents) is manufactured on a 550,000 tonne pa scale.

**6.8.3 Organic compounds containing boron–oxygen bonds**

Only a brief classification of this very large and important class of compounds will be given; most contain trigonal planar B though many 4-coordinate complexes have also been characterized. The orthoborates B(OR)₃ can readily be prepared by direct reaction of BCl₃ or BOH₃ with ROH, while transesterification with R'OH affords a route to unsymmetrical products B(OR)₂(OR'), etc. The compounds range from colourless volatile liquids to involatile white solids depending on molecular weight. R can be a primary, secondary, tertiary, substituted or unsaturated alkyl group or an aryl group, and orthoborates of polyhydric alcohols and phenols are also numerous.

Boronic acids RB(OH)₂ were first made over a century ago by the unlikely route of slow partial oxidation of the spontaneously flammable trialkyl boranes followed by hydrolysis of the ester so formed (E. Frankland, 1862):

\[
\text{BET}_3 + O_2 \rightarrow \text{EtB(OEt)}_2 + 2\text{H}_2\text{O} \rightarrow \text{EtB(OH)}_2
\]

Many other routes are now available but the most used involve the reaction of Grignard reagents or lithium alkyls on orthoborates or boron trihalides:

\[
\text{B(OR)}_3 + \text{ArMgX} \rightarrow \text{[ArB(OR)₂]MgX} \rightarrow \text{H}_2\text{O}^+ \rightarrow \text{ArB(OH)}_2
\]

Phenylboronic acid in particular has proved invaluable, since its complexes with cis-diols and -polyols have formed the basis of chromatographic separations, asymmetric syntheses, enzyme immobilization and the preparation of polymers capable of molecular recognition.\(^\text{117}\)

Boronic acids readily dehydrate at moderate temperatures (or over P₄O₁₀ at room temperature) to give trimeric cyclic anhydrides known as trialkyl(aryl)boroxines:

![Diagram of trialkyl(aryl)boroxine](image)

The related trialkoxyboroxines (ROBO)₃ can be prepared by esterifying B(OH)₃, B₂O₃ or metaboric acid BO(OH) with the appropriate mole ratio of ROH.

Endless variations have been played on these themes and the B atom can be surrounded by innumerable combinations of groups such as acyloxy (RCOO), peroxy (ROO), halogeno (X), hydrido, etc., in either open or cyclic arrays. However, no new chemical principles emerge.

**6.9 Boron–Nitrogen Compounds**

Two factors have contributed to the special interest that attaches to B–N compounds. First, the B–N unit is isoelectronic with C–C and secondly, the size and electronegativity of the 3 atoms are similar, C being the mean of B and N:

</tbody>
</table>

The repetition of much organic chemistry by replacing pairs of C atoms with the B–N

grouping has led to many new classes of compound but these need not detain us.\textsuperscript{(118)} By contrast, key points emerge from several other areas of B–N chemistry and, accordingly, this section deals briefly with the structure, properties and reaction chemistry of boron nitride, amine-borane adducts, aminoboranes, iminoboranes, cyclic borazines and azaborane clusters.

The synthesis of boron nitride, BN, involves considerable technical difficulty;\textsuperscript{(119)} a laboratory preparation yielding relatively pure samples involves the fusion of borax with ammonium chloride, whereas technical-scale production relies on the fusion of urea with B(OH)_3 in an atmosphere of NH_3 at 500–950°C. Only a brave (or foolhardy) chemist would attempt to write a balanced equation for either reaction. An alternative synthesis (>99% purity) treats BCl_3 with an excess of NH_3 (see below) and pyrolyses the resulting mixture in an atmosphere of NH_3 at 750°C. The hexagonal modification of BN has a simple layer structure (Fig. 6.27) similar to graphite but with the significant difference that the layers are packed directly on top of each other so that the B atom in one layer is located over an N atom in the next layer at a distance of 333 pm. Cell dimensions and other data for BN and graphite are compared in Table 6.5. Within each layer the B–N distance is only 145 pm; this is similar to the distance of 144 pm in borazine (p. 210) but much less than the sum of single-bond covalent radii (158 pm) and this has been taken to indicate substantial additional π bonding within the layer. However, unlike graphite, BN is colourless and a good insulator; it also resists attack by most reagents though fluorine converts it quantitatively to BF_3 and N_2 and HF gives NH_4BF_4 quantitatively. Hexagonal BN can be converted into a cubic form (zinc-blende type structure) at 1800°C and 85 000 atm pressure in the presence of an alkali or alkaline-earth metal catalyst. The lattice constant of cubic BN is 361.5 pm (cf. diamond 356.7 pm). A wurtzite-type modification (p. 1210) can be obtained at lower temperatures.

![Figure 6.27](image)

**Figure 6.27** Comparison of the hexagonal layer structures of BN and graphite. In BN the atoms of one layer are located directly above the atoms of adjacent layers with B·N contacts; in graphite the C atoms in one layer are located above interstices in the adjacent layer and are directly above atoms in alternate layers only.

Amine-borane adducts have the general formula R_3NBX_3 where R = alkyl, H, etc., and

§6.9  Boron–nitrogen compounds

X = alkyl, H, halogen, etc. They are usually colourless, crystalline compounds with mp in the range 0°–100° for X = H and 50°–200° for X = halogen. Synthetic routes, and factors affecting the stability of the adducts have already been discussed (p. 165 and p. 198). In cases where diborane undergoes unsymmetrical cleavage (e.g. with \( \text{NH}_3 \)) alternative routes must be devised:

\[
\text{B}_2\text{H}_6 + 2\text{NH}_3 \rightarrow [\text{BH}_2(\text{NH}_3)_2]^+\text{BH}_4^- \\
\text{NH}_4\text{Cl} + \text{LiBH}_4 \rightarrow \text{NH}_3\text{BH}_3 + \text{LiCl} + \text{H}_2
\]

The nature of the bonding in amine-boranes and related adducts has been the subject of considerable theoretical discussion and has also been the source of some confusion. Conventional representations of the donor-acceptor (or coordinate) bond use symbols such as \( R_3\text{N} \rightarrow BX_3 \) or \( R_3\text{N} - BX_3 \) to indicate the origin of the bonding electrons and the direction (but not the magnitude) of charge transfer. It is important to realize that these symbols refer to the relative change in electron density with respect to the individual separate donor and acceptor molecules. Thus, \( R_3\text{N} \) in the adduct has less electron density on \( \text{N} \) than has free \( R_3\text{N} \), and \( BX_3 \) has more electron density on \( \text{B} \) in the adduct than has free \( BX_3 \); this does not necessarily mean that \( \text{N} \) is positive with respect to \( \text{B} \) in the adduct. Indeed, several MO calculations indicate that the change in electron density on coordination merely reduces but is insufficient to reverse the initial positive charge on the \( \text{B} \) atom. Consistent with this, experiments show that electrophilic reagents always attack \( \text{N} \) in amine-borane adducts, and nucleophilic reagents attack \( \text{B} \).

A similar situation obtains in the aminoboranes where one or more of the substituents on \( \text{B} \) is an \( R_2\text{N} \) group (\( R = \text{alkyl, aryl, H} \)), e.g. \( \text{Me}_2\text{N} - \text{BMe}_2 \). Reference to Fig. 6.22 indicates the possibility of some \( p_n \) interaction between the lone pair on \( \text{N} \) and the “vacant” orbital on trigonal \( \text{B} \). This is frequently indicated as

\[
\text{N}^\text{\textdagger} = \text{B} \text{ or } \text{N}^\text{\textdagger} = \text{B}
\]

However, as with the amine-borane adducts just considered, this does not normally indicate the actual sign of the net charges on \( \text{N} \) and \( \text{B} \) because the greater electronegativity of \( \text{N} \) causes the \( \sigma \) bond to be polarized in the opposite sense. Thus, \( \text{N} - \text{B} \) bond moments in aminoboranes have been found to be negligible and MO calculations again suggest that the \( \text{N} \) atom bears a larger net negative charge than does the \( \text{B} \) atom. The partial double-bond formulation of these compounds, however, is useful in implying an analogy to the isoelectronic alkenes. Coordinative saturation in aminoboranes can be achieved not only through partial double bond formation but also by association (usually dimerization) of the monomeric units to form \( (\text{B} - \text{N})_n \) rings. For example, in the gas phase, aminodimethylborane exists as both monomer and dimer in reversible equilibrium:

\[
\begin{align*}
\text{2Me}_2\text{N} \rightarrow & \text{BMe}_2 \quad \text{Me}_2\text{B} \\
\end{align*}
\]

The presence of bulky groups on either \( \text{B} \) or \( \text{N} \) hinders dimer formation and favours monomers, e.g. \( (\text{Me}_2\text{N})_2\text{BF}_2 \) is dimeric whereas the larger halides form monomers at least in the liquid phase. Association to form trimers (6-membered heterocycles) is less common, presumably because of even greater crowding of substituents, though triborazane \( (\text{H}_2\text{NBH}_2)_3 \) and its \( N \)-methyl derivatives, \( (\text{MeHNBH}_2)_3 \) and \( (\text{Me}_2\text{NBH}_2)_3 \), are known in which the \( \text{B}_3\text{N}_3 \) ring adopts the cyclohexane chair conformation.

Preparative routes to these compounds are straightforward, e.g.:

\[
\begin{align*}
\text{R}_2\text{NH}_2\text{Cl} + \text{MBH}_4 & \rightarrow \text{R}_2\text{NBH}_2 + \text{MCl} + \text{H}_2 \\
(\text{R} = \text{H, alkyl, aryl}) \\
\text{R}_2\text{NH} + \text{R'}\text{BX} + \text{NEt}_3 & \rightarrow \text{R}_2\text{NBR'}_2 + \text{Et}_3\text{NHX} \\
(\text{R'} = \text{alkyl, aryl, halide}) \\
\text{B(NR}_2)_3 + 2\text{BR}_3 & \rightarrow \text{3R}_2\text{NBR}_2, \text{etc.}
\end{align*}
\]
In general monomeric products are readily hydrolysed but associated species (containing 4-coordinate B) are much more stable: e.g. (Me₂NBH₂)₂ does not react with H₂O at 50° but is rapidly hydrolysed by dilute HCl at 110° because at this temperature there is a significant concentration of monomer present.

Iminoboranes, R-N=BNR', are isoelectronic with alkynes and contain 2-coordinate boron; their chemistry has recently been reviewed. Likewise for amino iminoboranes, R₂N-B=NR'. In both classes of compound inductive and steric effects have an important influence on stability. Another stable 2-coordinate boron species is the linear anion BN₃⁻ (isoelectronic with CO₂, CNO⁻, NCO⁻, N₂O, NO₂⁺, N₃⁻ and CN₂⁻) which occurs in M₃BN₂ and M₅(BN₂)₂. For example, Na₃BN₂ can be prepared as light honey-coloured crystals by heating a 2:1 mixture of NaN₃ and BN at 4 GPa and 1000°C; the B-N distance is 134.5 pm. In neutral species, the well known decrease in interatomic distance in the sequence C-C(154 pm) > C≡C(133 pm), > C≡C (118 pm) is paralleled by the analogous sequence B-N(158 pm) > B≡N(140 pm) > B≡N(124 pm).

The cyclic borazine (-BH-NH-)₃ and its derivatives form one of the largest classes of B-N compounds. The parent compound, also known as "inorganic benzene", was first isolated as a colourless liquid from the mixture of products obtained by reacting B₂H₆ and NH₃ (A. Stock and E. Pohland, 1926):

\[
3\text{B}_2\text{H}_6 + 6\text{NH}_3 \xrightarrow{180^\circ} 2\text{B}_3\text{N}_3\text{H}_6 + 12\text{H}_2
\]

It is now best prepared by reduction of the B-trichloro derivative:

\[
3\text{BCl}_3 + 3\text{NH}_4\text{Cl} \xrightarrow{\text{heat}} \text{BClNH} \]

\[
\xrightarrow{\text{9-HCl}} \text{(BClNH)}_3
\]

\[
\xrightarrow{3\text{NaBH}_4} \text{B}_3\text{N}_3\text{H}_6 + 3\text{NaCl} + \frac{3}{2}\text{B}_2\text{H}_6
\]

Borazine has a regular plane hexagonal ring structure and its physical properties closely resemble those of the isoelectronic compound benzene (Table 6.6). Although it is possible to write Kekulé-type structures with N=B π bonding superimposed on the σ bonding, the weight of chemical evidence suggests that borazine has but little aromatic character. It reacts readily with H₂O, MeOH and HX to yield 1:3 adducts which eliminate 3H₂ on being heated to 100°, e.g.:

\[
\text{B}_3\text{N}_3\text{H}_6 + 3\text{H}_2\text{O} \xrightarrow{0^\circ} [\text{BH(OH)}\text{NH}_2]_3
\]

\[
\xrightarrow{100^\circ} [\text{B(OH)}\text{NH}]_3 + 3\text{H}_2
\]

(a) 1 dyne = 10⁻⁵ newton.

Numerous other reactions have been documented, most of which are initiated by nucleophilic attack on B. There is no evidence that electrophilic substitution of the borazine ring occurs and conditions required for such reactions in benzenoid systems disrupt the borazine ring by oxidation or solvolysis. However, it is known that the less-reactive hexamethyl derivative B₃N₃Me₆ (which can be heated to 460° for 3 h without significant decomposition)
Compounds with bonds to P, As or Sb

10.1 Compounds with bonds to P, As or Sb

Only minor echoes of the extensive themes of B–N chemistry occur in compounds containing B–P, B–As or B–Sb bonds but there are signs that the field is now beginning to expand rapidly. Few 1:1 phosphine-borane adducts are known, although the recently characterized white crystalline complex \( \text{C}_6\text{F}_{12} \text{B} \cdot \text{PH}_3 \), which dissociates reversibly above room temperature, has been suggested as a useful storage material for the safe purification and generation of \( \text{PH}_3 \).

The interesting compound \( \text{Na} \left[ \text{B} \left( \text{PH}_2 \right)_4 \right] \) can readily be made by reacting \( \text{BCl}_3 \) with 4 moles of \( \text{NaPH}_2 \); at moderate temperatures and in the presence of \( \text{thf} \) it rearranges to the diborate analogue \( \text{Na} \left[ \left( \text{PH}_2 \right)_3 \text{B} - \text{PH}_2 - \text{B} \left( \text{PH}_2 \right)_3 \right] \)

\[ 2(\text{Me}_2\text{N})_2\text{BCl} \xrightarrow{\text{Na/K}} [\text{B}_2(\text{NMe}_2)_4] \xrightarrow{\text{thermolysis}} [(\text{BNMe}_2)_6] \]

The \( \text{B}_6 \) ring has a chair conformation (dihedral angle 57.6°) with mean \( \text{B} - \text{B} \) distances of 172 pm. All 6 \( \text{B} \) and all 6 \( \text{N} \) are trigonal planar and the 6-exocyclic \( \text{NMe}_2 \) groups are each twisted at an angle of \( \sim 65^\circ \) from the adjacent \( \text{B}_3 \) plane, with \( \text{B} - \text{N} 140 \text{ pm} \). Structurally, this cyclohexaborane derivative resembles the radialenes, particularly the isoelectronic \( [\text{C}_6 (=\text{CHMe})_6] \) in which the \( \text{C}_6 \) ring likewise adopts the chair conformation.

Finally, the conceptual isoelectronic replacement of \( \text{C} - \text{C} \) by \( \text{B} - \text{N} \) can be applied to carboranes, thus leading (by appropriate synthetic routes) to azaboranes in which one or more of the cluster vertices of the borane is occupied by an \( \text{N} \) atom. So far, the following species have been characterized, the relevant cluster geometries and numbering schemes being given by the indicated structures on pp. 153–85: arachno-4-NB\(_6\)H\(_{13}\) (20), nido-6-NB\(_6\)H\(_{12}\) (11), closo-1-NB\(_6\)H\(_{10}\) (5), arachno-6,9-N\(_2\)B\(_6\)H\(_{12}\) (21), nido-7-NB\(_{10}\)H\(_{13}\) (41), nido-7-NB\(_{10}\)H\(_{11}\) (80), closo-1-NB\(_{11}\)H\(_{12}\) (7, 76) and anti-9-NB\(_7\)H\(_{20}\) (31).

6.10 Other Compounds of Boron

6.10.1 Compounds with bonds to P, As or Sb

\[ \text{Na} \left[ \text{B} \left( \text{PH}_2 \right)_4 \right] \]
and with BH$_3$·thf it gives the tetrakis(borane) adduct Na[B(PH$_2$·BH$_3$)$_4$].

Phosphinoboranes, like their aminoborane analogues (p. 209), tend to oligomerize, although monomeric examples with planar B and pyramidal P atoms have recently been prepared using bulky substituents, e.g. yellow Mes$_2$BPPh$_2$ (128), orange (Mes$_2$P)$_2$BBH (129) and colourless (Mes$_2$P)$_2$BOEt, mp 163°C (Mes = 2,4,6-Me$_3$C$_6$H$_2$-). By contrast, B(PMes)$_3$ is a dimer with a planar B$_2$P$_2$ ring of 4-coordinate B and P atoms (124). A planar 4-membered ring of 3-coordinate planar B and pyramidal P atoms is featured in the diphosphadiboretane {MesPB(tmp)$_2$}$_2$ (125) (tmp = 2,2,6,6-tetramethylpiperidino); (131) the corresponding diarsadiboretane is also known. A phosphorus analogue of borazine (p. 210) having a planar B$_2$P$_2$ ring is the pale yellow crystalline (MesBPC$_6$H$_{11}$)$_3$ (126), synthesized by reacting MesBBH$_2$ with C$_6$H$_{11}$PHLi in hexane at room temperature; (132) the B–P distances in the borophosphabenzenes are all essentially equal, averaging 184 pm, which is considerably shorter than the known range of single-bond distances (192–196 pm). The cyclohexyl group, C$_6$H$_{11}$, can be replaced by Ph, Mes, Bu', etc.

Phosphaborane cluster compounds have also been synthesized. For example, thermolysis of a 1:2 mixture of (Pr$_2$N)BCl and (Pr$_2$N)B(Cl)-(SiMes)$_2$ at 160°C results in the smooth elimination of Me$_3$SiCl to give colourless crystals of [closo-1,5-P$_2$(BNPr$_2$)$_3$] (127) in high yield:

\[
2(\text{Pr}_2\text{N})\text{B(Cl)}(\text{SiMe}_3)_2 + \text{Me}_3\text{SiCl} \rightarrow \text{Me}_3\text{SiCl} + \text{P}_2(\text{BNPr}_2)_3
\]

The structural analogy with the dicarbaborane C$_2$B$_3$H$_5$ (56) is obvious. Likewise, pyrolysis of a mixture of B$_2$Cl$_4$ and PCl$_3$ yields [closo-1,2-P$_2$B$_4$Cl$_4$] (128) as hygroscopic colourless crystals.

![Diagram of B-P distances](image)

and this can be capped using Et$_3$N-BH$_3$ in diglyme at 160°C to give the \textit{closo}-icosahedral anion B$_{11}$H$_{11}$As$^{-}$ in 51% yield. Other examples include B$_{11}$H$_{11}$Sb$^{-}$, 1,2-B$_{10}$H$_{10}$Sb$_2$, 1,2-B$_{10}$H$_{10}$AsSb and the arsenathia- and arsenaselena-
obreakdash-boranes B$_8$H$_8$As$_2$S and B$_8$H$_8$As$_2$Se.

\section*{6.10.2 Compounds with bonds to S, Se and Te}

The vast array of B–O minerals and compounds (pp. 139–40 and 203–7) finds no parallel in B–S or B–Se chemistry though thioborates of the type B(SR)$_3$, R'B(SR)$_2$ and R$_2$B(SR) are well documented. There are also a growing number of binary boron sulfides and boron–sulfur anions which feature chains, rings and networks. B$_2$S$_3$ itself has been known for many years as a pale-yellow solid which tends to form a glassy phase (cf. B$_2$O$_3$ and also B$_2$Se$_3$). This absence of a suitable crystalline sample prevented the structural characterization of this compound until as late as 1977. It has now been found that B$_2$S$_3$ has a fascinating layer structure which bears no resemblance to the three-dimensionally linked B$_2$O$_3$ crystal structure but is slightly reminiscent of BN. The structure (Fig. 6.29a) is made up of planar B$_3$S$_3$ 6-membered rings and B$_2$S$_2$ 4-membered rings linked by S bridges into almost planar two-dimensional layers.\(^{136}\) All the boron atoms are trigonal planar with B–S distances averaging 181 pm and the perpendicular interlayer distance is almost twice this at 355 pm. More recently\(^{137}\) a monomeric form of B$_2$S$_3$ was prepared by matrix-isolation techniques at 10 K and shown by vibrational spectroscopy to be a planar V-shaped molecule, S=B−S−B=S, with C$_{2v}$ symmetry, the angle subtended at the central S atom by the linear arms being about 120°.

Another boron sulfide, of stoichiometry BS$_2$, can be made by heating B$_2$S$_3$ and sulfur to 300°C under very carefully defined conditions.\(^{138}\) It is a colourless, moisture-sensitive material with a porphine-like molecular structure, B$_8$S$_{16}$, as shown in Fig. 6.29b. An alternative route to B$_8$S$_{16}$ involves the reaction of dibromotrithiadiborolane with trithiocarbonic acid in an H$_2$S generator in dilute CS$_2$ solution:

\[
4\text{BrBSSB(Br)S} + 4(\text{HS})_2\text{CS} \rightarrow \text{B}_8\text{S}_{16} + 4\text{CS}_2 + 8\text{HBr}
\]

The monomeric selenium compound BSe$_2$ has been identified mass-spectrometrically in the vapours formed by reacting solid boron with Se$_2$ and its thermodynamic properties evaluated.\textsuperscript{(139)}

Another expanding area of B–S chemistry is the synthesis and structural characterization of anionic species. The colourless thioborate RbBS$_3$ was formed by heating the stoichiometric amounts of Rb$_2$S, B and S at 600°. Its structure, and that of the yellow TiBS$_3$, features polymeric anionic chains that are spirocyclically connected via tetrahedral B atoms as shown schematically below:\textsuperscript{(140)}

![Schematic diagram of B–S compounds]

The sulfur-rich analogue Tl$_3$B$_3$S$_{10}$ was likewise prepared as yellow plates from the appropriate stoichiometric mixture of (3Tl$_2$S + 6B + 17S) at 850° and shown to have a similar polymeric anion with the extra S atoms inserted into each third pentatomic heterocycle to make it a hexatomic unit, >B(S$_2$)$_2$B<. With the smaller cation, Li$^+$, similar procedures generate Li$_5$B$_7$S$_{13}$ and Li$_9$B$_{19}$S$_{33}$ which again have novel polymeric anions. The [B$_3$S$_{13}$]$^{3-}$ polymer is formed by sharing B$_4$S$_{10}$ and B$_{10}$S$_{20}$ units, i.e. [B$_3$S$_{6}$S$_{4}$]$^{2-}$ \textsuperscript{(cf. P$_4$O$_{10}$)} and [B$_{10}$S$_{18}$S$_{4}$/2]$^{6-}$ both of which are built up from tetrahedral BS$_4$ subunits, whereas the [B$_{19}$S$_{33}$]$^{9-}$ polymer is formed from the conjoining of [B$_{19}$S$_{30}$S$_{6}$/2]$^{9-}$ units.\textsuperscript{(141)}

The structural principles and reaction chemistry of B–S compounds have recently been reviewed.\textsuperscript{(142)} This includes not only electron-precise 4-, 5- and 6-membered heterocycles of the types described above, but also electron-deficient polyhedral clusters based on closo-

§6.10.2 Compounds with bonds to S, Se and Te

nido- and arachno-boranes. Some typical interconversion reactions of thiaboranes are shown in the scheme on p. 213,\(^{142}\) and further examples are in references (143) and (144). Selena- and tellura-derivatives are also known\(^{135,145}\) and, like the thiaboranes, have structures that can be rationalized by the normal electron counting rules, taking the chalcogen atom as a 4-electron donor, e.g. \(\text{closo-B}_{11}H_{11}Te\), \(\text{nido-B}_{10}H_{12}Te\), \(\text{nido-B}_{10}H_{11}Te^-\), \(\text{nido-B}_{9}H_{11}Te\), \(\text{nido-B}_{9}H_{9}Se_2\), \(\text{nido-B}_{9}H_9SeTe\), \(\text{arachno-B}_{8}H_{10}Se_2\), \([\text{Fe}(\eta^5-B_{10}H_{10}Te)_2]^2-\) (green) and \([\text{Co}(\eta^5-C_5H_5)\eta^5-B_{10}H_{10}Te)]\) (yellow).

There appears to be no end to the structural ingenuity of boron and, whilst it is true that many regularities can now be discerned in its stereochemistry, much more work is still needed to unravel the reaction pathways by which the compounds are formed and to elucidate the mechanisms by which they isomerize and interconvert.

7

Aluminium, Gallium, Indium and Thallium

7.1 Introduction

Aluminium derives its name from alum, the double sulfate KAl(SO₄)₂·12H₂O, which was used medicinally as an astringent in ancient Greece and Rome (Latin alumen, bitter salt). Humphry Davy was unable to isolate the metal but proposed the name “aluminium” and then “aluminum”; this was soon modified to aluminium and this form is used throughout the world except in North America where the ACS decided in 1925 to adopt “aluminum” in its publications. The impure metal was first isolated by the Danish scientist H. C. Oersted using the reaction of dilute potassium amalgam on AlCl₃. This method was improved in 1827 by H. Wöhler who used metallic potassium, but the first commercially successful process was devised by H. St.-C. Deville in 1854 using sodium. In the same year both he and R. W. Bunsen independently obtained metallic aluminium by electrolysis of fused NaAlCl₄. So precious was the metal at this time that it was exhibited next to the crown jewels at the Paris Exposition of 1855 and the Emperor Louis Napoleon III used Al cutlery on state occasions. The dramatic thousand-fold drop in price which occurred before the end of the century (Table 7.1) was due first to the advent of cheap electric power following the development of the dynamo by W. von Siemens in the 1870s, and secondly to the independent development in 1886 of the electrolysis of alumina dissolved in cryolite (Na₃AlF₆) by P. L. T. Héroult in France and C. M. Hall in the USA; both men were 22 years old at the time. World production rose quickly and in 1893 exceeded 1000 tonnes pa for the first time.

Gallium was predicted as eka-aluminium by D. I. Mendeleev in 1870 and was discovered by P. E. Lecoq de Boisbaudran in 1875 by means of the spectroscope; de Boisbaudran was, in fact, guided at the time by an independent theory of his own and had been searching for the missing element for some years. The first indications came with the observation of two new violet lines in the spark spectrum of a sample deposited on zinc, and within a month he had isolated 1g of the metal starting from several hundred kilograms of crude zinc blende ore. The

Gallium was discovered by means of the spectroscope

C. A. Lamy in the preceding year 1861/2 and named after the characteristic bright green line in its flame spectrum (Greek θαλλος, thallos, a budding shoot or twig).

7.2 The Elements

7.2.1 Terrestrial abundance and distribution

Aluminium is the most abundant metal in the earth's crust (8.3% by weight); it is exceeded in abundance only by O (45.5%) and Si (25.7%), and is approached only by Fe (6.2%) and Ca (4.6%). Aluminium is a major constituent of many common igneous minerals including
feldspars and micas. These, in turn, weather in temperate climates to give clay minerals such as kaolinite \([\rm Al_2(OH)_4Si_2O_5]\), montmorillonite and vermiculite (p. 349). It also occurs in many well-known though rarer minerals such as cryolite \((\rm Na_3AlF_6)\), spinel \((\rm MgAl_2O_4)\), garnet \([\rm Ca_3Al_2(SiO_4)_3]\), beryl \((\rm Be_3Al_2Si_6O_{18})\), and turquoise \([\rm Al_2(OH)_3PO_4H_2O/Cu]\). Corundum \((\rm Al_2O_3)\) is one of the hardest substances known and is therefore used as an abrasive; many gemstones are impure forms of \(\rm Al_2O_3\), e.g. ruby (Cr), sapphire (Co), oriental emerald, etc. Commercially, the most important mineral is bauxite \(\rm AlO(OH)_3\); this occurs in a wide belt in tropical and subtropical regions as a result of the leaching out of both silica and various metals from aluminosilicates (see Panel).

Gallium, In and Tl are very much less abundant than Al and tend to occur at low concentrations in sulfide minerals rather than as oxides, though Ga is also found associated with Al in bauxite. Ga \((19\,\text{ppm})\) is about as abundant as N, Nb, Li and Pb; it is twice as abundant as B \((9\,\text{ppm})\) but is more difficult to extract because of the absence of major Ga-containing ores. The highest concentrations \((0.1-1\%)\) are in the rare mineral germanite \((\text{a complex sulfide of Zn, Cu, Ge and As})\); concentrations in sphalerite \((\text{ZnS})\), bauxite or coal, are a hundredfold less. Gallium always occurs in association either with Zn or Ge, its neighbours in the periodic table, or with Al in the same group. It was formerly recovered from flue dusts emitted during sulfide roasting or coal burning (up to 1.5\% Ga) but is now obtained as a byproduct of the vast Al industry. Since bauxites contain 0.003–0.01\% Ga, complete recovery would yield over 1000 tonnes pa. However, present consumption, though growing rapidly, is little more than 1\% of this and production is of the order of 50 tonnes pa (1986). This can be compared with the estimate of 5 tonnes for the total of Ga metal in the 90 y following its discovery \((1875-1965)\). Its price in 1928 was \$50\,\text{per g}; in 1965 it was \$1\,\text{per g}, similar to the then price of gold \((\$1.1\,\text{per g})\), and in 1986 it was \$0.45\,\text{per g}, i.e. \$450/kg for semiconductor grade metal \((99.9999\%)\).

Indium \((0.24\,\text{ppm})\) is similar in abundance to Sb and Cd, whereas Tl \((0.7\,\text{ppm})\) is close to Tm and somewhat less abundant than Mo, W and Tb \((1.2\,\text{ppm})\). Both elements are chalcophiles (p. 648), indium tending to associate with the similarly sized Zn in its sulfide minerals whilst the larger Tl tends to replace Pb in galena, PbS. Thallium(I) has a similar radius to Rb\(^+\) and so also concentrates with this element in the late magmatic potassium minerals such as feldspars and micas.

Indium is now commercially recovered from the flue dusts emitted during the roasting of Zn/Pb sulfide ores and can also be recovered during the roasting of Fe and Cu sulfide ores. Before 1925 only 1 g of the element was available in the world but production now exceeds 80000000 g

### Bauxite

The mixed aluminium oxide hydroxide mineral bauxite was discovered by P. Berthier in 1821 near Les Baux in Provence. In temperate countries (such as Mediterranean Europe) it occurs mainly as the “monohydrate” \(\text{AlOOH}\) (boehmite and diaspor) whereas in the tropics it is generally closer to the “trihydrate” \(\text{Al(OH)}_3\) (gibbsite and hydrargillite). Since \(\text{AlOOH}\) is less soluble in aqueous \(\text{NaOH}\) than is \(\text{Al(OH)}_3\), this has a major bearing on the extraction process for Al manufacture (p. 219). Typical compositions for industrially used bauxites are \(\text{Al}_2\text{O}_3\) 40–60\%, combined \(\text{H}_2\text{O}\) 12–30\%, \(\text{SiO}_2\) free and combined 1–15\%, \(\text{Fe}_2\text{O}_3\) 7–30\%, \(\text{TiO}_2\) 3–4\%, \(\text{F}, \text{P}_2\text{O}_5, \text{V}_2\text{O}_5\), etc., 0.05–0.2\%.

World production in 1989 was over 101 million tonnes and this is still increasing. Reserves are immense, being of the order of \(22 \times 10^9\) tonnes in all (Guinea 5.6, Australia 4.4, Brazil 2.8, Jamaica 2.0, India 1.0, USA 0.038 Gt). Australia is currently the largest producer of alumina with 36.6\%, followed by Guinea 16.6\%, Brazil 8.7\%, Jamaica 8.2\% the former Soviet Union 4.6\%, India 3.9\%, etc. Bauxite is easy to mine by open-cast methods since it occurs typically in broad layers 3–10 m thick with very little topsoil or other overburden. Apart from its preponderant use (>80\%) in Al extraction, bauxite is used to manufacture refractories, high-alumina cements and aluminium compounds, and smaller amounts are used as drying agents and as catalysts in the petrochemicals industry.
Preparation and uses of the metals

The huge difference in scale between the production of Al metal, on the one hand, and the other elements in the group is clear from the preceding section. The tremendous growth of the Al industry compared with all other non-ferrous metals is indicated in Table 7.3 and Al production is now exceeded only by that of iron and steel (p. 1072).

Production of Al metal involves two stages: (a) the extraction, purification and dehydration of bauxite, and (b) the electrolysis of Al₂O₃ dissolved in molten cryolite Na₃AlF₆. Bauxite is now almost universally treated by the Bayer process; this involves dissolution in aqueous NaOH, separation from insoluble impurities (red muds), partial precipitation of the trihydrate and calcining at 1200°. Bauxites approximating to the "monohydrate" AlOOH require higher concentrations of NaOH (200–300 g l⁻¹) and higher temperatures and pressures (200–250°C, 35 atm) than do bauxites approximating to Al(OH)₃ (100–150 g l⁻¹ NaOH, 120–140°C). Electrolysis is carried out at 940–980°C in a carbon-lined steel cell (cathode) with carbon anodes. Originally Al₂O₃ was dissolved in molten cryolite (Héroult–Hall process) but cryolite is a rather rare mineral and production from the mines in Greenland provide only about 30,000 tonnes pa, quite insufficient for world needs. Synthetic cryolite is therefore manufactured in lead-clad vessels by the reaction of HF on sodium aluminate (from the Bayer process):

\[
6\text{HF} + 3\text{NaAlO}_2 \rightarrow \text{Na}_3\text{AlF}_6 + 3\text{H}_2\text{O} + \text{Al}_2\text{O}_3
\]

No further cryolite is actually needed once the smelting process is in operation because it is produced in the reduction cells by neutralizing the Na₂O brought into the cell as an impurity in the alumina using AlF₃:

\[
4\text{AlF}_3 + 3\text{Na}_2\text{O} \rightarrow 2\text{Na}_3\text{AlF}_6 + \text{Al}_2\text{O}_3
\]

Thus operating cells need AlF₃ rather than cryolite, much of it being produced in a fluidized bed reactor from gaseous HF and activated alumina (made by partially calcining the alumina hydrate from the Bayer process). Typical electrolyte composition ranges are Na₃AlF₆ (80–85%), CaF₂ (5–7%), AlF₃ (5–7%), Al₂O₃ (2–8%—intermittently recharged). See also p. 70 for the beneficial use of Li₂CO₃. The detailed electrolysis mechanism is still imperfectly understood but typical operating conditions require up to 10⁵ A at 4.5 V and a current density of 0.7 A cm⁻². One tonne Al metal requires 1.89 tonnes Al₂O₃, ~0.45 tonnes C anode material, 0.07 tonnes Na₃AlF₆ and about 15,000 kWh of electrical energy. It follows that cheap electric power is the overriding commercial consideration. World production (1988) exceeded 17 million tonnes pa, the leading producers being the USA (23%), China (21%), the former Soviet Union (14%), Canada (9%), Australia (7%),

Brazmap, Norway and Czechoslovakia (5% each). In addition to this primary production, recycling of used alloys probably adds a further 3–4 million tonnes pa to the total AI metal consumed.

Some uses of AI and its alloys are noted in the Panel from which it will be seen that many of the mechanical properties of pure AI are greatly improved by alloying it with Cu, Mn, Si, Mg or Zn (Table A). The example of Cu is particularly important because of the insight which it gives into the subtle solid-state diffusion processes that occur during heat treatment. At room temperature

### Some Uses of Aluminium Metal and Alloys

Pure aluminium is a silvery-white metal with many desirable properties: it is light, non-toxic, of pleasing appearance, and capable of taking a high polish. It has a high thermal and electrical conductivity, excellent corrosion resistance, is non-magnetic, non-sparking and stands second only to gold for malleability and sixth for ductility. Many of its alloys have high mechanical and tensile strength. Aluminium and its alloys can be cast, rolled, extruded, forged, drawn or machined, and they are readily obtained as pipes, tubes, rods, bars, wires, plates, sheets or foils.

Aluminium resists corrosion not because of its position in the electrochemical series but because of the rapid formation of a coherent, inert, oxide layer. Contact with graphite, Fe, Ni, Cu, Ag or Pb is disastrous for corrosion resistance: the effect of contact with steel, Zn and Cd depends on pH and exposure conditions. Protection is enhanced by anodizing the metal; this involves immersing it in 15–20% H₂SO₄ and connecting it to the positive terminal so that it becomes coated with alumina:

\[
2\text{Al} + 3\text{O}^{2-} - 6e^- \rightarrow \text{Al}_2\text{O}_3
\]

A layer 10–20 µm thick gives excellent protection between pH 4.5–8.7 and is also adequate for external architectural use; thicker layers (50–100 µm) also impart abrasion resistance. The layer can be coloured by incorporating suitable organic or inorganic compounds in the bath and incorporation of photosensitive material enables photographic images to be developed. Decorative engraving using solutions of nitrate or NH₄HF₂ gives the metal a fine silky texture.

<thead>
<tr>
<th>Table A</th>
<th>Some aluminium alloys</th>
</tr>
</thead>
</table>

**1000 Series:** Commercially pure AI (<1% of other elements); good properties except for limited mechanical strength. Used in high thermal and electrical conductivity, excellent corrosion resistance. Used in high thermal and electrical conductivity, excellent corrosion resistance.

**2000 Series:** Cu alloys (~5%); excellent strength and machinability, limited corrosion resistance. Used for components requiring high strength/weight ratio, e.g. truck trailer panels, aircraft structure parts.

**3000 Series:** Mn alloys (~1.2%); moderate strength, high workability. Used for cooking utensils, heat exchangers, storage tanks, sawmills, furniture, highway signs, roofing, side panels, etc.

**4000 Series:** Si alloys (<12%); low mp and low coefficient of expansion. Used for castings and as filler material for brazing and welding; readily anodized to attractive grey colours.

**5000 Series:** Mg alloys (0.2–5%); good strength and weldability coupled with excellent corrosion resistance in marine atmospheres. Used for ornamental and decorative trim, street light standards, ships, boats, cryogenic vessels, gun mounts and crane parts.

**6000 Series:** Mg/Si alloys; good formability and high corrosion resistance. Used in buildings, transportation equipment, bridges, railings and welded construction.

**7000 Series:** Zn alloys (3–8%) plus Mg; when heat treated and aged have very high strength. Used principally for aircraft structures, mobile equipment and equipment requiring high strength/weight ratio.

Many of the uses listed in Table A are a matter of everyday observation. In addition we may note that the electrical conductivity of pure AI is 63.5% of the conductivity of an equal volume of pure Cu; when the lower density of AI is considered its conductivity is 2.1 times that of Cu on a wt. for wt. basis. This, coupled with its corrosion resistance and ready workability makes it an ideal metal for power lines and, indeed, more than 90% of all overhead electrical transmission lines in the USA are AI alloy.

Aluminium is now extensively used in the construction and aerospace industries throughout the world although in the USA packaging has replaced the construction industry as the largest consumer of AI and its alloys. For example, 95% of beer and soft drinks is packaged in two-piece cans comprising an AI/Mn alloy body and AI/Mg alloy ends. There is also extensive use in food packaging, aerosol cans, collapsible tubes for toiletries and pharmaceuticals and as foil (typically 0.18 mm thick).

Al dissolves only about 0.1% Cu and this has little effect on its properties. The solubility rises to a maximum of 5.65% Cu at 548°C and this remains in metastable solid solution to give a soft workable alloy when the alloy is rapidly quenched to temperatures below 65°C. Subsequent ageing of the shaped material at 100–150°C for a few minutes hardens the alloy due to the formation of Guinier–Preston zones: these zones, independently discovered in 1938 by A. Guinier (France) and G. D. Preston (England), are minute discs of material higher in Cu content than the matrix—they are about 4 atoms thick and up to 100 atoms across; they mesh coherently with the host lattice in two directions, the (100) planes, but not in the third. The coherency strains which thereby develop in the lattice are the basis for the hardening of the alloy. Besides its immense technological importance, this phenomenon is particularly significant in being one of the first recognized examples of a single phase which nevertheless varies regularly in composition throughout its extent.

Gallium metal is now obtained as a byproduct of the Al industry. The Bayer process for obtaining alumina from bauxite gradually enriches the alkaline solutions from an initial weight ratio Ga/Al of about 1/5000 to about 1/300; electrolysis of these extracts with an Hg electrode gives further concentration, and the solution of sodium gallate is then electrolysed with a stainless steel cathode to give Ga metal. Ultra high-purity Ga for semiconductor uses is obtained by further chemical treatment with acids and O₂ at high temperatures followed by crystallization and zone refining. Gallium has a beautiful silvery blue appearance; it wets glass, porcelain, and most other surfaces (except quartz, graphite, and teflon) and forms a brilliant mirror when painted on to glass. Its main use is in semiconductor technology (p. 258). For example, GaAs (isoelectronic with Ge) can convert electricity directly into coherent light (laser diodes) and is employed in electroluminescent light-emitting diodes (LEDs); it is also used for doping other semiconductors and in solid-state devices such as transistors.

The compound MgGa₂O₄, when activated by divalent impurities such as Mn²⁺, is used in ultraviolet-activated powders as a brilliant green phosphor. Another very important application is to improve the sensitivity of various bands used in the spectroscopic analysis of uranium. Minor uses are as high-temperature liquid seals, manometric fluids and heat-transfer media, and for low-temperature solders.

Indium, like Ga, is normally recovered by electrolysis after prior concentration in processes leading primarily to other elements (Pb/Zn). It is a soft, silvery metal with a brilliant lustre and (like Sn) it gives out a high-pitched “cry” when bent. Formerly it was much used to protect bearings against wear and corrosion but the pattern of use has been changing in recent years and now its most important applications are in low-melting alloys and in electronic devices. Thus meltalbe safety devices, heat regulators, and sprinklers use alloys of In with Bi, Cd, Pb and Sn (mp 50–100°C) and In-rich solders are valuable in sealing metal-nonmetal joints in high vacuum apparatus. Indium is of particular importance in the manufacture of p–n–p transistor junctions in Ge (p. 369) and to solder semiconductor leads at low temperature; the softness of the metal also minimizes stress in the Ge during subsequent cooling. So-called III–V semiconductors like InAs and InSb are used in low-temperature transistors, thermists and optical devices (photoconductors), and InP is used for high-temperature transistors. A further minor use, which exploits the high neutron capture cross-section of In, is as a component in control rods for certain nuclear reactors.

Technical grade Tl is purified from other flue-dust elements (Ni; Zn, Cd; In; Ge, Pb; As; Se, Te) by dissolving it in warm dilute acid, then precipitating the insoluble PbSO₄ and adding HCl to precipitate TlCl. Further purification is effected by electrolysing Tl₂SO₄ in dilute H₂SO₄ with short Pt wire electrodes, followed by fusion of the deposited Tl metal at 350–400°C under an atmosphere of H₂. Both the element and its compounds are extremely toxic; skin-contact, ingestion and inhalation are all dangerous, and
the maximum allowable concentration of soluble Tl compounds in air is 0.1 mg m$^{-3}$. In this context the position of Tl in the periodic table will be noted — it occurs between two other poisonous heavy metals Hg and Pb. Tl$_2$SO$_4$ was formerly widely used as a rodenticide and ant killer but it is both odourless and tasteless and is now banned in many countries as being too dangerous for general use. Many suggestions have been made for the use of Tl compounds in industry but none have been substantially developed. A few specialist uses have emerged in infrared technology since TlBr and TlI are transparent to long wavelengths, and there are possibilities for photosensitive diodes and infrared detectors. The very high density of aqueous solutions of Tl formate and malonate have found application in the small-scale separation of minerals and the determination of their densities; a saturated solution containing approximately equal weights of these salts (Clerici’s solution) has a density of 4.324 g cm$^{-3}$ at 20$^\circ$ and progressively lower densities can be obtained by dilution.

### 7.2.3 Properties of the elements

The atomic properties of the Group 13 elements (including boron) are compared in Table 7.4. All have odd atomic numbers and correspondingly few stable isotopes. The varying precision of atomic weights has been discussed (p. 17). The electronic configuration is $ns^2np^1$ in each case but the underlying core varies considerably: for B and Al it is the preceding noble gas core, for Ga and In it is noble gas plus $d^{10}$, and for Tl noble gas plus $4f^{14}5d^{10}$. This variation has a substantial influence on the trends in chemical properties of the group and is also reflected in the ionization energies of the elements. Thus, as shown in Fig. 7.1, the expected decrease from B to Al is not followed by a further decrease to Ga because of the “d-block contraction” in atomic size and the higher effective nuclear charge for this element which stems from the fact that the 10 added d electrons do not completely shield the extra 10 positive charges on the nucleus. Similarly, the decrease between Ga and In is reversed for Tl as a result of the further influence of the f block or lanthanide contraction. It is notable that these irregularities for the Group 13 elements do not occur for the Group 3 elements Sc, Y and La, which show a steady decrease in ionization energy from B and Al, all 5 elements having the same type of underlying core (noble gas). This has a decisive influence on the comparative chemistry of the two subgroups.

Boron is a covalently bonded, refractory, non-metallic insulator of great hardness and is thus not directly comparable in its physical properties with Al, Ga, In and Tl, which are all low-melting, rather soft metals having a very low electrical

resistivity (Table 7.5). The heats of fusion and vaporization of the metals are also much lower than those of boron and tend to decrease with increasing atomic number. In all these properties the metals resemble the neighbouring metals Zn, Cd, Hg; Sn, Pb, etc., and it is probable that in each case the properties are related to the rather small number of electrons available for metallic bonding. Some have seen this as a manifestation of the “inert-pair effect” (see p. 226). The interatomic distances in these elements are also somewhat longer than expected from general trends.

The crystal structure of Al is fcc, typical of many metals, each Al being surrounded by 12 nearest neighbours at 286 pm. Thallium also has a typical metallic structure (hcp) with 12 nearest neighbours at 340 pm. Indium has an unusual structure which is slightly distorted from a regular close-packed arrangement: the structure is face-centred tetragonal and each In has 4 neighbours at 324 pm and 8 at the slightly greater distance of 336 pm. Gallium has a unique orthorhombic (pseudotetragonal) structure in which each Ga has 1 very close neighbour at 244 pm and 6 further neighbours, 2 each at 270, 273 and 279 pm. The structure is very similar to that of iodine and the appearance of pseudo-molecules Ga₂ may result from partial pair-wise interaction on neighbouring atoms of the single p electron outside the [Ar]3d¹⁰4s² core which immediately follows the first transition series. As such it can be compared with Hg which also has a very low mp and completes the [Xe]4f¹⁴5d¹⁰6s² “pseudo-noble-gas” configuration following the lanthanide elements. Note that all interatomic contacts in metallic Ga are less than those in Al, again emphasizing the presence of a “d-block contraction”. Gallium is also unusual in contracting on melting, the volume of the liquid phase being 3.4% less than that of the solid; the

\(^{(a)}\) The resistivity of crystalline Ga is markedly anisotropic, the values in the three orthorhombic directions being \( a \) 17.5, \( b \) 8.20, \( c \) 55.3 \( \mu \text{ohm cm} \). The resistivity of liquid Ga at 30°C is 25.8 \( \mu \text{ohm cm} \).

\(^{(b)}\) \( E^+ \) for reaction \( \text{H}_3\text{BO}_3 + 3\text{H}^+ + 3e^- = \text{B}(s) + 3\text{H}_2\text{O} \).

\(^{(c)}\) This is the observed value for \( E^+(\text{Tl}^{3+}/\text{Tl}(s)) \), hence the calculated value for the corresponding \( E^+(\text{Tl}^{3+}/\text{Tl}(s)) \) is \(+0.73 \) V.

The Group 13 metals differ sharply from the non-metallic element boron both in their greater chemical reactivity at moderate temperatures and in their well-defined cationic chemistry for aqueous solutions. The absence of a range of volatile hydrides and other cluster compounds analogous to the boranes and carboranes is also notable. Aluminium combines with most non-metallic elements when heated to give compounds such as \( \text{AlN}, \text{Al}_2\text{S}_3, \text{AlX}_3, \text{etc.} \). It also forms intermetallic compounds with elements from all groups of the periodic table that contain metals. Because of its great affinity for oxygen it is used as a reducing agent to obtain Cr, Mn, V, etc., by means of the thermite process of J. W. Goldschmidt. Finely powdered Al metal explodes on contact with liquid \( \text{O}_2 \), but for normal samples of the metal a coherent protective oxide film prevents appreciable reaction with oxygen, water or dilute acids; amalgamation with \( \text{Hg} \) or contact with solutions of salts of certain electropositive metals destroys the film and permits further reaction. Aluminium is also readily soluble in hot concentrated hydrochloric acid and in aqueous \( \text{NaOH} \) or \( \text{KOH} \) at room temperature with liberation of \( \text{H}_2 \). This latter reaction is sometimes written as

\[
\text{Al} + \text{NaOH} + \text{H}_2\text{O} \rightarrow \text{NaAlO}_2 + \frac{3}{2}\text{H}_2
\]

though it is likely that the species in solution is the hydrated tetrahydroxoaluminate anion \( [\text{Al(OH)}_4]^- (\text{aq}) \) or \( [\text{Al(H}_2\text{O})_2(\text{OH})_4]^- \).
Al(OH)₃ is amphoteric, forming both salts and aluminates (Greek ἀμφότερος, amphoteros, in both ways). Thus the freshly precipitated hydroxide is readily soluble in both acid and alkali:

\[
\text{Al(OH)₃} \rightarrow \text{Al}^{3+} + 3\text{OH}^-
\]

Similarly, the cyanide, acetate and carbonate are unstable in aqueous solution. Hydrolysis of the halides and other salts such as the nitrate and sulfate is incomplete but aqueous solutions are acidic due to the ability of the hydrated cation \([\text{Al(H}_2\text{O)}₃]^{3+}\) to act as proton donor giving \([\text{Al(H}_2\text{O)}₃(\text{OH})]^{2+}\), \([\text{Al(H}_2\text{O)}₄(\text{OH})]^{+}\), etc. If the pH is gradually increased this deprotonation of the mononuclear species is accompanied by aggregation via OH bridges to give species such as

\[
[\text{Al(H}_2\text{O)}₄\text{Al(OH)}₂]^{4+}
\]

and then to precipitation of the hydrated oxide. This is of particular use in water clarification since the precipitating hydroxide nucleates on fine suspended particles which are thereby thrown out of suspension. Still further increase in pH leads to redissolution as an aluminate (Fig. 7.3). Similar behaviour is shown by Be⁺², Zn⁺², Ga⁺³, Sn⁺², Pb⁺², etc. A detailed quantitative theory of amphotericism is difficult to construct but it is known that amphoteric behaviour occurs when (a) the cation is weakly basic, (b) its hydroxide

\[
3\text{H}_2\text{S}, \text{AlN} \rightarrow \text{NH}_3, \text{and Al}_4\text{C}_3 \rightarrow 3\text{CH}_4.
\]
is moderately insoluble, and (c) the hydrated species can also act as proton donors.\(^{(2)}\)

Anhydrous Al salts cannot be prepared by heating the corresponding hydrate for reasons closely related to the amphoterism and hydrolysis of such compounds. For example, \(\text{AlCl}_3.6\text{H}_2\text{O}\) is, in reality, \([\text{Al(H}_2\text{O})_6]\text{Cl}_3\) and the strength of the Al–O interaction precludes the formation of Al–Cl bonds:

\[
2[\text{Al(H}_2\text{O})_6]\text{Cl}_3 \xrightarrow{\text{heat}} \text{Al}_2\text{O}_3 + 6\text{HCl} + 9\text{H}_2\text{O}
\]

The amphoteric behaviour of Ga\(^{\text{III}}\) salts parallels that of Al\(^{\text{III}}\); indeed, Ga\(_2\text{O}_3\) is slightly more acidic than Al\(_2\text{O}_3\) and solutions of gallates tend to be more stable than aluminates. Consistent with this, \(pK_a\) for the equilibrium

\[
[\text{M(H}_2\text{O})_6]^{3+} \rightleftharpoons [\text{M(H}_2\text{O})_5\text{OH}]^{2+} + \text{H}^+
\]

is 4.95 for Al and 2.60 for Ga. Indium is more basic than Ga and is only weakly amphoteric. The metal does not dissolve in aqueous alkali whereas Ga does. This alternation in the sequence of basicity can be related to the electronic and size factors mentioned on p. 222. Thallium behaves as a moderately strong base but is not strictly comparable with other members of the group because it normally exists as Tl\(^{\text{I}}\) in aqueous solution. Thus, Tl metal tarnishes readily and reacts with steam or moist air to give TlOH. The electrode potential data in Table 7.5 show that Tl\(^{\text{I}}\) is much more stable than Tl\(^{\text{III}}\) in aqueous solution and indicate that Tl\(^{\text{III}}\) compounds can act as strong oxidizing agents.

Compounds of Tl\(^{\text{I}}\) have many similarities to those of the alkali metals: TlOH is very soluble and is a strong base; Tl\(_2\text{CO}_3\) is also soluble and resembles the corresponding Na and K compounds; Tl\(^{\text{I}}\) forms colourless, well-crystallized salts of many oxoacids, and these tend to be anhydrous like those of the similarly sized Rb and Cs; Tl\(^{\text{I}}\) salts of weak acids have a basic reaction in aqueous solution as a result of hydrolysis; Tl\(^{\text{I}}\) forms polysulfides (e.g. Tl\(_2\text{S}_5\)) and polyiodides, etc. In other respects Tl\(^{\text{I}}\) resembles the more highly polarizing ion Ag\(^+\), e.g. in the colour and insolubility of its chromate, sulfide, arsenate and halides (except F), though it does not form ammine complexes in aqueous solution and its azide is not explosive.

The stability of the +1 oxidation state in Group 13 increases in the sequence Al < Ga < In < Tl, and numerous examples of M\(^{\text{I}}\) compounds will be found in the following sections. The occurrence of an oxidation state which is 2 less than the group valency is sometimes referred to as the "inert-pair effect" but it is important to recognize that this is a description not an explanation. The phenomenon is quite general among the heavier elements of the p block (i.e. the post-transition elements in Groups 13–16). For example, Sn and Pb commonly occur in both the +2 and +4 oxidation states; P, As, Sb and Bi in the +3 and +5; S, Se, Te and Po in the +2, +4, and +6 states. The term "inert-pair effect" is somewhat misleading since it implies that the energy required to involve the ns\(^2\) electrons in bonding increases in the sequence Al < Ga < In < Tl. Reference to Table 7.4 shows that this is not so (the sequence is, in fact, In < Al < Tl < Ga). The explanation lies rather in the decrease in bond energy with increase in size from Al to Tl so that the energy required

to involve the s electrons in bonding is not compensated by the energy released in forming the 2 additional bonds. The argument is difficult to quantify since the requisite energy terms are not known. Thus it is unrealistic to use the simple ionic bond model (p. 79) to calculate the heat of formation of MX₃ because compounds like TlCl₃ are not ionic, i.e. [Tl⁺⁺(Cl⁻)₃] — the energy for the ionization of M(g) to M³⁺(g) is greater than 5000 kJ mol⁻¹ for each element and substantial covalent interaction between M³⁺ and X⁻ would also be expected. In the absence of semi-empirical bond energy data or ab initio MO calculations it is only possible to note that the higher oxidation state becomes progressively less stable with respect to the lower oxidation state as atomic number increases within the group. This is seen, for example, by comparing the standard electrode potentials in aqueous solution for M³⁺ and M⁺ in Table 7.5. Similarly, from the somewhat fragmentary data available, it appears that the enthalpy of formation of the anhydrous halides remains approximately constant for MX but diminishes irregularly from Al to Tl for MX₃ (X = Cl, Br, I). The overall result depends not only on the simple Born–Haber terms (p. 82) but also on a combination of several other factors including changes in structure and bond type, covalency effects, enthalpies of hydration, entropy effects, etc., and a quantitative rationalization of all the data has not yet been achieved.

Group 13 metals furnish a good example of the general rule that an element is more electropositive in its lower than in its higher oxidation state: the lower oxide and hydroxide are more basic and the higher oxide and hydroxide more acidic. The reasons for this behaviour are similar to those already discussed when comparing Group 2 with Group 1 (p. 111) and turn on the relative magnitude of ionization energies, cationic size, hydration enthalpy and entropy, etc. Again, the higher the charge on an aquo cation [M(H₂O₃)]ⁿ⁺ the more readily will it act as a proton donor (p. 51).

Other group trends will emerge in subsequent sections. However, it is worth noting here an important vestigial structural relation of these elements to the icosahedral units in elementary boron (p. 142). Thus, the structures of both β-rhombohedral boron and the cubic alloy phase Al₃CuLi₃ can be constructed from 60-vertex truncated icosahedra, although linked in very different ways in the 3-dimensional crystalline lattice. Likewise, Ga₁₂ icosahedra have been found in intermetallic phases such as RbGa₇, CsGa₇, Li₂Ga₇, K₃Ga₁₃ and Na₂₂Ga₃₉. This has led to the proposal(3) that the Group 13 elements should be given the collective epithet of ‘icosagens’.

7.3 Compounds

7.3.1 Hydrides and related complexes

The extensive covalent cluster chemistry of the boron hydrides finds no parallel with the heavier elements of Group 13. AlH₃ is a colourless, involatile solid which is extensively polymerized via Al–H–Al bonds; it is thermally unstable above 150–200°, is a strong reducing agent and reacts violently with water and other protic reagents to liberate H₂. Several crystalline and amorphous modifications have been described and the structure of α-AlH₃ has been determined by X-ray and neutron diffraction(9) each Al is octahedrally surrounded by 6 H atoms at 172 pm and the Al–H–Al angle is 141°. The participation of each Al in 6 bridges, and the equivalence of all

---

Al–H distances suggests that 3-centre 2-electron bonding occurs as in the boranes (p. 157). The closest Al–Al distance is 324 pm, which is appreciably shorter than in metallic Al (340 pm), but there is no direct metal–metal bonding and the density of AlH₃ (1.477 g cm⁻³) is markedly less than that for Al (2.699 g cm⁻³); this is because in Al metal all 12 nearest neighbours are at 340 pm whereas in AlH₃ there are 6 Al at 324 and 6 at 445 pm.

AlH₃ is best prepared by the reaction of ethereal solutions of LiAlH₄ and AlCl₃ under very carefully controlled conditions:

\[3\text{LiAlH}_4 + \text{AlCl}_3 \xrightarrow{\text{Et}_2\text{O}} 4[\text{AlH}_3(\text{Et}_2\text{O})_n] + 3\text{LiCl}\]

The LiCl is removed and the filtrate, if left at this stage, soon deposits an intractable etherate of variable composition. To avoid this, the solution is worked up with an excess of LiAlH₄ and some added LiBH₄ in the presence of a large excess of benzene under reflux at 76–79°C. Crystals of α-AlH₃ soon form. Slight variations in the conditions lead to other crystalline modifications of unsolvated AlH₃, 6 of which have been identified.

AlH₃ readily forms adducts with strong Lewis bases (L) but these are more conveniently prepared by reactions of the type

\[\text{Et}_2\text{O} + \text{LiAlH}_4 + \text{NMe}_3\text{HCl} \rightarrow [\text{AlH}_3(\text{NMe}_3)] + \text{LiCl} + \text{H}_2\]

\[[\text{AlH}_3(\text{NMe}_3)]\] has a tetrahedral structure and can take up a further mole of ligand to give \[[\text{AlH}_3(\text{NMe}_3)_2]\]; this was the first compound in which Al was shown to adopt a 5-coordinate trigonal bipyramidal structure. Such complexes are now of interest since their thermal decomposition can be used to prepare ultra-thin carbon-free Al films by chemical vapour deposition on GaAs semiconductor devices.

LiAlH₄ is a white crystalline solid, stable in dry air but highly reactive towards moisture, protic solvents, and many organic functional groups. It is readily soluble in ether (~29 g per 100 g at room temperature) and is normally used in this solvent. LiAlH₄ has proved to be an outstandingly versatile reducing agent since its discovery some 50 y ago (see Panel opposite). It can be prepared on the laboratory (and industrial) scale by the reaction

\[4\text{LiH} + \text{AlCl}_3 \xrightarrow{\text{Et}_2\text{O}} \text{LiAlH}_4 + 3\text{LiCl}\]

On the industrial (multitonne) scale it can also be prepared by direct high-pressure reaction of the elements or preferably via the intermediate formation of the Na analogue.

\[\text{Na} + \text{Al} + 2\text{H}_2 \xrightarrow{\text{thf}/140^°/3h} \text{NaAlH}_4 (99\% \text{ yield})\]

The Li salt can then be obtained by metathesis with LiCl in Et₂O. The X-ray crystal structure of LiAlH₄ shows the presence of tetrahedral AlH₄ groups (Al–H 155 pm) bridged by Li in such a way that each Li is surrounded by 4H at 188–200 pm (cf. 204 pm in LiH) and a fifth H at 216 pm. The bonding therefore deviates considerably from the simple ionic formulation Li⁺AlH₄⁻ and there appears to be substantial covalent bonding as found in other complex hydrides (p. 67).

Other complex hydrides of Al are known including Li₃AlH₆, M¹AlH₄ (M¹ = Li, Na, K, Cs), M²(AlH₄)₂ (M² = Be, Mg, Ca), Ga(AlH₄)₃, M³(AlH₃R), M¹(AlH₂R₂), M²[AlH(OEt)₃], etc. (see Panel). The important complex Al(BH₄)₃ has already been mentioned (p. 169); it is a colourless liquid, mp ~64.5°, bp ~44.5°. It is best prepared

---

97.3.1 Hydrides and related complexes

Synthetic Reactions of LiAlH₄

LiAlH₄ is a versatile reducing and hydrogenating reagent for both inorganic and organic compounds. With inorganic halides the product obtained depends on the relative stabilities of the corresponding tetrahydroaluminate, hydride and element. For example, BeCl₂ gives Be(AlH₄)₂, whereas BCl₃ gives B₂H₆ and HgI₂ gives Hg metal. The halides of Ca, Ag, Au, Zn, Cd and Hg give some evidence of unstable hydrido species at low temperatures but all are reduced to the metal at room temperature. The halides of main groups 14 and 15 yield the corresponding hydrides since the AlH₄ derivatives are unstable or nonexistent. Thus SiCl₄, GeCl₄ and SnCl₄ yield MH₄ and substituted halides such as R₄SiH₄, give R₄SiH₄₄. Similarly, PCl₃ (and PCl₅), AsCl₃ and SbCl₅ afford MH₃ but BiCl₃ is reduced to the metal. PhAsCl₂ gives PhAsH₂ and Ph₃SbCl gives Ph₃SbH₂, etc. Less work has been done on oxides but COCl₂ yields MeOH, NO yields hyponitrous acid HON=NOH (which can be isolated as the Ag salt), and CO₂ gives LiAl(OMe)₄ or LiAl(OCH₂O)₄ depending on conditions.

The real importance of LiAlH₄ stems from the applications in organic syntheses. Its commercial introduction dates from 1948. By 1951 the number of functional groups that were known to react was 23 and this rose to more than 60 by the 1970s. Despite this, the heyday of LiAlH₄ seems to have been reached in the late 1960s and it has now been replaced in many systems by the more selective borohydrides (p. 167) or by organometallic hydrides (see below). Reaction is usually carried out in ether solution, followed by hydrolysis of the intermediate so formed when appropriate. Typical examples are listed below.

More recently, LiAlH₄ has been eclipsed as an organic reducing agent by the emergence of several cheaper organoaluminium hydrides which are also safer and easier to handle than LiAlH₄. Pre-eminent among these are Bu₃AlH and Na[AlEt₃H₂] which were introduced commercially in the early 1970s and Na[Al(OCH₂CH₂OMe)₂H₂], VITRIDE®, which became available in bulk during 1979. All three reagents can be prepared directly:

\[ 2\text{Me}_2\text{CH}≡\text{CH}_2 + \text{Al} + \text{H}_2 \rightarrow \text{Bu}_3\text{AlH} \]

\[ 2\text{CH}_2≡\text{CH}_2 + \text{Al} + 2\text{H}_2 \rightarrow \frac{1}{2}(\text{Et}_2\text{AlH})_2 \xrightarrow{\text{NaH}} \text{Na}[\text{AlEt}_2\text{H}_2] \]

\[ 2\text{MeOCH}_2\text{CH}_2\text{OH} + \text{Al} + \text{NaH}_2\text{PHMe} \rightarrow \text{Na}[\text{Al}(\text{OCH}_2\text{CH}_2\text{OMe})_2\text{H}_2] \]

All three are substantially cheaper than LiAlH₄ and are now produced on a far larger scale as indicated in the table overleaf. Data refer to US industrial use in 1980 and even larger markets are available outside the chemical industry (e.g. in polymerization catalysis).
in the absence of solvent by the reaction

$$3\text{NaBH}_4 + \text{AlCl}_3 \rightarrow \text{Al(BH}_4)_3 + 3\text{NaCl}$$

Al(BH$_4$)$_3$ was the first fluxional compound to be recognized as such (1955) and its thermal decomposition led to a new compound which was the first to be discovered and structurally characterized by means of nmr:

$$2\text{Al(BH}_4)_3 \rightarrow \text{Al}_2\text{B}_4\text{H}_{18} + \text{B}_2\text{H}_6$$

This binuclear complex is also fluxional and has the structure shown in Fig. 7.4a. Al(BH$_4$)$_3$ reacts readily with NMe$_3$ to give a 1:1 adduct in which Al adopts the unusual pentagonal bipyramidal 7-fold coordination as shown in Fig. 7.4b.$^{(15)}$

At room temperature Al(BH$_4$)$_3$ reacts quantitatively in the gas phase with Al$_2$Me$_6$ (p. 259) to give [Al($\eta^2$-BH$_4$)$_2$Me] (mp –76°) in which one of the BH$_4$ groups of the parent compound has been replaced by a Me group:

$$4\text{Al(BH}_4)_3 + \text{Al}_2\text{Me}_6 \rightarrow \text{Al}_2\text{B}_4\text{H}_{18}$$

Electron diffraction studies in the gas phase reveal an unusual structure in which the 5-coordinate Al atom has square-pyramidal

§7.3.1  

**Hydrides and related complexes**  

231

Figure 7.5 (a) Structure of [MeAl(η²-BH₄)₂] as revealed by electron diffraction, and (b) structure and key dimensions of [HGa(η²-BH₄)₂] as determined by low temperature X-ray diffractometry.

geometry (Fig. 7.5a). The heavy atoms CaB₂ are coplanar and the symmetry is close to C₂v. A similar structure (Fig. 7.5b) has been found by X-ray diffraction for [Ga(η²-BH₄)₂H], which was prepared by the dry reaction of LiBH₄ and GaCl₃ at -45°C, and this geometry is emerging as a notable structural feature of many AlH₄⁻ complexes (see next paragraph).

Many complexes in which AlH₄⁻ acts as a dihapto (or bridging bis-dihapto) ligand to transition metals have recently been characterized. These are usually stabilized by coligands such as tertiary phosphines or η⁵-cyclopentadienyls and are readily prepared by treating the corresponding chloro-complexes with LiAlH₄ in ether. Typical examples, frequently dimeric, are:

- [{(C₅H₅)₂Y(AlH₄)₂}₂] (Fig. 7.6a), [(C₅Me₅)₂Ta(AlH₄)₂] [[(PMe₃)₃H₂]₂-Mn(AlH₄)₂] and [(PPh₃)₃HRu(AlH₄)₂]. A few transition metal tetrahydroaluminates [M(AlH₄)₄] are also known but their structures have not yet been determined by X-ray crystallography, e.g.: [Y(AlH₃)₃], [Ti(AlH₄)₂], [Nb(AlH₄)₃] and [Fe(AlH₄)₂].

The synthesis and characterization of gallane, the binary hydride of gallium, has proved even more elusive than that of alane, AlH₃. Success was finally achieved by first preparing dimeric monochlorogallane, {H₂Ga(μ-Cl)}₂, and then reducing a freshly prepared sample of this liquid with freshly prepared LiGaH₄ under solvent-free conditions in an all-glass apparatus at -30°C:

\[
\begin{align*}
2\text{GaCl}_3 + 4\text{Me}_3\text{SiH} &\overset{-23^\circ}{\longrightarrow} \text{Ga}_2\text{Cl}_2\text{H}_4 + 4\text{Me}_3\text{SiCl} \\
\text{Ga}_2\text{Cl}_2\text{H}_4 + 2\text{LiGaH}_4 &\overset{-30^\circ}{\longrightarrow} \text{Ga}_2\text{H}_6 + 2\text{LiGaH}_3\text{Cl}
\end{align*}
\]

The volatile product, obtained in about 5% yield, condensed as a white solid at -50° and had a vapour pressure of about 1mmHg at -63°. Gallane decomposes into its elements at ambient temperatures. In the vapour phase it has a diborane-like structure, Ga₂H₆, with Ga–Hₑ 152 pm, Ga–H₂ 171 pm, and angle GaHGa 98° (electron diffraction).[19] In the solid state gallane tends to aggregate via Ga–H–Ga bonds to give (GaH₃)ₙ with n, perhaps equal to 4 but, in contrast to the structure...
of \( \alpha - \text{AlH}_3 \) (p. 227), some terminal Ga–H, bonds remain.

The known reactions of gallane appear mostly to parallel those of diborane (p. 165). Thus, at \(-95^\circ\), \( \text{NH}_3 \) causes unsymmetrical cleavage to give \( [\text{H}_2\text{Ga(NH}_3)_2]^+\text{[GaH}_4]^- \) whereas \( \text{NMMe}_3 \) effects symmetrical cleavage to give \( \text{Me}_3\text{N.GaH}_3 \) or \( (\text{Me}_3\text{N})_2\text{GaH}_3 \) according to the amount used.\(^{(19)} \) These last two adducts were already well known. \( \text{Me}_3\text{N.GaH}_3 \) can readily be prepared as a colourless crystalline solid, mp 70.5\(^\circ\), by the reaction of ethereal solutions of \( \text{LiGaH}_4 \) and \( \text{Me}_3\text{N.HCl} \).\(^{(21)} \) It is one of the most stable complexes of \( \text{GaH}_3 \) and, like its \( \text{Al} \) analogue, can take up a further mole of ligand to give the trigonal bipyramidal 2:1 complex.\(^{(22)} \) Numerous other complexes have been prepared and the stabilities of the 1:1 adducts decrease in the following sequences:\(^{(5)} \)

\[
\begin{align*}
\text{Me}_2\text{NH} &> \text{Me}_3\text{N} > \text{C}_5\text{H}_5\text{N} > \text{Et}_3\text{N} \\
&> \text{PhNMMe}_2 \gg \text{Ph}_3\text{N}
\end{align*}
\]

\[
\begin{align*}
\text{Me}_3\text{N} &\approx \text{Me}_3\text{P} > \text{Me}_2\text{PH} \\
\text{Ph}_3\text{P} &> \text{Ph}_3\text{N} > \text{Ph}_3\text{As} \\
\text{R}_3\text{N} &\text{or} \text{R}_3\text{P} > \text{R}_2\text{O} \text{ or} \text{R}_2\text{S}
\end{align*}
\]

Complexes of the type \([\text{GaH}_2\text{X(NMMe}_3)]\) and \([\text{GaHX}_2(\text{NMMe}_3)]\) are readily prepared by reaction of \( \text{HCl} \) or \( \text{HBr} \) on the \( \text{GaH}_3 \) complex at low temperatures or by reactions of the type

\[
2[\text{GaH}_3(\text{NMMe}_3)] + [\text{GaX}_3(\text{NMMe}_3)] \rightarrow \text{CaH}_6
\]

The relative stabilities of these various complexes can be rationalized in terms of the factors discussed on p. 198. A few mixed hydrides have also been characterized, e.g. galla-diborane, \( \text{H}_2\text{Ga}(\mu-\text{H})_2\text{BH}_2\)\(^{(23)} \) and \( \text{arachno}-\text{2-gallatetaborane}\)\(^{(10)} \), \( \text{H}_2\text{GaB}_3\text{H}_8\)\(^{(24)} \) as well as derivatives such as \( \text{tetramethylgallane, Me}_2\text{Ga}(\mu-\text{H})_2\text{GaMe}_2\).\(^{(25)} \)

\( \text{InH}_3 \) and \( \text{TiH}_3 \) appear to be too unstable to exist in the uncoordinated state though they may have transitory existence in ethereal solutions at low temperatures. A similar decrease in thermal stability is noted for the tetrahydro complexes; e.g. the temperature at which the \( \text{Li} \) salts decompose rapidly, follows the sequence

---

7.3.2 Halides and halide complexes

Several important points emerge in considering the wide range of Group 13 metal halides and their complexes. Monohalides are known for all 4 metals with each halogen though for Al they occur only as short-lived diatomic species in the gas phase or as cryogenically isolated solids. This may seem paradoxical, since the bond dissociation energies for Al-X are substantially greater than for the corresponding monohalides of the other elements and fall in the range 655 kJ mol\(^{-1}\) (AlF) to 365 kJ mol\(^{-1}\) (AlI). The corresponding values for the gaseous TIX decrease from 460 to 270 kJ mol\(^{-1}\) yet it is these latter compounds that form stable crystalline solids. In fact, the instability of AlX in the condensed phase at normal temperatures is due not to the weakness of the Al–X bond but to the ready disproportionation of these compounds into the even more stable AlX₃:

\[
\text{AlX(s)} \rightarrow \frac{2}{3}\text{Al(s)} + \frac{1}{3}\text{AlX}_3(s);
\]

\(\Delta H_{\text{disprop}}\) (see table below)

The reverse reaction to give the gaseous species AlX(g) at high temperature accounts for the enhanced volatility of AlF₃ when heated in the presence of Al metal, and the ready volatilization of Al metal in the presence of AlCl₃. Using calculations of the type outlined on p. 82 the standard heats of formation of the crystalline monohalides AlX and their heats of disproportionation have been estimated as:

The crystalline dihalides AlX₂ are even less stable with respect to disproportionation, value of \(\Delta H_{\text{disprop}}^{\circ}\) falling in the range -200 to -230 kJ mol\(^{-1}\) for the reaction

\[
\text{AlX}_2(s) \rightarrow \frac{1}{3}\text{Al(s)} + \frac{2}{3}\text{AlX}_3(s)
\]

Very recently the first AlI compound to be stable at room temperature, the tetrameric complex \([\text{AlI(NEt}_3)_4]_4\), has been prepared and shown to feature a planar Al₄ ring with Al–Al 265 pm, Al–I 265 pm and Al–N 207 pm.²⁵\(^a\)

### Aluminium trihalides

AlIF₃ is made by treating Al₂O₃ with HF gas at 700°C and the other trihalides are made by the direct exothermic combination of the elements. AlIF₃ is important in the industrial production of Al metal (p. 219) and is made on a scale approaching 700 000 tonnes per annum world wide. AlCl₃ finds extensive use as a Friedel–Crafts catalyst (p. 236): its annual production approaches 100 000 tpa and is dominated by Western Europe, USA and Japan. The price for bulk AlCl₃ is about $0.35/kg.

AlIF₃ differs from the other trihalides of Al in being involatile and insoluble, and in having a much greater heat of formation (Table 7.6). These differences probably stem from differences in coordination number (6 for AlF₃; change from 6 to 4 at mp for AlCl₃; 4 for AlBr₃ and AlI₃) and from the subtle interplay of a variety of other factors mentioned below, rather than from any discontinuous change in bond type between the fluoride and the other halides. Similar differences dictated by change in coordination number are noted for many other metal halides, e.g. SnF₄ and SnX₄ (p. 381), BiF₃ and BiX₃ (p. 559), etc., and even more dramatically for some oxides such as CO₂ and SiO₂. In AlF₃ each Al is surrounded by

a distorted octahedron of 6 F atoms and the 1:3 stoichiometry is achieved by the corner sharing of each F between 2 octahedra. The structure is thus related to the ReO$_3$ structure (p. 1047) but is somewhat distorted from ideal symmetry for reasons which are not understood. Maybe the detailed crystal structure data are wrong.$^{26}$ The relatively “open” lattice of AlF$_3$ provides sites for water molecules and permits the formation of a range of nonstoichiometric hydrates. In addition, well-defined hydrates AlF$_3$.nH$_2$O (n = 1, 3, 9) are known but, curiously, no hexahydrate corresponding to the familiar [Al(H$_2$O)$_6$]Cl$_3$. In the gas phase at 1000°C the AlF$_3$ molecule has trigonal planar symmetry (D$_{3h}$)$^{27}$ with Al–F 163.0(3) pm which is considerably shorter than in the solid phase 170–190 pm (for 6-coordinate Al).

The complex fluorides of Al$^{III}$ (and Fe$^{III}$) provide a good example of a family of structures with differing stoichiometries all derived by the sharing of vertices between octahedral {AlF$_6$} units,$^{26}$ edge sharing and face sharing are not observed, presumably because of the destabilizing influence of the close (repulsive) approach of 2 Al atoms each of which carries a net partial positive charge. Discrete {AlF$_6$} units occur in cryolite, Na$_3$AlF$_6$, and in the garnet structure Li$_3$Na$_3$Al$_2$F$_{12}$ (i.e. [Al$_2$Na$_3$(LiF$_4$)$_3$], see p. 348) but it is misleading to think in terms of {AlF$_6$}$^{3–}$ ions since the Al–F bonds are not appreciably different from the other M–F bonds in the structure. Thus the Na$_3$AlF$_6$ structure is closely related to perovskite ABO$_3$ (p. 963) in which one-third of the Na and all the Al atoms occupy octahedral {MF$_6$} sites and the remaining two-thirds of the Na occupy the 12-coordinate sites. When two opposite vertices of {AlF$_6$} are shared the stoichiometry becomes {AlF$_5$} as in TI$_3$AlF$_5$ (and TI$_2$GaF$_5$). The sharing of 4 equatorial vertices of {AlF$_6$} leads to the stoichiometry {AlF$_4$} in TI$^3$AlF$_4$. The same structural motif is found in each of the “isoelectronic” 6-coordinate layer lattices of K$_2$Mg$^{II}$F$_4$, KA$^{II}$F$_4$ and Sn$^{IV}$F$_4$, none of which contain tetrahedral [MF$_4$] units.

More complex patterns of sharing give intermediate stoichiometries as in Na$_3$Al$_2$F$_{14}$ which features layers of {Al$_3$F$_{14}$$^{5–}$} built up by one-third of the {AlF$_6$} octahedra sharing 4 equatorial vertices and the remainder sharing 2 opposite vertices. Again, Na$_2$MgAlF$_7$ comprises linked {AlF$_6$} and {MgF$_6$} octahedra in which 4 vertices of {AlF$_6$} and all vertices of {MgF$_6$} are shared. Likewise, Sm$^{II}$AlF$_5$ features {Al$_2$F$_{10}$$^{4–}$} biocahedra and linear chains of trans corner-sharing {AlF$_6$},$^{28}$ and Ba$_3$Al$_2$F$_{12}$ has a tetrameric ({F$_2$AlF$_2$/2})$_4$$^{8–}$ ring, i.e [Ba$_4$F$_6$(Al$_4$F$_{20}$)].$^{29}$ which is unique for fluorometallates, being previously encountered only in neutral molecules (MF$_5$)$_4$ where M is Nb, Ta (p. 990); Mo, W (p. 1020); Ru, Os (p. 1083). In all of these structures the degree of charge separation, though considerable, is unlikely to approach the formal group charges: thus AlF$_3$ should not be regarded as a network of alternating ions Al$^{3+}$ and F$^–$ nor, at the other extreme, as an alternating set of Al$^{3+}$ and AlF$_6^{3–}$, and lattice energies calculated on the basis of such formal charges placed at the observed interatomic distances are bound to be of limited reliability. Equally, the structure is not well described as a covalently bonded network of Al atoms and F atoms, and detailed MO calculations would be required to assess the actual extent of charge separation, on the one hand, and of interatomic covalent bonding, on the other.

The structure of AlCl$_3$ is similarly revealing. The crystalline solid has a layer lattice with 6-coordinate Al but at the mp 192.4$^\circ$ the structure changes to a 4-coordinate molecular dimer Al$_2$Cl$_6$; as a result there is a dramatic increase in volume (by 85%) and an even more dramatic drop in electrical conductivity almost to zero. The mp therefore represents a substantial change in the nature of the bonding. The covalently bonded

molecular dimers are also the main species in the gas phase at low temperatures (~150–200°) but at higher temperature there is an increasing tendency to dissociate into trigonal planar AlCl₃ molecules isostructural with BX₃ (p. 196).

By contrast, Al₂Br₆ and Al₂I₆ form dimeric molecular units in the crystalline phase as well as in the liquid and gaseous states and fusion is not attended by such extensive changes in properties. In the gas phase \( \Delta H_{\text{dissoc}} = 59 \text{kJ mol}^{-1} \) for AlBr₃ and 50 kJ mol\(^{-1}\) for AlI₃. In all these dimeric species, as in the analogous dimers Ga₂Cl₆, Ga₂Br₆, Ga₂I₆ and In₂I₆, the M–X distance is 10–20 pm shorter than the M–X\(_\mu\) distance; the external angle XₐMXₐ is in the range 110–125° whereas the internal angle XₐMXₐ is in the range 79–102°.

The trihalides of Al form a large number of addition compounds or complexes and these have been extensively studied because of their importance in understanding the nature of Friedel–Crafts catalysis.\(^{30,31}\) The adducts vary enormously in stability from weak interactions to very stable complexes, and they also vary widely in their mode of bonding, structure and properties. Aromatic hydrocarbons and olefins interact weakly though in some cases crystalline adducts can be isolated, e.g. the clathrate-like complex Al₂Br₆·C₆H₆, mp 37° (decomp). With mesitylene (C₆H₃Me₃) and the xylenes (C₆H₄Me₂) the interaction is slightly stronger, leading to dissociation of the dimer and the formation of weak monomeric complexes AlBr₃L both in solution and in the solid state. At the other end of the stability scale NMe₃ forms two crystalline complexes: [AlCl₃(NMe₃)] mp 156.9° which features molecular units with 4-coordinate tetrahedral Al, and [AlCl₃(NMe₃)₂] which has 5-coordinate Al with trigonal bipyramidal geometry and trans axial ligands. By contrast, the adduct AlCl₃·3NH₃ has been shown by X-ray diffraction analysis to consist of elongated octahedra [AlCl₂(NH₃)₄]⁺ and compressed octahedra [AlCl₄(NH₃)₂]⁻, the

arrangement being further stabilized by a network of N–H⋯Cl hydrogen bonds.\(^{32}\)

Alkyl halides interact rather weakly and vibrational spectroscopy suggests bonding of the type R–X⋯AlX\(_3\). However, for readily ionizable halides such as Ph\(_3\)CCl the degree of charge separation is much more extensive and the complex can be formulated as Ph\(_3\)C\(^+\)AlCl\(_4^-\). Acyl halides RCOX may interact either through the carbonyl oxygen, PhC(Cl)\(=\)O⋯AlCl\(_3\), or through the halogen, RCOX⋯AlX\(_3\) or RCO\(^+\)AlX\(_4^-\). Again, vibrational spectroscopy is a sensitive, though not always reliable, diagnostic for the mode of bonding. X-ray crystal structures of several complexes have been obtained but these do not necessarily establish the predominant species in nonaqueous solvents because of the delicate balance between the various factors which determine the structure (p. 198). Even in the crystalline state the act of coordination may lead to substantial charge separation. For example, X-ray analysis has established that AlCl\(_3\)ICl\(_3\) comprises chains of alternating units which are best described as ICl\(_2^+\) and AlCl\(_4^-\) with rather weaker interactions between the ions.

Another instructive example is the ligand POC\(_13\) which forms 3 crystalline complexes AlCl\(_3\)POC\(_13\) mp 186.5\(^\circ\), AlCl\(_3\)(POC\(_13\))\(_2\) mp 164\(^\circ\) (d), and AlCl\(_3\)(POC\(_13\))\(_6\) mp 41\(^\circ\) (d). Although the crystal structures of these adducts have not been established it is known that POC\(_13\) normally coordinates through oxygen rather than chlorine and very recently a Raman spectroscopic study of the 1:1 adduct in the gas phase suggests that it is indeed Cl\(_2^+\)P=O⋯AlCl\(_3\) with \(C\_3\)\(^v\) symmetry.\(^{33}\) Also consistent with oxygen ligation is the observation that there is no exchange of radioactive \(^{36}\)Cl when AlCl\(_3\) containing \(^{36}\)Cl is dissolved in inactive POC\(_13\). However, such solutions are good electrical conductors and spectroscopy reveals AlCl\(_4^-\) as a predominant solute species. The resolution of this apparent paradox was provided by means of \(^{27}\)Al nmr spectroscopy\(^{34}\) which showed that ionization occurred according to the reaction

\[
4\text{AlCl}_3 + 6\text{POCl}_3 \rightarrow \text{[Al(OPOCl)_3]}^3^+ + 3[\text{AlCl}_4^-]
\]

It can be seen that all the Cl atoms in [AlCl\(_4^-\)] come from the AlCl\(_3\). It was further shown that the same two species predominated when Al\(_2\)I\(_6\) was dissolved in an excess of POCl\(_3\):

\[
2\text{Al}_{2}\text{I}_6 + 12\text{POCl}_3 \leftrightarrow 4\{\text{AlCl}_3\} + 12\text{POCl}_3\text{I}
\]

\[
4\{\text{AlCl}_3\} + 6\text{POCl}_3 \rightarrow \text{[Al(OPOCl)_3]}^3^+ + 3[\text{AlCl}_4^-]
\]

No mixed Al species were found by \(^{27}\)Al nmr in this case.

AlCl\(_3\) is a convenient starting material for the synthesis of a wide range of other Al compounds, e.g.:

\[
\text{AlCl}_3 + 3\text{LiY} \rightarrow 3\text{LiCl} + \text{AlY}_3
\]

\((Y = \text{R}, \text{NR}_2, \text{N} = \text{CR}_2)\)

\[
\text{AlCl}_3 + 4\text{LiY} \rightarrow 3\text{LiCl} + \text{LiAlY}_4
\]

\((Y = \text{R}, \text{NR}_2, \text{N} = \text{CR}_2, \text{H})\)

Similarly, NaOR reacts to give Al(OR\(_3\)) and NaAl(OR\(_4\)). AlCl\(_3\) also converts non-metal fluorides into the corresponding chloride, e.g.

\[
\text{BF}_3 + \text{AlCl}_3 \rightarrow \text{AlF}_3 + \text{BCl}_3
\]

This type of transhalogenation reaction, which is common amongst the halides of main group elements, always proceeds in the direction which pairs the most electropositive element with the most electronegative, since the greatest amount of energy is evolved with this combination.\(^{35}\)

The major industrial use of AlCl\(_3\) is in catalytic reactions of the type first observed in 1877 by C. Friedel and J. M. Crafts. AlCl\(_3\) is now extensively used to effect alkylations (with RCl, ROH or RCH=CH\(_2\)), acylations (with RCOCl), and

various condensation, polymerization, cyclization, and isomerization reactions.\textsuperscript{36} The reactions are examples of the more general class of electrophilic reactions that are catalysed by metal halides and other Lewis acids (electron pair acceptors). Of the 30,000 tonnes of AlCl\textsubscript{3} produced annually in the USA, about 15\% is used in the synthesis of anthraquinones for the dyestuffs industry:

A further 15\% of the AlCl\textsubscript{3} is used in the production of ethyl benzene for styrene manufacture, and 13\% in making EtCl or EtBr (for PbEt\textsubscript{4}):

\[
\begin{align*}
\text{CH}_2=\text{CH}_2 + \text{PhH} & \quad \overset{\text{AlCl}_3}{\longrightarrow} \quad \text{PhEt} \\
\text{CH}_2=\text{CH}_2 + \text{HX} & \quad \overset{\text{AlCl}_3}{\longrightarrow} \quad \text{EtX}
\end{align*}
\]

The isomerization of hydrocarbons in the petroleum industry and the production of dodecyl benzene for detergents accounts for a further 10\% each of the AlCl\textsubscript{3} used.

\textbf{Trihalides of gallium, indium and thallium}

These compounds have been mentioned several times in the preceding sections. As with AlX\textsubscript{3} (p. 233), the trifluorides are involatile and have much higher mps and heats of formation than the other trihalides;\textsuperscript{31} e.g. GaF\textsubscript{3} melts above 1000\°, sublimes at \textasciitilde950\° and has the 6-coordinate FeF\textsubscript{3}-type structure, whereas GaCl\textsubscript{3} melts at 77.8\°, boils at 201.2\°, and has the 4-coordinate molecular structure Ga\textsubscript{2}Cl\textsubscript{6}. GaF\textsubscript{3} and InF\textsubscript{3} are best prepared by thermal decomposition of (NH\textsubscript{4})\textsubscript{3}MF\textsubscript{6}, e.g.:

\[
\begin{align*}
\text{(NH}_4\text{)}_3\text{InF}_6 & \quad 120-170\° \quad \text{NH}_4\text{InF}_4 & \quad 300\° & \quad \text{InF}_3
\end{align*}
\]

Preparations using aqueous HF on M(OH)\textsubscript{3}, M\textsubscript{2}O\textsubscript{3}, or M metal give the trihydrate. TlF\textsubscript{3} is best prepared by the direct fluorination of Tl\textsubscript{2}O\textsubscript{3} with F\textsubscript{2}, BrF\textsubscript{3} or SF\textsubscript{4} at 300\°. Trends in the heats of formation of the Group 13 trihalides show the same divergence from BX\textsubscript{3}, AlX\textsubscript{3} and the Group 3 trihalides as was found for trends in other properties such as \(I_m\), \(E^\circ\) and \(\chi\) (pp. 223–5) and for the same reasons. For example, the data for \(\Delta H_f\) for the trifluorides and tribromides are compared in Fig. 7.7 from which it is clear that the trend noted for the sequence B, Al, Sc, Y, La, Ac is not followed for the Group 13 metal trihalides which become progressively less stable from Al to Tl.

The volatile trihalides MX\textsubscript{3} form several ranges of addition compounds MX\textsubscript{3}L, MX\textsubscript{3}L\textsubscript{2}, MX\textsubscript{3}L\textsubscript{3}, and these have been extensively studied because of the insight they provide on the relative influence of the underlying d\textsuperscript{10} electron configuration on the structure and stability of the complexes. With halide ions X\textsuperscript{−} as ligands the stoichiometry depends sensitively on crystal lattice effects or on the nature of the solvent and the relative concentration of the species in solution. Thus X-ray studies have established the tetrahedral ions \([\text{GaX}_4]^-\), \([\text{InCl}_4]^-\), etc., and these persist in ethereal
solution, though in aqueous solution \([\text{InCl}_4]^–\) loses its \(T_d\) symmetry due to coordination of further molecules of \(\text{H}_2\text{O}\). \([\text{NET}_4]_2[\text{InCl}_3]\) is remarkable in featuring a square-pyramidal ion of \(C_{4v}\) symmetry (Fig. 7.8) and was one of the first recorded examples of this geometry in nontransition element chemistry (1969), cf \(\text{SbPh}_5\) on p. 598 and the hydrido aluminate species on p. 231. The structure is apparently favoured by electrostatic packing considerations though it also persists in nonaqueous solution, possibly due to the formation of a pseudo-octahedral solvate \([\text{InCl}_3\text{S}]^{2–}\). It will be noted that \([\text{InCl}_5]^{3–}\) is not isostructural with the isoelectronic species \(\text{SnCl}_5^–\) and \(\text{SbCl}_5\) which have the more common \(D_{3h}\) symmetry. Substituted 5-coordinate chloroderivatives of \(\text{In}^{III}\) and \(\text{Tl}^{III}\) often have geometries intermediate between square pyramidal and trigonal bipyramidal.\(^{(37)}\)

![Figure 7.8](image_url) The structure of \(\text{InCl}_5^{2–}\) showing square-pyramidal \((C_{4v})\) geometry. The In–\(\text{Cl}_\text{apex}\) distance is significantly shorter than the In–\(\text{Cl}_\text{base}\) distances and In is 59 pm above the basal plane; this leads to a \(\text{Cl}_\text{apex}–\text{In}–\text{Cl}_\text{base}\) angle of 103.9° which is very close to the theoretical value required to minimize \(\text{Cl}–\cdots\text{Cl}\) repulsions whilst still retaining \(C_{4v}\) symmetry (103.6°) calculated on the basis of a simple inverse square law for repulsion between ligands. \([\text{NET}_4]_2[\text{TiCl}_3]\) is isomorphous with \([\text{NET}_4]_2[\text{InCl}_3]\) and presumably has a similar structure for the anion.

With neutral ligands, \(\text{L}, \text{GaX}_3\) tend to resemble \(\text{AlX}_3\) in forming predominantly \(\text{MX}_3\text{L}\) and some \(\text{MX}_3\text{L}_2\), whereas \(\text{InX}_3\) are more varied.\(^{(38)}\) \(\text{InX}_3\text{L}_3\) is the commonest stoichiometry for N and O donors and these are probably predominantly 6-coordinate in the solid state, though in coordinating solvents \((\text{S})\) partial dissociation into ions frequently occurs:

\[
\text{InX}_3\text{L}_3 + \text{S} \rightarrow [\text{InX}_2\text{SL}_3]^+ + \text{X}^–
\]

More extensive ionization occurs if, instead of the halides \(\text{X}^–\), a less strongly coordinating anion \(\text{Y}^–\) such as \(\text{ClO}_4^–\) or \(\text{NO}_3^–\) is used; in such cases the coordinating stoichiometry tends to be 1:6, e.g. \([\text{InL}_6]^{3+}(\text{Y}^–)_3\), \(L = \text{Me}_2\text{SO, Ph}_2\text{SO, (Me}_2\text{N})_2\text{CO, HCO(NMe}_2\text{), P(OMe}_3\text{), etc. Bulky ligands such as PPh}_3\) and AsPh}_3\) tend to give 1:4 adducts \([\text{InL}_4]^{3+}(\text{Y}^–)_3\). The same effect of ionic dissociation can be achieved in 1:3 complexes of the trihalides themselves by use of bidentate chelating ligands \((\text{B})\) such as en, bipy, or phen, e.g. \([\text{InB}_3]^{3+}(\text{X}^–)_3\) \((X = \text{Cl, Br, I, NCO, NCS, NCSe})\). \(\text{InX}_3\) complexes having 1:2 stoichiometry also have a variety of structures. Trigonal bipyramidal geometry with axial ligands is found for \(\text{InX}_3\text{L}_2\), where \(L = \text{MNe}_3, \text{PMe}_3, \text{PPh}_3, \text{Et}_2\text{O}, \text{etc. By contrast, the crystal structure of the 1:2 complex of InI}_3\) with \(\text{Me}_2\text{SO}\) shows that it is fully ionized as \([\text{cis-InI}_2(\text{OSMe}_2)_4]^+[\text{InI}_4]^-\), and fivefold coordination is avoided by a disproportionation into 6- and 4-coordinate species. Complexes having 1:1 stoichiometry are rare for \(\text{InX}_3\); \(\text{InCl}_3\) forms \([\text{InCl}_3(\text{OPCl}_3)]\), \([\text{InCl}_3(\text{OCMe}_2)]\) and \([\text{InCl}_3(\text{OCPh}_2)]\) and py forms a 1:1 (and a 1:3) adduct with \(\text{InI}_3\). Frequently, of course, a given donor–acceptor pair combines in more than one stoichiometric ratio.

The thermochemistry of the Group 13 trihalide complexes has been extensively studied\(^{(38,39)}\) and several stability sequences have been

established which can be interpreted in terms of the factors listed on p. 198. In addition, Ga and In differ from B and Al in having an underlying $d^{10}$ configuration which can, in principle, take part in $d_{\pi}-d_{\pi}$ back bonding with donors such as S (but not N or O); alternatively (or additionally), some of the trends can be interpreted in terms of the differing polarizabilities of B and Al, as compared to Ga and In, the former pair behaving as class-a or “hard” acceptors whereas Ga and In frequently behave as class-b or “soft” acceptors. Again, it should be emphasized that these categories tend to provide descriptions rather than explanations. Towards amines and ethers the acceptor strengths as measured by gas-phase enthalpies of formation decrease in the sequence $MC_3 > MBr_3 > MI_3$ for $M = Al$, Ga or In. Likewise, towards phosphines the acceptor strength decreases as $GaC_3 > GaBr_3 > GaI_3$. However, towards the “softer” sulfur donors $Me_2S$, Et$_2S$ and $C_4H_8S$, whilst $AlX_3$ retains the same sequence, the order for $GaX_3$ and $InX_3$ is reversed to read $MI_3 > MBr_3 > MCl_3$. A similar reversal is noted when the acceptor strengths of individual $AlX_3$ are compared with those of the corresponding $GaX_3$: towards N and O donors the sequence is invariably $AlX_3 > GaX_3$ but for S donors the relative acceptor strength is $GaX_3 > AlX_3$. These trends emphasize the variety of factors that contribute towards the strength of chemical bonds and indicate that there are no unique series of donor or acceptor strengths when the acceptor atom is varied, e.g.:

towards $MeCO_2Et$: $BCl_3 > AlCl_3 > GaCl_3 > InCl_3$

towards py: $AlPh_3 > GaPh_3 > BPh_3 \approx InPh_3$

towards py: $AlX_3 > BX_3 > GaX_3$ (X = Cl, Br)

towards $Me_2S$: $GaX_3 > AlX_3 > BX_3$ (X = Cl, Br)

Regularity is more apparent when the acceptor atom remains constant and the attached groups are varied; e.g., for all ligands so far studied the acceptor strength diminishes in the sequence $MX_3 > MPh_3 > MMMe_3$ (M = B, Al, Ga, In)

It has also been found that halide-ion donors (such as $X^-$ in $AlX_4^-$ and $GaX_4^-$) are more than twice as strong as any neutral donor such as X in $M_2X_6$, or N, P, O and S donors in $MX_3L$ (39)

Finally, the complexity of factors influencing the strength of such bonds can be gauged from the curious alternation of the gas-phase enthalpies of dissociation of the dimers $M_2X_6$ themselves; e.g. $\Delta H^{98}_{\text{dissoc}}$ for $Al_2C_6$, $Ga_2C_6$, and $In_2C_6$ are respectively 126.8, 93.9 and 121.5 kJ mol$^{-1}$ (40)

The corresponding entropies of dissociation $\Delta S^{98}$ are 152.3, 150.4 and 136.0 J mol$^{-1}$.

The trihalides of Tl are much less stable than those of the lighter Group 13 metals and are chemically quite distinct from them. $TlF_3$, mp 550$^\circ$ (decomp), is a white crystalline solid isomorphous with $\beta$-$BiF_3$ (p. 560); it does not form hydrates but hydrolyses rapidly to $Tl(OH)_3$ and HF. Nor does it give $TlF_4^-$ in aqueous solution, and the compounds $LiTlF_4$ and $NaTlF_4$ have structures related to fluorite, $CaF_2$ (p. 118): in $NaTlF_4$ the cations have very similar 8-coordinate radii (Na 116 pm, Tl 100 pm) and are disordered on the Ca sites (Ca 112 pm); in $LiTlF_4$, the smaller size of Li (~83 pm for eightfold coordination) favours a superlattice structure in which Li and Tl are ordered on the Ca sites.

$Na_3TlF_6$ has the cryolite structure (p. 234).

$TlCl_3$ and $TlBr_3$ are obtained from aqueous solution as the stable tetrahydrates and $TlCl_3.4H_2O$ can be dehydrated with $SOCl_2$ to give anhydrous $TlCl_3$, mp 155$^\circ$; it has the $YCl_3$-type structure which can be described as $NaCl$-type with two-thirds of the cations missing in an ordered manner.

$TlI_3$ is an intriguing compound which is isomorphous with $NH_4I_3$ and $CsI_3$ (p. 836); it therefore contains the linear $I_3^-$ ion† and is a compound of $Tl^{I}$ rather than $Tl^{III}$. It is obtained as black crystals by evaporating an equimolar solution of $TlI$ and $I_2$ in concentrated aqueous HI. The formulation $Tl^{I}(I_3^-)$ rather than $Tl^{III}(I^-)_3$ is consistent with the standard reduction potentials $E''(Tl^{III}/Tl^{I}) + 1.26 V$ and $E''(\frac{1}{2}I_2/I^-) + 0.54 V$.

---

† Note that this X-ray evidence by itself does not rule out the possibility that the compound is $[I^- - Tl^{III} - I^-]^+.1^-$.
which shows that uncomplexed $\text{Tl}^\text{III}$ is susceptible to rapid and complete reduction to $\text{Tl}^\text{I}$ by $\text{I}^-$ in acid solution. The same conclusion follows from a consideration of the I$_3^-$/I$^-\text{I}^-$ couple for which $E^\circ = +0.55$ V. Curiously, however, in the presence of an excess of $\text{I}^-$, the $\text{Tl}^\text{III}$ state is stabilized by complex formation

$$\text{Tl}^\text{II}I(s) + \text{I}^- \rightarrow [\text{Tl}^\text{III}I_4]^-$$

Moreover, solutions of $\text{TlH}_3$ in MeOH do not show the visible absorption spectrum of I$_3^-$ and, when shaken with aqueous Na$_2$CO$_3$, give a precipitate of $\text{Tl}_2\text{O}_3$, i.e.:

$$2\text{TlH}_3 + 6\text{OH}^- \rightarrow \text{Tl}_2\text{O}_3 + 6\text{I}^- + 3\text{H}_2\text{O}$$

This is due partly to the great insolubility of $\text{Tl}_2\text{O}_3$ ($2.5 \times 10^{-10}$ g l$^{-1}$ at $25^\circ$) and partly to the enhanced oxidizing power of iodine in alkaline solution as a result of the formation of hypoiodate:

$$\text{I}_3^- + 2\text{OH}^- \rightarrow \text{OI}^- + 2\text{I}^- + \text{H}_2\text{O}$$

Consistent with this, even KI$_3$ is rapidly decolorized in alkaline solution. The example is a salutary reminder of the influence of pH, solubility, and complex formation on the standard reduction potentials of many elements.

Numerous tetrahedral halogeno complexes $[\text{Tl}^\text{III}X_4]^-$ ($X = \text{Cl}, \text{Br}, \text{I}$) have been prepared by reaction of quaternary ammonium or arsonium halides on TlX$_3$ in nonaqueous solution, and octahedral complexes $[\text{Tl}^\text{III}X_6]^-$ ($X = \text{Cl}, \text{Br}$) are also well established. The binuclear complex $\text{Cs}_3[\text{Tl}^\text{II}I_2\text{Cl}_6]$ is an important structural type which features two TiCl$_6$ octahedra sharing a common face of 3 bridging Cl atoms (Fig. 7.9); the same binuclear complex structure is retained when $\text{Tl}^\text{III}$ is replaced by $\text{Tl}^\text{II}$, $\text{V}^\text{III}$, $\text{Cr}^\text{III}$ and $\text{Fe}^\text{III}$ and also in $\text{K}_3\text{W}_2\text{Cl}_9$ and $\text{Cs}_3\text{Bi}_2\text{I}_9$, etc.

**Lower halides of gallium, indium and thallium**

Like AlX (p. 233), GaF and InF are known as unstable gaseous species. The other mono-halides are more stable. GaX can be obtained as reactive sublimates by treating GaX$_3$ with

$$2\text{Ga} + 6\text{Cl}_2 \rightarrow \text{Ga}_2\text{Cl}_6$$

$$2\text{Ga} + 6\text{Br}_2 \rightarrow \text{Ga}_2\text{Br}_6$$

$$2\text{Ga} + 6\text{I}_2 \rightarrow \text{Ga}_2\text{I}_6$$

2Ga: stability increases with increasing size of the anion and GaI melts at 271°C. Stability is still further enhanced by coordination of the anion with, for example, AlX$_3$ to give $\text{Ga}[\text{Al}^\text{III}X_4]$. Likewise, the very stable “dihalides” $\text{Ga}[\text{Ga}^\text{III}X_4]$, Ga[GaBr$_4$], and Ga[GaI$_4$] can be prepared by heating equimolar amounts of GaX$_3$ and Ga, or more conveniently by halogenation of Ga with the stoichiometric amount of Hg$_2$X$_2$ or HgX$_2$. They form complexes of the type $[\text{Ga}^L_4]^-+[\text{Ga}^\text{III}X_4]^-$. Note, however, that the complexes with dioxan $[\text{Ga}_2\text{X}_4(\text{C}_4\text{H}_8\text{O}_2)_2]$, do in fact contain Ga$_2^{-}$ and a Ga–Ga bond, e.g. the chloro complex is a discrete molecule with Ga–Ga 240.6 pm (cf. 239.0 pm in Ga$_2\text{Cl}_6^{2-}$),

$$[\text{Ga}_2\text{X}_4(\text{C}_4\text{H}_8\text{O}_2)_2]$$

the coordination about each Ga atom is essentially tetrahedral and the compound surprisingly adopts an essentially eclipsed structure rather than the staggered structure of Ga$_2\text{Cl}_6^{2-}$. Likewise $[\text{Ga}_2\text{L}_4]$, where L is a wide range of organic ligands with N, P, O or S donor atoms, have been shown by vibration spectroscopy to have a Ga–Ga bond.

---

Indium monohalides, InX, can be prepared as red crystals either directly from the elements or by heating In metal with HgX\(_2\) at 320–350°. They have a TII-type structure (p. 242) with 
\[ \text{In}^{3+} \text{... In}^{3+} \text{... In}^{3+} \] rather than 6-fold coordination of In by X, leading to rather close In'...In' contacts of 362, 356 and 357 pm respectively for X = Cl, Br and I. \(^{43}\) Again, InI is the most stable, and mixed halides of the type In\(_3\)[Al\(_3\)Cl\(_4\)], In\(_3\)[Ga\(_3\)Cl\(_4\)] and Tl\(_3\)[In\(_3\)Cl\(_4\)] are known. Numerous intermediate halides have also been reported and structural assignments of varying degrees of reliability have been suggested, e.g. In\(_3\)[In\(_3\)Cl\(_4\)] for InX\(_2\) (Cl, Br, I); and In\(_3\)[In\(_3\)Cl\(_4\)] for In\(_2\)Cl\(_3\). In contrast to the chloride, In\(_2\)Br\(_3\) has the unexpected structure \([\text{In}^{3+}\text{Br}_6^{-2}]\). \(^{44}\) The compounds In\(_4\)X\(_7\) and In\(_5\)X\(_7\) (Cl, Br) and In\(_7\)Br\(_9\) are also known. In all of these halides the observed stoichiometry is achieved by varying the ratio of In' to In\(_2\) or In\(_3\), e.g. \([\text{In}^{3+}\text{Br}_6^{-2}]\) and \([\text{In}^{3+}\text{Br}_6^{-2}]\). \(^{45}\) Compounds containing In\(_2\) were unknown until 1976 when the \([\text{In}_2\text{X}_6^{-2}]\) dianions having an ethane-like structure were prepared: \(^{47}\)

\[
2\text{Bu}_4\text{NX} + \text{In}_2\text{X}_4 \rightarrow [\text{NBu}_4]_2[\text{X}_3\text{In}^{-} - \text{InX}_3]^{2-}
\]

\(X = \text{Cl, Br, I}\)

The analogous Ga compounds, e.g. [NEt\(_4\)]\(_2\)[Cl\(_3\)-Ga–GaCl\(_3\)], have been known for rather longer (1965). Oxidation of In\(_2\)X\(_2\)\(^2-\) with halogens Y\(_2\) yields the mononuclear mixed halide complexes InX\(_3\)Y\(^-\) and In\(_2\)X\(_2\)Y\(_2\)\(^-\) \((X \neq Y = \text{Cl, Br, I})\). \(^{48}\)

Thallium(I) is the stable oxidation state for the halides of this element (p. 226) and some physical properties are in Table 7.7. TIF is readily obtained by the action of aqueous HF on Tl\(_2\)CO\(_3\); it is very soluble in water (in contrast to the other TIX) and has a distorted NaCl structure in which there are 3 pairs of Tl–F distances at 259, 275 and 304 pm. TICl, TIBr and TII are all prepared by addition of the appropriate halide ion to acidified solutions of soluble Tl\(_3\) salts (e.g. perchlorate, sulfate, nitrate). TICl and TIBr have the CsCl structure (p. 80) as befits the large Tl\(_3\) cation and both salts (and TII) are photosensitive (like AgX). Yellow TII has a curious orthorhombic layer structure related to NaCl (Fig. 7.10), and this transforms at 175° or at 4.7 kbar to a metastable red cubic form with 8-iodine neighbours at 364 pm (CsCl type). This transformation is accompanied by 3% reduction in volume. Further application of pressure steadily reduces the volume and at pressures above about 160 kbar, when the volume has decreased by about 35%, the compound becomes a metallic conductor with a resistivity of the order of \(10^{-4}\) ohm cm at room temperature and a positive temperature coefficient. TICl and TIBr behave similarly. All three compounds are excellent insulators at normal pressures with negligible conductivity and an energy gap between the valence band and conduction band.

of about 3 eV (~300 kJ mol⁻¹), and the onset of metallic conduction is presumably due to the spreading and eventual overlap of the two bands as the atoms are forced closer together.⁴⁹

Several other lower halides of Tl are known: TlCl₂ and TlBr₂ are Tl[TlIIIIX₄], Tl₂Cl₃ and Tl₂Br₃ are Tl₂[TlIIIIX₆]. In addition there is Tl₃I₄, which is formed as an intermediate in the preparation of TlI₃ from TlII and I₂ (p. 239).

### 7.3.3 Oxides and hydroxides

The structural relations between the many crystalline forms of aluminium oxide and hydroxide are exceedingly complex but they are of exceptional scientific interest and immense technological importance. The principal structural types are listed in Table 7.8 and many intermediate and related structures are also known. Al₂O₃ occurs as the mineral corundum (α-Al₂O₃, d 4.0 g cm⁻³) and as emery, a granular form of corundum contaminated with iron oxide and silica. Because of its great hardness (Mohs 9), high mp (2045°C), involatility (10⁻⁶ atm at 1950°C), chemical inertness and good electrical insulating properties, it finds many applications in abrasives (including toothpaste), refractories, and ceramics, in addition to its major use in the electrolytic production of Al metal (p. 219). Larger crystals, when coloured with metal-ion impurities, are prized as gemstones, e.g. ruby (CrIII red), sapphire (FeII/III, Ti IV blue), oriental emerald (CrIII/VIII green), oriental amethyst (CrIII/Ti IV violet) and oriental topaz (FeIII, yellow). Many of these gems are also made industrially on a large scale by the fusion process first developed at the turn of the century by A. Verneuil. Pure α-Al₂O₃ is made industrially by igniting Al(OH)₃ or Al₂O(OH) at high temperatures (~1200°C); it is also formed by the combustion of Al and by calcination of various Al salts. It has a rhombohedral crystal structure comprising a hcp array of oxide ions with Al ordered on two-thirds of the octahedral interstices as shown in Fig. 7.11.⁴⁶ The same α-M₂O₃ structure is adopted by several other elements with small MIII (r 62-67 pm), e.g. Ga, Ti, V, Cr, Fe and Rh.⁵

---

⁵ On the Mohs scale diamond is 10 and quartz 7. An alternative measure is the Knoop hardness (kg mm⁻²) as measured with a 100-g load; typical values on this scale are diamond 7000, boron carbide 2750, corundum 2100, topaz 1340, quartz 820, hardened tool steel 740.

⁶ For somewhat larger cations (r 70-96 pm) the C-type rare-earth M₂O₃ structure (p. 1238) is adopted, e.g. for In.
The second modification of alumina is the less compact cubic $\gamma$-$\text{Al}_2\text{O}_3$ ($d$ 3.4 g cm$^{-3}$); it is formed by the low-temperature dehydration ($<450^\circ$) of gibbsite, $\gamma$-$\text{Al(OH)}_3$, or boehmite, $\gamma$-$\text{AlO(OH)}$. It has a defect spinel-type structure (p. 248) comprising a face-centred cubic (fcc) arrangement of 32 oxide ions and a random occupation of $21\frac{1}{3}$ of the 24 available cation sites (16 octahedral, 8 tetrahedral). This structure forms the basis of the so-called “activated aluminas” and progressive dehydration in the $\gamma$-series leads to open-structured materials of great value as catalysts, catalyst-supports, ion exchangers and chromatographic media. Calcination of $\gamma$-$\text{Al}_2\text{O}_3$ above 1000$^\circ$ converts it irreversibly to the more stable and compact $\alpha$-form ($\Delta H_{\text{trans}}$ = $-20$ kJ mol$^{-1}$). Yet another form of $\text{Al}_2\text{O}_3$ occurs as the protective surface layer on the metal: it has a defect NaCl-type structure with Al occupying two-thirds of the octahedral (Na) interstices in the fcc oxide lattice. Perhaps the most ingenious and sophisticated development in aluminium technology has been the recent production of $\text{Al}_2\text{O}_3$ fibres which can be fabricated into a variety of textile forms, blankets, papers, and boards. Some idea of the many possibilities of such high-temperature inert fabrics is indicated in the Panel on p. 244.

Diaspore, $\alpha$-$\text{AlO(OH)}$ occurs in some types of clay and bauxite; it is stable in the range 280–450$^\circ$ and can be made by hydrothermal treatment of boehmite, $\gamma$-$\text{AlO(OH)}$, in 0.4% aqueous NaOH at 380$^\circ$ and 500 atm. Crystalline boehmite is readily prepared by warming the amorphous, gelatinous white precipitate which first forms when aqueous NH$_3$ is added to cold solutions of Al salts. In $\alpha$-$\text{AlO(OH)}$ the O atoms are arranged in hcp; continuous chains of edge-shared octahedra are stacked in layers.
Fibrous Alumina and Zirconia

A new family of lightweight inorganic fibres made its commercial debut in 1974 when ICI announced the production of “Saffil”, fibrous Al₂O₃ and ZrO₂. On an initial scale of 100 tonnes pa, Du Pont also has a process for α-Al₂O₃ fibres and the current world production of fibrous Al₂O₃ is of the order of 1000 tonnes per annum. The price is about $60/kg (1986).

The fibres, which have no demonstrable toxic effects (cf. asbestos), have a diameter of ~3 μm (cf. human hair ~70 μm), and each fibre is extremely uniform along its length (2–5 cm). The fibres are microcrystalline (5–50 pm diam) and are both flexible and resilient with a high tensile strength. They have a soft, silky feel and can be made into rope, yarn, cloth, blankets, fibre mats, paper of various thickness, semi-rigid and rigid boards, and vacuum-formed objects of any required shape. The surface area of Saffil alumina is 100–150 m² g⁻¹ due to the presence of small pores 2–10 pm diameter between the microcrystals, and this enhances its properties as an insulator, filtration medium, and catalyst support. The fibres withstand extended heating to 1400°C (Al₂O₃) or 1600°C (ZrO₂) and are impervious to attack by hot concentrated alkalis and most hot acids except conc H₂SO₄, conc H₃PO₄ and aq HF. This unique combination of properties provides the basis for their use in high-temperature insulation, heat shields, thermal barriers, and expansion joints and seals. Fibrous alumina and zirconia are also valuable in thermocouple protection, electric-cable sheathing, and heating-element supports in addition to their use in the high-temperature filtration of corrosive liquids. Both oxides are stabilized by incorporation of small amounts of other inorganic oxides which inhibit disruptive transformation to other crystalline forms.

Alumina fibres can also be used to strengthen metals. Molten metals (e.g. Al, Mg, Pb) or their alloys are forced into moulds containing up to 70% by volume of α-Al₂O₃ fibre. For example, fibre-reinforced Al containing 55% fibre by volume is 4–6 times stiffer than unreinforced Al even up to 370°C and has 2–4 times the fatigue strength. Potential applications for which high structural stiffness, heat resistance, and low weight are required include helicopter housings, automotive and jet engines, aerospace structures, and lead-acid batteries. For example, fibre reinforced composites of Al or Mg could eventually replace much of the steel used in car bodies without decreasing safety, since the composite has the stiffness of steel but only one-third of its density.

In addition to the production of stabilized Al₂O₃ fibres there is also a huge production of melt-spun glassy fibres containing approximately equal proportions by weight of Al₂O₃ and SiO₂. This is used mainly for thermal insulation at temperatures up to 1400°C and current world production exceeds 20 000 tonnes per annum.

and are further interconnected by H bonds. The underlying hcp structure ensures that diaspore dehydrates directly to α-Al₂O₃ (corundum) which has the same basic hcp arrangement of O atoms. The structure is also adopted by several other α-MO(OH) (M = Ga, V, Mn and Fe); this contrasts with the structure of boehmite, γ-AlO(OH), which as a whole is not close-packed, though within each layer the O atoms are arranged in cubic close packing. Dehydration at temperatures up to 450°C proceeds via a succession of phases to the cubic γ-Al₂O₃ and the α (hexagonal) structure cannot be attained without much more reconstruction of the lattice at 1100–1200°C as noted above [and of γ-ScO(OH) and γ-FeO(OH)].

Bayerite, α-Al(OH)₃, does not occur in nature but can be made by rapid precipitation from alkaline solutions in the cold:

\[ 2[\text{Al(OH)}_3]^- \text{aq} + \text{CO}_2(\text{g}) \rightarrow 2\text{Al(OH)}_3 + \text{CO}_3^{2-}(\text{aq}) + \text{H}_2\text{O} \]

Gibbsite (or hydargillite), γ-Al(OH)₃, is a more stable form and can be prepared by slow precipitation from warm alkaline solutions or by digesting the α-form in aqueous sodium aluminate solution at 80°C. In both bayerite (α) and gibbsite (γ) there are layers of composition Al(OH)_₃ built up by the edge sharing of Al(OH)_₆ octahedra to give a pair of approximately close-packed OH layers with Al atoms in two-thirds of the octahedral interstices (Fig. 7.12a). The two crystalline modifications differ in the way this layer is stacked: it is approximately hcp in α-Al(OH)₃ but in the γ-form the OH groups on the under side of one layer rest directly above the OH groups of the layer below as shown in Fig. 7.12b. A third form of Al(OH)₃, nordstrandite, is obtained from the gelatinous
Oxides and hydroxides

97.3.3

Oxides and hydroxides 245

(a) Part of a layer of Al(OH)₃ (idealized); the heavy and light open circles represent OH groups above and below the plane of the Al atoms. In α-Al(OH)₃ the layers are stacked to give approximately hcp. (b) Structure of γ-Al(OH)₃ viewed in a direction parallel to the layers; the OH groups labelled C and D are stacked directly beneath A and B. The six OH groups A, B, C, D and B', D' (behind B and D), form a distorted H-bonded trigonal prism.

hydroxide by ageing it in the presence of a chelating agent such as ethylenediamine, ethylene glycol, or edta; this aligns the OH to give a stacking arrangement which is intermediate between those of the α- and γ-forms.

As expected from the foregoing structural discussion, gibbsite can be dehydrated to boehmite at 100° and to anhydrous γ-Al₂O₃ at 150°, but ignition above 800° is required to form α-Al₂O₃. Numerous recipes have been devised for preparing catalysts of differing reactivity and absorptive power, based on the partial dehydration and progressive reconstitution of the Al/O/OH system. In addition to pore size, surface area and general reactivity, the basic character of the surface diminishes (and its acidic character increases) in the following series as indicated by the pH of the isoelectric point:

\[(\text{amorph.} \rightarrow \gamma-\text{Al(OH)}_3 \rightarrow \alpha-\text{Al(OH)}_3 \rightarrow \gamma-\text{Al(OH)}_3 \rightarrow \gamma-\text{Al}_2\text{O}_3)\]

\[
\begin{align*}
\text{Al oxide} & \quad \text{boehmite} & \quad \text{bayerite} & \quad \text{gibbsite} & \quad \text{hydrate} \\
pH & : 9.45 & 9.45-9.40 & 9.20 & 8.00 \\
(\text{isoelec. pt.)} & & & & \\
\end{align*}
\]

The aqueous solution chemistry of Al and the other group 13 metals is rather complicated. The aquo ions are acidic with pKₐ ≈ 10⁻⁵, 10⁻³, 10⁻⁴ and 10⁻¹, respectively, for \([\text{M(H}_2\text{O)}_6]^{3+} \rightleftharpoons [\text{M(OH)(H}_2\text{O)}_5]^{2+} + \text{H}^+\) (M = Al, Ga, In, Tl). The solution chemistry of Al in particular has been extensively investigated because of its industrial importance in water treatment plants, its use in many toiletry formulations, its possible implication in both Alzheimer’s disease and the deleterious effects of acid rain, and the ubiquity of Al cooking utensils. For example, hydrated aluminium sulphate (10–30 g m⁻³) can be added to turbid water supplies at pH 6.5–7.5 to flocculate the colloids, some 3 million tonnes per annum being used worldwide for this application alone. Likewise kilotonne amounts of “Al(OH)₂Cl₂O₅” in concentrated (6M) aqueous solution are used in the manufacture of deodorants and antiperspirants.

The use of ²⁷Al nmr (see Panel) has been particularly valuable in characterizing the species present in aqueous solution of Al salts. These depend very much on both concentration and pH and include the mononuclear ions [Al(OH)₄]⁻, [Al₂H₂O₆]³⁺ and [Al(OH)(H₂O)₅]²⁺. This latter species can deprotonate further to [Al(OH)₂(H₂O)₄]⁺ and readily dimerizes via hydroxyl bridges to [(H₂O)₄Al(μ-OH)₂Al(H₂O)₄]⁺, i.e. [H₁₈Al₂O₁₀]⁺, which has also been found in several crystalline salts. Higher oligomers probably include appropriately hydrated forms of [Al₃(0H)₁₁]²⁻, [Al₁₀(OH)₁₅]³⁺ and [Al₈(OH)₂₂]²⁺. A particularly important species is the well-characterized tridecameric cation [Al₁₃O₄(OH)₂₄(H₂O)₁₂]⁺ which has the well-known Keggin structure (p. 1014),

---

27Al in Nuclear Magnetic Resonance Spectroscopy

Aluminium is a very convenient element for nmr spectroscopy because 27Al is 100% abundant and has a high nmr sensitivity, its receptivity being 0.206 when compared to 1H and 1170 when compared to 13C. It also has a high operating frequency (26.077 MHz when scaled to 100 MHz for 1H) and a wide range of chemical shifts, δ (~300 ppm). The nuclear spin quantum number is 5/2 and the magnetogyric ratio γ is 6.9763 rad s⁻¹T⁻¹. The only disadvantage is the presence of a nuclear quadrupole moment (Q = 0.149 × 10⁻²⁸ m²) which leads to substantial line broadening for many species. The narrowest lines (ω₁/2 ~ 2 Hz) are obtained for highly symmetrical species such as [Al(H₂O)₆]³⁺ and [Al(OH)₄]⁻, but line widths of 1000 Hz or more are not uncommon and the use of special curve-analysis techniques is needed to extract the required parameters.

As expected, chemical shifts depend on coordination number (CN) and also on the nature of the atoms directly bonded to Al. Organometallic species, i.e. those with Al-C bonds, resonate at low field (high frequency): those with CN 3 have δ in the range 275–220 ppm, those with CN 4 have δ 220–140 ppm and those with CN 5 have δ 140–110 ppm. Tetrahalogenoaluminates, AlX₄⁻, AlX₄Y₄⁻, and 4-coordinate ligand adducts in general have δ in the range 120–50 ppm with the curious exception of Al₄⁶⁻, which shows a resonance at a higher field than for any other Al species so far, δ being –26.7 ppm. Five-coordinate adducts have δ in the range 65–25 ppm and octahedral species have δ in the range 40 to –25 ppm. Typical parameters for some of the species mentioned in the main text are:

These values show some dependence on concentration, pH and temperature. Note also the much smaller linewidth for the central, symmetrically 4-coordinated Al atom of the tridecameric Al₁₃ species when compared with that of the twelve less symmetrically coordinated octahedral Al atoms, and the possibility of extracting a reasonably precise value of δ for this latter resonance which has a linewidth of some 8000 Hz.

Solid-state 27Al nmr spectroscopy has been much used in recent years to study the composition and structure of aluminosilicates (pp. 351–9) and other crystalline or amorphous Al compounds. The technique of magic angle spinning (MAS) must be used in such cases.(55)

[AlO₄{Al(OH)₂(H₂O)}₁₂]⁷⁺, in which the central tetrahedral AlO₄ group is surrounded by corner-and edge-shared AlO₆ octahedra. The ion, which is almost spherical, has been further characterized by an X-ray diffraction study of crystalline Na[Al₁₃O₄(OH)₂₄(H₂O)₁₂](SO₄)₄.13H₂O.

The binary oxides and hydroxides of Ga, In and Tl have been much less extensively studied. The Ga system is somewhat similar to the Al system and a diagram summarizing the transformations in the systems is in Fig. 7.13. In general the α- and γ-series have the same structure as their Al counterparts. β-Ga₂O₃ is the most stable crystalline modification (mp 1740°C); it has a unique crystal structure with the oxide ions in distorted ccp and Ga³⁺ in distorted tetrahedral and octahedral sites. The structure appears to owe its stability to these distortions and, because of the lower coordination of half the Ga³⁺, the density is ~10% less than for the α-(corundum-type) form. This preference of Ga³⁺ for fourfold coordination despite the fact that it is larger than Al³⁺ may again indicate the polarizing influence of the d¹⁰ core; a similar tetrahedral site preference is observed for Fe³⁺.

In₂O₃ has the C-type M₂O₃ structure (p. 1238) and InO(OH) (prepared hydrothermally from In(OH)₃ at 250–400°C and 100–1500 atm) has a deformed rutile structure (p. 961) rather than the layer lattice structure of AlO(OH) and GaO(OH). Crystalline In(OH)₃ is best prepared by addition of NH₃ to aqueous InCl₃ at 100°C and ageing the precipitate for a few hours at this temperature; it has the simple ReO₃-type structure distorted somewhat by multiple H bonds.(26)

Thallium is notoriously different. Tl₂O₃ forms as black platelets when Tl₂CO₃ is heated in N₂ at 700°C (mp 596°C, d 10.36 g cm⁻³); it is hygroscopic and gives TlOH with water. Tl₃O₃ is brown-black (mp 716°C, d 10.04 g cm⁻³) and can be made by oxidation of aqueous TlNO₃ with Cl₂ or Br₂ followed by precipitation.

Figure 7.13 Chart illustrating transformation relationships among the forms of gallium oxide and its hydrates. Conversion (wet) of the phase designated as $\text{Ga}_2_\text{A}_1_0_3$ to $\beta$-$\text{Ga}_2_\text{O}_3$ occurs only where $x < 1.3$; where $x > 1.3$ an $\alpha$-$\text{Al}_2_\text{O}_3$ structure forms.

of the hydrated oxide $\text{Ti}_2\text{O}_3.1\frac{1}{2}\text{H}_2\text{O}$ and desiccation; single crystals have a very low electrical resistivity (e.g. $7 \times 10^{-5}$ ohm cm at room temperature). A mixed oxide $\text{Ti}_4\text{O}_3$ (black) is known and also a violet peroxide $\text{Ti}_2\text{O}_2$ made by electrolysis of an aqueous solution of $\text{Ti}_2\text{SO}_4$ and oxalic acid between Pt electrodes. $\text{TiOH}$ has been mentioned previously (p. 226).

7.3.4 Ternary and more complex oxide phases

This section considers a number of extremely important structure types in which Al combines with one or more other metals to form a mixed oxide phase. The most significant of these from both a theoretical and an industrial viewpoint are spinel ($\text{MgAl}_2\text{O}_4$) and related compounds, Na-$\beta$-alumina ($\text{NaAl}_1\text{O}_1\text{7}$) and related phases, and tricalcium aluminate ($\text{Ca}_3\text{Al}_2\text{O}_6$) which is a major constituent of Portland cement. Each of these compounds raises points of fundamental importance in solid-state chemistry and each possesses properties of crucial significance to modern technology. For aluminosilicates see p. 351 and for aluminophosphates see p. 526.

Spinels and related compounds

Spinels form a large class of compounds whose crystal structure is related to that of the mineral spinel itself, $\text{MgAl}_2\text{O}_4$. The general formula is $\text{AB}_2\text{X}_4$ and the unit cell contains 32 oxygen atoms in almost perfect ccp array, i.e. $\text{A}_8\text{B}_16\text{O}_{32}$. In the normal spinel structure (Fig. 7.14) 8 metal atoms (A) occupy tetrahedral sites and 16 metal atoms (B) occupy octahedral sites, and the structure can be regarded as being built up of alternating cubelets of ZnS-type and NaCl-type structures. The two factors that determine which combinations of atoms can form a spinel-type structure are (a) the total formal cation charge, and (b) the relative sizes of the 2 cations with respect both to each other and to the

Figure 7.14 Spinel structure $\text{AB}_2\text{O}_4$. The structure can be thought of as 8 octants of alternating $\text{AO}_4$ tetrahedra and $\text{B}_4\text{O}_4$ cubes as shown in the left-hand diagram; the 40 have the same orientation in all 8 octants and so build up into a fcc lattice of 32 ions which coordinate A tetrahedrally and B octahedrally. The 4 A octants contain 4 A ions and the 4 B octants contain 16 B ions. The unit cell is completed by an encompassing fcc of A ions (●) as shown in the right-hand diagram; this is shared with adjacent unit cells and comprises the remaining 4 A ions in the complete unit cell $\text{A}_8\text{B}_{16}\text{O}_{32}$. The location of two of the $\text{B}_4\text{O}_4$ cubes is shown for orientation.

anion. For oxides of formula $\text{AB}_2\text{O}_4$ charge balance can be achieved by three combinations of cation oxidation state: $\text{A}^{II}\text{B}^{III}\text{O}_4$, $\text{A}^{IV}\text{B}^{II}\text{O}_4$, and $\text{A}^{VI}\text{B}^{II}\text{O}_4$. The first combination is the most numerous and examples are known with

$$\text{A}^{II} = \text{Mg}, (\text{Ca}); \text{Cr}, \text{Mn}, \text{Fe}, \text{Co}, \text{Ni}, \text{Cu}; \text{Zn}, \text{Cd}, (\text{Hg}); \text{Sn}$$

$$\text{B}^{III} = \text{Al}, \text{Ga}, \text{In}; \text{Ti}, \text{V}, \text{Cr}, \text{Mn}, \text{Fe}, \text{Co}, \text{Ni}; \text{Rh}$$

The anion can be $\text{O}$, $\text{S}$, $\text{Se}$ or $\text{Te}$. Most of the $\text{A}^{II}$ cations have radii (6-coordinate) in the range 65–95 pm and larger cations such as $\text{Ca}^{II}$ (100 pm) and $\text{Hg}^{II}$ (102 pm) do not form oxide spinels. The radii of $\text{B}^{III}$ fall predominantly in the range 60–70 pm though $\text{Al}^{III}$ (53 pm) is smaller, and $\text{In}^{III}$ (80 pm) normally forms sulfide spinels only.

Examples of spinels with other combinations of oxidation state are:

$$\text{A}^{IV}\text{B}_2\text{X}_4^{-II} : \text{TiMg}_2\text{O}_4, \text{PbFe}_2\text{O}_4, \text{SnCu}_2\text{S}_4$$

$$\text{A}^{VI}\text{B}_2\text{X}_4^{-II} : \text{MoAg}_2\text{O}_4, \text{MoNa}_2\text{O}_4, \text{WNa}_2\text{O}_4$$

$$\text{A}^{III}\text{B}_2\text{X}_4^{-I} : \text{NiLi}_2\text{F}_4, \text{ZnK}_2(\text{CN})_4, \text{CdK}_2(\text{CN})_4$$

Many of the spinel-type compounds mentioned above do not have the normal structure in which A are in tetrahedral sites (t) and B are in octahedral sites (o); instead they adopt the inverse spinel structure in which half the B cations occupy the tetrahedral sites whilst the other half of the B cations and all the A cations are distributed on the octahedral sites, i.e. $(\text{B})_2[\text{AB}]_8\text{O}_4$. The occupancy of the octahedral sites may be random or ordered. Several factors influence whether a given spinel will adopt the normal or inverse structure, including (a) the relative sizes of A and B, (b) the Madelung constants for the normal and inverse structures, (c) ligand-field stabilization energies (p. 1131) of cations on tetrahedral and octahedral sites, and (d) polarization or covalency effects.\(^{56}\)

Thus, if size alone were important it might be expected that the smaller cation would occupy the site of lower coordination number, i.e. $\text{Al}^{III}[\text{MgAl}]_2\text{O}_4$; however, in spinel itself this is outweighed by the greater lattice energy achieved by having the cation of higher charge, $(\text{Al}^{III})$ on the site of higher coordination and
the normal structure is adopted: \((\text{Mg})_2[\text{Al}_2]_\text{O}_4\). An additional factor must be considered in a spinel such as \(\text{NiAl}_2\text{O}_4\) since the crystal field stabilization energy of \(\text{Ni}^{\text{II}}\) is greater in octahedral than tetrahedral coordination; this redresses the balance, making the normal and inverse structures almost equal in energy and there is almost complete randomization of all the cations on all the available sites: \((\text{Al}_{0.75}\text{Ni}_{0.25})_2[\text{Ni}_{0.75}\text{Al}_{1.25}]_\text{O}_4\).

Inverse and disordered spinels are said to have a defect structure because all crystallographically identical sites within the unit cell are not occupied by the same cation. A related type of defect structure occurs in valency disordered spinels where, for example, the divalent \(\text{A}^{\text{II}}\) cations in \(\text{AB}_2\text{O}_4\) are replaced by equal numbers of \(\text{M}^{\text{IV}}\) and \(\text{M}^{\text{III}}\) of appropriate size. Thus, in spinel itself, which can be written \(\text{Mg}_8\text{Al}_{16}\text{O}_{32}\), the 8\(\text{Mg}^{\text{II}}\) (72 pm) can be replaced by 4\(\text{Li}^{\text{I}}\) (76 pm) and 4\(\text{Al}^{\text{III}}\) (53 pm) to give \(\text{Li}_4\text{-Al}_{20}\text{O}_{32}\), i.e. \(\text{LiAl}_4\text{O}_8\). This has a defect spinel structure in which two-fifths of the \(\text{Al}\) occupy all the tetrahedral sites: \((\text{Al}^{\text{III}})_2[\text{Li}^{\text{I}}\text{Al}^{\text{III}}]_5\text{O}_8\). Other compounds having this cation-disordered spinel structure are \(\text{LiGa}_5\text{O}_8\) and \(\text{LiFe}_5\text{O}_8\). Disordering on the tetrahedral sites occurs in \(\text{CuAl}_3\text{S}_8\), \(\text{CuIn}_3\text{S}_8\), \(\text{AgAl}_3\text{S}_8\) and \(\text{AgIn}_3\text{S}_8\), i.e. \((\text{Cu}^{\text{I}}\text{Al}^{\text{III}})_2[\text{Al}^{\text{IV}}]_5\text{O}_8\), etc. Valency disordering can also be achieved by replacing \(\text{A}^{\text{II}}\) completely by \(\text{M}^{\text{IV}}\), thus necessitating replacement of half the \(\text{B}^{\text{III}}\) by \(\text{M}^{\text{IV}}\), e.g. \((\text{Li}^{\text{I}})_3[\text{Al}^{\text{III}}\text{Ti}^{\text{IV}}]_3\text{O}_4\). Even more extensive substitution of cations has been achieved in many cubic spinel phases, e.g. \(\text{Li}_2\text{Zn}_8\text{Al}_5\text{Ge}_9\text{O}_{36}\) (and the \(\text{Ga}^{\text{III}}\) and \(\text{Fe}^{\text{III}}\) analogues), and the possibilities are virtually limitless.

The sensitive dependence of the electrical and magnetic properties of spinel-type compounds on composition, temperature, and detailed cation arrangement has proved a powerful incentive for the extensive study of these compounds in connection with the solid-state electronics industry. Perhaps the best-known examples are the ferrites, including the extraordinary compound magnetite \(\text{Fe}_3\text{O}_4\) (p. 1089) which has an inverse spinel structure \((\text{Fe}^{\text{III}})_3[\text{Fe}^{\text{II}}\text{Fe}^{\text{III}}]_3\text{O}_4\).

It will also be recalled that \(\gamma\)-\(\text{Al}_2\text{O}_3\) (p. 243) has a defect spinel structure in which not all of the cation sites are occupied, i.e. \(\text{Al}^{\text{III}}_{21/3}\square_{2/3}\text{O}_{32}\): the relation to spinel \((\text{Mg}^{\text{III}}\text{Al}^{\text{III}}\text{O}_{32})\) is obvious, the 8\(\text{Mg}^{\text{II}}\) having been replaced by the isoelectronically equivalent 5\(\text{Al}^{\text{III}}\). This explains why \(\text{MgAl}_2\text{O}_4\) can form a complete range of solid solutions with \(\gamma\)-\(\text{Al}_2\text{O}_3\): the oxygen builds on to the complete fcc oxide ion lattice and the \(\text{Al}^{\text{III}}\) gradually replaces \(\text{Mg}^{\text{II}}\), electrical neutrality being achieved simply by leaving 1 cation site vacant for each 3\(\text{Mg}^{\text{II}}\) replaced by 2\(\text{Al}^{\text{III}}\).

**Sodium-β-alumina and related phases**

Sodium-β-alumina has assumed tremendous importance as a solid-state electrolyte since its very high electrical conductivity was discovered at the Ford Motor Company by J. T. Kummer and N. Weber in 1967. The compound, which has the idealized formula \(\text{NaAl}_{11}\text{O}_{17}(\text{Na}_2\text{O}\cdot 11\text{Al}_2\text{O}_3)\) was originally thought to be a form of \(\text{Al}_2\text{O}_3\) and hence called β-alumina (1916); the presence of Na, which was at first either undetected or ignored, is now known to be essential for stability. X-ray analysis shows that the structure is closely related to that of spinel, no fewer than 50 of the 58 atoms in the unit cell being arranged exactly as in spinel. The large Na atoms are situated exclusively in loosely packed planes together with an equal number of O atoms as shown in Fig. 7.15; these planes are 1123 pm apart, being separated by the “spinel blocks”. The close-packed oxygen layers above and below the Na planes are mirror images of each other 476 pm apart and they are bound together not only by the Na atoms but by an equal number of Al–O–Al bonds. There are several other sites in the mirror plane which can physically accommodate Na and this permits rapid two-dimensional diffusion of Na within the basal

---

Figure 7.15 Crystal structure of Na-\(\beta\)-alumina (see text). This section, which is a plane parallel to the \(c\)-axis, does not show the closest Na–Na distance.

plane; it also explains the very low resistivity of the order of 30 ohm cm. The structure can also accommodate supernumerary Na ions, and the compound, even in the form of single crystals, is massively defective, having typically 20–30% more Na than indicated by the idealized formula; this is probably compensated by additional Al vacancies in the “spinel blocks” adjacent to the mirror planes, e.g. Na\(_{2.58}\)Al\(_{2.18}\)O\(_{3.4}\).

Sodium-\(\beta\)-alumina can be prepared by heating Na\(_2\)CO\(_3\) (or NaNO\(_3\) or NaOH) with any modification of Al\(_2\)O\(_3\) or its hydrates to \(\sim 1500^\circ\) in a Pt vessel suitably sealed to avoid loss of Na\(_2\)O (as Na\(_2\)O\(_2\)). In the presence of NaF or AlF\(_3\) a temperature of 1000\(^\circ\) suffices. Na-\(\beta\)-alumina melts at \(\sim 2000^\circ\) (probably incongruently) and has \(d\) 3.25 g cm\(^{-3}\). The Na can be replaced by Li, K, Rb, Cu\(^I\), Ag\(^I\), Ga\(^I\), In\(^I\) or Ti\(^I\) by heating with a suitable molten salt, and Ag\(^I\) can be replaced by NO\(^+\) by treatment with molten NOCl/AlCl\(_3\). The ammonium compound is also known and H\(_2\)O–\(\beta\)-alumina can be prepared by reduction of the Ag compound. Similarly, Al\(^{III}\) can be replaced by Ga\(^{III}\) or Fe\(^{III}\) in the preparation, leading to compounds of (idealized) formulae Na\(_2\)O.11Ga\(_2\)O\(_3\), Na\(_2\)O.11Fe\(_2\)O\(_3\), K\(_2\)O.11Fe\(_2\)O\(_3\), etc. Altervalent substitution is also possible, e.g. in Na-\(\beta''\)-alumina, Na\(_{1.67}\)M\(_{0.67}\)Al\(_{10.33}\)O\(_{17}\) and the excess Na charge is compensated for by substituting the divalent or univalent cation into the lattice sites normally occupied by Al.\(^{58}\)

Apart from the intriguing structural implications of these fast-ion solid-state conductors, Na-\(\beta\)-alumina and related phases have been extensively used as permeable membranes in the Na/S battery system (p. 678): this requires an air-stable membrane that is readily permeable to Na ions but not to Na atoms or S, that is non-reactive with molten Na and S, and that is not an electronic conductor. Not surprisingly, few compounds have been found to compete with Na-\(\beta\)-alumina in this field, although Na-\(\beta''\)-alumina has the remarkable additional property of enabling the rapid diffusion of a large proportion of cations in the periodic table (whereas Na-\(\beta\)-alumina itself is restricted mainly to univalent cations). Indeed, the \(\beta''\)-aluminas are the first family of high conductivity solid electrolytes which permit fast ion transport of multivalent cations in solids.\(^{58}\)

Unrelated to the \(\beta\)- and \(\beta''\)-aluminas are a group of white, hygroscopic sodium-rich aluminates which have recently been prepared by heating Na\(_2\)O and Al\(_2\)O\(_3\) in appropriate stoichiometric ratios at 700\(^\circ\)C for 18–24 hours.\(^{59}\) Na\(_5\)Al\(_4\)O\(_4\), which is isostructural with Na\(_3\)FeO\(_4\), contains isolated [AlO\(_4\)] tetrahedra with Al–O, 176–179 pm. Na\(_7\)Al\(_3\)O\(_8\) features a novel ring structure made up of six AlO\(_4\) tetrahedra sharing corners to form a non-planar 12-membered ring which is then joined by pairs of oxygen atom bridges to adjacent rings, thus generating an infinite chain of alternating 12- and 8-membered rings with Al–O\(_\mu\) 175–179 pm and Al–O, 173–4 pm. Finally, Na\(_{17}\)Al\(_5\)O\(_{16}\) has discrete chains composed of five AlO\(_4\) tetrahedra sharing corners with almost linear angles (160\(^\circ\) and 173\(^\circ\)) at the bridging O atoms and with

the various Al–O distances again falling in the range 170–180 pm. Note that the unusual formula Na\textsubscript{17}Al\textsubscript{5}O\textsubscript{16} (i.e. Na\textsubscript{3.4}Al\textsubscript{3.2}O\textsubscript{12}) is nearly the same as Na\textsubscript{3}AlO\textsubscript{3} which would have been the stoichiometry if the chains of AlO\textsubscript{4} tetrahedra had been infinite.

**Tricalcium aluminate, Ca\textsubscript{3}Al\textsubscript{2}O\textsubscript{6}**

Tricalcium aluminate is an important component of Portland cement yet, despite numerous attempts dating back over the preceding 50 y, its structure remained unsolved until 1975.\textsuperscript{60} The basic unit is now known to be a 12-membered ring of 6 fused [AlO\textsubscript{4}] tetrahedra [Al\textsubscript{6}O\textsubscript{18}]{\textsuperscript{18–}} as shown in Fig. 7.16; there are 8 such rings per unit cell surrounding holes of radius 147 pm, and the rings are held together by Ca ions in distorted sixfold coordination to give the structural formula Ca\textsubscript{9}Al\textsubscript{6}O\textsubscript{18}. The rather short Ca–O distance (226 pm) and the observed compression of the [CaO\textsubscript{6}] octahedra may indicate some strain and this, together with the large holes in the lattice, facilitate the rapid reaction with water. The products of hydration depend sensitively on the temperature. Above 21° Ca\textsubscript{3}Al\textsubscript{2}O\textsubscript{6} gives the hexahydrate Ca\textsubscript{3}Al\textsubscript{2}O\textsubscript{6}.6H\textsubscript{2}O, but below this temperature hydrated di- and tetra-calcium aluminates are formed of empirical composition 2CaO.Al\textsubscript{2}O\textsubscript{3}.5–9H\textsubscript{2}O and 4CaO.Al\textsubscript{2}O\textsubscript{3}.12–14H\textsubscript{2}O. This is of great importance in cement technology (see Panel) since, in the absence of a retarder, cement reacts rapidly with water giving a sharp rise in temperature and a "flash set" during which the various calcium aluminate hydrates precipitate and congeal into an unmanageable mass. This can be avoided by grinding in 2–5% of gypsum (CaSO\textsubscript{4}.2H\textsubscript{2}O) with the cement clinker; this reacts rapidly with dissolved aluminates in the presence of Ca(OH)\textsubscript{2} to give the calcium sulfatoaluminate, 3CaO.Al\textsubscript{2}O\textsubscript{3}.3CaSO\textsubscript{4}.31H\textsubscript{2}O, which is much less soluble than the hydrated calcium aluminates and therefore preferentially precipitates and prevents the premature congealing.

Another important calcium aluminate system occurs in high-alumina cement (ciment fondu). This is not a Portland cement but is made by fusing limestone and bauxite with small amounts of SiO\textsubscript{2} and TiO\textsubscript{2} in an open-hearth furnace at 1425–1500°; rotary kilns with tap-holes for the molten cement can also be used. Typical analytical compositions for a high-alumina cement are ~40% each of Al\textsubscript{2}O\textsubscript{3} and CaO and about 10% each of Fe\textsubscript{2}O\textsubscript{3} and SiO\textsubscript{2}; the most important compounds in the cement are CaAl\textsubscript{2}O\textsubscript{4}, Ca\textsubscript{2}Al\textsubscript{2}SiO\textsubscript{7} and Ca\textsubscript{6}Al\textsubscript{8}FeSiO\textsubscript{21}. Setting and hardening of high-alumina cement are probably due to the formation of calcium aluminate gels such as CaO.Al\textsubscript{2}O\textsubscript{3}.10H\textsubscript{2}O, and the more basic 2CaO.Al\textsubscript{2}O\textsubscript{3}.8H\textsubscript{2}O, 3CaO.Al\textsubscript{2}O\textsubscript{3}.6H\textsubscript{2}O and 4CaO.Al\textsubscript{2}O\textsubscript{3}.13H\textsubscript{2}O, though these empirical formulae give no indication of the structural units involved. The most notable property of high-alumina cement is that it develops very high strength at a very early stage (within 1 day). Long exposure to warm, moist conditions may lead to failure but resistance to corrosion by sea water and sulfate brines, or by weak mineral acids, is outstanding. It has also been much used as a refractory cement to withstand temperatures up to 1500°.

---

Portland Cement\(^{61}\)

The name “Portland cement” was first used by J. Aspdin in a patent (1824) because, when mixed with water and sand, the powder hardened into a block that resembled the natural limestone quarried in the Isle of Portland, England. The two crucial discoveries which led to the production of strong, durable, hydraulic cement that did not disintegrate in water, were made in the eighteenth and nineteenth centuries. In 1756 John Smeaton, carrying out experiments in connection with building the Eddystone Lighthouse (UK), recognized the importance of using limes which contained admixed clays or shales (i.e. aluminosilicates), and by the early 1800s it was realized that firing must be carried out at sintering temperatures in order to produce a clinker now known to contain calcium silicates and aluminates. The first major engineering work to use Portland cement was in the tunnel constructed beneath the Thames in 1828. The first truly high-temperature cement (1450–1600°C) was made in 1854, and the technology was revolutionized in 1899 by the introduction of rotary kilns.

The important compounds in Portland cement are dicalcium silicate \((\text{Ca}_2\text{SiO}_4)\) 26\%, tricalcium silicate \((\text{Ca}_3\text{SiO}_5)\) 51\%, tricalcium aluminate \((\text{Ca}_3\text{Al}_2\text{O}_6)\) 11\% and the tetracalcium species \(\text{Ca}_4\text{Al}_2\text{Fe}_{10}\text{O}_{10}\) (1\%). The principal constituent of moistened cement paste is a tobermorite gel which can be represented schematically by the following idealized equations:

\[
\begin{align*}
2\text{Ca}_2\text{SiO}_4 + 4\text{H}_2\text{O} &\rightarrow 3\text{CaO}.2\text{SiO}_2.3\text{H}_2\text{O} + \text{Ca(OH)}_2 \\
2\text{Ca}_3\text{SiO}_5 + 6\text{H}_2\text{O} &\rightarrow 3\text{CaO}.2\text{SiO}_2.3\text{H}_2\text{O} + 3\text{Ca(OH)}_2
\end{align*}
\]

The adhesion of the tobermorite particles to each other and to the embedded aggregates is responsible for the strength of the cement which is due, ultimately, to the formation of \(-\text{Si-O-Si}\) bonds.

Portland cement is made by heating a mixture of limestone (or chalk, shells, etc.) with aluminosilicates (derived from sand, shales, and clays) in carefully controlled amounts so as to give the approximate composition \(\text{CaO - 70\%}, \text{SiO}_2 - 20\%, \text{Al}_2\text{O}_3 - 5\%, \text{Fe}_2\text{O}_3 - 3\%.\) The presence of \(\text{Na}_2\text{O}, \text{K}_2\text{O}, \text{MgO}\) and \(\text{P}_2\text{O}_5\) are detrimental and must be limited.

The raw materials are ground to pass 200-mesh sieves and then heated in a rotary kiln to \(-1500^\circ\) to give a sintered clinker; this is reground to 325-mesh and mixed with 2–5\% of gypsum. An average-sized kiln can produce 1000–3000 tonnes of cement per day and the world's largest plants can produce up to 8000 tonnes per day. The vast scale of the industry can be gauged from the US production figures in the table below. Price (1990) was \$45–55 per tonne for bulk supplies. In the same year China emerged as the world’s largest cement producer (200 million tonnes per annum). Total world production continues to grow dramatically, from 590 Mtpa in 1970 and 881 Mtpa in 1980 to nearly 1200 Mtpa in 1990, of which Europe (including the European parts of the former Soviet Union) accounted for some 40\%.

7.3.5 Other inorganic compounds

Chalcogenides

At normal temperatures the only stable chalcogenides of A1 are \(\text{Al}_2\text{S}_3\) (white), \(\text{Al}_2\text{Se}_3\) (grey) and \(\text{Al}_2\text{Te}_3\) (dark grey). They can be prepared by direct reaction of the elements at \(\sim1000^\circ\) and all hydrolyse rapidly and completely in aqueous solution to give \(\text{Al(OH)}_3\) and \(\text{H}_2\text{X}\) (X = S, Se, Te). The small size of A1 relative to the chalcogens dictates tetrahedral coordination and the various polymorphs are related to wurtzite (hexagonal \(\text{ZnS}\), p. 1210), two-thirds of the available metal sites being occupied in either an ordered (\(\alpha\)) or a random (\(\beta\)) fashion. \(\text{Al}_2\text{S}_3\) also has a \(\gamma\)-form related to \(\gamma\)-\(\text{Al}_2\text{O}_3\) (p. 243), and very recently a novel high-temperature hexagonal modification of \(\text{Al}_2\text{S}_3\) containing 5-coordinate A1 has been obtained by annealing \(\alpha\)-\(\text{Al}_2\text{S}_3\) at \(550^\circ\text{C}\);\(^{62}\) in this new form half the A1 atoms are tetrahedrally coordinated (\(\text{Al-S} 223–227 \text{pm}\)) whereas the other half are in trigonal bipyramidal coordination with \(\text{Al-S}_\text{eq} 227–232 \text{pm}\) and \(\text{Al-S}_\text{ax} 250–252 \text{pm}\).

The chalcogenides of Ga, In and Tl are much more numerous and at least a dozen different structure types have been established by X-ray

crystallography.\textsuperscript{(63)} The compounds have been extensively studied not only because of their intriguing stoichiometries, but also because many of them are semiconductors, semi-metals, photoconductors or light emitters, and Tl\textsubscript{5}Te\textsubscript{3} has been found to be a superconductor at low temperatures. (See p. 1182 for high-temperature superconductors, including Tl\textsubscript{2}Ca\textsubscript{2}Ba\textsubscript{2}Cu\textsubscript{3}O\textsubscript{10+x}, which has one of the highest known superconducting transition temperatures, $T_c = 125$ K.) The chalcogenides, as expected from their position in the periodic table, are far from ionic, but formal oxidation states remain a useful device for electron counting and for checking the overall charge balance. Well-established compounds are summarized in Table 7.9. The following points are noteworthy. The hexagonal $\alpha$- and $\beta$-forms of Ga\textsubscript{2}S\textsubscript{3} are isostructural with the Al analogues and an additional form, $\gamma$-Ga\textsubscript{2}S\textsubscript{3}, adopts the related defect sphalerite structure derived from cubic ZnS (zinc blende, p. 1210). The same structure is found for Ga\textsubscript{2}Se\textsubscript{3} and Ga\textsubscript{2}Te\textsubscript{3} but for the larger In\textsuperscript{III} atom octahedral coordination also becomes possible. The corresponding Tl\textsuperscript{III} sesquichalcogenides Tl\textsubscript{2}X\textsubscript{3} are either

[Tl\textsubscript{2}S\textsubscript{3} known]

Tl\textsubscript{2}S\textsubscript{2} Tl\textsuperscript{I} polysulfide

Tl\textsubscript{2}S\textsubscript{3} (red and black forms) Tl\textsuperscript{I} polysulfide

Tl\textsubscript{2}S\textsubscript{8} Tl\textsuperscript{I} polysulfide

non-existent or of dubious authenticity, perhaps because of the ready reduction to Tl⁺ (see TlI₃, p. 239).

GaS (yellow, mp 970°) has a hexagonal layer structure with Ga–Ga bonds (248 pm); each Ga is coordinated by 3S and 1Ga, and the sequence of layers along the c-axis is...SGaGaS,SGaGaS...; the compound can therefore be considered as an example of Ga⁺. The structures of GaSe, GaTe, red InS and InSe are similar. By contrast, InTe, TlS (black) and TlSe (black, metallic) have a structure which can be formalized as M'[M‴X₂]; each Tl‴ is tetrahedrally coordinated by 4 Se at 268 pm and the tetrahedra are linked into infinite chains by edge sharing along the c-axis (see structure), whereas each Tl⁺ lies between these chains and is surrounded by a distorted cube of 8 Se at 342 pm. This explains the marked anisotropy of properties, especially the metallic conductivity in the (001) plane and the semiconductivity along the c-axis. Similar edge-linked [GeSe₄] tetrahedra are found in Cs₁₀Ga₆Se₁₄ which was obtained as transparent pale-yellow crystals by heating an equimolar mixture of GaSe and Cs in a carefully controlled temperature programme; the compound features the unprecedented finite complex anion [S₂Ga(μ-Se₂Ga)₃Se₂]¹⁻ which is 1900 pm long.(64)

In₆S₇ (and the isostructural In₆Se₇) have a curious structure comprising two separate blocks of almost ccp S which are rotated about the b-axis by 61° with respect to each other; the In is in octahedral coordination. The compound can be formulated as In₁(In‴S₆)⁴⁺In‴S₇⁻. There are also numerous ternary In/Tl sulfides in which In⁺ has been replaced by Tl⁺, e.g.: Tl⁺In‴S₇, Tl‴In‴S₅, Tl‴In‴S₇, Tl‴In‴S₃, Tl‴(In‴S₆)⁴⁺In‴S₆, Tl‴In‴S₆ and Tl‴(In‴S₆)⁴⁺In‴S₇.(64a)

The crystal structures of In₄Se₃ and In₄Te₃ show that they can be regarded to a first approximation as In¹[In₃]⁵⁺(X⁻)³ but the compound does not really comprise discrete ions. The triatomic unit [In‴—in‴—In‴] is bent, the angle at the central atom being 158° and the In—in distances 279 pm (cf. 324–326 pm in metallic In). However, it is also possible to discern non-planar 5-membered heterocycles in the structure formed by joining 2 In from 1 {In₃} to the terminal In of an adjacent {In₃} via 2 bridging Se (or Te) atoms so that the structure can be represented schematically as in Fig. 7.17. The In‴—Se distances average 268 pm.

---

---

Figure 7.17 Schematic structure of In₄Se₃.
269 pm compared with the closest In^I–Se contact of 297 pm. The [In^{III}]^{V} unit can be compared with the isoelectronic species [Hg^{II}]^{III}. The compound Tl_{4}S_{3}, which has the same stoichiometry as In_{4}X_{3}, has a different structure in which chains of corner-shared \{Tl^{II}S_{4}\} tetrahedra of overall stoichiometry \{TlS_{3}\} are bound together by Tl^{I}; within the chains the Tl^{III}–S distance is 254 pm whereas the Tl^{I}–S distances vary between 290–336 pm. A comparison of the formal designation of the two structures In^{I}[\{In^{III}\}]^{V}(Se^{II})_{3} and (Tl^{I})_{3}[Tl^{II}S_{3}]^{–III} again illustrates the increasing preference of the heavier metal for the +1 oxidation state. The trend continues with the polysulfides Tl^{II}S_{2}, Tl^{II}S_{5} and Tl^{II}S_{9} already alluded to on p. 253.

Compounds with bonds to N, P, As, Sb or Bi

The binary compounds of the Group 13 metals with the elements of Group 15 (N, P, As, Sb, Bi) are structurally less diverse than the chalcogenides just considered but they have achieved considerable technological application as III–V semiconductors isoelectronic with Si and Ge (cf. BN isoelectronic with C, p. 207). Their structures are summarized in Table 7.10: all adopt the cubic ZnS structure except the nitrides of Al, Ga and In which are probably more ionic (less covalent or metallic) than the others. Thallium does not form simple compounds.

(a) \(L = \) BN layer lattice (p. 208).
\(S = \) sphalerite (zinc blende), cubic ZnS (p. 1210).
\(W = \) wurtzite, hexagonal ZnS structure (p. 1210).

M^{III}X^{V}: the explosive black nitride Tl^{I}N is known, and the azides Tl^{I}N_{3} and Tl^{I}[Tl^{III}(N_{3})_{4}]; the phosphides Tl_{3}P, TlP_{3} and TlP_{5} have been reported but are not well characterized. With As, Sb and Bi thallium forms alloys and intermetallic compounds Tl_{3}X, Tl_{7}Bi_{2} and TlBi_{2}.

The III–V semiconductors can all be made by direct reaction of the elements at high temperature and under high pressure when necessary. Some properties of the Al compounds are in Table 7.11 from which it is clear that there are trends to lower mp and energy band-gap \(E_{g}\) with increasing atomic number.

Analogous compounds of Ga and In are grey or semi-metallic in appearance and show similar trends (Table 7.12). These data should be compared with those for Si, Ge, Sn and Pb on p. 373 and for the isoelectronic II–VI semiconductors of Zn, Cd and Hg with S, Se and Te (p. 1210). In addition, GaN is obtained by reacting Ga and NH_{3} at 1050° and InN by reducing and nitridding In_{2}O_{3} with NH_{3} at 630°. The
Aluminium, Gallium, Indium and Thallium

Ch. 7

nitrides show increasing susceptibility to chemical attack, AlN being inert to both acids and alkalis, GaN being decomposed by alkali, but not acid, and InN being decomposed by both acids and alkalis. Most of the other III–V compounds decompose slowly in moist air, e.g. AlP gives Al(OH)₃ and PH₃. As a consequence, semiconductor devices must be completely encapsulated to prevent reaction with the atmosphere. The great value of III–V semiconductors is that they extend the range of properties of Si and Ge and by judicious mixing in ternary phases they permit a continuous interpolation of energy band gaps, current-carrier mobilities and other characteristic properties. Some of their uses are summarized in the Panel on p. 258.

Other compounds containing Al–N or Ga–N bonds, including heterocyclic compounds and cluster organometallic compounds, are considered in section 7.3.6.

Some unusual stereochemistries

While it remains true that tetrahedral and octahedral coordination modes are the predominant stereochemistries adopted by the group 13 metals, nevertheless increasing diversity is being achieved by carefully selecting appropriate electronic and geometric features to enhance the stabilization of unusual stereochemistries. Some representative examples follow.

Trigonal planar Al is found in the [AlSb₃]⁶⁻ “anions” in [Cs₆K₃Sb(AlSb₃)], which is formed by heating a stoichiometric mixture of 6Cs, 3KSb and AlSb in a sealed Nb ampoule at 677°C. The Ga analogue was prepared similarly. The planar anions are embedded between columns of condensed icosahedra (Cs₆K₆/2)²⁺ which in turn are centred by the remaining unique monatomic Sb⁵⁻ anion.

The indium molybdate In₁₇Mo₄₀O₄₂, prepared by heating the appropriate mixture of In, Mo and MoO₂ at 1100°C, features novel quasi-linear chain cations. In₅⁷⁺ and In₆⁸⁺ in channels between condensed clusters of Mo₆ octahedra. The intrachain distances are 262–266 pm in In₅⁷⁺ and 265–269 pm in In₆⁸⁺, which are the shortest known In–In interatomic distances cf. 325 and 337 pm in In metal itself, and 333 pm for the closest distances between In atoms in neighbouring chains in the molybdate. Interatomic angles within the chains are 158° and 163° respectively and, when the coordination around each In atom by contiguous In and O atoms is considered, the chains can be formulated as [In₅⁺(In⁺ₙIn⁺²)], n = 3, 4.

Square-pyramidal 5-coordinate In¹⁺ occurs in certain organoindium compounds such as the bis(2-methylaminopyridinato-) adduct [MeIn-(MeNC(CH)₃N₂)](Cl⁵⁻) — cf. InCl₃ (p. 238). The less familiar pentagonal planar coordination has been established for the InMn₅ group in the dianion [(µ₅-In)(Mn(CO)₄)₅]²⁻ which is readily prepared by treatment of InCl₃ with the manganese carbonyl cluster compound K₃[In(CO)₂(CO)₅]. The mean Mn–Mn distance in the encircling plane-pentagonal “ligand” [Mn(CO)₄]₅ is 317 pm; the mean In–Mn distance is 265 pm, and the In atom is only 4.6 pm from the best plane of the five Mn atoms. Note also that the ligand is isosbolar with cyclopentadienyl, C₅H₅.

Seven-coordinate pentagonal-bipyramidal In¹⁺ has been found in the chloroindium complex of 1,4,7-triazacyclononanetriacetic acid [(CH₂)₂N(CH₂CO₂H)₃], (LH₃). The neutral, monoprotonated 7-coordinate complex [InCl(LH)] features Cl and one N in axial positions (angle Cl–In–N 168°) with the other two N atoms and three carboxylate O atoms in the pentagonal plane. Interest in such compounds stems between condensed clusters of Mo₆ octahedra.

---

from the use of the γ-active $^{111}$In isotope ($E_γ$ 173, 247 keV, $t_{1/2}$ 2.81 d) in radio-labelled monoclonal antibodies to detect tumours. Interestingly, the 7-coordinate crystalline complex reverts to a stable neutral hexacoordinate species in aqueous solution. Other 7-coordinate macrocyclic In$^{III}$ complexes of potential relevance in radiopharmaceutical applications have been prepared, including [InL] where L is the triacetate of the tetraaza macrocycle shown in Fig. 7.18(a).\(^{70}\) In this case the coordination polyhedron is a trigonal prism with one of its quadrilateral faces capped by a carboxylate O atom as shown schematically in Fig. 7.18(b).

Indium clusters have also recently been characterized, notably in intermetallic compounds. Thus, the Zintl phase, Rb$_2$In$_3$, (prepared by direct reaction between the two metals at 1530°C) has layers of octahedral closo-In$_6$ clusters joined into sheets through exo bonds at four coplanar vertices.\(^{71}\) These four In atoms are therefore each bonded to five neighbouring In atoms at the corners of a square-based pyramid, whereas the remaining two (trans) In atoms in the In$_6$ cluster show pyramidal 4-fold bonding only, to contiguous In atoms in the same cluster. Cs$_2$In$_3$ is isostructural. The intermetallic compound K$_3$Na$_{26}$In$_{48}$ (synthesized from the elements in sealed Nb ampoules at 600°C) has a more complicated structure in which the In forms both closo icosahedral In$_{12}$ clusters and hexagonal antiprismatic In$_{12}$ clusters.\(^{72}\) All the various In$_{12}$ clusters are interconnected by 12 exo bonds forming a covalent 3D network (In-In 291–315 pm) and the In$_{12}$ hexagonal antiprisms are additionally centred by single Na atoms. The phase contains several other interesting structural features and the original paper (in English) makes rewarding reading.

### 7.3.6 Organometallic compounds

Many organoaluminium compounds are known which contain 1, 2, 3 or 4 Al–C bonds per Al atom and, as these have an extensive reaction chemistry of considerable industrial importance, they will be considered before the organometallic compounds of Ga, In and Tl are discussed.

Organoauminium Compounds

Aluminium trialkyls and triaryls are highly reactive, colourless, volatile liquids or low-melting solids which ignite spontaneously in air and react violently with water; they should therefore be handled circumspectly and with suitable precautions. Unlike the boron trialkyls and triaryls they are often dimeric, though with branched-chain alkyls such as Pr', Bu' and Me₃CCH₂ this tendency is less marked. Al₂Me₆ (mp 15°, bp 126°) has the methyl-bridged structure shown and the same dimeric structure is found for Al₂Ph₆ (mp 225°).

Applications of III–V Semiconductors

The 9 compounds that Al, Ga and In form with P, As and Sb have been extensively studied because of their many applications in the electronics industry, particularly those centred on the interconversion of electrical and optical (light) energy. For example, they are produced commercially as light-emitting diodes (LEDs) familiar in pocket calculators, wrist watches and the alpha-numeric output displays of many instruments; they are also used in infrared-emitting diodes, injection lasers, infrared detectors, photocathodes and photomultiplier tubes. An extremely elegant chemical solid-state technology has evolved in which crystals of the required properties are deposited, etched and modified to form the appropriate electrical circuits. The ternary system GaAs₁₋ₓPₓ now dominates the LED market for α-numeric and graphic displays following the first report of this activity in 1961. GaAs₁₋ₓPₓ is grown epitaxially on a single-crystal substrate of GaAs or GaP by chemical vapour deposition and crystal wafers as large as 20 cm² have been produced commercially. The colour of the emitted radiation is determined by the energy band gap $E_g$; for GaAs itself $E_g$ is 138 kJ mol⁻¹ corresponding to an infrared emission ($λ$ 870 nm), but this increases to 184 kJ mol⁻¹ for $x ∼0.4$ corresponding to red emission ($λ$ 650 nm). For $x > 0.4$ $E_g$ continues to increase until it is 218 kJ mol⁻¹ for GaP ($λ$ 550 nm). Commercial yellow and green LEDs contain the added isoelectronic impurity N to improve the conversion efficiency. A schematic cross-section of a typical GaAs₁₋ₓPₓ epitaxial wafer doped with Te and N is shown in the diagram: Te (which has one more valence electron per atom than As or P) is the most widely used dopant to give n-type impurities in this system at concentrations of $10^{16}–10^{18}$ atoms cm⁻³ (0.5–50 ppm). The p–n junction is then formed by diffusing Zn (1 less electron than Ga) into the crystal to a similar concentration.

An even more recent application is the construction of semiconductor lasers. In normal optical lasers light is absorbed by an electronic transition to a broad band which lies above the upper laser level and the electron then drops into this level by a non-radiative transition. By contrast the radiation in a semiconductor laser originates in the region of a p–n junction and is due to the transitions of injected electrons and holes between the low-lying levels of the conduction band and the uppermost levels of the valence band. (Impurity levels may also be involved.) The efficiency of these semiconductor injection lasers is very much higher than those of optically pumped lasers and the devices are much smaller; they are also easily adaptable to modulation. As implied by the band gaps on p. 255, emission wavelengths are in the visible and near infrared. A heterostructure laser based on the system GaAs–Al₉Ga₁₋₉As was the first junction laser to run continuously at 3000 K and above (1970). In the two types of device just considered, namely light emitting diodes and injection lasers, electrical energy is converted into optical energy. The reverse process of converting optical energy into electrical energy (photoconductivity and photovoltaic effects) has also been successfully achieved by III–V semiconductor systems. For example, the small band-gap compound InSb is valuable as a photoconductive infrared detector, and several compounds are being actively studied for use in solar cells to convert sunlight into useful sources of electrical power. The maximum photon flux in sunlight occurs at 75–95 kJ mol⁻¹ and GaAs shows promise, though other factors make Cu₂S–CdS cells more attractive commercially at the present time.
In each case Al–Cμ is about 10% longer than Al–Cτ (cf. Al₂X₆, p. 235; B₂H₆, p. 157).

The enthalpy of dissociation of Al₂Me₆ into monomers is 84 kJ mol⁻¹. Al₂Et₆ (mp −53°) and Al₂Pr₆ (mp −107°) are also dimeric at room temperature but crystalline trimethyl aluminium (mesityl = 2,4,5-trimethylphenyl) is monomeric with planar 3-coordinate Al; the mesityl groups adopt a propeller-like configuration with a dihedral angle of 56° between the aromatic ring and the AlC₃ plane and with Al–C 199.5 pm. 

As with Al(BH₄)₃ and related compounds (p. 230), solutions of Al₂Me₆ show only one proton nmr signal at room temperature due to the rapid interchange of bridging and terminal Me groups; at −75° this process is sufficiently slow for separate resonances to be observed.

Al₂Me₆ can be prepared on a laboratory scale by the reaction of HgMe₂ on Al at ~90°C. Al₂Ph₆ can be prepared similarly using HgPh₂ in boiling toluene or by the reaction of LiPh on Al₂Cl₆. On the industrial (kilotonne) scale Al₂Cl₃ is alkylated by means of RX or by alkenes plus H₂. In the first method the sesquichloride R₃Al₂Cl₃ is formed in equilibrium with its disproportionation products:†

\[ 2\text{Al} + 3\text{RCl} \xrightleftharpoons{\text{AlCl₃ or AlR₃}} \text{R₃Al₂Cl₃} \]

Addition of NaCl removes R₂Al₂Cl₄ as the complex (2NaAlCl₃R) and enables R₄Al₂Cl₂ to be distilled from the mixture. Reaction with Na yields the trialkyl, e.g.:

\[ 3\text{Me₃AlCl₂} + 6\text{Na} \rightarrow \text{2Al₂Me₆} + 2\text{Al} + 6\text{NaCl} \]

Higher trialkyls are more readily prepared on an industrial scale by the alkene route (K. Ziegler et al., 1960) in which H₂ adds to Al in the presence of preformed AlR₃ to give a dialkylaluminium hydride which then readily adds to the alkene:

\[ 2\text{Al} + 3\text{H₂} + 2\text{Al₂Et₆} \xrightarrow{150°} [6\text{Et₃AlH}] \]

\[ \xrightarrow{70°} 3\text{Al₂Et₆} \]

Similarly, Al, H₂ and Me₂C=CH₂ react at 100° and 200 atm to give AlBu₃ in a single-stage process, provided a small amount of this compound is present at the start; this is required because Al does not react directly with H₂ to form AlH₃ prior to alkylation under these conditions. Alkene exchange reactions can be used to transform AlBu₃ into numerous other trialkyls. AlBu₃ can also be reduced by potassium metal in hexane at room temperature to give the novel brown compound K₂Al₂Bu₈ (mp 40°) which is notable in providing a rare example of an Al–Al bond in the diamagnetic anion [Bu₈Al₂AlBu₈]²⁻.  

Al₂R₆ (or AlR₃) react readily with ligands to form adducts, LAIR₃. They are stronger Lewis acids than are organoboron compounds, BR₃, and can be considered as 'hard' (or class a)

---

† It is interesting to note that the reaction of EtI with Al metal to give the sesqui-iodide "Et₃Al₁₂I₃" was the first recorded preparation of an organoaluminium compound (W. Hallwachs and A. Schafarik, 1859).

Acids; for example, the stability of the adducts LAIme₃ decreases in the following sequence of L: Me₃N > Me₃P > Me₃As > Me₂O > Me₂S > Me₂Se. With protonic reagents they react to liberate alkanes:

\[ \text{Al}_2R_6 + 6HX \rightarrow 6RH + 2\text{AlX}_3 \]

\( X = \text{OH, OR, Cl, Br} \)

Reaction with halides or alkoxides of elements less electropositive than Al affords a useful route to other organometallics:

\[ \text{MX}_n + \text{excess AlR}_3 \rightarrow \text{MR}_n + \frac{2}{3} \text{AlX}_3 \]

\( M = \text{B, Ga, Si, Ge, Sn, etc.} \)

The main importance of organoaluminium compounds stems from the crucial discovery of alkene insertion reactions by K. Ziegler, and an industry of immense proportions based on these reactions has developed during the past 40 y. Two main processes must be distinguished: (a) "growth reactions" to synthesize unbranched long-chain primary alcohols and alkenes (K. Ziegler et al., 1955), and (b) low-pressure polymerization of ethene and propene in the presence of organometallic mixed catalysts (1955) for which K. Ziegler (Germany) and G. Natta (Italy) were jointly awarded the Nobel Prize for Chemistry in 1963.

In the first process alkenes insert into the Al-C bonds of monomeric AlR₃ at ~150° and 100 atm to give long-chain derivatives whose composition can be closely controlled by the temperature, pressure and contact time:

\[ \text{Al} - \text{Et} \rightarrow \text{C}_2\text{H}_4 \rightarrow \text{Et}_2\text{AlCH}_2\text{Et} \rightarrow \frac{n\text{C}_2\text{H}_4}{r\text{C}_2\text{H}_4}\text{Et} \]

The reaction is thought to occur by repeated \( \eta^2 \)-coordination of ethene molecules to Al followed by migration of an alkyl group from Al to the alkenecarbon atom (see Scheme).

Unbranched chains up to C₂₀₀ can be made, but prime importance attaches to chains of 14–20 C atoms which are synthesized industrially in this way and then converted to unbranched aliphatic alcohols for use in the synthesis of biodegradable detergents:

\[ \text{Al} (\text{CH}_3\text{CH}_2\text{R})_3 \overset{(i) \text{O}_2, (ii) \text{H}_3\text{O}^+}{\rightarrow} 3\text{RCH}_2\text{CH}_2\text{OH} \]

Alternatively, thermolysis yields the terminal alkene RCH=CH₂. Note that, if propene or higher alkenes are used instead of ethene, then only single insertion into Al-C occurs. This has been commercially exploited in the catalytic dimerization of propene to 2-methylpentene-1, which can then be cracked to isoprene for the production of synthetic rubber (cis-1,4-polyisoprene):

\[ 2\text{MeCH} \rightarrow \text{CH}_2 \rightarrow \text{Me} \]

Even more important is the stereoregular catalytic polymerization of ethene and other alkenes to give high-density polyethene ("polythene") and other plastics. A typical Ziegler-Natta catalyst can be made by mixing TiCl₄ and Al₂Et₆ in heptane: partial reduction to Ti and alkyl transfer occur, and a brown suspension forms which rapidly absorbs and polymerizes ethene even at room temperature and atmospheric pressure. Typical industrial conditions are 50–150°C and 10 atm. Polyethene
produced at the surface of such a catalyst is 85–95% crystalline and has a density of 0.95–0.98 g cm⁻³ (compared with low-density polymer 0.92 g cm⁻³); the product is stiffer, stronger, has a higher resistance to penetration by gases and liquids, and has a higher softening temperature (140–150°). Polyethene is produced in megatonne quantities and used mainly in the form of thin film for packaging or as molded articles, containers and bottles; electrical insulation is another major application. Stereoregular (isotactic) polypropene and many copolymers of ethene are also manufactured. Much work has been done in an attempt to elucidate the chemical nature of the catalysts and the mechanism of their action; the active site may differ in detail from system to system but there is now general agreement that polymerization is initiated by 𝜋² coordination of ethene to the partly alkylated lower-valent transition-metal atom (e.g. Tiᴵᴵ) followed by migration of the attached alkyl group from transition-metal to carbon (the Cossee mechanism, see Scheme below). An alternative suggestion involves a metal–carbene species generated by α-hydrogen transfer from carbon to the transition metal.⁷⁶

Coordination of the ethene or propene to Tiᴵᴵ polarizes the C–C bond and allows ready migration of the alkyl group with its bonding electron-pair. This occurs as a concerted process, and transforms the 𝜋²-alkene into a σ-bonded alkyl group. As much as 1 tonne of polypropylene can be obtained from as little as 5 g Ti in the catalyst.

Finally, in this subsection, we mention a few recent examples of the use of specific ligands to stabilize particular coordination geometries about the organoaluminium atom (see also p. 256). Trigonal planar stereochemistry has been achieved in R₂AlCH₂AlR₂ (R = (Me₃Si)₂CH⁻), which was prepared as colourless crystals by reacting CH₂(AlCl₂)₂ with 4 moles of LiCH(SiMe₃)₂ in pentane.⁷⁷ It is also noteworthy that the bulky R groups permit the isolation for the first time of a molecule having the AlCH₂Al grouping, by preventing the dismutation which spontaneously occurs with the Me an Et derivatives.

The linear cation [AlMe₂]⁺ has been stabilized by use of crown ethers (p. 96).⁷⁸ For example, 15-crown-5 gives overall pentagonal bipyramidal 7-fold coordination around Al with axial Me groups having Al–C 200 pm and angle Me–Al–Me 178° (see Fig. 7.19a). With the larger ligand 18-crown-6, the Al atom is bonded to only three of the six O atoms to give unsymmetrical 5-fold coordination with Al–C 193 pm and angle Me–Al–Me 141°. Symmetrical (square-pyramidal) 5-coordinate Al is found.

---

in the complex \([\text{AlEt}_2\text{L}]\) (Fig. 7.19b) formed by reacting \(\text{Al}_2\text{Et}_6\) in hexane solution with \(\text{H}_2[\text{C}_{22}\text{H}_{22}\text{N}_4]\), i.e. \(\text{H}_2\text{L}\), shown in Fig. 7.19c.\(^{79}\) The average Al–N distance is 196.7 pm, Al–C is 197.6 pm (close to the value for the terminal Al–C in \(\text{Al}_2\text{Me}_6\), p. 259) and the Al atom is 57 pm above the \(\text{N}_4\) plane. A further notable feature is the great stability of the Al–C bond: the compound can be recrystallized unchanged from hydroxylic or water-containing solvents and does not decompose even when heated to 300°C in an inert atmosphere.

Heterocyclic and cluster organoaluminium compounds containing various sequences of Al–N bonds are discussed on p. 265.

### Organometallic compounds of Ga, In and Tl

Organometallic compounds of Ga, In and Tl have been less studied than their Al analogues. The trialkyis do not dimerize and there is a general tendency to diminishing thermal stability with increasing atomic weight of M. There is also a general decrease of chemical reactivity of the M–C bond in the sequence Al > Ga ≈ In > Tl, and this is particularly noticeable for compounds of the type \(\text{R}_2\text{MX}\); indeed, Tl gives air-stable non-hydrolysing ionic derivatives of the type \([\text{TlR}_2]\)X, where \(X = \text{halogen, CN, NO}_3, \frac{1}{2}\text{SO}_4\), etc. For example, the ion \([\text{TlMe}_2]^+\) is stable in aqueous solution, and is linear like the isoelectronic \(\text{HgMe}_2\) and \([\text{PbMe}_2]^2+\).

\(\text{GaR}_3\) can be prepared by alkylating Ga with \(\text{HgR}_2\) or by the action of \(\text{RMgBr}\) or \(\text{AIR}_3\) on \(\text{GaCl}_3\). They are low-melting, mobile, flammable liquids. The corresponding In and Tl compounds are similar but tend to have higher mps and bps; e.g.

The triphenyl analogues are also monomeric in solution but tend to associate into chain structures in the crystalline state as a result of weak intermolecular M⋯C interactions: \(\text{GaPh}_3\) mp...
37.3.6 Organometallic compounds

166°, InPh₃ mp 208°, TlPh₃ mp 170°. For Ga and In compounds the primary M–C bonds can be cleaved by HX, X₂ or MX₃ to give reactive halogen-bridged dimers (R₂MX)₂. This contrasts with the unreactive ionic compounds of Tl mentioned above, which can be prepared by suitable Grignard reactions:

\[ \text{TlX}_3 + 2\text{RMgX} \rightarrow [\text{TlR}_2]\text{X} + 2\text{MgX}_2 \]

As in the case of organoaluminium compounds, unusual stereochemistries can be imposed by suitable design of ligands. Thus, reaction of GaCl₃ with 3,3',3''-nitrilotris(propyl)magnesium chloride), [N{(CH₂)₃MgCl}₃], yields colourless crystals of [Ga(CH₂)₃N] in which intramolecular N–Ga coordination stabilizes a planar trigonal monopyramidal geometry about Ga as shown schematically in Fig. 7.20(a). Because of steric constraints, the Ga–N distance of 209.5 pm is about 7% longer than the sum of the covalent radii (195 pm), although not so long as in Me₃GaMe₃ (220 pm). Long bonds are also a feature of the unique 6-coordinate complex of InMe₃ with the heterocyclic triazine ligand (Pr'NCH₂)₃. The air-sensitive adduct, [Me₃In[Pr'NCH₂]₃], can be prepared by direct reaction of the donor and acceptor in ether solution, and is the first example of a tridentate cyclotriazine complex; it is also the first example of InMe₃ accepting three lone pairs of electrons rather than the more usual one or two. The structure (Fig. 7.20b) features a shallow InC₃ pyramid with C–In–C angles of 114°–117° and extremely acute N–In–N angles (48.6°) associated with the long In–N bonds (278 pm). The three Pr' groups are all in equatorial positions.

Cyclopentadienyl and arene complexes of Ga, In and Tl have likewise attracted increasing attention during the past decade and provide a rich variety of structural types and of chemical diversity. [Ga(C₅H₅)₃], prepared directly from GaCl₃ and an excess of LiC₅H₅ in Et₂O, was found to have simple trigonal planar Ga bonded to three η¹-C₅H₅ groups. The more elusive C₅Me₅ derivative was finally prepared from GaCl₃ and an excess of NaC₅Me₅ in thf solution, or by reduction of Ga(C₅Me₅)₃Cl₃-n (n = 1, 2) with sodium naphthalenide in thf. The structure (Fig. 7.20c) features a shallow C₅Me₅ pyramid with C–C–C angles of 114°–117° and extremely acute N–C–N angles (48.6°) associated with the long C–N bonds (278 pm). The three Pr' groups are all in equatorial positions.

Figure 7.20 (a) Structure of [Ga(CH₂)₃N] showing trigonal planar monopyramidal 4-fold coordination about Ga and tetrahedral coordination about N. (b) Structure of [Me₃In[Pr'NCH₂]₃] — see text for dimensions. (c) Structure of polymeric [In(η⁵-C₅H₅)].
is a colourless, sublimable, crystalline solid, mp 168°, and appears to be a very weak Lewis acid.

As distinct from the cyclopentadienyls of Ga\textsuperscript{III}, those of In and Tl involve the +1 oxidation state of the metal and pentahapto bonding of the ligand. \([\text{In}(\eta^5-C_5\text{H}_5)]\) is best prepared by metathesis between LiC\textsubscript{5}H\textsubscript{5} and a slurry of InCl in Et\textsubscript{2}O.\textsuperscript{(83)} It is monomeric in the gas phase with a ‘half-sandwich’ structure, the In–C\textsubscript{5}(centroid) distance being 232 pm, but in the solid state it is a zig-zag polymer with significantly larger In–C\textsubscript{5}(centroid) distances as shown in Fig. 7.20c.\textsuperscript{(84)} The crystalline pentamethyl derivative, by contrast, is hexameric and features an octahedral In\textsubscript{6} cluster each vertex of which is \(\eta^5\)-coordinated by C\textsubscript{5}Me\textsubscript{5}.\textsuperscript{(85)} \([\text{Tl}(\eta^5-C_5\text{H}_5)]\) precipitates as air-stable yellow crystals when aqueous TlOH is shaken with cyclopentadiene. In the gas phase the compound is monomeric with \(C_{5v}\) symmetry, the Tl atom being 241 pm above the plane of the ring (microwave), whereas in the crystalline phase there are zig-zag chains of equispaced alternating C\textsubscript{5}H\textsubscript{5} rings and Tl atoms similar to the In homologue.

Hexahapto (\(\eta^6\)-arene) complexes of Ga\textsuperscript{I} and In\textsuperscript{I} can be obtained from solutions of the lower halides (p. 240) in aromatic solvents, and some of these have surprisingly complex structures.\textsuperscript{(86)} With bulky ligands such as C\textsubscript{6}Me\textsubscript{6} simple adducts crystallize in which the cations \([\text{M}(\eta^6-C_6\text{Me}_6)]^+\) have the \(C_{6v}\) ‘half-sandwich’ structure shown in Fig. 7.21a, e.g. \([\text{Ga}(\eta^6-C_6\text{Me}_6)][\text{GaCl}_4]\) mp 168° and \([\text{Ga}(\eta^6-C_6\text{Me}_6)][\text{GaBr}_4]\) mp 146°.\textsuperscript{(87)} With less bulky ligands such as mesitylene (1,3,5-C\textsubscript{6}H\textsubscript{3}Me\textsubscript{3}), a 2:1 stoichiometry is possible to give cations \([\text{M}(\eta^6-C_6\text{H}_3\text{Me}_3)_2]^+\) shown schematically in Fig. 7.21b, although further ligation from the anion may also occur; e.g. \([\text{In}(\eta^6-C_6\text{H}_3\text{Me}_3)_2][\text{InBr}_4]\) features polymeric helical chains in which bridging \([\mu-\eta^1,\eta^2-\text{InBr}_4]\) units connect the cations as shown in Fig. 7.21c.\textsuperscript{(88)} With still less bulky ligands such as benzene itself, discrete dimers can be formed as in the solvated complex \([\text{Ga}(\eta^6-C_6\text{H}_6)_2][\text{GaCl}_4]\).3C\textsubscript{6}H\textsubscript{6}. This features tilted bis(arene)Ga\textsuperscript{I} units linked through bridging GaCl\textsubscript{4} units to form the dimeric structure shown in Fig. 7.22a.\textsuperscript{(86)} Mixed adducts can also be prepared. Thus, when

\[\text{In}(\eta^5-C_5\text{H}_5)\] precipitates as air-stable yellow crystals when aqueous TlOH is shaken with cyclopentadiene. In the gas phase the compound is monomeric with \(C_{5v}\) symmetry, the Tl atom being 241 pm above the plane of the ring (microwave), whereas in the crystalline phase there are zig-zag chains of equispaced alternating C\textsubscript{5}H\textsubscript{5} rings and Tl atoms similar to the In homologue.

Hexahapto (\(\eta^6\)-arene) complexes of Ga\textsuperscript{I} and In\textsuperscript{I} can be obtained from solutions of the lower halides (p. 240) in aromatic solvents, and some of these have surprisingly complex structures.\textsuperscript{(86)} With bulky ligands such as C\textsubscript{6}Me\textsubscript{6} simple adducts crystallize in which the cations \([\text{M}(\eta^6-C_6\text{Me}_6)]^+\) have the \(C_{6v}\) ‘half-sandwich’ structure shown in Fig. 7.21a, e.g. \([\text{Ga}(\eta^6-C_6\text{Me}_6)][\text{GaCl}_4]\) mp 168° and \([\text{Ga}(\eta^6-C_6\text{Me}_6)][\text{GaBr}_4]\) mp 146°.\textsuperscript{(87)} With less bulky ligands such as mesitylene (1,3,5-C\textsubscript{6}H\textsubscript{3}Me\textsubscript{3}), a 2:1 stoichiometry is possible to give cations \([\text{M}(\eta^6-C_6\text{H}_3\text{Me}_3)_2]^+\) shown schematically in Fig. 7.21b, although further ligation from the anion may also occur; e.g. \([\text{In}(\eta^6-C_6\text{H}_3\text{Me}_3)_2][\text{InBr}_4]\) features polymeric helical chains in which bridging \([\mu-\eta^1,\eta^2-\text{InBr}_4]\) units connect the cations as shown in Fig. 7.21c.\textsuperscript{(88)} With still less bulky ligands such as benzene itself, discrete dimers can be formed as in the solvated complex \([\text{Ga}(\eta^6-C_6\text{H}_6)_2][\text{GaCl}_4]\).3C\textsubscript{6}H\textsubscript{6}. This features tilted bis(arene)Ga\textsuperscript{I} units linked through bridging GaCl\textsubscript{4} units to form the dimeric structure shown in Fig. 7.22a.\textsuperscript{(86)} Mixed adducts can also be prepared. Thus, when

(b) The ‘bent-sandwich’ structure found in ions of the type \([\text{In}(\eta^6-C_5\text{H}_3\text{Me}_3)]^+\). (c) A section of the helical chain in \([\text{In}(\eta^6-\text{mes})_2][\text{InBr}_4]\) showing the \([\mu-\eta^1,\eta^2-\text{InBr}_4]\) unit bridging ions of the type shown in (b); the tilting angle is 133° and the ring-centres of the two arene ligands are almost equidistant from In (283 and 289 pm).
87.3.6 Organometallic compounds

Figure 7.22 (a) Structure of the dimeric unit in the solvated complex \([\text{Ga}(\eta^6-C_6H_6)_2][\text{GaCl}_4]_2\cdot3C_6H_6\) indicating the principal dimensions; the six benzene molecules of solvation per dimer lie outside the coordination spheres of the gallium atoms. (b) Structure of the ion-pair \([\text{Ga}([\eta^8]-[2.2.2] \text{paracyclophane})][\text{GaBr}_4]\); the four Ga–Br distances within the tetrahedral anion are in the range 230.5–233.3 pm, the distance for Ga–Br$_\mu$ being 231.9 pm; the Ga$^+\ldots$Br$_\mu$ distance is 338.8 pm.

dilute toluene solutions of Ga$_2$Cl$_4$ and durene (1,2,4,5-C$_6$H$_2$Me$_4$) are cooled to 0°C, crystals containing the centrosymmetric dimer \([\text{Ga}(\eta^6\text{-dur})(\eta^6\text{-tol})\text{GaCl}_4]_2\) are obtained. The structure resembles that in Fig. 7.22a, with each Ga$^+$ centre $\eta^6$-bonded to one durene molecule at 264 pm and one toluene molecule at 304 pm. These bent-sandwich moieties are then linked into dimeric units via three of the four Cl atoms of each of the two GaCl$_4$ tetrahedra.

An even more remarkable structure emerges for the monomeric complex of Ga$_2$Br$_4$ with the tris(arene) ligand [2.2.2]paracyclophane (Fig. 7.22b): the Ga$^+$ centre is encapsulated in a unique $\eta^{18}$ environment which has no parallels even in transition-metal coordination chemistry. The Ga$^+$ cation is almost equidistant from the three ring centres (265 pm) but is displaced away from the ligand centre by 43 pm towards the GaBr$_4^-$ counter anion. The complex was prepared by dissolving the dimeric benzene complex \([[[\text{C}_6\text{H}_6]_2\text{Ga.GaBr}_4]_2\) (cf. Fig. 7.22a) in benzene and adding the cyclophane.

**AI–N heterocycles and clusters**

Finally, in this chapter, attention should be drawn to a remarkable range of heterocyclic and cluster organoaluminium compounds containing various sequences of Al–N bonds (91) (cf. B–N compounds, p. 207). Thus the adduct [AlMe$_3$(NH$_2$Me)] decomposes at 70°C with loss of methane to give the cyclic amido trimers cis- and trans-[Me$_2$AlNHMe]$_3$ (structures 2 and 3) and at 215°C to give the oligomeric imido cluster compounds (MeAlNMe)$_3$; (structure 6) and (MeAlNMe)$_8$ (structure 7), e.g.:

\[
21\text{AlMe}_3 + 21\text{NH}_2\text{Me} \rightarrow 7(\text{Me}_2\text{AlNHMe})_3
\]

\[
\rightarrow 3(\text{MeAlNMe})_7
\]

Similar reactions lead to other oligomers depending on the size of the R groups and the conditions of the reaction, e.g. cyclo-(Me$_2$AlNMe)$_2$ (structure 1) and the imido-clusters (PhAlNPh)$_4$, (HAINP$_4$)$_4$ or 6,

---

Intermediate amido-imido compounds have also been isolated from the reaction, e.g. \([\text{Me}_2\text{AlNHMe}_2\text{MeAlINMe}]\) (structure 8). Oligomers up to \((\text{RAINR'})_6\) have been obtained although not necessarily structurally characterized. The known structures are all built up from varying numbers of fused 4-membered and 6-membered AIN heterocycles.

Until recently tetramers such as (4) were the smallest oligomers involving alternating Al and N atoms. It will be noted, however, that the hexamer (5) comprises a hexagonal prism formed by conjoining two plane six-membered rings. By increasing the size of the exocyclic groups it has proved possible to isolate a planar trimer, \((\text{MeAlINAr})_3\), which is isoelectronic with borazine (p. 210). Thus, thermolysis of a mixture of \text{AlMe}_3\) and \text{ArNH}_2\) (\(\text{Ar} = 2,6-\text{Pr}_2\text{C}_6\text{H}_3\)) in toluene at 110° results in the smooth elimination of \text{CH}_4\) to give the dimer, \((\text{Me}_2\text{AlNHAr})_2\), which, when heated to 170°, loses more methane to give a high yield of the trimer, \((\text{MeAlINAr})_3\), as colourless, air- and moisture-sensitive crystals.\(^{92}\) The six ipso-C atoms are coplanar with the planar 6-membered \(\text{Al}_3\text{N}_3\) ring and the \(\text{Al}–\text{N}\) distance of 178 pm is significantly shorter than in the higher (4-coordinate) oligomers (189–196 pm). Comparison with other 3-coordinate Al and N centres is difficult because of the paucity of examples but the homoleptic monomer \([\text{Al[N(SiMe}_3)_2]_3}\) has also been reported to have \(\text{Al}–\text{N}\) distances of 178 pm.

Several analogous gallium compounds are also known, e.g. \([\text{Me}_2\text{GaNHMe}_2\text{MeGaNMe}_6]\)

---

Likewise, $(R_2GaPBu)_2$ and $(R_2GaAsBu)_2$ ($R = Me, Bu$) have structures analogous to (1).\(^{(93)}\) A more complex 12-membered Ga$_5$As$_7$ cluster has been characterized in $[(PhAsH)(R_2Ga)(PhAs)_6(RGa)_4]$ ($R = Me_3SiCH_2$).\(^{(94)}\) The cyclic trimer, $[[(triph)-GaP(chex)]_3]$, (where triph = 2,4,6-Ph$_3$C$_6$H$_2$ and chex = cyclo-C$_6$H$_{11}$) is of interest in being the first well characterized heterocycle consisting entirely of heavier main-group elements. It is obtained as pale yellow crystals by reacting (triph)GaCl$_2$ with Li$_2$P(chex) and is formally iso-electronic with borazine (p. 210). Indeed, it has short Ga–P distances (mean 229.7 pm) but the ring is markedly non-planar and there is a slight, statistically significant alternation in Ga–P distances with three averaging at 228.5(4) pm and three at 230.8(4) pm.\(^{(95)}\) Much of the burgeoning interest in this area of volatile compounds of Group 13 elements has come from attempts to devise effective routes to thin films of III–V semiconductors such as GaP, GaAs, etc. via MOCVD (metal-organic chemical vapour deposition).

8
Carbon

8.1 Introduction

One thing is absolutely certain — it is quite impossible to do justice to the chemistry of carbon in a single chapter; or, indeed, a single book. The areas of chemistry traditionally thought of as organic chemistry will largely be omitted except where they illuminate the general chemistry of the element. The field of organometallic chemistry is discussed in Section 19.7: this has been one of the most rapidly developing areas of the subject during the past 40 y and has led to major advances in our understanding of the structure, bonding and reactivity of molecular compounds. In fact, the unifying concepts emerging from organometallic chemistry emphasize the dangers of erecting too rigid a barrier between various branches of the subject, and nowhere is the boundary between inorganic and organic chemistry more arbitrary and less helpful than here. The present chapter gives a general account of the chemistry of carbon and its compounds; a more detailed discussion of specific organometallic systems will be found under the individual elements. Discussion of Group trends and the comparative chemistry of the Group 14 elements C, Si, Ge, Sn and Pb is deferred until Chapter 10.

Carbon was known as a substance in prehistory (charcoal, soot) though its recognition as an element came much later, being the culmination of several experiments in the eighteenth century.(1) Diamond and graphite were known to be different forms of the element by the close of the eighteenth century, and the relationship between carbon, carbonates, carbon dioxide, photosynthesis in plants, and respiration in animals was also clearly delineated by this time (see Panel). The great upsurge in synthetic organic chemistry began in the 1830s and various structural theories developed following the introduction of the concept of valency in the 1850s. Outstanding achievements in this area were F. A. Kekulé's use of structural formulae for organic compounds and his concept of the benzene ring, L. Pasteur's work on optical activity and the concept of tetrahedral carbon (J. H. van't Hoff).†

† J. A. Le Bel, whose name is often also associated with this concept, did indeed independently suggest a 3-dimensional model for the 4-coordinate C atom, but vigorously opposed the tetrahedral stereochemistry of van't Hoff for many years and favoured an alternative square pyramidal arrangement of the bonds.
Early History of Carbon and Carbon Dioxide

Carbon known as a substance in prehistory (charcoal, soot) but not recognized as an element until the second half of the eighteenth century.

- BC: “Indian inks” made from soot used in the oldest Egyptian hieroglyphs on papyrus.
- AD 1273-1564: Ordinance prohibiting use of coal in London as prejudicial to health — the earliest known attempt to reduce smoke pollution in Britain.
- 1562: Lead pencils first manufactured commercially during Queen Elizabeth’s reign, using Cumberland graphite.
- 1752/4: CO₂ (“fixed air”), prepared by Joseph Black (aged 24–26), was the first gas other than air to be characterized: (i) chalk when heated lost weight and evolved CO₂ (genesis of quantitative gravimetric analysis), and (ii) action of acids on carbonates liberates CO₂.
- 1757: J. Black showed that CO₂ was produced by fermentation of vegetables, by burning charcoal and by animals (humans) when breathing; turns lime water turbid.
- 1771: J. Priestley established that green plants use CO₂ and “purify air” when growing. He later showed that the “purification” was due to the new gas oxygen (1774).
- 1779: Elements of photosynthesis elucidated by J. Ingenhousz: green plants in daylight use CO₂ and evolve oxygen; in the dark they liberate CO₂.
- 1789: The word “carbon” (Fr. carbone) coined by A. L. Lavoisier from the Latin carbo, charcoal. The name “graphite” was proposed by A. G. Werner and D. L. G. Harsten in the same year. Greek γραφεῖν (graphein), to write. The name “diamond” is probably a blend of Greek διαφανής (diaphanes), transparent, and άδαμας (adamas), indomitable or invincible, in reference to its extreme hardness.
- 1796: Diamond shown to be a form of carbon by S. Tennant who burned it and weighed the CO₂ produced; graphite had earlier been shown to be carbon by C. W. Scheele (1779); carbon recognized as essential for converting iron to steel (R.-A.-F de Réaumur and others in the late eighteenth century).
- 1805: Humphry Davy showed carbon particles are the source of luminosity in flames (lamp black).

The first metal carbonyl compounds Ni(CO)₄ and Fe(CO)₅ were prepared and characterized by L. Mond and his group in 1889–91 and this work has burgeoned into the huge field of metal carbonyl cluster compounds which is still producing results of fundamental importance. Even more extensive is the field of organometallic chemistry which developed rapidly after the seminal papers on the “sandwich” structure of ferrocene (E. O. Fischer and W. Pfab, 1952; G. Wilkinson, M. Rosenblum, M. C. Whiting and R. B. Woodward, 1952) and the “π bonding” of ethylene complexes (M. J. S. Dewar 1951, J. Chatt, and L. A. Duncanson, 1953). The constricting influence of classical covalent-bond theory was finally overcome when it was realized that carbon in many of its compounds can be 5-coordinate (Al₂Me₆, p. 258), 6-coordinate (C₂B₁₀H₁₂, p. 185) or even 7-coordinate (Li₄Me₄, p. 104). A compound featuring an 8-coordinate carbon atom is shown on p. 1142. In parallel with these developments in synthetic chemistry and bonding theory have been the development of ¹⁴C radioactive dating techniques (W. F. Libby, 1949), the commercial availability of ¹³C nmr instruments in the early 1970s, and the industrial production of artificial diamonds (General Electric Company, 1955). These and other notable dates in carbon chemistry are summarized in the Panel on p. 270.

The most exciting recent development in the chemistry of carbon has been the intriguing discovery of a whole new range of soluble molecular forms of elemental carbon, the fullerenes, of which C₆₀ and C₇₀ are the most prominent members. This was recognized by the 1996 Nobel Prize for Chemistry and has stimulated an enormous amount of research which is discussed in Section 8.2.4 (p. 279).

8.2 Carbon

8.2.1 Terrestrial abundance and distribution

Carbon occurs both as the free element (graphite, diamond) and in combined form (mainly as the
Some Notable Dates in Carbon Chemistry

1807 J. J. Berzelius classified compounds as "organic" or "inorganic" according to their origin in living matter or inanimate material.

1825–7 W. C. Zeise prepared K[Pt(C2H3)Cl3] and related compounds; though of unknown structure at the time they later proved to be the first organometallic compounds.

1828 The vitalist theory of Berzelius challenged by F. Wöhler (aged 28) who synthesized urea, (NH2)2CO, from NH3 and CO2.

1830+ Rise of synthetic organic chemistry.

1848 L. Pasteur (aged 26) began work on optically active sodium ammonium tartrate.

1849 First metal alkyls, e.g. ZnEt2, made by E. Frankland (aged 24); he also first propounded the theory of valency (1852).

1858 F. A. Kekulé’s structural formulae for organic compounds; tetrahedral 4-coordinate carbon proposed by J. H. van’t Hoff (aged 22) see also footnote to p. 268.

1874-7 W. C. Zeise prepared K[Pt(C2H?)C1?] and related compounds; though of unknown structure at the time they later moved to be the first organometallic compounds.

1874 Rise of synthetic organic chemistry.

1880 L. Pasteur (aged 36) began work on optically active sodium ammonium tartrate.

1891 Carborundum, SiC, made by E. G. Acheson.

1896 First paper by V. Grignard (aged 29) on RMgX syntheses. Nobel Prize 1912.

1899 Solid CO2 introduced commercially as a refrigerant.

1900 Carbonates of Ca, Mg and other electropositive elements. It also occurs as CO2 a minor but crucially important constituent of the atmosphere.

1901 Estimates of the overall abundance of carbon in crustal rocks vary considerably, but a value of 180 ppm can be taken as typical; this places the element seventeenth in order of abundance after Ba, Sr and S but before Zr, V, Cl and Cr.

1906 Isotopes of C (12C and 13C) discovered by A. S. King and R. T. Birge in the band spectrum of C2, CO and CN (previously undetected by mass spectrometry).

1924 First metal halide-graphite intercalation compound made with FeCl3.

1925 First metal halide-graphite intercalation compound made with FeCl3.

1926 Tetrahedral, 4-coordinate carbon proposed by J. H. van’t Hoff (aged 22) see also footnote to p. 268.

1932 First metal halide-graphite intercalation compound made with FeCl3.

1936 Radiocarbon 14C* established as the product of an (n,p) reaction on 12N by W. E. Burcham and M. Goldhaber.

1940 Chemically significant amounts of 13C synthesized by S. Ruben and M. D. Kamen.

1948 Concept and feasibility of 14C dating established by W. F. Libby (awarded Nobel Prize in 1960).

1953 First authentic production of artificial diamonds by ASEA. Sweden: commercial production achieved by General Electric (USA) in 1955.

1955 Stereoregular polymerization of ethene and propene by catalysts developed by K. Ziegler and by G. Natta (shared Nobel Prize 1963).

1956 Cyclobutadiene-transition metal complexes predicted by H. C. Longuet-Higgins and L. E. Orgel 3 y before they were first synthesized.

1960 π-allylic metal complexes first recognized.

1961 13C = 12 internationally adopted as the unified atomic weight standard by both chemists and physicists.

1964 6-coordinate carbon established in various carboranes by W. N. Lipscomb and others. (Nobel Prize 1976 for structure and bonding of boranes).

1965 Mass spectrometric observation of CH5+ by F. H. Field and M. S. B. Munson, and subsequent extensive study of hypercoordinate C compounds by G. A. Olah et al.

1966 CS2 complexes such as [Pt(CS2)(PhPPh3)]2 first prepared in G. Wilkinson’s laboratory.

1976 8-coordinate carbon established in [CO3(CO)18]2− by V. G. Albano, P. Chini et al. (Cubic coordination of C in the antifluorite structure of Be2C known since 1948.)

1985 Discovery of C60 and C70 molecules (fullerenes) by H. Kroto, R. E. Smalley and their colleagues.

1994 Nobel Prize to G. A. Olah for contributions to carbocation chemistry.

Graphite is widely distributed throughout the world though much of it is of little economic importance. Large crystals or “flake” occur in metamorphosed sedimentary silicate rocks such as quartz, mica schists and gneisses; crystal size varies from <1 mm up to about 6 mm (average ~4 mm) and the deposits form lenses up to 30 m thick stretching several
§8.2.1 Terrestrial abundance and distribution

Production and Uses of Graphite\(^{(2)}\)

There is a world shortage of natural graphite which is particularly marked in North America and Europe. As a result, prices have risen steeply; they vary widely in the range $500–1500 per tonne (1989) depending on crystalline quality: "amorphous" graphite is $220–440 per tonne. The annual world production of 649 ktonnes was distributed as follows in 1988: China 200 kt, South Korea 108, the former Soviet Union 84, India 52, Mexico 42, Brazil 32, North Korea 25, Czechoslovakia 25, Others 81 kt.

The USA used 37 ktonnes of natural graphite in 1989, nearly all imported; in addition, over 300 ktonnes of graphite was manufactured. Natural graphite is used in refractories (27%), lubricants (17%), foundries (14%), brake linings (12%), pencils (5.3%), crucibles, retorts, stoppers, sleeves and nozzles (4.0%) etc.

Artificial graphite was first manufactured on a large scale by A. G. Acheson in 1896. In this process coke is heated with silica at \(\sim 2500^\circ C\) for 25–35 h:

\[
\text{SiO}_2 + 2\text{C} \xrightarrow{2500^\circ} \text{SiC} \xrightarrow{2500^\circ} \text{Si(g)} + \text{C(graphite)}
\]

In the USA artificial graphite is now made on a scale exceeding 300 kilotonnes pa (1989), and is used mainly for electrodes, crucibles and vessels, and various unmachined shapes; specialist uses include motor brushes and contacts and refractories of various sorts.

Carbon (graphite) fibres are also being manufactured on an increasing scale: The global market (1990) is of the order of 6 million kg per annum and prices range from $20–2000/kg depending on specifications (diameter, strength, stiffness, etc.). The two main production methods are the oxidative thermolysis of polyacrylonitrile fibres at 200–300°C under tension or the thermolysis of pitch at 370° followed by die-extrusion and stretching to give filaments which are then heated progressively in dry air to 2500°. Ultra-high-purity graphite is made on a substantial scale for use as a neutron moderator in nuclear reactors. Carbon whiskers grown from highly purified graphite are finding increasing use in high-strength composites; the whiskers are manufactured by striking a carbon arc at 3600°C under 90 atm Ar — the maximum length is \(\sim 50\) mm and the average diameter 5 \(\mu\)m.

kilometres across country. Average carbon content is 25% but can rise as high as 60% (Malagasy). Beneficiation is by flotation followed by treatment with HF and HCl, and then by heating to 1500°C in vacuo. Microcrystalline graphite (sometimes referred to as "amorphous") occurs in carbon-rich metamorphosed sediments and some deposits in Mexico contain up to 95% C. World production has remained fairly constant for the past few years and was 649 ktonnes in 1988 (see Panel above).

Diamonds are found in ancient volcanic pipes embedded in a relatively soft, dark coloured basic rock called "blue ground" or "kimberlite", from the South African town of Kimberley where such pipes were first discovered in 1870. Diamonds are also found in alluvial gravels and marine terraces to which they have been transported over geological ages by the weathering and erosion of pipes. The original mode of formation of the diamond crystals is still a subject of active investigation. The diamond content of a typical kimberlite pipe is extremely low, of the order of 1 part in 15 million, and the mineral must be isolated mechanically by crushing, sluicing and passing the material over greased belts to which the diamonds stick. This, in part, accounts for the very high price of gem-quality diamonds which is about 1 million times the price of flake graphite. The pattern of world production has changed dramatically over the past few decades as indicated in the Panel on p. 272.

Three other forms of carbon are manufactured on a vast scale and used extensively in industry: coke, carbon black, and activated carbon. The production and uses of these impure forms of carbon are briefly discussed in the Panel on p. 274.

In addition to its natural occurrence as the free element, carbon is widely distributed in the

Production and Uses of Diamond (2.2a)

Gemstone diamonds have been greatly prized in eastern countries for over 2000 y though their introduction and recognition in Europe is more recent. The only sources were from India and Borneo until they were also found in Brazil in 1729. In South Africa diamonds were discovered in alluvial deposits in 1867 and the first kimberlite pipe was identified in 1870 with dramatic consequences. Many other finds of economic importance were made in Africa during the first half of this century: most notably in Tanzania where large-scale production began in 1940 following the discovery of the enormous Williamson pipe — still the largest in the world and covering an area of 1.4 km². During the 1950s 99% of the world output of diamonds was from Africa but then the USSR began to emerge as a major producer following the discovery of alluvial diamonds in Siberia in 1948 and the first kimberlite-type pipe at Yakutia later the same year. Within a decade more than 20 pipes had been located in the great basin of the Vilyui River 4000 km east of the Urals, and Siberia was established as a major producer of both gem-quality and industrial diamonds. However, year-round production in Siberian conditions posed severe developmental problems, and production is now supplemented by newer finds in the Urals near Sverdlovsk. Impressive finds of kimberlite pipes have also been made in North-western Australia since 1978 and this area is now one of the world’s largest producers of industrial diamonds.

Diamond is the hardest and least perishable of all minerals, and these qualities, coupled with its brilliant sparkle, which derives from its transparency and high refractive index, make it the most prized of gemstones. By far the largest natural diamond ever found (25 January 1905) was the Cullinan; it weighed 3106 carats (621.2 g) and measured \( \sim 10 \times 6.5 \times 5 \) cm³ (the size of a man’s clenched fist). Other famous stones are in the range 100–800 carats though specimens larger than 50 carats are only rarely encountered. Most naturally occurring diamonds, however, are of industrial rather than gem-stone quality. They are used as single-point tools for engraving or cutting, and for surgical knives, bearings and wire dies, as well as for industrial abrasives for grinding and polishing. Other uses are as thermistors and radiation detectors, and as optical windows for lasers, etc.

Since the late 1950s the supply of natural diamonds has been progressively augmented by diamonds synthesized at high pressures and temperatures (p. 278) and this source now accounts for 90% of all industrial diamonds. The price for such diamond grit is relatively low, about $5–25 per g, the higher prices being for the largest crystals (0.3–1 mm on edge). Total world production (1990) approached 100 tonnes (500 megacarats) and was worth about $10^9. In 1985, Sumitomo Electric (Japan) began commercial production of diamond crystals of up to 2 carats (as large as 8 mm in length) and de Beer’s (South Africa) have made single crystals up to 17 mm long. Such diamonds, which are pale yellow due to nitrogen inclusions, are used as heat sinks in the electronics industry because of the very high thermal conductivity of diamond. The synthetic stones are machined and laser cut to about 3 x 3 x 1 mm³ and are commercially available for $150 a piece. Synthetic industrial diamonds are manufactured in 16 countries, the major producers being in USA, Japan, China and Russia.

Exciting developments are also occurring in the emerging technology of large-area thin films of synthetic diamond. Such films are of interest as heat sinks for components in the electronics industry and, when bonded to inexpensive non-diamond surfaces, can also provide the unexcelled hardness, wear resistance and chemical inertness of diamond at lower cost than that of the bulk element. The films are made by low pressure (50 mbar) chemical vapour deposition of metastable diamond at 1000°C, the crucial feature of the method being the simultaneous presence of a plasma of atomic H to prevent the concurrent deposition of graphite from the decomposing organic vapours (see p. 278).

Reservoirs of carbon and the flow between them are illustrated in Fig. 8.1 from which it is clear that there are two distinct cycles — one on land and one in the sea, dynamically inter-connected by the atmosphere. CO₂ in the atmosphere (~6.7 x 10¹¹ tonnes) accounts for only 0.003% of carbon in the earth’s crust (~2 x 10¹⁶ tonnes). It is in rapid circulation with the biosphere being removed by plant photosynthesis and added to by plant and animal respiration, and the decomposition of dead organic matter; it is also produced by the activities of man, notably the combustion of fossil fuels for energy and the calcination of limestone for cement. These last

---

† Note that the weight of diamonds is usually quoted in carats (1 carat = 0.200 g); this unit is quite different from the carat used to describe the quality of gold (p. 1176).
Figure 8.1: Diagrammatic model of the global carbon cycle. Questions marks indicate that no estimates are available. Figures are in units of $10^9$ tonnes of contained carbon but estimates from various sources sometimes differ by factors of 3 or more. The diagram is based on one by B. Bolin modified to include more recent data.

Two activities have increased dramatically in recent years and give some cause for concern. Interchange on a similar scale occurs between the atmosphere and ocean waters, and the total residence time of CO$_2$ in the atmosphere is $\sim 10^{-15}$ y (as measured by $^{14}$C experiments).

An increase in the concentration of atmospheric CO$_2$ has been thought by some to expose the planet to the dangers of a "greenhouse effect" whereby the temperature is raised due to the trapping of the earth's thermal radiation by infrared absorption in the CO$_2$ molecules. In fact, the greenhouse gases, especially water vapour and CO$_2$, play a crucial role in regulating the temperature of the earth and its atmosphere. In the absence of these gases the average surface temperature would be $-18^\circ$C instead of the $+15^\circ$C observed at present.

---

Production and Uses of Coke, Carbon Black and Activated Carbon

The high-temperature carbonization of coal yields metallurgical coke, a poorly graphitized form of carbon; most of this (92%) is used in blast furnaces for steel manufacture (p. 1072). World production of coke is of the order of 400 million tonnes per annum and was dominated, as expected, by the large industrial nations. Carbon black (soot) is made by the incomplete combustion of liquid hydrocarbons or natural gas; the scale of operations is enormous, world production in 1992 being nearly 7 million tonnes. The particle size of carbon black is exceedingly small (0.02–0.30 μm) and its principal application (90%) is in the rubber industry where it is used to strengthen and reinforce the rubber in a way that is not completely understood. For example, each car tyre uses 3 kg carbon black and each truck tyre ~9 kg. Its other main uses are as a pigment in plastics (4.4%) in printing inks (3.6%) and paints (0.7%).

Activated carbons, being highly specialized products, are produced on a correspondingly smaller scale. World production capacity in 1990 being some 400 kilotonnes (USA 146, Western Europe 108, Japan 72 kt). They are distinguished by their enormous surface area which is typically in the range 300–2000 m² g⁻¹. Activated carbon can be made either by chemical or by gas activation. In chemical activation the carbonaceous material (sawdust, peat, etc.) is mixed or impregnated with materials which oxidize and dehydrate the organic substrate when heated to 500–900°C, e.g. alkali metal hydroxides, carbonates or sulfates, alkaline earth metal chlorides, carbonates or sulfates, ZnCl₂, H₂SO₄ or H₃PO₄. In gas activation, the carbonaceous matter is heated with air at low temperature or with steam, CO₂ or flue gas at high temperature (800–1000°C).

Activated carbon is used extensively in the sugar industry as a decolorizing agent and this accounts for some 20% of the output; related applications are in the purification of chemicals and gases including air pollution (15%), and in water and waste water treatment (50%). Notable catalytic uses are the aerial oxidation in aqueous solutions of Fe²⁺, [Fe²⁺(CN)₆]³⁻, [As³⁺O₃]⁻ and [N⁷⁺O₂]⁻, the manufacture of COCl₂ from CO and Cl₂, and the production of SO₂Cl₂ from SO₂ and Cl₂. The cost of activated carbon (USA, 1990) was $0.70–5.50 per kg depending on the grade.

There has also been concern that the increased concentration of CO₂ will significantly lower the pH of surface ocean waters thereby modifying the solution properties of CaCO₃ with potentially disastrous consequences to marine life. Informed opinion now discounts such global catastrophes but there has undoubtedly been a measurable perturbation of the carbon cycle in the last few decades, and the prudent course is to conserve resources, minimize wasteful practices and improve efficiency, whilst simultaneously collecting reliable data on the magnitude of the various carbon-containing reservoirs and the rates of transfer between them.5

8.2.2 Allotropic forms

Carbon can exist in at least 6 crystalline forms in addition to the many newly prepared fullerenes described in Section 8.2.4: α- and β-graphite, diamond, Lonsdaleite (hexagonal

---

diamond), chaoite, and carbon(VI). Of these, α-(or hexagonal) graphite is thermodynamically the most stable form at normal temperatures and pressures. The various modifications differ either in the coordination environment of the carbon atoms or in the sequence of stacking of layers in the crystal. These differences have a profound effect on both the physical and the chemical properties of the element.

Graphite is composed of planar hexagonal nets of carbon atoms as shown in Fig. 8.2. In normal α- (or hexagonal) graphite the layers are arranged in the sequence ...ABAB... with carbon atoms in alternate layers vertically above each other, whereas in β- (or rhombohedral) graphite the stacking sequence is ...ABCABC.... In both forms the C−C distance within the layer is 141.5 pm and the interlayer spacing is much greater, 335.4 pm. The two forms are interconvertible by grinding (α → β) or heating above 1025°C (β → α), and partial conversion leads to an increase in the average spacing between layers; this reaches a maximum of 344 pm for turbostratic graphite in which the stacking sequence of the parallel layers is completely random. The enthalpy difference between α- and β-graphite is only 0.59± 0.17 kJ mol⁻¹.

In diamond, each C atom is tetrahedrally surrounded by 4 equidistant neighbours at 154.45 pm, and the tetrahedra are arranged to give a cubic unit cell with \( a_0 = 356.68 \) pm as in Fig. 8.3. Note that, although the diamond structure itself is not close-packed, it is built up of 2 interpenetrating fcc lattices which are off-set along the body diagonal of the unit cell by one-quarter of its length. Nearly all naturally occurring diamonds (≈98%) are of this type but contain, in addition, a small amount of nitrogen atoms (0.05–0.25%) in platelets of approximate composition C₃N (type Ia) or, very occasionally (≈1%), dispersed throughout the

Carbon Ch. 8

Figure 8.3 Structure of diamond showing the tetrahedral coordination of C; the dashed lines indicate the cubic unit cell containing 8 C atoms.

crystal (type Ib). A small minority of natural diamonds contain no significant amount of N (type IIa) and a very small percentage of these (including the highly valued blue diamonds, type IIb), contain Al. The exceedingly rare hexagonal modification of diamond, Lonsdaleite, was first found in the Canyon Diablo Meteorite, Arizona, in 1967; each C atom is tetrahedrally coordinated but the tetrahedra are stacked so as to give a hexagonal wurtzite-like lattice (p. 1210) rather than the cubic sphalerite-type lattice (p. 1210) of normal diamond. Lonsdaleite can be prepared at room temperature by static pressure along the c-axis of a single crystal of α-graphite, though it must be heated above 1000° under pressure to stabilize it (a₀ 252 pm, c₀ 412 pm, d_{obs} 3.3 g cm⁻³, d_{calc} 3.51 g cm⁻³).

Two other crystalline forms of carbon have been discovered in the recent past. Chaoite, a new white allotrope, was first found in shock-fused graphitic gneiss from the Ries Crater, Bavaria, in 1968; it can be synthesized artificially as white dendrites of hexagonal symmetry by the sublimation etching of pyrolytic graphite under free vaporization conditions above ~2000°C and at low pressure (~10⁻⁴ mmHg). The crystals were only 0.5 μm thick and 5–10 μm long and had a₀ 894.5 pm, c₀ 1407.1 pm and d_{calc} 3.43 g cm⁻³. Finally, in 1972, a new hexagonal allotrope, carbon(VI), was obtained together with chaoite when graphitic carbons were heated resistively or radiatively at ~2300°C under any pressure of argon in the range 10⁻⁴ mmHg to 1 atm; laser heating was even more effective (a₀ 533 pm, c₀ 1224 pm, d > 2.9 g cm⁻³). The detailed crystal structures of chaoite and carbon(VI) have not yet been determined but they appear to be based on a carbyne-type motif —C≡C—C≡C; both are much more resistant to oxidation and reduction than graphite and their properties are closer to those of diamond. Indeed, it now seems possible that there is a sequence of at least 6 stable carbyne allotropes in the region between stable graphite and the mp of carbon.

The structural differences between graphite and diamond are reflected in their differing physical and chemical properties, as outlined in the following sections.

8.2.3 Atomic and physical properties

Carbon occurs predominantly as the isotope ¹²C but there also is a small amount of ¹³C; the concentration of ¹³C varies slightly from 0.99 to 1.15% depending on the source of the element, the most usual value being 1.10% which leads to an atomic weight for "normal" carbon of 12.0107(8). Like the proton, ¹³C has a nuclear spin quantum number I = ½, and this has been exploited with increasing effectiveness during the past two decades in Fourier transform NMR spectroscopy. In addition to ¹²C and ¹³C, carbon dioxide in the atmosphere contains 1.2 × 10⁻¹⁰% of radioactive ¹⁴C which is continually being formed by the ¹⁴N(p,n)¹⁵C reaction with thermal neutrons resulting from cosmic ray activity. ¹⁴C decays by β⁻ emission (E_{max} 0.156 MeV, E_{mean} 0.049 MeV) with a half-life of 5715 ± 30 years and this is sufficiently long to enable a steady-state equilibrium concentration to be established in the biosphere. Plants and animals therefore contain 1.2 × 10⁻¹⁰% of their carbon as ¹⁴C whilst they are living, and this leads to a β-activity of 15.3 counts per min per gram.

---

of contained C. However, after death the dynamic interchange with the environment ceases and the $^{14}$C concentration decreases exponentially. This is the basis of W. F. Libby’s elegant radio-carbon dating technique for which he was awarded the Nobel Prize for Chemistry in 1960. It is particularly valuable for archeological dating.\(^{10}\) (A modern variant is to count the number of $^{14}$C atoms directly in a mass spectrometer.) The practical limit is about 50000 y since by this time the $^{14}$C activity has fallen to about 0.2% of its original valuable and becomes submerged in the background counts. $^{14}$C is also extremely valuable as a radioactive tracer for mechanistic studies using labelled compounds, and many such compounds, particularly organic ones, are commercially available (p. 310).

Carbon is the sixth element in the periodic table and its ground-state electronic configuration is $\text{[He]}2s^22p^2$. The first 4 ionization energies of C are 1086.5, 2352.6, 4620.5 and 6222.7 kJ mol$^{-1}$, all much higher than those for the other Group 14 elements Si, Ge, Sn and Pb (p. 372). Excitation energies from the ground-state to various low-lying electron configurations of importance in valence theory are also well established:

<table>

</tbody>
</table>

Of these, all are experimentally observable except the $^{5}S_{\text{valence state}}$ level which is a calculated value for a carbon atom with 4 unpaired and uncorrelated electron spins; this is a hypothetical state, not amenable to experimental observation, but is helpful in some discussions of bond energies and covalent bonding theory.

The electronegativity of C is 2.5, which is fairly close to the values for other members of the group (1.8–1.9) and for several other elements: B, As (2.0); H, P (2.1); Se (2.4); S, I (2.5); many of the second- and third-row transition metals also have electronegativities in the range 1.9–2.4.

The “single-bond covalent radius” of C can be taken as half the interatomic distance in diamond, i.e. $r(C) = 77.2$ pm. The corresponding values for “doubly-bonded” and “triply-bonded” carbon atoms are usually taken to be 66.7 and 60.3 pm respectively though variations occur, depending on details of the bonding and the nature of the attached atom (see also p. 292). Despite these smaller perturbations the underlying trend is clear: the covalent radius of the carbon atom becomes smaller the lower the coordination number and the higher the formal bond order.

Some properties of $\alpha$-graphite and diamond are compared in Table 8.1. As expected from its structure, graphite is less dense than diamond and many of its properties are markedly anisotropic. It shows ready cleavage parallel to the basal plane, and this accounts for its flaky appearance, softness, and use as a lubricant although this latter property is due not so much to weak interplanar forces on an atomic scale as to the presence of adsorbed gases, since the coefficient of friction of graphite increases 5-fold at high altitudes and by a factor of 8 in a vacuum. By contrast, diamond can be cleaved in many directions, thus enabling many facets to be cut in gem-stones, but it is extremely hard and involatile because of the strong C–C bonding throughout the crystal. Interestingly, diamond has the highest thermal conductivity of any known substance (more than 5 times that of Cu) and for this reason the points of diamond cutting tools do not become overheated. Diamond also has one of the lowest known coefficients of thermal expansion: $1.06 \times 10^{-6}$ at room temperature.

The optical and electrical properties of the two forms of carbon likewise reflect their differing structures. Graphite is a black, highly reflecting semi-metal with a resistivity $\rho \sim 10^{-4}$ ohm cm within the basal plane though this increases by a factor of $\sim5000$ along the c-axis. Diamond, on the other hand, is transparent and has a high refractive index; there is a band energy gap of

~580 kJ mol⁻¹ so that diamond has a negligible electrical conductivity, the specific resistivity being of the order 10¹⁴–10¹⁶ ohm cm. (For other properties and industrial applications of diamond, see ref. 11.)

As may be seen from the heats of combustion, α-graphite is more stable than diamond at room temperature, the heat of transformation being about 1.9 kJ mol⁻¹. However, as the molar volume of diamond (3.418 cm³) is much smaller than that of graphite (5.301 cm³), it follows that diamond can be made from graphite by application of a suitably high pressure, provided that the temperature is also sufficiently high to permit movement of the atoms. Such transformations were first successfully achieved in 1953–5, using pressures up to 100 kbar and temperatures in the range 1200–2800 K,⁽²ᵃ⁾ the presence of molten-metal catalysts such as Cr, Fe, or Ni was also found to be necessary, suggesting that the transformation may proceed via the formation of unstable metal carbide intermediates. Very recently red phosphorus has also been shown to catalyse the conversion of graphite to diamond at 77 kbar and 1800°C.⁽¹²⁾ The use of kinetically controlled non-equilibrium processes to deposit thin films of crystalline diamond has already been mentioned (p. 272). The relationship between the conditions for these various processes is summarized in Fig. 8.4 which shows the phase diagram of carbon near its triple point.⁽¹³⁾ This schematic representation does not explicitly include the several carbyne-like carbon phases⁽⁷⁾ which have been identified at very low pressures (10⁻⁴–10⁻⁸ kbar) in the region marked X.

Figure 8.4 Phase diagram of carbon showing regions of importance for the production of synthetic diamond.⁽¹³⁾

8.2.4 Fullerenes

One of the most exciting and challenging developments in recent chemistry has been the synthesis and characterization of many new, soluble, molecular modifications of carbon. As a result, the number of identified allotropes of this element has increased enormously and their intriguing chemistry is gradually being elucidated. The new allotropes form an extensive series of polyhedral cluster molecules, $C_n$ ($n$ even), comprising fused pentagonal and hexagonal rings of C atoms. The first member to be characterized was $C_{60}$ which features 12 pentagons separated by 20 fused hexagons as shown in Fig. 8.5. It has full icosahedral symmetry (p. 141) and was given the name buckminsterfullerene in honour of the architect R. Buckminster Fuller whose buildings popularized the geodesic dome, which uses the same tectonic principle. Other fullerenes which have been isolated and characterized include $C_{70}$, $C_{76}$ (chiral), $C_{78}$ (3 isomers), $C_{84}$ (3 isomers), $C_{90}$ and $C_{94}$, but there is mass spectrometric evidence for all even $C_n$ from $C_{30}$ to $C_{560}$, (m.wt. 7206.6).

The fullerene story began in September 1985 when a group lead by H. W. Kroto (Sussex, UK) and R. E. Smalley (Rice, Texas) laser-blasted graphite at $T > 10^4$°C and showed mass spectrometrically that the product contained a series of molecules with even numbers of atoms from $C_{44}$ to $C_{90}$.$^{14}$ Concentrations of the individual molecules varied with conditions but the peak for $C_{60}$ was always by far the strongest, followed by $C_{70}$. This experiment showed the existence of new molecular forms of carbon but was not a bulk preparation. However, in a brilliant flash of insight it was conjectured that the stability of $C_{60}$ might result from the football-like “spherical” structure of a truncated icosahedron, the most symmetrical of all possible structures in 3-dimensional space (Nobel Prize, 1996, see p. 270).

Three years later two astrophysicists, W. Krätschmer (Heidelberg, Germany) and D. R. Huffman (Tucson, Arizona), remembered an unusual and unexpected UV spectrum they had obtained in 1983 from soot obtained by striking an arc between graphite electrodes at about 3500°C under a low pressure of helium gas. They re-examined the material mass-spectrometrically and found it contained high concentrations of $C_{60}$ and $C_{70}$ which were soluble in aromatic hydrocarbon solvents such as benzene and toluene.$^{15}$ Here was a stunningly simple preparation of fullerenes in bulk, although separation of individual members proved to

---

be more difficult. Pure C\textsubscript{60} and C\textsubscript{70} were obtained for the first time on 22 August 1990 by chromatographic separation (alumina, hexane).\(^{(16)}\) The process can easily be scaled up using multi-rod apparatus to give about 20 g/day of soot containing up to 10\% of fullerenes; this can be extracted with toluene to yield about 15 g/week of mixed fullerenes which can be further separated if required. Commercial availability has also assisted progress, typical prices (1994) being £150/g for C\textsubscript{60} (99.9\%) and £2000/g for C\textsubscript{70} (98\%).

Other routes to C\textsubscript{60} and C\textsubscript{70} are being developed, e.g. (i) heating naphthalene vapour (C\textsubscript{10}H\textsubscript{8}) in argon at about 1000°C followed by extraction with CS\textsubscript{2}; (ii) burning soot in a benzene/oxygen flame at about 1500°C with argon as a diluent. C\textsubscript{60} and C\textsubscript{70} have also been detected in several naturally occurring minerals, e.g. in carbon-rich semi-anthracite deposits from the Yarrabee mine in Queensland, Australia;\(^{(17a)}\) in shungite, a highly metamorphosed meta-anthracite from Shunga, Karelia, Russia;\(^{(17b)}\) and in a Colorado, USA fulgurite (a glassy mineral which can be formed when lightning strikes the ground).\(^{(17c)}\) Most recently, significant finds of naturally occurring fullerenes have been made in Sudbury (Canada) and New Zealand.\(^{(17d)}\)

The purified fullerenes have very attractive colours. Thin films of C\textsubscript{60} are mustard-coloured (dark brown in bulk) and solutions in aromatic hydrocarbons are a beautiful magenta. Thin films of C\textsubscript{70} are reddish brown (greyish black in bulk) and solutions are port-wine red. C\textsubscript{76}, C\textsubscript{78} and C\textsubscript{84} are yellow.\(^{(16)}\)

**Structure of the fullerenes**

The structural motif of the fullerenes is a sequence of polyhedral clusters, C\textsubscript{n}, each with 12 pentagonal faces and \((\frac{1}{2}n - 10)\) hexagonal faces. C\textsubscript{60} itself has 20 hexagonal faces and, significantly, is the first member for which all 12 pentagonal faces are non-adjacent. Smaller homologues have increasing numbers of contiguous pentagonal faces; e.g. C\textsubscript{32} is expected to have only 6 hexagonal faces. As can be seen from Fig. 8.5, all C atoms in C\textsubscript{60} are structurally identical and, consistent with this, only one signal is observed in the \(^{13}\)C nmr spectrum (at 142.68 ppm). However, there are two geometrically distinct types of C–C bond: those at an edge shared between two fused hexagons, and those at an edge between a hexagon and a pentagon.

By contrast, C\textsubscript{70} has 25 hexagonal faces and \(D_{5h}\) symmetry (Fig. 8.6a) with 5 types of C atom (a, b, c, d, e) and 8 types of C–C bond. Five \(^{13}\)C nmr signals are therefore expected, with intensities in the ratio 10:10:20:20:10, and these are observed in the range 150.77–130.28 ppm.\(^{(16)}\) Again, a \(^{13}\)C nmr study of chromatographically isolated of C\textsubscript{76} showed it to have 28 hexagonal faces and a fascinating chiral structure of \(D_2\) symmetry, consisting of a spiralling double helical arrangement of edge-sharing pentagons and hexagons (Fig. 8.6b and c) uniquely consistent with the observed 19 \(^{13}\)C nmr signals in the range 150.03–129.56 ppm, and each of equal intensity (19 \(\times\) 4 = 76).\(^{(18)}\)

The total potential number of geometric isomers increases enormously with increase in cluster size, being, for example, three for C\textsubscript{30}, 40 for C\textsubscript{40}, 271 for C\textsubscript{50} and no fewer than 1812 for C\textsubscript{60}.\(^{(19)}\) However, the number becomes much more manageable if one considers only those isomers that have no contiguous pentagons. The theoretical justifications for this

R. TAYLOR (and 12 others), Pure Appl. Chem. 65, 135–42 (1993).

Figure 8.6  (a) The $D_{5h}$ structure of $C_{70}$ with the 5-fold rotation axis vertical; the five sets of geometrically distinct C atoms are labelled a-e (see text). (b), (c) Line drawings of the two enantiomers of $C_{76}$ viewed along the short $C_2$ rotation axis and illustrating the chiral $D_2$ symmetry of the molecule.

restriction would be (a) that isomers with fused pentagons are expected to have greater σ-bonding strain energy and (b) that, since two fused pentagons have an 8-cycle around their periphery, there would be a further Hückel antiaromatic destabilizing effect on the overall $\pi$ electron system. In fact, in the range $C_{20}-C_{70}$ this restriction of isolated pentagons eliminates all structures except the observed $C_{60}(l_h)$ and $C_{70}(D_{5h})$. From mass-spectrometric evidence other oligomers clearly exist, though not yet in isolable concentrations. Above $C_{70}$ the number of distinct geometric isomers (i) with isolated pentagons increases rather rapidly with $n$ as indicated below: \(^{(19)}\)

Numerous other fullerenes have been isolated by the same techniques and their structures elucidated by $^{13}$C nmr spectroscopy, e.g., $C_{76}$ (see above); $C_{78}$ [3 isomers: $C_{2v}(18(4C) + 3(2C) \text{ nmr lines})$, $D_3(13(6C))$ and $C_{2v}(17(4C) + 5(2C))]$; $C_{82}$ [3 isomers: $C_2(41(2C))$, $C_{2v}(17(4C) + 7(2C))$ and $C_{3v}(12(6C) + 3(3C) + 1(1C))]$; and $C_{84}$ [2 isomers: $D_2(21(4C))$ and $D_{2d}(10(8C) + 1(4C))]$. \(^{(20)}\) A copiously illustrated atlas of fullerenes elaborating and enumerating the numbers and structures of all possible fullerenes and fullerene isomers $C_n$ as a function of $n$ up to high $n$ has recently been published. \(^{(20a)}\)

Except for $C_{60}$, lack of sufficient quantities of pure material has prevented more detailed structural characterization of the fullerenes by X-ray diffraction analysis, and even for $C_{60}$ problems of orientational disorder of the quasi-spherical molecules in the lattice have exacerbated the situation. At room temperature $C_{60}$ crystallizes in a face-centred cubic lattice ($Fm\overline{3}$) but below 249 K the molecules become orientationally ordered and a simple cubic lattice ($Pa\overline{3}$) results. A neutron diffraction analysis of the ordered phase at 5 K led to the structure shown in Fig. 8.7a; \(^{(21)}\) this reveals that the ordering results from the fact that

---

the electron-rich short bonds between pentagons (139.1 ± 1.8 pm) are positioned directly above the electron-poor pentagon face-centres of adjacent C₆₀ units. The bonds within a given pentagon are somewhat longer (145.5 ± 1.2 pm).

The structures of the black crystalline benzene solvate C₆₀.4C₆H₆,(22) the black charge-transfer complex with bis(ethylendithio)tetraathiafulvene, [C₆₀(BEDT-TTF)₂],(23) and the black ferrocene adduct [C₆₀[Fe(Cp)₂]₂] (Fig. 8.7b)(24) have also been solved and all feature the packing of C₆₀ clusters.

Other molecular allotropes of carbon

Quite apart from the fullerene cluster molecules, numerous other molecular allotropes of carbon, Cₙ, have been discovered in the gases formed by the laser vaporization/subsonic expansion of graphite. The products are detected by mass spectrometry after separation into identifiable series by gas-ion chromatography.(25) The technique suggests that linear oligomers exist from n = 3–10 and an overlapping series of monocyclic planar ring isomers from n = 7–36. Planar bicyclic rings appear for n = 21–44 and yet other series of condensed rings occur in the ranges n = 37–54 and 55–61. Three-dimensional fused ring clusters form a series with n = 28–35, and the fullerenes from C₃₀–C₇₀ were seen as a quite distinct series. For each value of n from 29–41 there are at least three isomers: e.g. C₃₂⁺ comprises 23% monocyclic ring, 71% bicyclic ring, 2.4% open 3D cluster and 3.2% fullerene. The structural assignments are tentative.

Chemistry of the fullerenes

The tremendous burst of excitement which attended the initial isolation in 1990 of weigable amounts of separated fullerenes has been followed by an unparalleled and sustained surge of activity as chemists throughout the world rushed to investigate the chemical reactivity of these novel molecular forms of carbon.

---

Considerable attention has been paid to possible mechanisms of formation\(^{26,27}\) since a firm understanding of this aspect could lead to the development of more effective synthetic routes to the individual fullerenes. It is also known that, when thin films of C\(_{60}\) and C\(_{70}\) are laser-vaporized into a rapid stream of an inert gas, individual molecules of C\(_{60}\) or C\(_{70}\) can themselves coalesce to form stable larger fullerenes such as C\(_{120}\) or C\(_{140}\), and higher multiples. Even more dramatically, when a sample of C\(_{60}\) is subjected to a pressure of 20 GPa (i.e. 200 kbar), it apparently immediately transforms into polycrystalline diamond.

Most solvents will only dissolve a few mg/l of the fullerenes. Solubility in benzene, toluene or CS\(_2\) is somewhat higher but even so the acquisition of \(^{13}\)C nmr data is still a lengthy and tedious business. By far the best solvents to date for C\(_{60}\) at 25°C are \(\sigma\)-dichlorobenzene (25 mg cm\(^{-3}\)), 1-methylnaphthalene (33 mg cm\(^{-3}\)) and 1-Br-2-Me-naphthalene (35 mg cm\(^{-3}\)).\(^{28}\) Colours in a range of some 30 solvents are variously pink, magenta, magenta-brown, brown-yellow, brown-green and brown, no doubt reflecting the varying interaction of the solute with the solvent (cf. I\(_2\), p. 807).

**Hydrogenation** — One of the first chemical reactions of C\(_{60}\) to be studied was its Birch reduction. In a typical procedure, Li metal was added under an argon atmosphere to a suspension of C\(_{60}\) in liquid NH\(_3\)/thf, followed after 30 min by addition of Bu'OH. Initially the off-white product was thought to be C\(_{60}\)H\(_{36}\) but subsequent work using a variety of techniques\(^{29}\) has shown that the product at low temperatures is a mixture of polyhydrofullerenes ranging from C\(_{60}\)H\(_{18}\) to C\(_{60}\)H\(_{36}\) with C\(_{60}\)H\(_{32}\) being the predominant species. This mixture is thermally labile and in the mass spectrometer probe (>250°C) C\(_{60}\)H\(_{36}\) predominates, consistent with a molecule in which the 12 isolated pentagons of the C\(_{60}\) cluster each retain one double bond, i.e. \([(C_2)_12(CH)_36]\). A cleaner route to pure, white C\(_{60}\)H\(_{36}\) is by using a 120-fold molar excess in inert gas, individual molecules of C\(_{60}\) or C\(_{70}\) of 9,10-dihydroanthracene (1) as a H-transfer reagent at 350°C for 30 min. Prolonging the reaction time to 24 h produces C\(_{60}\)H\(_{18}\) as a second product and the method has the added advantage that it permits the ready synthesis of C\(_{60}\)D\(_{36}\), by use of 9,9',10,10'\([D_4]\)dihydroanthracene.\(^{30}\)

**Oxidation reactions** — Direct fluorination of solid C\(_{60}\) with F\(_2\) gas at 70° proceeds slowly in a stepwise manner via several coloured partially fluorinated materials to give, after a period of several days, the colourless fully fluorinated product C\(_{60}\)F\(_{60}\).\(^{31}\) Rapid fluorination under more forcing conditions (F\(_2\) gas/UV irradiation/250°) yields C\(_{60}\)F\(_{48}\) as the main product, plus an intractable mixture of other fluorides C\(_{60}\)F\(_{2n}\) including some hyperfluorinated materials (\(2n > 60\)) which would require the opening of some skeletal C–C bonds.\(^{32}\) C\(_{60}\)F\(_{48}\) itself has over 20 million possible isomers but, astonishingly, the high-yield synthesis of just one of these has recently been achieved by heating a mixture of C\(_{60}\) and NaF under F\(_2\) at 275° for several days.\(^{33}\) Actually a racemic mixture of the two

chiral enantiomers shown in Fig. 8.8 is obtained. Shorter reaction times give complex mixtures of C$_{60}$F$_{46}$ and C$_{60}$F$_{48}$ isomers.

Direct chlorination of C$_{60}$ with Cl$_2$ gas at 250–400°C led to an intractable pale orange mixture of polychlorinated species having on average about 24 Cl atoms per cluster molecule, but milder conditions using Cl$_2$ at various temperatures in a range of chloro organic solvents produced no detectable reaction.(34) By contrast, treatment of C$_{60}$ with an excess of ICl in benzene or toluene at room temperature gave a quantitative yield of deep orange C$_{60}$Cl$_6$ which is isostructural with C$_{60}$Br$_6$ (see below).

Bromination of C$_{60}$ in solution gives C$_{60}$Br$_6$ (magenta plates) and C$_{60}$Br$_8$ (dark brown prisms). The former has a structure involving one monobrominated pentagon with a long C–Br bond (203 pm) itself adjacent to five other monobrominated pentagons (C–Br 196 pm) as shown in Fig. 8.9a. It disproportionates on being warmed to give C$_{60}$ and C$_{60}$Br$_8$ which has a C$_{2v}$ structure with pairs of Br atoms arranged meta on four 6-membered rings (Fig. 8.9b).(36)

Bromination with liquid Br$_2$ yields the somewhat more stable C$_{60}$Br$_{24}$ which has $T_h$ symmetry (Fig. 8.9c) with 12 hexagons disubstituted para and in pairs with boat conformation but mutually meta on the other 8 hexagons which have the chair conformation. The structure has 18 C–C arranged one per pentagon (12) and one at each 6:6 bond (6).(37) All three bromides can be completely dehalogenated on strong heating, as can the polychlorides. Iodine appears not to add directly to C$_{60}$ but forms an intercalation product.

Fullerene epoxide, C$_{60}$O, is formed by the UV irradiation of an oxygenated benzene solution of C$_{60}$.(38) The O atom bridges a 6:6 bond of the closed fullerene structure. The same compound is also formed as one of the products of the reaction of C$_{60}$ with dimethyldioxirane, Me$_2$CWO (see later).(39)

Fullerols, C$_{60}$(OH)$_n$ ($n = 24–26$), can be synthesized directly by aerobic oxidation of a benzene solution of C$_{60}$ using an aqueous solution of NaOH containing a few drops of Bu$_4$NOH as the most efficient catalyst: the deep violet benzene solution rapidly decolorizes and a brown sludge precipitates; further reaction with more water over a period of 10 h gives a clear red-brown solution from which the

---

brown solid product is obtained by vacuum evaporation.\(^{(40)}\) Hydroboration of \(\text{C}_6\text{O}\) followed by treatment either with glacial acetic acid or aqueous NaOH/H\(_2\)\(\text{O}_2\) affords another route to water-soluble fullerols, suggesting that C–H bonds on the fullerene cluster are readily oxidized to C–OH groups.\(^{(41)}\)

Reduction of fullerenes to fullerides — Reversible electrochemical reduction of \(\text{C}_6\text{O}\) in anhydrous dimethylformamide/toluene mixtures at low temperatures leads to the air-sensitive coloured anions \(\text{C}_6\text{O}^{n-}\), \((n = 1–6)\). The successive mid-point reduction potentials, \(E_{1/2}\) at \(-60\)°C are \(-0.82\), \(-1.26\), \(-1.82\), \(-2.33\), \(-2.89\) and \(-3.34\) V, respectively.\(^{(42)}\) Liquid NH\(_3\) solutions can also be used.\(^{(43)}\) \(\text{C}_6\text{O}\) is thus a very strong oxidizing agent, its first reduction potential being at least 1 V more positive than those of polycyclic aromatic hydrocarbons. \(\text{C}_{70}\) can also be reversibly reduced and various ions up to \(\text{C}_{70}^{6-}\) have been detected.

Chemical reduction by alkali metals leads to solid fullerides which are sometimes solvated. Thus, fullerides \(\text{M}_n\text{C}_{60}\) are known for \(n = 1\) when \(\text{M} = \text{Rb}, \text{Cs}\) and for \(n = 2, 3, 4\) and 6 when \(\text{M} = \text{Na}, \text{K}, \text{Rb}\) and \(\text{Cs}\). An important alternative route treats \(\text{C}_{60}\) in toluene with a solution of Na[\(\text{Mn}(\eta^5-\text{C}_5\text{Me}_5)_2\)] in thf to give an 80% yield of the dark-purple, air- and moisture-sensitive crystalline solvate \(\text{NaC}_{60}\cdot\text{thf}\).\(^{(44)}\)

Interest in the unsolvated compounds \(\text{M}_n\text{C}_{60}\) increased dramatically when several were found to be good electrical conductors. \(\text{C}_{60}\) films when doped with alkali metal vapour become organic metals, some of which show superconductivity at low temperatures. For example, \(\text{K}_3\text{C}_{60}\), prepared from stoichiometric amounts of solid \(\text{C}_{60}\) and potassium vapour, has \(T_c\) 19.3 K: it has an fcc structure derived from that of \(\text{C}_{60}\) itself by incorporating K ions into all the octahedral and tetrahedral interstices of the host lattice as shown in Fig. 8.10.\(^{(45)}\) \(\text{Rb}_3\text{C}_{60}\) has an even higher superconducting critical temperature, \(T_c \sim 28\) K. It seems that, when electrons are added to \(\text{C}_{60}\) from an alkali metal, they enter a conduction band composed of the triply degenerate \(t_{1u}\) \(\pi\) orbitals of the individual \(\text{C}_{60}\) molecules. Maximum conductivity is observed when this band is half-filled (at \(\text{C}_{60}^{3-}\)) after which the conductivity gradually decreases until the composition \(\text{M}_6\text{C}_{60}\) when it is full, consistent

---

Fig. 8.11 and was, in fact, the first definitive X-ray structural determination of a fullerene derivative.\(^{(47)}\)

Other addition reactions are shown in the scheme.\(^{(48)}\) Thus, \(\text{C}_{60}\) reacts as an olefin towards \([\text{Pt}(\text{PPh}_3)_2]\) to give the \(\eta^2\) adduct \([\text{Pt}(\eta^2\text-C_{60})(\text{PPh}_3)_2]\). Indeed six \(M^0\) centres can simultaneously be coordinated by a single fullerene cluster to give \([\text{C}_{60}[M(\text{PEt}_3)_2]_6]\), \((M = \text{Ni, Pd, Pt})\), with the \(6M\) arranged octahedrally about the \((\eta^2)_6\text-C_{60}\) core.\(^{(49)}\) Likewise, reaction of \(\text{C}_{60}\) with \([\text{Ir}(\text{CO})\text{Cl}(\text{PPh}_3)_2]\) provides two conformational isomers of \([[(\eta^2,\eta^2\text-C_{60})\text{-} [\text{Ir}(\text{CO})\text{Cl}(\text{PPh}_3)_2]_2]\) in both of which the \(\text{Ir}\) atoms are ligated by 6:6 double bonds at diametrically opposite sides of the fullerene. Similarly,\(^{(50)}\) \(\text{C}_{70}\) reacts with \([\text{Ir}(\text{CO})\text{Cl}(\text{PPh}_3)_2]\) in benzene solution to give brown crystals of \([\text{Ir}(\eta^2\text-C_{70})(\text{CO})\text{Cl}(\text{PPh}_3)_2]\), ligation occurring from a 6:6 double bond near one of the poles (i.e. an a-b bond in Fig. 8.6), and the bis-adduct \([[(\eta^2,\eta^2\text-C_{70})[\text{Ir}(\text{CO})\text{Cl}(\text{PPh}_3)_2]_2]]\) involves a-b bonds at opposite poles. Very recently, in addition to \(\eta^2\) dihapto and

Addition reactions — The fullerenes \(\text{C}_{60}\) and \(\text{C}_{70}\) react as electron-poor olefins with fairly localized double bonds. Addition occurs preferentially at a double bond common to two annelated 6-membered rings (a 6:6 bond) and a second addition, when it occurs, is generally in the opposite hemisphere. The first characterizable mono adduct was \([\text{C}_{60}\text{OsO}_4(\text{NC}_5\text{H}_4\text{Bu}^t)_2]\), formed by reacting \(\text{C}_{60}\) with an excess of \(\text{OsO}_4\) in 4-butylpyrididine. The structure is shown in Fig. 8.11 and was, in fact, the first definitive X-ray structural determination of a fullerene derivative.\(^{(47)}\)

---

yield the derivatives $C_{60}CR_2$ and $C_{60}SiR_2$. The structurally related epoxide $C_{60}O$ has already been mentioned (p. 284). Benzyne yields a [2+2] adduct as shown, since the [4+2] adduct would require the formation of an energetically unfavourable 5:6 double bond. Nucleophilic reactions with Grignard reagents and Li alkyls yield intermediates which, after protonolysis, afford 1,9-$C_{60}RH$ derivatives, whereas hydroboration (not shown) yields $C_{60}H(BH_2)$ which on protonolysis gives the parent 1,9-dihydrofullerene, $C_{60}H_2$. Diels–Alder reactions give highly regioselective addition products which can be isolated in high yield. By contrast, diphenylidiazomethane and related diazoalkanes and diazoacetates give substituted dihydropyrazole intermediates (via a [3+2] cycloaddition reaction) which then lose $N_2$ to form the thermally stable final products; these may be opened $\pi$ homoaromatic structures bridged at either a 5:6 or a 6:6 ring junction (Fig. 8.12a,b), or a closed $\sigma$ homoaromatic fullerene bridged at a 6:6 ring junction (Fig. 8.12c). In the special case of diazomethane, $C_{60}(CH_2N_2)$ is formed as a thermally unstable brown solution in toluene; this loses $N_2$ when heated under reflux and $C_{61}H_2$ can be isolated as a dark powder from the now purple solution.\(^{51}\) Extensive cluster opening can also occur, as in the cobalt(I) cyclopentadienyl adduct of the purple $C_{60}$/butadiene fulleroid, [Co($\eta^5$-$C_5H_5$)($\eta^2,\eta^2$-$C_{60}C_4H_4$)], which features an unprecedented fifteen-membered “trimethano[15]annulene” opening within the $C_{60}$ framework.

Returning now to the reactions in the scheme it can be seen that carbenes and silenes

---

**Figure 8.12** Structures (a), (b), (c) and (d); see text.
obtained from C60 and organic azides, RN3, by [3 + 2] cycloaddition and subsequent loss of N2.

**Heteroatom fullerene-type clusters** — The possibility of incorporation of hetero atoms into Cn clusters has excited the attention of both theoreticians and experimentalists since the earliest days of fullerene chemistry, particularly in view of the known stability and ubiquity of organic heterocycles. The structural relationship between C60 and β-rhombohedral boron has already been alluded to (p. 142).

Laser vaporization of a composite pressed disc of graphite and BN using He as carrier gas, followed by mass spectrometric analysis, gave a range of clusters with even numbers of atoms from less than 50 to well above 72. The peak with 60 atoms was the most abundant and, in a typical run, was shown to be a mixture of clusters: C60 (22%), C59B (21%), C58B2 (24%), C57B3 (18%), C56B4 (9%), C55B5 (4%) and C54B6 (2%). Brief exposure of this mixture of 60-atom clusters to NH3 at 1 Torr for 2 s led, typically, to the formation of C6O–X{B.NH2}.

Preliminary experiments with contact-arc vaporization of graphite in a stream of He containing N2 or NH3 yielded nitrogen-containing products tentatively assigned to species such as C70N2 and C59NX (x = 2, 4, 6) of as yet undetermined structure.

The possibility of the isoelectronic replacement of pairs of C atoms by contiguous BN groups (p. 207) in fullerenes is particularly intriguing, e.g. C58BN, C60–2x(BN)x. Because each fullerene, Cn, contains 12 pentagonal faces, the limit of such substitution of C2 by alternating BN would seem to be at C12B24N24, since there is a structural frustration at the odd (fifth) C atom of each pentagon.\(^{54}\)

**Encapsulation of metal atoms by fullerene clusters** — It is readily apparent that there is sufficient space inside fullerene clusters to accommodate several other atoms: the trick has been in learning how to synthesize such species. When a composite rod of graphite/La2O3 was vaporized at 1200°C in argon and the resulting “soot” extracted with pyridine, the products included not only C60 and C70 but also LaC60, LaC70, LaC74 and LaC82.\(^{55}\) Photo fragmentation by laser irradiation can then strip off C atoms pairwise to “shrink wrap” the metal with ever smaller clusters down to about LaC44. In each of these compounds the La is encapsulated by Cn, i.e. it is an *endo* compound, in contradistinction to the alkali metal fullerides discussed on p. 285. The accepted symbolism for this novel type of compound is [La@C60] etc., and esr shows that the correct electronic formulation is [La3+@C603−]. The smallest endohedral metallafullerene so far is [U@C28].\(^{56}\) It is notable that C28 would have its 12 pentagons as 4 sets of 3, plus 4 hexagons, all arranged tetrahedrally to give Td symmetry. MO calculations suggest that neutral C28 lacks 4e− to fill completely its bonding MOs and these are supplied by M in [M4+@C284−], (M = U, Ti, Zr, Hf).

The first dimetalla analogue to be characterized was [La2@C60], and mixed metal and trimetalla compounds are also known, e.g. [YLa@C80]\(^{57}\) and [Sc3@C82].\(^{58}\) Other known compounds include the monometalla species [M@C82] for M = La, Ce, Nd, Sm, Eu, Gd, Tb, Dy, Ho and Er,\(^{59}\) the dimetalla compounds [Ce2@C80], [Tb2@C80], [Sc2@C82], [Y2@C82], [La2@C82] and [Sc2@C84], and the trimetalla species [La3@C106] and [La3@C112]. The products

---

obtained depend sensitively on the relative concentrations of metal oxide and carbon in the electrode material.\(^{59}\) Note also that only metals from the left-hand side of the periodic table have so far been encapsulated and there are no substantiated examples with M = Fe, Cu, Ag, Au, etc.

Some recent books and general reviews on the preparation, properties and chemical reactions of the fullerenes and their derivatives are in ref. 60.

The endohedral metallofullarenes just described (and the alkali metal fullerides described on p. 285) are all formally examples of metal carbides, M\(_4\)C\(_{20}\), but they have entirely different structure motifs and properties from the classical metal carbides and the more recently discovered metallacarbohedrenes (metalcarbons) on the one hand (both to be considered in Section 8.4) and the graphite intercalation compounds to be discussed in Section 8.3. Before that, however, we must complete this present section on the various forms of the element carbon by describing and comparing the chemical properties of the two most familiar forms of the element, diamond and graphite.

### 8.2.5 Chemical properties of carbon

Carbon in the form of diamond is extremely unreactive at room temperature. Graphite, although thermodynamically more stable than diamond under normal conditions, tends to react more readily due to its more vulnerable layer structure. For example, it is oxidized by hot concentrated HNO\(_3\) to mellitic acid, C\(_6\)(CO\(_2\)H)\(_6\), in which planar-hexagonal C\(_{20}\) units are preserved. Graphite reacts with a suspension of KClO\(_4\) in a 1:2 mixture (by volume) of conc HNO\(_3\)/H\(_2\)SO\(_4\) to give “graphite oxide” an unstable, pale lemon-coloured product of variable stoichiometry and structure. Similar products can be prepared by anodic oxidation of graphite or by reaction with NaNO\(_3\)/KMnO\(_4\)/concentrated H\(_2\)SO\(_4\). Graphite oxide decomposes slowly at 70°C, and at 200°C it undergoes a spectacular deflagration with the formation of CO, CO\(_2\), H\(_2\)O and soot. Infrared and X-ray evidence suggest that the structure-motif is a puckered hexagonal network of C\(_6\) rings predominantly in the “chair” conformation but with a few remaining C=C bonds; in addition there are terminal and bridging O atoms and pendant OH groups; keto-enol tautomerism is implied and the empirical formula can be represented as C\(_6\)O\(_x\)(OH)\(_y\) with x \(~\sim 1.0–1.7\) and y \(~\sim 2.25–1.7\).

Graphite reacts with an atmosphere of F\(_2\) at temperatures between 400–500°C to give “graphite monofluoride” CF\(_x\) (x \(~\sim 0.68–0.99\)). The reaction is catalysed by HF and can then occur at much lower temperatures (leading, on occasion, to the destruction of graphite electrodes during the preparation of F\(_2\) by the electrolysis of KF/HF melts, p. 797). At \(~\sim 600°C\) the reaction proceeds with explosive violence to give a mixture of CF\(_4\), C\(_2\)F\(_6\), and C\(_2\)F\(_{12}\). The colour of CF\(_x\) depends on the reaction temperature and on the fluorine content, becoming progressively lighter from black (x \(~\sim 0.7\)) to grey (x \(~\sim 0.8\)), silver (x \(~\sim 0.9\)) and transparent white (x \(~\sim 0.98\)).\(^{61}\) The structure has not been definitely established but the idealized layer lattice shown in Fig. 8.13a accounts for the observed interplanar spacings, infrared data, colour, and lack of electrical conductivity (\(\rho > 3000\) ohm cm). CF is very unreactive, but when heated slowly between

600–1000° it gradually liberates fluorocarbons, CnF2n+2.

When gaseous mixtures of F2/HF are allowed to react with finely powdered graphite at room temperature an inert bluish-black compound with a velvety appearance is formed with a composition which varies in the range C4F to C3.57F. The in-plane C–C distance remains as in graphite but the interlayer spacing increases to 534–550 pm depending on the F content. The infrared and X-ray data are best interpreted in terms of the structure shown in Fig. 8.13b. The electrical conductivity, though less than that of graphite, is still appreciable, the resistivity being ~2–4 ohm cm. Other chemical and electrochemical routes to CxF (x < 2) and C14F(HF), have also been explored.\(^{62}\)

At high temperatures, C reacts with many elements including H (in the presence of a finely divided Ni catalyst), F (but not the other halogens), O, S, Si (p. 334), B (p. 149) and many metals (p. 297). It is an active reducing agent and reacts readily with many oxides to liberate the element or form a carbide. These reactions, which reflect the high enthalpy of formation of CO and CO\(_2\), are of great industrial importance (p. 307).

Carbon is known with all coordination numbers from 0 to 8 though compounds in which it is 3- or 4-coordinate are the most numerous. Some typical examples are summarized in the Panel (p. 291). Particular mention should also be made of hypercoordinate “non-classical” carbonium ions such as 5-coordinate CH\(_5^+\), square pyramidal C\(_5\)H\(_5^+\) (cf. the isoelectronic cluster B\(_5\)H\(_9\), p. 154), pentagonal pyramidal C\(_6\)Me\(_6^{2+}\) (cf. iso-electronic B\(_6\)H\(_{10}\), p. 154) and the bicyclic cation 2-norbornyl, C\(_7\)H\(_{11}^+\).\(^{63}\)

---

Interatomic distances vary with the type of bond and the nature of the other atoms or groups attached to the bonded atoms. For example, the formally single-bonded C–C distance varies from 146 pm in Me-CN to 163.8 pm in Bu\textsubscript{3}PhC–CPhBu\textsubscript{2}\textsuperscript{(74)} and 167 pm in 3,5-Bu\textsubscript{2}C\textsubscript{6}H\textsubscript{3}C–C(C\textsubscript{6}H\textsubscript{3}-3,5-Bu\textsubscript{2})\textsubscript{3} and (CF\textsubscript{3})\textsubscript{2}(4-FC\textsubscript{6}H\textsubscript{4})C–C(C\textsubscript{6}H\textsubscript{4}-4-F)(CF\textsubscript{3})\textsubscript{2}.\textsuperscript{(75)} Some typical examples are in Fig. 8.14. Note that because of the breadth of some of these ranges the interatomic distance between quite different pairs of atoms can be identical. For example, the value 133 pm includes C–F, C–O, C–N and C–C; likewise the value of 185 pm includes C–Br, C–S, C–Se, C–P and C–Si. The conventional classification into single, double and triple bonds is adopted for simplicity, but bonding is frequently more subtle and more extended than these localized descriptions imply. Bond energies are listed on p. 374, where they are compared with those for other elements of Group 14. It should perhaps be emphasized that interatomic distances are experimentally observable, whereas bond orders depend on theoretical models and the estimation of bond energies in polyatomic molecules depends additionally on various assumptions as to how the total energy is apportioned. Nevertheless, taken together, the data indicate that an increase in the order of a bond between 2 atoms is accompanied both by a decrease in bond length and by an increase in bond energy. Similarly, for a given bond order between C and a series of other elements (e.g. C–X), the bond energy increases as the bond length decreases.

Graphite Intercalation Compounds

The large interlayer distance between the parallel planes of C atoms in graphite implies that the interlayer bonding is relatively weak. This accounts for the ready cleavage along the basal plane and the remarkable softness of the crystals. It also enables a wide range of substances to intercalate between the planes under mild conditions to give lamellar compounds of variable composition. These reactions are often reversible (unlike those with O and F discussed above) and the graphitic nature of the host lattice is retained. The compounds have quite different structures and properties from those previously encountered in this book and so will be described in some detail. They may be compared with the materials formed by intercalation into certain sheet silicates.

The first alkali-metal graphite compound was reported in 1926: bronze-coloured C$_8$K was formed by direct reaction of graphite with K vapour at 300°C. Rubidium and Cs behave similarly. When heated at $\sim$360°C under reduced pressure the metal is removed in stages to give a series of intercalation compounds C$_8$M (bronze-red), C$_{24}$M (steel-blue), C$_{36}$M (dark blue), C$_{48}$M (black) and C$_{60}$M (black). The compounds can also be prepared by electrolysis of fused melts with graphite electrodes, by reaction of graphite with solutions of M in liquid ammonia or amines, and by exchange reactions using aromatic radical anions. Intercalation is more difficult to achieve with Li and Na though direct reaction with highly purified graphite at 500°C yields C$_6$Li (brass coloured), C$_{12}$Li (copper), and C$_{18}$Li (steel), and reaction with Li/naphthalene in thf yields C$_{16}$Li and C$_{40}$Li. Corresponding reaction of graphite and molten Na at 450°C gives C$_{64}$Na (deep violet) whereas Na/naphthalene gives C$_{32}$Na and C$_{120}$Na.

The crystal structure of C$_8$K is shown in Fig. 8.15(a); the graphite layers remain intact but are stacked vertically above each other instead of in the sequence $\ldots$ABAB$\ldots$ found in $\alpha$-graphite itself. Each graphite layer is interleaved by a layer of K atoms having a commensurate lattice in which the spacing between each K is twice the spacing between the centres of the graphite hexagons (Fig. 8.15(b)). The stoichiometries of the other stages can then be achieved by varying the frequency of occurrence of the intercalated M layers in the host lattice. An idealized representation of this model is shown in Fig. 8.16. Difficulties are encountered in devising a plausible mechanistic route to the formation of these compounds since the direct preparation of one stage from an adjacent stage apparently requires both the complete emptying and the complete filling of inserted layers. It may be that the situation is more complex, with distributions of stages rather than a single uniform arrangement for each stoichiometry. Very recently a new metal-rich phase has been prepared by reacting graphite with molten potassium; the composition is very close to C$_4$K and the structure comprises double planes of K atoms intercalated between each graphite sheet, with a consequent increase in the interplanar spacing to 850 pm.

The electrical resistance of graphite intercalation compounds is even lower than for graphite itself, resistance along the a-axis dropping by a factor of $\sim$10 and that along the c-axis by $\sim$100; moreover, in contrast to graphite, which is diamagnetic, the compounds have a temperature-independent (Pauli) paramagnetism and also behave as true metals in having a resistivity that increases with increase in temperature. This is illustrated by the comparative data shown in Table 8.2.

These data, and the other properties of C$_8$M, suggest that bonding occurs by transfer of electrons from the alkali metal atoms to the conduction band of the host graphite. Consistent with
Figure 8.15  (a) Crystal lattice of $C_3K$ showing the vertical packing of graphitic layers. The C–C distance within layers almost identical to that in graphite itself but the interplanar spacing (540 pm) is much larger than for graphite (335 pm) due to the presence of K atoms. The spacing increases still further to 561 pm for $C_3Rb$ and to 595 pm for $C_3Cs$. (b) Triangular location of K atoms in $C_3K$ showing the relation to the host graphite layers. In the other alkali-metal graphite compounds $C_{12n}M$ the central M atom is missing, leading to a stoichiometry of $C_{12}M$ if every alternate layer is M, $C_{24}M$ if each third layer is M, etc.

Figure 8.16  Layer-plane sequence along the c-axis for graphite in various stage 1–5 of alkali-metal graphite intercalation compounds. Comparison with Fig. 8.15 shows that the horizontal planes are being viewed diagonally across the figure. $l_c$ is the interlayer repeat distance along the c-axis.

this, direct metal intercalation has only been observed with the most electropositive elements (Group 1) though Ba, with a first-stage ionization energy intermediate between those of Li and Na, was recently (1974) found to give C$_6$Ba.

Alkali-metal graphites are extremely reactive in air and may explode with water. In general, reactivity decreases with ease of ionization of M in the sequence Li > Na > K > Rb > Cs. Under controlled conditions H$_2$O or ROH produce only H$_2$, MOH and graphite, unlike the alkali-metal carbides M$_2$C$_2$ (p. 297) which produce hydrocarbons such as acetylene. In an important new reaction CsK has been found to react smoothly with transition metal salts in tetrahydrofuran at room temperature to give the corresponding transition metal lamellar compounds:\(^{(78)}\)

$$nC_8K + MX_n \xrightarrow{\text{thf}} C_{8n}M + nKX$$

Examples include reaction of Ti(OPr')$_4$, MnCl$_2$·4H$_2$O, FeCl$_3$, CoCl$_2$·6H$_2$O, CuCl$_2$·2H$_2$O, and ZnCl$_2$ to give C$_{32}$Ti, C$_{16}$Mn, C$_{24}$Fe, C$_{16}$Co, C$_{16}$Cu and C$_{16}$Zn, respectively.

A quite different sort of graphite intercalation compound is formed by the halides of many elements, particularly those halides which themselves have layer structures or weak intermolecular binding. The first such compound (1932) was with FeCl$_3$; chlorides, in general, have been the most studied, but fluoride and bromide intercalates are also known. Halides which have been reported to intercalate include the following:

- HF; ClF$_3$, BrF$_3$, IF$_5$; XeF$_6$, XeOF$_4$
- CrO$_2$F$_2$, SbF$_3$Cl$_2$, TiF$_4$
  
- MF$_5$ (M = As, Sb, Nb, Ta); UF$_6$
- MCl$_2$: $M = $ Be; Mn, Co, Ni, Cu; Zn, Cd, Hg
- MCl$_3$: $M = $ B, Al, Ga, In, Ti; Y; Sm, Eu, Gd, Tb, Dy; Cr, Fe, Co; Ru, Rh, Au; I
- MCl$_4$: $M = $ Zr, Hf; Re, Ir; Pd, Pt
- MCl$_5$: $M = $ Sb; Mo; U
- MCl$_6$: $M = $ W, U; also CrO$_2$Cl$_2$, UO$_2$Cl$_2$
- Mixtures of AlCl$_3$ plus Br$_2$, I$_2$, ICl$_3$; FeCl$_3$, WCl$_6$
- Bromides: CuBr$_2$, AlBr$_3$, GaBr$_3$; AuBr$_3$

The intercalates are usually prepared by heating a mixture of the reactants though sometimes the presence of free Cl$_2$ is also necessary, particularly for “non-oxidizing” chlorides such as MnCl$_2$, NiCl$_2$, ZnCl$_2$, AlCl$_3$, etc. Many of the compounds appear to show various stages of intercalation, the first stage usually exhibiting a typical blue colour. A common feature of many of the intercalated halides is their ability to act as electron-pair acceptors (Lewis acids). Low heat of sublimation is a further characteristic of most of the intercalating compounds. It may be that an important feature is an ability of the guest molecule to form a layer lattice commensurate with the host graphite. For example, in C$_{6,69}$FeCl$_3$ the intercalated FeCl$_3$ has a layer structure similar to that in FeCl$_3$ itself with Cl in approximately close-packed arrangement though with some distortion, and with extensive stacking disorder. The “first-stage” compound varies in composition in the range C$_{6-7}$FeCl$_3$; in addition a “second-stage” compound corresponding to C$_{12}$FeCl$_3$ is known, and also a “third-stage” with composition in the range C$_{24-30}$FeCl$_3$. Another well-characterized phase occurs with MoCl$_5$: layers of close-packed Mo$_2$Cl$_{10}$ molecules alternate with sets of 4 graphite layers along the c-axis.

There appears to be a small but definite transfer of electron charge from the graphite to the guest species and this has led to formulations such as C$_{70}$Cl$^+$.FeCl$_2$·5FeCl$_3$. Similarly, the intercalate of AlCl$_3$ (which is formed in the presence of free Cl$_2$) has been formulated as C$_{27}$Cl$^-$.3AlCl$_3$. This would explain the enhanced conductivity of the graphite-metal...
halide compounds, due to the formation of positive holes near the top of the valence band. However, despite extensive work using a variety of techniques, many structural problems remain unresolved and there is still no consensus on the detailed description of the bonding. Recent work includes studies on intercalation and staging in main-group element fluoride systems, e.g. (using ionic formulations)

\[
\begin{align*}
2C_{12}^+\text{AsF}_6^- + \text{AsF}_3 & \rightleftharpoons 3C_8\text{AsF}_5 \quad (79) \\
C_{12}^+\text{GeF}_5^- + \frac{1}{2}F_2 & \rightleftharpoons C_{12}^2+\text{GeF}_6^2- \quad (80) \\
C_{24}^+\text{SiF}_5^- + 2\text{PF}_5 & \rightarrow \text{SiF}_4(g) \\
& + [C_{24}^+\text{PF}_6^-\cdot\text{PF}_5]^31 \\
24C + \text{PF}_5 + \frac{1}{2}F_2 & \xrightarrow{20\text{°} / 24 - 32 \text{ h}} C_{24}^+\text{PF}_6^-
\end{align*}
\]

The halogens themselves show a curious alternation of behaviour towards graphite. \(\text{F}_2\) gives the compounds \(\text{CF}, \text{C}_2\text{F}\) and \(\text{C}_4\text{F}\) (p. 289) whereas liquid \(\text{Cl}_2\) reacts slowly to give \(\text{C}_8\text{Cl}\), and \(\text{I}_2\) appears not to intercalate at all. By contrast, \(\text{Br}_2\) readily intercalates in several stages to give compounds of formula \(\text{C}_8\text{Br}\), \(\text{C}_{12}\text{Br}\), \(\text{C}_{16}\text{Br}\) and \(\text{C}_{20}\text{Br}\); the compounds \(\text{C}_{14}\text{Br}\) and \(\text{C}_{28}\text{Br}\) have also been well-characterized crystallographically but may be metastable phases. A notable feature of the \(\text{Br}_2\) intercalation reaction is that it is completely prevented by prior coating of the basal plane of the sample of graphite with a layer impervious to \(\text{Br}_2\). The lamellar character of blue \(\text{C}_8\text{Br}\) has been confirmed by X-ray diffraction and the intercalation of bromine, is accompanied by a marked decrease in the resistivity of the graphite — more than tenfold along the \(a\)-axis and twofold along the \(c\)-axis. \(\text{C}_8\text{ICl}\) and \(\text{C}_{36}\text{ICl}\) have also been prepared.

Numerous oxides, sulfides and oxoacids have been found to intercalate into graphite. For example, lamellar compounds with \(\text{SO}_3\), \(\text{N}_2\text{O}_5\) and \(\text{Cl}_2\text{O}_7\) are known (but not with \(\text{SO}_2\), \(\text{NO}\) or \(\text{NO}_2\)). \(\text{CrO}_3\) and \(\text{MoO}_3\) readily intercalate as do several sulfides such as \(\text{V}_2\text{S}_3\), \(\text{Cr}_2\text{S}_3(+\text{S})\), \(\text{WS}_2\), \(\text{PdS}(+\text{S})\) and \(\text{Sb}_2\text{S}_5\). Metal nitrates and oxonitrates can also form intercalates, e.g. \(\text{Cu(NO}_3)_2\), \(\text{Zn(NO}_3)_2\), \(\text{Zr(NO}_3)_4\), \(\text{CrO}_2(\text{NO}_3)_2\), \(\text{NbO(NO}_3)_3\) and \(\text{TaO(NO}_3)_3\). A recent example is \([\text{C}_{28}\text{MoO}_2(\text{NO}_3)_2.0.3\text{N}_2\text{O}_5]\) \(82\).

The reversible intercalation of various oxoacids under oxidizing conditions leads to lamellar graphite "salts" some of which have been known for over a century and are now particularly well characterized structurally. For example, the formation of the blue, "first-stage" compound with conc \(\text{H}_2\text{SO}_4\) can be expressed by the idealized equation

\[
24\text{C} + 3\text{H}_2\text{SO}_4 + \frac{1}{4}\text{O}_2 \rightarrow C_{24}^+\text{HSO}_4^-\cdot2\text{H}_2\text{SO}_4 + \frac{1}{2}\text{H}_2\text{O}
\]

The overall stoichiometry is thus close to \(\text{C}_8\text{H}_2\text{SO}_4\) and the structure is very similar to that of \(\text{C}_8\text{K}\) (p. 293) except for the detail of vertical alignment of the carbon atoms in the \(c\) direction which is \(\cdots\text{ABAB}\cdots\). Several later stages (2, 3, 4, 5, 11) have been established and their properties studied. Intercalation is accompanied by a marked decrease in electrical resistance. A series of graphite nitrates can be prepared similarly, e.g. \(\text{C}_{24}^+\text{NO}_3^-\cdot2\text{HNO}_3\) (blue), \(\text{C}_{48}^+\text{NO}_3^-\cdot3\text{HNO}_3\) (black), etc. Other oxoacids which intercalate (particularly under electrolytic conditions) include \(\text{HClO}_4\), \(\text{HSO}_3\), \(\text{HSO}_3\text{Cl}\), \(\text{H}_2\text{SeO}_4\), \(\text{H}_3\text{PO}_4\), \(\text{H}_2\text{P}_2\text{O}_7\), \(\text{H}_3\text{AsO}_4\), \(\text{CF}_3\text{CO}_2\text{H}\), \(\text{CCl}_3\text{CO}_2\text{H}\), etc. The extent of intercalation depends both on the strength of the acid and its concentration, and the reactions are of considerable technological importance because they can lead to the swelling and eventual destruction of the graphite electrodes used in many electrochemical processes.

---

8.4 Carbides

Carbon forms binary compounds with most elements: those with metals are considered in this section whilst those with H, the halogens, O, and the chalcogens are discussed in subsequent sections. Alkali metal fullerides and encapsulated (endohedral) metallafullerenes have already been considered (pp. 285, 288 respectively) and metalcarbohedrenes (metcars) will be dealt with later in this section (p. 300). Silicon carbide is discussed on p. 334. General methods of preparation of metal carbides are:\(^{83}\)

1. Direct combination of the elements above ~2000°C.
2. Reaction of the metal oxide with carbon at high temperature.
3. Reaction of the heated metal with gaseous hydrocarbon.
4. Reaction of acetylene with electropositive metals in liquid ammonia.

Attempts to classify carbides according to structure or bond type meet the same difficulties as were encountered with hydrides (p. 64) and borides (p. 145) and for the same reasons. The general trends in properties of the three groups of compounds are, however, broadly similar, being most polar (ionic) for the electropositive metals, most covalent (molecular) for the electronegative non-metals and somewhat complex (interstitial) for the elements in the centre of the d block. There are also several elements with poorly characterized, unstable, or non-existent carbides, namely the later transition elements (Groups 11 and 12), the platinum metals, and the post transition-metal elements in Group 13.

Salt-like carbides containing individual C "anions" are sometimes called "methanides" since they yield predominantly CH\(_4\) on hydrolysis. Be\(_2\)C and Al\(_4\)C\(_3\) are the best-characterized examples, indicating the importance of small compact cations. Be\(_2\)C is prepared from BeO and C at 1900–2000°C; it is brick-red, has the antifluorite structure (p. 118), and decomposes to graphite when heated above 2100°. Ab initio calculations suggest that the structure is predominantly ionic with charges close to the nominal Be\(_2\)C\(_4\).\(^{84}\) Al\(_4\)C\(_3\), prepared by direct union of the elements in an electric furnace, forms pale-yellow crystals, mp 2200°C. It has a complex structure in which \{AlC\(_4\)\} tetrahedra of two types are linked to form a layer lattice: this defines two types of C atom, one surrounded by a deformed octahedron of 6 Al at 217pm and the other surrounded by 4 Al at 190–194pm and a fifth Al at 221pm. The closest C...C approach is at the nonbonding distance of 316pm. Although it is formally possible to describe the structure as ionic, \((\text{Al}^{3+})_4(\text{C}^{4-})_3\), such a gross separation of charges is unlikely to occur over the observed interatomic distances.

Carbides containing a C\(_2\) unit are well known; they are exemplified by the acetylides (ethynides) of the alkali metals, M\(_1\)C\(_2\), alkaline earth metals, M\(_{12}\)C\(_2\), and the lanthanoids LnC\(_2\) and Ln\(_2\)C\(_3\) \((\text{Ln} = \text{Lu})\). The corresponding compounds of Group 11 (Cu, Ag, Au) are explosive and those of Group 12 (Zn, Cd, Hg) are poorly characterized. M\(_1\)C\(_2\) are best prepared by the action of C\(_2\)H\(_2\) on a solution of alkali metal in liquid NH\(_3\); they are colourless crystalline compounds which react violently with water and oxidize to the carbonate on being heated in air. M\(_{12}\)C\(_2\) can be prepared by heating the alkaline earth metal with ethyne above 500°C. By far the most important compound in this group is CaC\(_2\) --- it is manufactured on a huge scale, 6.4 million tonnes worldwide in 1982 and is used as a major source of ethyne for the chemical industry and for oxyacetylene welding. US production peaked at 1.03 Mt in 1964 but then declined substantially as ethyne became available from petrochemical feedstocks, from the thermal cracking of hydrocarbons and as a byproduct of C\(_2\)H\(_4\) manufacture. US production of CaC\(_2\)

---

83 Reference 2, pp. 841–911: Carbides (p. 841); Cemented carbides (p. 848); Industrial hard carbides (p. 861); Calcium carbide (p. 878); Silicon carbide (p. 891).

has been below 250,000 tonnes per annum for the past 20 years and was 236,000 tonnes in 1990 (price $515/t). Europe (3.25 Mtpa) and Asia/Australia (2.42 Mtpa) are currently the major producers.

Industrially, CaC$_2$ is produced by the endothermic reaction of lime and coke:

$$\text{CaO} + 3\text{C} \rightarrow \text{CaC}_2 + \text{CO}; \quad \Delta H = 465.7 \text{ kJ mol}^{-1}$$

Subsequent hydrolysis is highly exothermic and must be carefully controlled:

$$\text{CaC}_2 + 2\text{H}_2\text{O} \rightarrow \text{C}_2\text{H}_2 + \text{Ca(OH)}_2; \quad \Delta H = -120 \text{ kJ mol}^{-1}$$

Another industrially important reaction of CaC$_2$ is its ability to fix N$_2$ from the air by formation of calcium cyanamide:

$$\text{CaC}_2 + \text{N}_2 \rightarrow \text{CaCN}_2 + \text{C}; \quad \Delta H = -296 \text{ kJ mol}^{-1}$$

CaCN$_2$ is widely used as a fertilizer because of its ready hydrolysis to cyanamide, H$_2$NCONH$_2$ (p. 323).

Pure CaC$_2$ is a colourless solid, mp 2300°C. It can be prepared on the laboratory scale by passing ethyne into a solution of Ca in liquid NH$_3$, followed by decomposition of the complex so formed, under reduced pressure at ~325°C:

$$\text{Ca(liquid NH}_3\text{)} + 2\text{C}_2\text{H}_2 \rightarrow \text{H}_2 + \text{CaC}_2\cdot\text{C}_2\text{H}_2 \rightarrow ^{80^\circ} \text{CaC}_2 + \text{C}_2\text{H}_2 \rightarrow ^{325^\circ} \text{CaC}_2 + \text{C}_2\text{H}_2$$

It exists in at least four crystalline forms, the one stable at room temperature being a tetragonally distorted NaCl-type structure (Fig. 8.17) in which the C$_2$ units are aligned along the c-axis. The ethynides of Mg, Sr and Ba have the same structure and also hydrolyse to give ethyne. In addition, BaC$_2$ absorbs N$_2$ from the atmosphere to give Ba(CN)$_2$ (cf. CaC$_2$ above).

![Figure 8.17 Crystal structure of tetragonal CaC$_2$ showing the resemblance to NaCl (p. 242). Above 450°C the parallel alignment of the C$_2$ units breaks down and the structure becomes cubic.](image)

Carbides containing the essentially linear C$_4$$^-$ unit are known, e.g. Li$_4$C$_3$, Mg$_2$C$_3$, and the recently characterized Ca$_3$C$_3$Cl$_2$ and Sc$_3$C$_4$. Thus Ca$_3$C$_3$Cl$_2$ forms as transparent red crystals when CaCl$_2$ is heated with graphite in sealed Ta capsules at 900°C for 1 day (C–C 134.6 pm, angle 169.0°). By contrast Sc$_3$C$_4$ is a grey-black metallic substance with Pauli paramagnetism: it contains C$^-$ and C$_2^{2-}$ ions, and supernumerary electrons e$^-$ in addition to C$_3$$^4-$ (C–C 134.2 pm, angle 175.8°). It can best be represented as IOSc$_3$C$_4 \equiv [(\text{Sc}^{3+})_{30}(\text{C}^{4-})_{12}(\text{C}_2^{2-})_2(\text{C}_3^{4-})_8(\text{e}^-)]$.\(^{\text{(85)}}\)

The carbides of the lanthanoids and actinoids can be prepared by heating M$_2$O$_3$ with C in an electric furnace or by arc-melting compressed pellets of the elements in an inert atmosphere. They contain the C$_2$ unit and have a stoichiometry MC$_2$ or M$_4$(C$_2$)$_3$. MC$_2$ have the CaC$_2$ structure or a related one of lower symmetry in which the C$_2$ units lie at right-angles to the c-axis of an orthogonal NaCl-type cell.\(^{\text{(86)}}\) They are more reactive than the alkaline-earth metal

---

Carbides, combining readily with atmospheric oxygen and hydrolysing to a complex mixture of hydrocarbons. This derives from their more complicated electronic structure and, indeed, LnC₂ are metallic conductors (not insulators like CaC₂); they are best regarded as ethynides of Ln^{III} with the supernumerary electron partly delocalized in a conduction band of the crystal. This would explain the evolution of H₂ as well as C₂H₂ on hydrolysis, and the simultaneous production of the reduced species C₂H₄ and C₂H₆ together with various other hydrocarbons up to C₆H₁₀:

\[
\text{LnC}_2 + 3\text{H}_2\text{O} \rightarrow \text{Ln(OH)}_3 + \text{C}_2\text{H}_2 + [\text{H}]
\]

An interesting feature of the ethynides MC₂ and M₄(C₂)₃ is the variation in the C–C distance as measured by neutron diffraction. Typical values (in pm) are:

<table>

The C–C distance in CaC₂ is close to that in ethyne (120.5 pm) and it has been suggested that the observed increase in the lanthanoid and actinoid carbides results from a partial localization of the supernumerary electron in the antibonding orbital of the ethynide ion \([\text{C}≡\text{C}]^{2-}\) (see p. 932). The effect is noticeably less in the sesquicarbidic than in the dicarbidic. The compounds EuC₂ and YbC₂ differ in their lattice parameters and hydrolysis behaviour from the other LnC₂ and this may be related to the relative stability of Eu^{III} and Yb^{III} (p. 1237).

The lanthanoids also form metal-rich carbides of stoichiometry M₃C in which individual C atoms occupy at random one-third of the octahedral C1 sites in a NaCl-like structure. Several of the actinoids (e.g. Th, U, Pu) form monocarbides, MC, in which all the octahedral C1 sites in the NaCl structure are occupied and this stoichiometry is also observed for several other carbides of the early transition elements, e.g. M = Ti, Zr, Hf; V, Nb, Ta; Mo, W. These are best considered as interstitial carbides and in this sense the lanthanoids and actinoids occupy an intermediate position in the classification of the carbides, as they did with the hydrides (p. 66).

Interstitial carbides are infusible, extremely hard, refractory materials that retain many of the characteristic properties of metals (lustre, metallic conductivity).\(^{87}\) Reported mps are frequently in the range 3000–4000°C. Interstitial carbides derive their name from the fact that the C atoms occupy octahedral interstices in a close-packed lattice of metal atoms, though the arrangement of metal atoms is not always the same as in the metal itself. The size of the metal atoms must be large enough to generate a site of sufficient size to accommodate C, and the critical radius of M seems to be \(\sim 135 \text{ pm}\); thus the transition metals mentioned in the preceding paragraph all have 12-coordinate radii \(> 135 \text{ pm}\), whereas metals with smaller radii (e.g. Cr, Mn, Fe, Co, Ni) do not form MC and their interstitial carbides have a more complex structure (see below). If the close-packed arrangement of M atoms is hexagonal (h) rather than cubic (c) then the 2 octahedral interstices on either side of a close-packed M layer are located directly above one another and only one of these is ever occupied. This gives a stoichiometry M₂C as in V₂C, Nb₂C, Ta₂C and W₂C. Intermediate stoichiometries are encountered when the M atom stacking sequence alternates, e.g. M₀₃C₂ (hcc) and V₄C₃ (hhcc). Ordered defect NaCl-type structures are also known, e.g. V₈C₇ and V₆C₅, thus illustrating the wide range of stoichiometries which occur among interstitial carbides. Unlike the “ionic” carbides, interstitial carbides do not react with water and are generally very inert, though some do react with air when heated above 1000°C and most are degraded by conc HNO₃ or HF. The extreme hardness and inertness of WC and TaC have led to their extensive use as high-speed cutting tools.

The carbides of Cr, Mn, Fe, Co and Ni are profuse in number, complicated in structure, and of great importance industrially. Cementite, Fe$_3$C, is an important constituent of steel (p. 1075). Typical stoichiometries are listed in Table 8.3 though it should be noted that several of the phases can exist over a range of composition.

The structures, particularly of the most metal-rich phases, are frequently related to those of the corresponding metal-rich borides (and silicides, germanides, phosphides, arsenides, sulfides and selenides), in which the non-metal is surrounded by a trigonal prism of M atoms with 0, 1, 2, or 3 additional neighbours beyond the quadrilateral prism faces (p. 148). e.g. Fe$_3$C (cementite), Mn$_3$C and Co$_3$B; Mn$_5$C$_2$ and Pd$_5$B$_2$; Cr$_7$C$_3$ and Re$_7$B$_3$. Numerous ternary carbides, carbonitrides, and oxocarbides are also known.

The carbides of Cr, Mn, Fe, Co and Ni are much more reactive than the interstitial carbides of the earlier transition metals. They are rapidly hydrolysed by dilute acid and sometimes even by water to give H$_2$ and a mixture of hydrocarbons. For example, M$_3$C give H$_2$ (75%), CH$_4$ (15%) and C$_2$H$_6$ (8%) together with small amounts of higher hydrocarbons.

**Metallocarbohedrenes (met-cars)**

An entirely novel group of binary metal carbides, reminiscent of the fullerenes (p. 279), were discovered by accident in 1992. When Ti metal is vaporized in a laser plasma reactor in the presence of He gas containing a hydrocarbon such as methane, ethene, ethyne or benzene, the mass spectrum of the emerging beam contains a single dominant peak at 528 corresponding to Ti$_8$C$_{12}$ [isotope $^{48}$Ti 73.8% abundant: $(8 \times 48) + (12 \times 12) = 528$]. Detailed isotope distribution studies confirmed the molecular formula. The proposed structure, shown in Fig. 8.18a, is a pentagonal dodecahedron of $T_h$ symmetry comprising 12 mutually fused Ti$_2$C$_3$ pentagons.

Each Ti bonds to 3C via σ bonds and each C bonds to 2Ti and one C. The all-carbon analogue, C₂₀, is not expected to be stable because of severe internal strain; (it would be the smallest possible fullerene, p. 280). Note, however, that dodecahedrane, C₂₀H₂₀, is known. An alternative description of the structure (Fig. 8.18b) would be as a weakly bonded cube, Ti₈, each face of which is capped by a C₂ unit. The calculated distances are Ti⋯Ti 302 pm, Ti–C 199 pm and C–C 140 pm (implying some multiple bonding; cf. 140 pm in benzene). An alternative Tₙ structure for Ti₈C₁₂, which is calculated to have a lower energy, has also been proposed. In this, the Ti₈ array is a tetracapped tetrahedron containing six Ti₄ faces in butterfly conformation; each of these Ti₄ faces can then accommodate a C₂ unit as shown in Fig. 8.18c.

Other met-cars that have been detected mass spectrometrically are M₈C₁₂ (M = V, Zr, Hf) and there is some evidence for higher members such as Zr₁₃C₂₂, Zr₁₄C₂₃, Zr₁₈C₂₉ and Zr₂₃C₃₂ which may feature fused clusters of clusters. The possibility of a super-pentagonal cluster, M₃₀C₄₅, of D₅₈₆ symmetry has also been mooted.

As with the fullerenes, further detailed studies will depend on the discovery of viable bulk preparations of the met-cars. Macroscopic amounts of Ti₈C₁₂ and V₈C₁₂ have indeed been made by DC arc discharge techniques using electrodes of compacted metal and graphite powders and He as the quenching carrier gas. The resulting soot contains about 1% of air-stable M₈C₁₂ plus some C₆₀ (unstable in air). Solution studies have not yet been reported but there is mass spectrometric evidence for Ti₈C₁₂L₅ (L = NH₃, ND₃, H₂O) as well as for Ti₈C₁₂(MeOH)₄.

8.5 Hydrides, Halides and Oxohalides

The ability of C to catenate (i.e. to form bonds to itself in compounds) is nowhere better illustrated than in the compounds it forms with H. Hydrocarbons occur in great variety in petroleum deposits and elsewhere, and form various homologous series in which the C atoms are linked into chains, branched chains and rings. The study of these compounds and their derivatives forms the subject of organic chemistry and is fully discussed in the many textbooks and treatises on that subject. The matter is further considered on p. 374 in relation to the much smaller ability of other Group 14 elements to form such catenated compounds. Methane, CH₄, is the archetype of tetrahedral coordination in molecular compounds; some of its properties are listed in Table 8.4 where they are compared with those of the...
corresponding halides. Unsaturated hydrocarbons such as ethene (C\textsubscript{2}H\textsubscript{4}), ethyne (C\textsubscript{2}H\textsubscript{2}), benzene (C\textsubscript{6}H\textsubscript{6}), cyclooctatetraene (C\textsubscript{8}H\textsubscript{8}) and homocyclic radicals such as cyclopentadienyl (C\textsubscript{5}H\textsubscript{5}) and cycloheptatrienyl (C\textsubscript{7}H\textsubscript{7}) are effective ligands to metals and form many organometallic complexes (pp. 930–43).

Methane is unique among hydrocarbons in being thermodynamically stable with respect to its elements. It follows that pyrolytic reactions to convert it to other hydrocarbons are energetically unfavourable and will be strongly equilibrium-limited. This is in marked contrast to the boranes where mild thermolysis of B\textsubscript{2}H\textsubscript{6} or B\textsubscript{4}H\textsubscript{10}, for example, readily yields mixtures of the higher boranes (p. 164). Vast natural reserves of CH\textsubscript{4} gas exist but much is wasted by flaring (direct burning off at the petroleum production site) because of the uneconomical cost of transport. However, in convenient locations such as the North Sea, natural gas is piped ashore for use as domestic or industrial fuel or as chemical feedstock. After CO\textsubscript{2}, methane is the most important “greenhouse gas” (p. 273) accounting for an estimated 15–20% of the atmospheric global warming (CO\textsubscript{2} \(> 50\%\)). The major sources of atmospheric CH\textsubscript{4} are natural wetlands (25%), rice cultivation (22%), animals (mainly domestic ruminants) (17%) and the mining of fossil fuels (16%), the total “production” being some 460 million tonnes per annum.

Notable recent advances in the chemistry of hydrocarbons include the synthesis and
molecular structure determination of the tetrahexadrene derivative, C₄Bu'₄ (1), the carbon-rich molecules tetraethynylmethane, C(≡C)H₄ i.e. C₉H₂ (94) and tetraethynylethene, C₂(≡C)H₄ i.e. C₁₀H₄ (2), the highly strained [1.1.1]propellane (3) (96) and the preparation of the largest discrete hydrocarbon molecules yet synthesized, the polyphenylethyne dendrimers C₁₁₃₄H₁₄₆ and C₁₃₉₈H₁₂₇₈ (mol wts 14 777.6 and 18 079.6). (97) There is also increasing interest in hydrocarbon salts R⁺⁺R⁻⁻. The first example was the stable, greenish-black crystalline compound C₄₉H₅₁⁺⁺C₆₁H₃₉⁻⁻ (mp 230°C decomp.) obtained by mixing thf solutions of Agranat’s carbocation (4) and Kuhn’s carbanion (5). (98) Of special interest is the covalent molecular hydrocarbon R₃⁻⁻R₂⁺⁺ (6) which exists in chloroform solution but which crystallizes on evaporation or cooling to give the ionic salt R₃⁺⁺R₂⁻⁻ (7). (99)

This reversible ionic-covalent equilibrium is reminiscent of similar behaviour in certain halides such as AlCl₃ (p. 234), PCl₅ (p. 499) and TeCl₄ (p. 772), etc.

Fullerene derivatives such as C₆₀H₄ (p. 283), C₆₀H₂ (p. 287), and C₆₁H₂ (p. 287), and hypercoordinated non-classical carbonium ions (p. 290) have already been briefly mentioned.

Turning next to the simple halides of carbon: tetrafluoromethane (CF₄) is an exceptionally stable gas with mp close to that of CH₄ (see Table 8.4). It can be prepared on a laboratory scale by reacting SiC with F₂ or by fluorinating CO₂, CO or COCl₂ with SF₄. Industrially it is prepared by the aggressive reaction of F₂ on CF₂Cl₂ or CF₃Cl, or by electrolysis of MF or MF₂ using a C anode. CF₄ was first obtained pure in 1926; C₂F₆ was isolated in 1930 and C₂F₄ in 1933; but it was not until 1937 that the various homologous series of fluorocarbons were isolated and identified. Replacement of H by F greatly increases both thermal stability and chemical inertness because of the great strength of the C–F

bond (Table 8.4). Accordingly, fluorocarbons are resistant to attack by acids, alkalis, oxidizing agents, reducing agents and most chemicals up to 600°. They are immiscible with both water and hydrocarbon solvents, and when combined with other groups they confer water-repellance and stain-resistance to paper, textiles and fabrics. Tetrafluoroethylene (C₂F₄) can be polymerized to a chemically inert, thermosetting plastic PTFE (polytetrafluoroethylene); this has an extremely low coefficient of friction and is finding increasing use as a protective coating in non-stick kitchen utensils, razor blades and bearings. PTFE is made by partial fluorination of chloroform using HF in the presence of SbFCl₄ as catalyst, followed by thermolysis to C₂F₄ and subsequent polymerization:

\[
\text{CCl}_3\text{H} \rightarrow \text{CF}_2\text{ClH} \xrightarrow{\Delta} \text{C}_2\text{F}_4 \rightarrow (\text{C}_2\text{F}_4)_n
\]

As a ligand towards metals, C₂F₄ and other unsaturated fluorocarbons differ markedly from alkenes (p. 931).

CCl₄ is a common laboratory and industrial solvent with a distinctive smell, usually prepared by reaction of CS₂ or CH₄ with Cl₂. Its use as a solvent has declined somewhat because of its toxicity, but CCl₄ is still extensively used as an intermediate in preparing “Freons” such as CFC₃, CF₂Cl₂ and CF₃Cl:(100)

\[
\text{C}_4\text{Cl}_4 + \text{HF} \xrightarrow{\text{SbFCl}_4} \text{C}_3\text{F}_3 + \text{HCl}
\]

\[
\text{C}_3\text{F}_3 + \text{HF} \xrightarrow{\text{SbFCl}_4} \text{CF}_2\text{Cl}_2 + \text{HCl}
\]

The catalyst is formed by reaction of HF on SbCl₅. The Freons have a unique combination of properties which make them ideally suited for use as refrigerants and aerosol propellants. They have low bp, low viscosity, low surface tension and high density, and are non-toxic, non-flammable, odourless, chemically inert and thermally stable. The most commonly used is CF₂Cl₂, bp, −29.8°. The market for Freons and other fluorocarbons expanded rapidly in the sixties: production in the USA alone exceeded 200 000 tonnes in 1964 (417 000 tonnes in 1990) and global production was about three times this amount. Already in 1977 there was an annual production of 2.4 × 10⁹ spray-cans. However, there has been growing concern that chlorofluorocarbons from spray-cans gradually work their way into the upper atmosphere where they may, through a complex chemical reaction, deplete the earth’s ozone layer (p. 608). For this reason there was an enforced progressive elimination of this particular application in the USA starting 15 October 1978 and production of CFCs will effectively be completely phased out following the Montreal Protocol of September 1981.

CBr₄ is a pale-yellow solid which is markedly less stable than the lighter tetrahalides. Preparation involves bromination of CH₄ with HBr or Br₂ or, more conveniently, reaction of CCl₄ with Al₂Br₆ at 100°. The trend to diminishing thermal stability continues to Cl₄ which is a bright-red crystalline solid with a smell reminiscent of I₂. It is prepared by the AlCl₃-catalysed halogen exchange reaction between CCl₄ and EtI.

Carbon oxohalides are reactive gases or volatile liquids which feature planar molecules of C₂v symmetry; they are isoelectronic with BX₃ (p. 196) and the bonding is best described in terms of molecular orbitals spanning all 4 atoms rather than in terms of localized orbitals as implied by the formulation \(\text{X} \rightarrow \text{C} = \text{O}\). Some physical properties and molecular dimensions are in Table 8.5. The values call for little comment except to note that the XCX angle is significantly less (as expected) than the value of 120° found for the more symmetrical isoelectronic species BX₃ and CO₃²⁻. The C–Br distance is unusually long; it comes from a very early diffraction measurement and could profitably be checked.

Mixed oxohalides are also known and their volatilities are intermediate between those of the

Oxides and Carbonates

8.6 Oxides and Carbonates

Carbon forms 2 extremely stable oxides, CO and CO₂, 3 oxides of considerably lower stability, C₃O₂, C₅O₂ and C₁₂O₉, and a number of unstable or poorly characterized oxides including C₂O, C₂O₃ and the nonstoichiometric graphite oxide (p. 289). Of these, CO and CO₂ are of outstanding importance and their chemistry will be discussed in subsequent paragraphs after a few brief remarks about some of the others.

Tricarbon dioxide, C₃O₂, often called "carbon suboxide" and ponderously referred to in Chemical Abstracts as 1,2-propadiene-1,3-dione, is a foul-smelling gas obtained by dehydrating malonic acid, CH₂(CO₂H)₂, at

\[
C(\text{NH})(\text{NH}_2)_2; \text{ biuret, NH}_2\text{CONHCONH}_2; \text{ and cyanuric acid, i.e. cyclo-[CO(NH)]}_3 \text{ (p. 323).}
\]

COBr₂ has recently been shown to be a useful general brominating reagent for the preparation of d- and f-block bromides and oxide bromides. Thus, when V₂O₅ is heated with an excess of COBr₂ in a sealed Carrius tube at 125°C for 10 days, a quantitative yield of VOBr₂ is obtained by a reaction that is driven thermodynamically by the formation of CO₂: [V₂O₅ + 3COBr₂ → 2VOBr₂ + 3CO₂ + Br₂]. Similarly, MoO₂, Re₂O₇, Sm₂O₃ and UO₃ were smoothly converted to MoO₂Br₂, ReOBr₄, SmBr₃ and UOBr₃, respectively.

reduced pressure over P₄O₁₀ at 140°, or by thermolysis of bis(trimethylsilyl) malonate, CH₂(CO₂SiMe₃)₂.¹⁰² It has mp -112.5°, bp 6.7°, is stable at -78°, and polymerizes at room temperature to a yellow solid. C₃O₂ forms linear molecules (D₁₈ₙ,symmetry) which can be written as O=C=C=C=O, consistent with the short interatomic distances C=C 128 pm and C=O 116 pm. Above 100°, polymerization yields a ruby-red solid; at 400° the product is violet and at 500° the polymer decomposes to C. The basic structure of all the polymers appears to be a polycyclic 6-membered lactone. C₅O₂ readily rehydrates to malonic acid, and reacts with NH₃ and HCl to give respectively the corresponding amide and acid chloride: CH₂(CONH₂)₂ and CH₂(COC₁)₂. Thermolysis of C₅O₂ in a flow system has been reported to give a liquid product C₅O₂ though a better preparation is the photolysis or thermolysis of the tris(diazo)ketone, cyclo-1,3,5-C₆O₃(N₂)₃.¹⁰³ C₃O₂ is a yellow solid which decomposes above -90°; in solution it apparently remains unchanged for several days even at room temperature. Note that C₅O₂ is the next member after CO₂ and C₃O₂ of the linear catenated series OCₙO with n odd as required by simple π-bond theory. The other moderately stable lower oxide is C₁₂O₉, a white sublimable solid which is the anhydride of mellitic acid, C₆(COOH)₆.

Direct oxidation of C in a limited supply of oxygen or air yields CO; in a free supply CO₂ results. Some properties of these familiar gases and of C₅O₂ are in Table 8.6. The great strength of the C–O bond confers considerable thermal stability on these molecules but the compounds are also quite reactive chemically, and many of the reactions are of major industrial importance. Some of these are discussed more fully in the Panel.

The nature of the bonding, particularly in CO, has excited much attention because of the unusual coordination number (1) and oxidation state (+2) of carbon; it is discussed on p. 926 in connection with the formation of metal–carbonyl complexes.

Pure CO can be made on a laboratory scale by dehydrating formic acid (HCOOH) with conc H₂SO₄ at ~140°. CO is a colourless, odourless, flammable gas; it has a relatively high toxicity due to its ability to form a complex with haemoglobin that is some 300 times more stable than the oxygen–haemoglobin complex (p. 1099): the oxygen-transport function of the red corpuscles in the blood is thereby impeded. This can result in unconsciousness or death, though recovery from mild poisoning is rapid and complete in fresh air and the effects are not cumulative. CO can be detected by its ability to reduce an aqueous solution of PdCl₂ to metallic Pd:

\[
\text{CO + PdCl}_2 + \text{H}_2\text{O} \rightarrow \text{Pd} + \text{CO}_2 + 2\text{HCl}
\]

Quantitative estimation relies on the liberation of I₂ from I₂O₅ or (in the absence of C₂H₂) on absorption in an acid solution of CuCl to form the adduct [Cu(CO)Cl(H₂O)₂].
§8.6 Oxides and carbonates

Industrially Important Reactions of Oxygen and Oxides with Carbon

Carbon monoxide is widely used as a fuel in the form of producer gas or water gas and is also formed during the isolation of many metals from their oxides by reduction with coke. Producer gas is obtained by blowing air through incandescent coke and consists of about 25% CO, 4% CO₂ and 70% N₂, together with traces of H₂, CH₄ and O₂. The reactions occurring during production are:

\[ \text{2C} + \text{O}_2 \rightarrow 2\text{CO}; \quad \Delta H^\circ = -221.0 \text{kJ/mol O}_2; \quad \Delta S^\circ = 179.4 \text{J K}^{-1} \text{mol}^{-1} \]

\[ \text{C} + \text{O}_2 \rightarrow \text{CO}_2; \quad \Delta H^\circ = -393.5 \text{kJ mol}^{-1}; \quad \Delta S^\circ = 2.89 \text{J K}^{-1} \text{mol}^{-1} \]

Water gas is made by blowing steam through incandescent coke: it consists of about 50% H₂, 40% CO, 5% CO₂ and 5% N₂ + CH₄. The oxidation of C by H₂O is strongly endothermic:

\[ \text{C} + \text{H}_2\text{O} \rightarrow \text{CO} + \text{H}_2; \quad \Delta H^\circ = +131.3 \text{kJ mol}^{-1}; \quad \Delta S^\circ = 133.7 \text{J K}^{-1} \text{mol}^{-1} \]

Consequently, the coke cools down and the steam must be intermittently replaced by a flow of air to reheat the coke.

At high temperatures, particularly in the presence of metal catalysts, CO undergoes reversible disproportionation:

\[ 2\text{CO} \rightarrow \text{C} + \text{CO}_2; \quad \Delta H^\circ = -172.5 \text{kJ/mol CO}_2; \quad \Delta S^\circ = -176.5 \text{J K}^{-1} \text{mol}^{-1} \]

The equilibrium concentration of CO is 10% at 550°C and 99% at 1000°C. As the forward reaction involves a reduction in the number of gaseous molecules it is accompanied by a large decrease in entropy. Remembering that \( \Delta G = \Delta H - T\Delta S \) this implies that the reverse reaction becomes progressively more favoured at higher temperatures. The thermodynamic data for the formation of CO and CO₂ can be represented diagramatically on an Ellingham diagram (Fig. 19) which plots standard free energy changes per mol of O₂ as a function of the absolute temperature. The oxidation of C to CO results in an increase in the number of gaseous molecules; it is therefore accompanied by a large increase in entropy and is favoured at high temperature. By contrast, oxidation to CO₂ leaves the number of gaseous molecules unchanged; there is little change in entropy (\( \Delta S = 2.93 \text{J K}^{-1} \text{mol}^{-1} \)), and the free energy is almost independent of temperature. The two lines (and that for the oxidation of CO to CO₂) intersect at 983 K: it follows that \( \Delta G \) for the disproportionation reaction is zero at this temperature. The diagram also includes the plots of \( \Delta G \) (per mole of O₂) for the oxidation of several representative metals. On the left of the diagram (at \( T = 0 \text{K} \)) \( \Delta G = \Delta H \) and the sequence of elements is approximately that of the electrochemical series. The slope of most of the lines is similar and corresponds to the loss of 1 mol of gaseous O₂; small changes of slope occur at the temperature of phase changes or the mp of the metal, and a more dramatic increase in slope signals the bp of the metal. For example, for MgO(s), the slope increases about three-fold at the bp of Mg since, above this temperature, reaction removes three gaseous species (2Mg + O₂) rather than one (O₂).

Such diagrams are of great value in codifying a mass of information of use in extractive metallurgy.\(^{103}\) For example, it is clear that below 710°C (983 K) carbon is a stronger reducing agent when it is converted into CO₂ rather than CO, whereas above this temperature the reverse is true. Again, as reduction of metal oxides with C will occur when the accompanying \( \Delta G \) is negative, such reduction becomes progressively more feasible the higher the temperature: Zn (and Cd) can be reduced at relatively low temperatures but MgO can only be reduced at temperatures approaching 2000 K. Caution should be exercised, however, in predicting the outcome of such reactions since a number of otherwise reasonable reductions cannot be used because the metal forms a carbide (e.g. Cr, Ti). The temperature at which the oxygen dissociation pressure of the various metal oxides reaches a given value can also be obtained from the diagram: as \( -\Delta G = RT \ln K_p = \log(p(O_2)/atm) \) for the reactions considered \( \Delta G \) follows that the line drawn from the point \( (\Delta G = 0, T = 0) \) to the appropriate scale mark on the right-hand side of the diagram intercepts the free-energy line for the element concerned at the required temperature. (Establish to your own satisfaction that this statement is approximately true — what assumptions does it embody?)

\[^{103}\text{Note however that, at all pressures, there is a fairly wide range of temperatures in which CO}_2 \text{ dissociates directly into CO and O}_2 \text{ without precipitation of carbon:}^{104}\]

\[ \text{CO}_2 \rightarrow \text{CO} + \frac{1}{2}\text{O}_2 \]

For example, the temperature range is 250—370°C at 10⁻¹ atm, 320—480°C at 1 atm, and 405—630°C at 100 atm. At higher temperatures in each case, C is also formed, but always in the presence of some O₂.

CO reacts at elevated temperatures to give formates with alkali hydroxides, and acetates with methoxides:

$$\text{CO} + \text{NaOH} \rightarrow \text{HCO}_2\text{Na};$$

$$\text{CO} + \text{MeONa} \rightarrow \text{MeCO}_2\text{Na}$$

Reaction with alkali metals in liquid NH₃ leads to reductive coupling to give colourless crystals of the salt Na₂C₃O₂ which contains linear groups NaOC\(\equiv\)CONa packed in chains. CO reacts with Cl₂ and Br₂ to give COX₂ (p. 305) and with liquid S to give COS. It cleaves B₂H₆ at high pressures to give the “symmetrical” adduct BH₃CO (p. 165), but in the presence of NaBH₄/thf the reaction takes a different course to yield the cyclic B-trimethylboroxine.
\[
\frac{3}{2} \text{B}_2\text{H}_6 + 3\text{CO} \xrightarrow{\text{thf}} \text{MeBOB(Me)OB(Me)O} \\
\]

With BR₃, CO inserts in successive stages to give, ultimately, the corresponding trialkylmethylboroxine (R₃CBO)₃. Alternative products are obtained in the presence of other reagents, e.g. aqueous alkali yields R₃COH; water followed by alkaline peroxide yields R₂CO; and alkaline NaBH₄ yields RCH₂OH (p. 167). CO can also insert into M–C bonds (M = Mo, W; Mn, Fe, Co; Ni, Pd, Pt):

\[
\text{MeMn(CO)₅} + \text{CO} \rightarrow \text{Me(CO)Mn(CO)₅} \\
\]

A detailed discussion of CO as a ligand and the chemistry of metal carbonyls is on pp. 926–9. CO is a key intermediate in the catalytic production of a wide variety of organic compounds on an industrial scale. These include:\(^{106,107}\)

1. Catalytic reduction to methanol (230–400°C, 50–100 atm):

\[
\text{CO} + 2\text{H}_2 \rightarrow \text{CH}_3\text{OH} \\
\]

2. Homogeneous methanol carboxylation with \(\Gamma/\text{Rh}\) catalyst (175–195°C, 30 atm), this is now a leading route to acetic acid:

\[
\text{MeOH} + \text{CO} \rightarrow \text{MeCO}_2\text{H} \\
\]

3. Hydroformylation of olefins to alcohols (the oxo process):\(^{108}\)

\[
\text{RCH} = \text{CH}_2 + \text{CO} + \text{H}_2 \xrightarrow{\text{H}_2\text{O}} \text{RCH}_2\text{CH}_2\text{CHO} \rightarrow \text{R(CH}_2)_3\text{OH} \\
\]

4. The Reppe synthesis of methyl acrylate and acrylic acid (100–190°C, 30 atm, Ni catalyst: or 40°C and 1 atm using Ni(CO)₄ as both the source of CO and the catalyst):

\[
\text{HC}=\text{CH} + \text{MeOH} + \text{CO} \rightarrow \text{CH}_2=\text{CHCO}_2\text{Me} \rightarrow \text{CH}_2=\text{CHCO}_2\text{H} \\
\]

5. Sabatier methanation (230–450°C, 1–100 atm, Ni catalyst):

\[
\text{CO} + 3\text{H}_2 \rightarrow \text{CH}_4 + \text{H}_2\text{O} \\
\]

6. Fischer-Tropsch hydrogenation to a mixture of straight chain aliphatic, olefinic and oxygenated hydrocarbons.\(^{109}\) Despite an enormous amount of research during the past two decades, this is still not an economically viable process except in special circumstances, such as in South Africa.\(^{110}\)

Most industrial CO is produced and used on site. Prices for commercial supplies vary enormously depending on volume and purity required.\(^{106}\) For large volumes (~28,000 m³/day), “over the fence” prices can be as low as $0.30/m³ whereas for tube-trailer loads (1500–3000 m³) prices are nearer $1.40/m³. For CO supplied in high-pressure cylinders current prices (1993) are $15.00–35.00/m³ for commercial grade (98–99% purity), $63/m³ for ultra high purity grade (99.8%) and $68–1580/m³ for research grades (99.97–99.98%).

Further reactions of CO of potential industrial or research significance are continually being explored. Recent examples include:

1. Amination with ammonia over zeolite catalysts at 350–400°C to give methylamine (and some dimethylamine):\(^{111}\)

\[^{110}\text{R. C. EVERSON and D. T. THOMPSON, Platinum Metals Review 25, 50–6 (1981).}\]

2. Reductive coupling of two CO ligands to form a coordinated alkyne derivative, e.g. treatment of the Ta complex \([\text{Ta}(\text{CO})_2(\text{dmpe})_2\text{Cl}]\) with activated Zn dust in thf and then with Me_3SiCl gave a 25\% yield of \([\text{Ta}(\text{Me}_3\text{SiOC}≡\text{COSiMe}_3)(\text{dmpe})_2\text{Cl}]\) which can in turn be hydrolysed to the corresponding complex of the novel dihydroxyacetylene, HOC≡COH.\(^{112}\)

CO_2 is much less volatile than CO (p. 306). It is a major industrial chemical but its uses, though occasionally chemical, more frequently depend on its properties as a refrigerant, as an inert atmosphere, or as a carbonating (gasifying) agent in drinks and foam plastic (see Panel).\(^{113}\)

Of more chemical interest is the synthesis of radioactive \(^{14}\text{C}\) compounds from \(^{14}\text{CO}_2\) which is conveniently stored as a carbonate. \(^{14}\text{C}\) is generated by an (n,p) reaction on a nitride or nitrate in a nuclear reactor (see p. 1256). More than 500 compounds specifically labelled with \(^{14}\text{C}\) are now available commercially, the starting point of many of the syntheses being one of the following reactions:

1. \(\text{NaH}^{14}\text{CO}_3 + \text{H}_2/\text{Pd/C} \longrightarrow \text{H}^{14}\text{CO}_2\text{H}\)
2. \(^{14}\text{CO}_2 + \text{RMgX} \longrightarrow \text{R}^{14}\text{CO}_2\text{H}\)
3. \(^{14}\text{CO}_2 + \text{LiAlH}_4 \longrightarrow \text{H}_2\text{C}^{14}\text{O}_2\text{H}\)
4. \(\text{Ba}^{14}\text{CO}_3 + \text{Ba} \longrightarrow \text{Ba}^{14}\text{C}_2 \longrightarrow \text{H}_2\text{CO}_3^{14}\text{C}\)
5. \(\text{Ba}^{14}\text{CO}_3 + \text{NH}_3 \longrightarrow \text{Ba}^{14}\text{CN}_2^{14}\text{C}^{14}\text{N}\text{ compounds}\)

When \(\text{CO}_2\) dissolves in water at 25\°C it is only partly hydrated to carbonic acid according to the equilibrium

\[
\text{H}_2\text{CO}_3 \rightleftharpoons \text{CO}_2 + \text{H}_2\text{O};
\]

\[
K = [\text{CO}_2]/[\text{H}_2\text{CO}_3] \approx 600
\]

Interpretation of acid–base behaviour in this system is further complicated by the slowness of some of the reactions and their dependence on pH. The main reactions are:

\[
\begin{align*}
\text{CO}_2 + \text{H}_2\text{O} & \rightleftharpoons \text{H}_2\text{CO}_3 \text{ (slow)} \\
\text{H}_2\text{CO}_3 + \text{OH}^- & \rightleftharpoons \text{HCO}_3^- + \text{H}_2\text{O} \text{ (fast)} \\
\text{CO}_2 + \text{OH}^- & \rightleftharpoons \text{HCO}_3^- \text{ (slow)} \\
\text{HCO}_3^- + \text{OH}^- & \rightleftharpoons \text{CO}_3^{2-} + \text{H}_2\text{O} \text{ (fast)}
\end{align*}
\]

In the range pH 8–10 both sets of equilibria are important. The apparent dissociation constant of carbonic acid is

\[
K_1 = [\text{H}^+][\text{HCO}_3^-]/[\text{CO}_2 + \text{H}_2\text{CO}_3]
\]

\[
= 4.45 \times 10^{-7} \text{ mol} \text{ l}^{-1}
\]

As \([\text{CO}_2]/[\text{H}_2\text{CO}_3] = K \approx 600\), it follows that the true dissociation constant is:

\[
K_a = [\text{H}^+][\text{HCO}_3^-]/[\text{H}_2\text{CO}_3]
\]

\[
= K_1(1 + K) \approx 2.5 \times 10^{-4} \text{ mol} \text{ l}^{-1}
\]

This value is in the range expected from an acid of structure \((\text{HO})_2\text{CO}\) (p. 50). The second dissociation constant is given by

\[
K_2 = [\text{H}^+][\text{CO}_3^{2-}]/[\text{HCO}_3^-]
\]

\[
= 4.84 \times 10^{-11} \text{ mol} \text{ l}^{-1}
\]

A hydrate \(\text{CO}_2\cdot 8\text{H}_2\text{O}\) can be crystallized from aqueous solutions at 0\°C and \(p(\text{CO}_2) \sim 45\text{ atm}.\) There is also evidence for a hydrogen-bonded sesquicarbonate ion, \(\text{H}_3\text{C}_2\text{O}_6^{-}\); this was originally suggested to have the sandwich

§8.6 Oxides and carbonates

Production and Uses of CO₂

CO₂ can be readily obtained in small amounts by the action of acids on carbonates. On an industrial scale the main source is as a byproduct of the synthetic ammonia process in which the H₂ required is generated either by the catalytic reaction (a) or by the water-gas shift reaction (b):

(a) \( \text{CH}_4 + 2\text{H}_2\text{O} \rightarrow \text{CO}_2 + 4\text{H}_2 \); \hspace{1cm} (b) \( \text{CO} + \text{H}_2\text{O} \rightleftharpoons \text{CO}_2 + \text{H}_2 \)

CO₂ is also recovered economically from the flue gases resulting from combustion of carbonaceous fuels, from fermentation of sugars and from the calcination of limestone: recovery is by reversible absorption either in aqueous Na₂CO₃ or aqueous ethanolamine (Girbotol process).

\[
\text{Na}_2\text{CO}_3 + \text{H}_2\text{O} + \text{CO}_2 \xrightarrow{\text{cool}} 2\text{NaHCO}_3 \xrightarrow{\text{heat}} 2\text{Na}_2\text{CO}_3
\]

\[
2\text{HO}_2\text{C}_2\text{H}_4\text{NH}_2 + \text{H}_2\text{O} + \text{CO}_2 \xrightarrow{25-65^\circ} (\text{HO}_2\text{C}_2\text{H}_4\text{NH}_2)_2\text{CO}_3 \xrightarrow{100-150^\circ}
\]

In certain places CO₂ can be obtained from natural gas wells. H₂S impurity is removed by oxidation using a buffered alkaline solution saturated with KMnO₄:

\[
3\text{H}_2\text{S} + 2\text{KMnO}_4 + 2\text{CO}_2 \rightarrow 3\text{S} + 2\text{MnO}_2 + 2\text{KHCO}_3 + 2\text{H}_2\text{O}
\]

The scale of production has increased rapidly in recent years and in 1980 exceeded 33 million tonnes in the USA alone though much of this is used in integrated plants, on site.

The most extensive application of CO₂ is as a refrigerant, some 52% of production being consumed in this way. CO₂ can be liquefied at any temperature between its triple point \(-56.6^\circ\) (5.11 atm) and its critical point \(+31.1^\circ\) (72.9 atm). The gas can either be pressurized to 75 atm and then water-cooled to room temperature, or precooled to about \(-15^\circ\) (\(\pm 5^\circ\)) and then pressurized to 15.25 atm. Solid CO₂ is obtained by expanding liquid CO₂ from cylinders to give a “snow” which is then mechanically compressed into blocks of convenient size. Until about 40 y ago the bulk of CO₂ refrigerant was in the form of solid CO₂, but since 1960 production of liquid CO₂ has overtaken the solid form because of lower production costs and ease of transporting and metering the material. Some typical production figures are shown in the Table. Supercritical CO₂ is also finding increasing use as a versatile solvent for chemical reactions.

<td>Total</td>
</tr>
</tbody>
</table>

Solid CO₂ is used as a refrigerant for ice-cream, meat and frozen foods, and as a convenient laboratory cooling agent and refrigerant. Liquid CO₂ is extensively used to improve the grindability of low-melting metals (and hamburger meat), and for the rapid cooling of loaded trucks and rail cars; it is also used for inflating life rafts, in fire extinguishers, and in blasting shells for coal mining. A related application of growing importance is as a replacement for chlorofluorocarbon aerosol propellants (p. 304) though this application will never consume large amounts of the gas since the amount in each tin is extremely small.

Gaseous CO₂ is extensively used to carbonate soft drinks and this use alone accounts for 20% of production. Other quasi-chemical applications are its use as a gas purge, as an inert protective gas for welding, and for the neutralization of caustic and alkaline waste waters. Small amounts are also used in the manufacture of sodium salicylate, basic lead carbonate ("white lead"), and various carbonates such as M₂CO₃ and M₄HCO₃ (M¹ = Na, K, NH₄, etc.). One of the most important uses of CO₂ is to manufacture urea via ammonium carbamate:

\[
\text{CO}_2 + 2\text{NH}_3 \xrightarrow{185^\circ, 200 \text{ atm}} \text{NH}_2\text{CO}_2\text{NH}_4 \xrightarrow{-\text{H}_2\text{O}} \text{CO} (\text{NH}_2)_2
\]

Urea is used to make urea-formaldehyde plastics and resins and, increasingly, as a nitrogenous fertilizer (46.7% N). World production of urea was 23 million tonnes in 1984.

structure (1)\textsuperscript{(114)} though later \textit{ab initio} calculations favour the all-planar structure (2).\textsuperscript{(115)} Solid alkali-metal peroxocarbonates Li$_2$CO$_4$, MHCO$_4$ and M$_2$C$_2$O$_6$ (M = Na, K, Rb, Cs) are known and the anion HCO$_4^-$ (CO$_4^{2-}$ at high pH) can be prepared in solution by reaction of HCO$_3^-$ with aqueous H$_2$O$_2$.\textsuperscript{(116)} The peroxodianion, C$_2$O$_6^{2-}$ (3), can be prepared in aprotic solvents such as MeCN, dmf and dmso, via nucleophilic oxidation of CO$_2$ by the superoxide ion O$_2^-$: [2CO$_2$ + 2O$_2^-$ $\rightarrow$ C$_2$O$_6^{2-}$ + O$_2$].\textsuperscript{(117)} The amusing all-planar squarate ion, C$_4$O$_4^{2-}$ (4), although chemically unrelated to the preceding species, may be mentioned here as a further well-characterized binary C/O anion.\textsuperscript{(118,119)} The short C–C and C–O distances have been interpreted in terms of $\pi$-electron delocalization.

The coordination chemistry of CO$_2$ is by no means as extensive as that of CO (p. 926) but some exciting developments have recently been published.\textsuperscript{(120)} The first transition metal complexes with CO$_2$ were claimed by M. E. Volpin's group in 1969: tertiary phosphine or N$_2$ ligands were displaced from Rh and Ni complexes to give binuclear products whose definitive structure has not yet been established. CO$_2$ also displaced N$_2$ from [Co(N$_2$)(PPh$_3$)$_3$] to give [Co(CO$_2$)(PPh$_3$)$_3$]. The Ni$^0$ complexes [Ni(PEt$_3$)$_4$] (violet) and [Ni(PBu$_3^-$)$_4$] (red) react in toluene at room temperature with CO$_2$ (1 atm) to give the yellow complexes [Ni(CO$_2$)Cl$_2$]. The structure of the analogous complex with P(C$_6$H$_5$)$_3$ was established by X-ray diffraction analysis; it features a pseudo-3-coordinate Ni atom $\mu$-bonded to a bent CO$_2$ ligand as in Fig. 8.20a. The isoelectronic Rh$^+$ appears to form two types of complex: an orange-red series [Rh(CO$_2$)ClL$_3$] which is thought to contain the ligand configuration $\mu$-C$=$O, and a somewhat less-stable yellow series [Rh(CO$_2$)ClL$_3$] which is thought to contain the ligand configuration RH–C$\because$. A Pt compound which had earlier (1965) been thought to contain CO$_2$ as a ligand was subsequently found to require the presence of O$_2$ for its formation and to be, in fact, a novel bidentate carbonato complex (Fig. 8.20b).
M - COOH. Likewise, normal insertion into M – C yields alkyl carboxylates M – OOCR, though metalloacid esters M – COOR are sometimes obtained. The reactions have obvious catalytic implications and are being actively studied at the present time by several groups.\(^{(12)}\)

CO\(_2\) insertion into M – C bonds has, of course, been known since the first papers of V. Grignard in 1901 (p. 134). Organo-Li (and other M' and M'') also react extremely vigorously to give salts of carboxylic acids, RCO2Li, (RCO2)2Be, etc. Zinc dialkyls are much less reactive towards CO\(_2\), e.g.

\[
\text{ZnEt}_2 + 2\text{CO}_2 \rightarrow (\text{EtCOO})_2\text{Zn},
\]

and organo-Cd and -Hg compounds are even less reactive. With AlR\(_3\), one CO\(_2\) inserts at room temperature and a second at 220° under pressure to give R\(_2\)Al(OOCR) and RAl(OOCR)\(_2\), respectively. B–C, Si–C, Ge–C, and Sn–C are rather inert to CO\(_2\) but insertion readily occurs into bonds between these elements and N. A few examples are:

\[
\text{PhB(NHEt)}_2 + \text{CO}_2 \rightarrow \text{PhB(OCONH)}_2
\]

\[
\text{Mo}_3\text{SiNEt}_2 + \text{CO}_2 \rightarrow \text{Me}_3\text{SiOCONEt}_2
\]

\[
\text{Me}_3\text{SnNMe}_2 + \text{CO}_2 \rightarrow \text{Me}_3\text{SnOCONMe}_2
\]

\[
\text{As(NMe)}_2 + 1(3)\text{CO}_2 \rightarrow \text{As(OCONMe)}_2
\]

\[
\text{Ti(NMe)}_4 + \text{CO}_2 \rightarrow \text{Ti(OCONMe)}_2
\]

Returning briefly to CO\(_2\) as a ligand: in addition to the various mono-CO\(_2\) complexes referred to above, several \(\text{bis(}\eta^2\text{-CO}_2\) complex transition-metal adducts are known, e.g. \(\text{trans-}[\text{Mo}(\eta^2\text{-CO}_2)\text{Me}_3]_2\) (5) and \(\text{trans,mer-}[\text{Mo}(\eta^2\text{-CO}_2)_2(\text{PMc}_3)_2(\text{CNPr})_2]\).\(^{(12)}\) The first homo-bimetallic bridging-CO\(_2\) complex has also been structurally characterized by X-ray analysis, viz. \([\text{dppp}(\text{CO})_2\text{Re(\eta^2\text{-O},O':\eta^-\text{C})Re(\text{CO})_3}\text{dppp}]) (6) [dppp = 1,3-bis(diphenylphosphino)propane].\(^{(12)}\)

The carbonate ion, CO\(_2\)^\(-\), by contrast, is a classic Werner ligand which forms innumerable complexes as a monohapto, dihapto or bridging donor. Examples of this latter mode

\[^{(12)}\text{S. K. MANDAL, J. A. KRAUSE and M. ORCHIN, Polyhedron 12, 423 5 (1993).}\]
are the complex cation $[(\text{CuL}_2)_2(\mu-\eta^2,\eta^2-\text{CO}_3)]^{2-}$, where L is a tridentate macrocyclic triaza ligand (Fig. 8.21a), and in the binuclear molecular complex molecule $[[\text{CuCl} (\text{Me}_2\text{NCH}_2\text{CH}_2\text{CH}_2\text{NMe}_2)]_2(\mu-\text{CO}_3)]$ (Fig. 8.21b). This mode of coordination confers some unusual properties including diamagnetism on these Cu$II$ complexes. Even more extensive ligation occurs in the deep violet hexanuclear vanadium (IV) complex $(\text{NH}_4)_5[(\text{VO})_6(\text{CO}_3)_4(\text{OH})_6].10\text{H}_2\text{O}$ which was made by reacting $\text{VOC}_1_2$ with aqueous $\text{NH}_4\text{HCO}_3$ under $\text{CO}_2$. The novel anion $(\text{Fig. 8.22})$ features a unique tris(bidentate) sextuply bridging carbonato ligand as well as three bidentate $\mu_2$-carbonato ligands. Other chelating and bridging coordination modes are also known.

**8.7 Chalcogenides and Related Compounds**

Carbon forms a great many sulfides in addition to the well known $\text{CS}_2$. $\text{CS}$ (unlike $\text{CO}$) is an unstable reactive radical even at $-196^\circ$; it reacts with the other chalcogens and with halogens to give $\text{CSSe}$, $\text{CSTe}$, and $\text{CSX}_2$. It is formed by action of a high-frequency discharge on $\text{CS}_2$ vapour. (See p. 319 for complexes of $\text{CS}$.) Passage of an electric discharge or arc through liquid or gaseous $\text{CS}_2$ yields $\text{C}_3\text{S}_2$, a red liquid mp $-5^\circ$; it has a linear molecular structure, $S=\text{C}==\text{C}==\text{S}$, which polymerizes slowly at room temperature (cf. $\text{C}_3\text{O}_2$).

---

127 M. T. BECH and G. B. KAUFFMAN, *Polyhedron* **5**, 775–81 (1986) and references cited therein. (This paper also gives an accessible account of the history of the discovery and applications of $\text{COS}$, i.e. $\text{O}==\text{C}==\text{S}$.)
During the past decade there has been an astonishing proliferation of further binary carbon-sulfur species, both anionic and neutral.\(^{128}\) Of the anions, the beige coloured dianion \(\text{C}_3\text{S}_3^{2-}\) (made from tetrachlorocyclopropane) has the \(D_{3h}\) structure (1) and the yellow \(\text{C}_4\text{S}_2^{2-}\) (made from squaric acid, p. 312) has the \(D_{4h}\) structure (2). The off-white \(\text{C}_6\text{S}_6^{6-}\), (3), (made from \(\text{C}_6\text{Cl}_6\)) is air-sensitive but can readily be protonated to give the more stable hexathiol \(\text{C}_6(\text{SH})_6\). Reduction of \(\text{CS}_2\) either electrochemically or by alkali metals yields \(\text{C}_3\text{S}_5^{2-}\) which can exist in two isomeric forms, (4) and (5):

\[
\text{4CS}_2 \xrightarrow{\Delta \text{e}} \text{CS}_4^{2-} + S = \text{C}_3\text{S}_5^{2-}\]

Treatment of the primary product with a zinc salt leads to separation of \(\alpha\)-\(\text{C}_3\text{S}_5^{2-}\) from its coproduct \(\text{CS}_3^{2-}\), and multigram amounts of its complexes [\(\text{NR}_4\)]\([\text{Zn}(\alpha\text{-C}_3\text{S}_5)]\) and of the corresponding \(\beta\)-isomer's complexes afford convenient starting points for the synthesis of \textit{molecular} binary sulfides as indicated below.

The sulfide \(\text{C}_4\text{S}_6\) is known in three isomeric forms (6), (7) and (8).\(^{128}\) The yellow-orange \(D_{2h}\) isomer (6) is readily prepared

\[\text{Figure 8.22} \quad \text{Perspective view of the hexanuclear anion } [(\text{VO})_6(\mu_3-\eta^2,\eta^2,\eta^2-\text{CO})\text{(CO)}_3](\mu_2\text{-OH})_3]^5^- \text{. Averaged interatomic distances: vanadyl } \text{V}=O \text{ 161.6 pm, V-O(syn) 195.6 pm, V-O(anti)} \text{ 201.2 pm, V-O (\text{CO})_3} 200.2 \text{pm, V-O (\text{CO}) 228.7 pm, C (O\mu)} 129.1 \text{pm, C-O(exo) 126.6 pm.}^{128}\]

by the reaction of CSCl₂ with \( \alpha\text{-C}_3\text{S}_5 \)^{2–},
whilst the \( C_1 \) isomer (7) results from the corresponding reaction with \( \beta\text{-C}_3\text{S}_5 \)^{2–}. The
\( C_{2h} \) isomer (8) is less well characterized but is said to result from the reaction of
hexachlorobutadiene, CCl₂=CCl=CCl=CCl₂, with polysulfide anions. The treatment of S₂Cl₂
with \([\text{NBu}_4]_2[\text{Zn}(\alpha\text{-C}_3\text{S}_8)_2] \) yields a mixture of
\( \text{C}_3\text{S}_8 \) and \( \text{C}_6\text{S}_{12} \) which can be separated by
fractional crystallization from CS₂:

\[
[Zn(C_3S_8)_2]^{2–} + 2S_2Cl_2 \rightarrow [ZnCl_4]^{2–} + 0.5C_6S_{12} + C_3S_8
\]

\( \text{C}_3\text{S}_8 \) is a bicyclic species composed of the
\( \alpha\text{-C}_3\text{S}_5 \) unit capped by a polysulfide linkage
(9), whereas \( \text{C}_6\text{S}_{12} \) features two cisoid eclipsed
planar \( \alpha\text{-C}_3\text{S}_5 \) units conjoined by further sulfur
linkages to form a third ring (10); note that,
if each of the two \( \text{C}_2 \) groups in this 10-
membered ring are notionally replaced by an
\( \text{S} \) atom, the conformation of the resulting
\( \text{S}_8 \) ring is reminiscent of the familiar crown
configuration for this species (p. 655). Oxidation
of \([\text{NEt}_4]_2[\text{Zn}(\beta\text{-C}_3\text{S}_5)_2] \) with SOCl₂ affords
small amounts of the yellow \( \text{C}_6\text{S}_8 \) (11) which
features an almost planar molecule with \( \text{S} \cdots \text{S} \)
fold angles <3.8°. By contrast, oxidation of
\([\text{NBu}_4]_2[\text{Zn}(\alpha\text{-C}_3\text{S}_8)_2] \) with SO₂Cl₂ yields the
orange dimer \( \text{C}_6\text{S}_{10} \) (12) in which the two planar
\( \text{C}_3\text{S}_5 \) groups are interconnected by a pair of
transoid \( \text{S}_2 \) linkages to give an overall chair
configuration. Finally we should mention the two
known isomers of \( \text{C}_9\text{S}_9 \). The simpler, formed
by the reaction of \( \text{C}_6\text{S}_6 \) (3) with CSCl₂,
is the tris(trithiocarbonate) (13) which sublimes at
310° and can be recrystallized from 1,2-C₆H₄Cl₂.
The second \( \text{C}_9\text{S}_9 \) isomer is synthesized by

\[
\begin{align*}
\text{S} & \text{C} \\
\text{S} & \text{C} \\
\text{S} & \text{C} \\
\text{S} & \text{C} \\
\text{S} & \text{C} \\
\text{S} & \text{C} \\
\text{S} & \text{C} \\
\text{S} & \text{C} \\
\end{align*}
\]
reaction of the benzene derivative 1,3,5-C₆Cl₃-2,4,6-(CH₃NMe₂)₃ with sulfur and H₂S in boiling quinoline; it forms red crystals of the planar D₃h molecule (14) which has a non-classical structure with three 3-coordinate S atoms. Both isomers are formally also oligomeric isomers of the diatomic monomer CS (p. 314).

![Chemical structure](image)

(14)

By far the most important sulfide is CS₂, a colourless, volatile, flammable liquid (mp -111.6°C, bp 46.25°C, flash point -30°C, auto-ignition temperature 100°C, explosion limits in air 1.25-50%). Impure samples have a fetid almost nauseating stench due to organic impurities but the purified liquid has a rather pleasant ethereal smell; it is very poisonous and can have disastrous effects on the nervous system and brain. CS₂ was formerly manufactured by direct reaction of S vapour and coke in Fe or steel retorts at 750-1000°C but, since the early 1950s, the preferred synthesis has been the catalysed reaction between sulfur and natural gas:

\[ \text{CH}_4 + 4S \xrightarrow{\text{SiO}_2 \text{ gel or Al}_2\text{O}_3, \sim 600^\circ} \text{CS}_2 + 2\text{H}_2\text{S} \]

World production in 1991 was about 1 million tonnes the principal industrial uses being in the manufacture of viscose rayon (35-50%), cellophane films (15%) (see below), and CCl₄ (15 30%) depending on country. Indeed the CCl₄ application dropped to zero in USA in 1991 because of environmental concerns (p. 304).

CS₂ reacts with aqueous alkali to give a mixture of M₂CO₃ and the trithiocarbonate M₂CS₃. NH₃ gives ammonium dithiocarbamate NH₄[H₂NCS₂]; under more forcing conditions in the presence of Al₂O₃ the product is NH₄CNS and this can be isomerized at 160° to thiourea, (NH₂)₂CS. Water itself reacts only reluctantly, yielding COS at 200° and H₂S + CO₂ at higher temperatures; many other oxocompounds also convert CS₂ to COS, e.g. MgO, SO₃, HSO₃Cl and urea. With aqueous NaOH/EtOH carbon disulfide yields sodium ethyl dithiocarbonate (xanthate):

\[ \text{CS}_2 + \text{NaOH} + \text{EtOH} \rightarrow \text{Na}[\text{SC(S)OEt}] \]

When ethanol is replaced by cellulose, sodium cellulose xanthate is obtained; this dissolves in aqueous alkali to give a viscous solution (viscose) from which either viscose rayon or cellophane can be obtained by adding acid to regenerate the (reconstituted) cellulose. Trithiocarbonates (CS₃²⁻), dithiocarbonates (COS₂²⁻), xanthates (CS₂OR⁻), dithiocarbamates (CS₂NR₂⁻) and 1,2-dithiolates have an extensive coordination chemistry which has been reviewed. ¹²⁹

Chlorination of CS₂, when catalysed by Fe/FeCl₃, proceeds in two steps:

\[ \text{CS}_2 + 3\text{Cl}_2 \rightarrow \text{CCl}_4 + \text{S}_2\text{Cl}_2 \]
\[ \text{CS}_2 + 2\text{S}_2\text{Cl}_2 \rightarrow \text{CCl}_4 + 6\text{S} \]

With I₂ as catalyst the main product is perchloromethylthiol (Cl₃CSCl). Reaction products with F₂ depend on the conditions used, typical products being SF₄, SF₆, S₂F₁₀, F₂C(SF₃)₂, F₂C(SF₅)₂, F₂CSF₅ and F₃SCF₂SF₅.

CS₂ is rather more reactive than CO₂ in forming complexes and in undergoing insertion reactions. The field was opened up by G. Wilkinson and his group in 1966 when they showed that [Pt(PPh₃)₃] reacts rapidly and

quantitatively with CS$_2$ at room temperature to give orange needles of [Pt(CS$_2$)(PPh$_3$)$_2$], mp 170°. X-ray crystal diffraction analysis revealed the structure shown diagramatically in Fig. 8.23(a). The geometry of the bent CS$_2$ ligand is similar to that in the first excited state of the molecule and the CS$_2$ is almost coplanar with PtP$_2$ (dihedral angle 6°). Bonding is considered to involve a 1-electron transfer via the intermediary of Pt from the highest filled $\pi$ MO of the ligand to its lowest antibonding MO, and the Pt can be thought of as being oxidized from Pt$^0$ to Pt$^{II}$. However, the substantial difference between the two Pt-P distances and the wide deviation of the angles of Pt from 90° emphasize the inadequacy of describing the bonding of such complicated species in terms of simple localized bonding theory. The orange complex [Pd(CS$_2$)(PPh$_3$)$_2$] is isostructural and further work yielded deep-green [V($\eta^5$-C$_5$H$_5$)$_2$(CS$_2$)], dimeric [(Ph$_3$P)Ni($\mu$-CS$_2$)$_2$Ni(PPh$_3$)] and various CS$_2$ complexes of Fe, Ru, Rh and Ir. The deep-red complex [Rh(CS$_2$)$_2$Cl(PPh$_3$)$_2$] probably involves pseudo-octahedral Rh$^{III}$ with one of the CS$_2$ ligands $\eta^2$-bonded as above and the other one $\sigma$-bonded via a single S atom. By contrast, reaction of [Fe$_3$(CO)$_{12}$] with an excess of CS$_2$ in hexane for several hours at 80°C under a 10 atm pressure of CO/Ar gave the orange complex [[Fe$_2$(CO)$_6$]$_2$(μ$_4$-C$_2$S$_2$)] as one of the products (1–2%). As can be seen from Fig. 8.23(b), the structure has two [Fe$_2$(CO)$_6$] units bridged by a planar $\{S_2C \equiv C_2S_2\}$ group, which can in turn be regarded as an ethenetetrathiol moiety formed by the C–C coupling of two CS$_2$ molecules.$^{130}$

The numerous $\eta^1, \eta^2$, and bridging modes of coordination now known for CS$_2$ are indicated schematically below.$^{131}$

---

(p. 312) and also for M–N bonds involving SbIII, ZrIV, NbV, TaV, etc. Reaction of CS2 with Au2Cl6 results in its novel insertion into Au–Cl bonds to form orange crystals of the chlorodithioformate complex [AuCl2(\(\eta^2\)-S2CCl)].(132) The parent dithioformate ligand, HCS2−, has been prepared by insertion of CS2 into the Ru–H bond of [Ru(H(CO)Cl(PPh3)2(4-vinyl pyridine)] to form the yellow complex [Ru(CO)Cl(PPh3)2(\(\eta^2\)-S2CH)].(133) Perhaps even more intriguingly, treatment of the orange nido 11-vertex metallathiaborane cluster [8,8-(PPh3)2-8,7-nido-RhSB9H10] (cf. structure (42), p. 178) with CS2 under reflux gives a 31% yield of the pale orange nido cluster [8,8-(PPh3)2-8,9-(\(\eta^2\)-S2CH)-8,7-RhSB9H9] which features a unique dithioformate bridge between Rh(8)-B(9), perhaps by addition of B-H across a C-S bond.(134)

Stable thiocarbonyl complexes containing the elusive CS ligand are also now well established and known coordination modes, which include terminal, bridging and polyhapto, are as shown at the top of the next column.(135) Likewise complexes of CSe and CTe have been characterized.(136) The structure and reactivity of

CS complexes has been well reviewed(137) and exciting work in this area continues.(138)

8.8 Cyanides and Other Carbon–Nitrogen Compounds

The chemistry of compounds containing the CN group is both extensive and varied. The types of compound to be discussed are listed in Table 8.7, which also summarizes some basic structural information. The names cyanide, cyanogen, etc., refer to the property of forming deep-blue pigments such as Prussian blue (p. 1094) with iron salts (Greek "κυανός, cyanos, dark blue").

A useful theme for cohering much of the chemistry of compounds containing the CN group is the concept of pseudohalogens, a term introduced in 1925 for certain strongly bound, univalent radicals such as CN, OCN, SCN, SeCN, etc., etc.). These groups can form anions X−, hydracids HX, and sometimes neutral species X2.

</table>

\(^{(a)}\)Several groups can also act as bridging ligands in metal complexes, e.g. −CN−, >NCO, −SCN−

XY, etc. It is also helpful to recognize that CN\(^{-}\) is isoelectronic with C\(_2\)\(^{2−}\) (p. 299) and with several notable ligands such as CO, N\(_2\) and NO\(^+\). Similarly, the cyanate ion OCN\(^{-}\) is isoelectronic with CO\(_2\), N\(_3\)\(^−\), fulminate (CNO\(^−\)), etc.\(^{(139)}\)

Cyanogen, (CN)\(_2\), is a colourless poisonous gas (like HCN) mp \(-27.9°\), bp \(-21.2°\) (cf. Cl\(_2\), Br\(_2\)). When pure it possesses considerable thermal stability (800°C) but trace impurities normally facilitate polymerization at 300–500° to paracyanogen a dark-coloured solid which may have a condensed polycyclic structure (3).

The polymer reverts to (CN)\(_2\) above 800° and to CN radicals above 850°. (CN)\(_2\) can be prepared in 80% yield by mild oxidation of CN\(^{-}\) with aqueous Cu\(^{II}\); the reaction is complex but can be idealized as

\[
2\text{CuSO}_4 + 4\text{KCN} \xrightarrow{\text{H}_2\text{O}/60°} (\text{CN})_2 + 2\text{CuCN} + 2\text{K}_2\text{SO}_4
\]
S8.8 Cyanides and other carbon–nitrogen compounds

CH$_4$ and NH$_3$, e.g.:\(^{(141)}\)

Andrussow process:

$$\text{CH}_4 + \text{NH}_3 + 1\frac{1}{2}\text{O}_2 \xrightarrow{\text{Pt/Rh or Pt/Ir}} 2\text{atm}/1000-1200^\circ \text{C} \xrightarrow{\text{PtCl}_3} \text{HCN} + 3\text{H}_2\text{O}$$

Degussa process:

$$\text{CH}_4 + \text{NH}_3 \xrightarrow{\text{Pt}} 1200-1300^\circ \text{C} \xrightarrow{\text{PtCl}_3} \text{HCN} + 3\text{H}_2$$

Both processes rely on a fast flow system and the rapid quenching of product gases; yields of up to 90% can be attained. It is salutary to note that US production of this highly toxic compound is 600000 tonnes pa (1992) and world production exceeds one million tonnes pa. Of this, 41% is used to manufacture adiponitrile for nylon and 28% for acrylic plastics:

$$\text{HCN} + \text{Me}_2\text{CO} \rightarrow \text{acetone cyanohydrin}$$

 Industrially it is now made by direct gas-phase oxidation of HCN with O$_2$ (over a silver catalyst), or with Cl$_2$ (over activated charcoal), or NO$_2$ (over CaO glass). (CN)$_2$ is fairly stable in H$_2$O, EtOH and Et$_2$O but slowly decomposes in solution to give HCN, HNCO, (H$_2$N)$_2$CO and H$_2$NC(O)C(O)NH$_2$ (oxamide). Alkaline solutions yield CN$^-$ and (OCN)$^-$ (cf. halogens).

$$(\text{CN})_2 + 2\text{OH}^- \xrightarrow{\text{H}_2\text{O/heat}} \text{CN}^- + \text{OCN}^- + \text{H}_2\text{O}$$

HCN is now also used to make (ClCN)$_3$ for pesticides (9%), NaCN for gold recovery (13%), and chelating agents such as edta (4%), etc.

As noted above, CN$^-(\text{aq})$ is fairly easily oxidized to (CN)$_2$ or OCN$^-; E^\circ$ values calculated from free energy data (p. 435) are:

$$\frac{1}{2}(\text{CN})_2 + \text{H}^+ + e^- \rightleftharpoons \text{HCN}; \quad E^\circ = 0.37 \text{ V}$$

$$\text{OCN}^- + 2\text{H}^+ + 2e^- \rightleftharpoons \text{CN}^- + \text{H}_2\text{O}; \quad E^\circ = 0.14 \text{ V}$$

HCN can also be reduced to MeNH$_2$ by powerful reducing agents such as Pd/H$_2$ at 140°.

The alkali metal cyanides MCN are produced by direct neutralization of HCN; they crystallize

\(^{(141)}\) Ref. 2, Vol. 7 (1993), Cyanides (including HCN, M\(^{II}\)CN, and M\(^{III}\)(CN)$_2$), pp. 753–82; Cyanamides including CaCN$_2$, H$_2$CN, dicyandiamide, and melamine), pp. 736–52; cyanuric and isocyanuric acids, pp. 834–51.
with the NaCl structure \((M = \text{Na, K, Rb})\) or the CsCl structure \((M = \text{Cs, Tl})\) consistent with “free” rotation of the \(\text{CN}^-\) group. The effective radius is \(~190\, \text{pm}\), intermediate between those of \(\text{Cl}^-\) and \(\text{Br}^-\). At lower temperatures the structures transform to lower symmetries as a result of alignment of the \(\text{CN}^-\) ions. LiCN differs in having a loosely packed 4-coordinate arrangement and this explains its low density \((1.025\, \text{g/cm}^3)\) and unusually low mp \((160^\circ\text{C})\), cf. NaCN \(564^\circ\text{C}\), KCN \(634^\circ\text{C}\). World production of alkali metal cyanides was \(~340,000\, \text{tonnes}\) in 1989. NaCN readily complexes metallic Ag and Au under mildly oxidizing conditions and is much used in the extraction of these metals from their low-grade ores (first patented in 1888 by R. W. Forrest, W. Forrest and J. S. McArthur):

\[
8\text{NaCN} + 4M + 2\text{H}_2\text{O} + \text{O}_2 \rightarrow 4\text{Na}[M(\text{CN})_2] + 4\text{NaOH}
\]

Until the 1960s, when HCN became widely available, NaCN was made by the Castner process via sodamide and sodium cyanamide:

\[
2\text{Na} + \text{C} + 2\text{NH}_3 \overset{750^\circ\text{C}}{\rightarrow} 2\text{NaCN} + 3\text{H}_2
\]

The \(\text{CN}^-\) ion can act either as a monodentate or bidentate ligand.\(^{142}\) Because of the similarity of electron density at C and N it is not usually possible to decide from X-ray data whether C or N is the donor atom in monodentate complexes, but in those cases where the matter has been established by neutron diffraction C is always found to be the donor atom (as with CO). Very frequently \(\text{CN}^-\) acts as a bridging ligand - \(\text{CN}^-\) as in AgCN, and AuCN (both of which are infinite linear chain polymers), and in Prussian-blue type compounds (p. 1094). The same tendency for a coordinated \(\text{M CN}\) group to form a further donor–acceptor bond using the lone-pair of electrons on the N atom is illustrated by the mononuclear BF\(_3\) complexes with tetracyanonickelates and hexacyanoferrates, e.g. \(\text{K}_2[\text{Ni(CN.BF}_3]_4\) and \(\text{K}_4[\text{Fe(CN.BF}_3]_6\).

The complex \(\text{CuCN.NH}_3\) provides an unusual example of \(\text{CN}\) acting as a bridging ligand at C, a mode which is common in \(\mu\)-CO complexes (p. 928); indeed, the complex is unique in featuring tridentate CN groups which link the metal atoms into plane nets via the grouping \(\text{C} - \text{N} - \text{Cu}\) as shown in Fig. 8.24.

Other cyanide complexes are discussed under the appropriate metals. In organic chemistry, both nitriles \(\text{R-CN}\) and isonitriles (isocyanides) \(\text{R-NC}\) are known. Isocyanides have been extensively studied as ligands (p. 926).\(^{143}\) More

The Cyanamide Industry

The basic chemical of the cyanamide industry is calcium cyanamide CaCN, mp 1340°, obtained by nitrogenation of CaC2.

\[
\text{CaC}_2 + \text{N}_2 \xrightarrow{1000°} \text{CaCN} + \text{C}
\]

CaCN is used as a direct application fertilizer, weed killer, and cotton defoliant; it is also used for producing cyanamide, dicyandiamide and melamine plastics. Production formerly exceeded 1.3 million tonnes pa, but this has fallen considerably in the last few years, particularly in the USA where the use of CaCN as a nitrogenous fertilizer has been replaced by other materials. In 1990 most of the world's supply was made in Japan, Germany and Canada.

Acidification of CaCN yields free cyanamide, H2NCN, which reacts further to give differing products depending on pH: at pH ≤ 2 or >12 urea is formed, but at pH 7–9 dimerization to dicyandiamide NCNC(NH2)2 occurs. Solutions are most stable at pH ~ 5; accordingly commercial preparation of H2NCN is by continuous carbonation of an aqueous slurry of CaCN in the presence of graphite: the overall reaction can be represented

\[
\text{CaCN} + \text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{H}_2\text{NCN} + \text{CaCO}_3
\]

Reaction of H2NCN with H2S gives thiourea, SC(NH2)2.

Dicyandiamide forms white, non-hygroscopic crystals which melt with decomposition at 209°. Its most important reaction is conversion to melamine (Fig. 8.25) by pyrolysis above the mp under a pressure of NH3 to counteract the tendency to deamination. Melamine is mainly used for melamine-formaldehyde plastics. Total annual production of both H2NCN and NCNC(NH2)2 is on the 30000 tonne scale.

Several of these compounds and their derivatives are commercially and industrially important. Urea has already been mentioned on p. 311. Again, world production of chloroisocyanurates, (ClN=O)3, in 1987 was ca. 80 000 tonnes (50 000 tonnes in USA alone, of which 75% went for swimming pool disinfection and most of the rest for scouring powders, household bleaches and dishwashing powder formulations). Alkali metal cyanates are stable and readily obtained by mild oxidation of aqueous cyanide solutions using oxides of PbII or PbIV. The commercial preparation of NaNCO is by reaction of urea with Na2CO3.

\[
\text{Na}_2\text{CO}_3 + 2\text{OC(NH}_2)_2 \xrightarrow{\text{heat}} ^{\text{dry}} 2\text{NaNCO}
\]

The pseudohalogen concept (p. 319) might lead one to expect the existence of a cyanate analogue of cyanogen but there is little evidence for NCO−OCN, consistent with the known reluctance of oxygen to catenate. By contrast, thiocyanogen (SCN)2 is moderately stable; it can be prepared as white crystals by suspending AgSCN in Et2O or SO2 and oxidizing the anion at low temperatures with Br2 or I2. (SCN)2 melts at ~−7° to an unstable orange suspension which rapidly polymerizes to the brick-red solid parathiocyanogen (SCN)2. This ready polymerization hampers structural studies but it is probable that the molecular structure is N≡C−S−S−C≡N with a nonlinear central C−S−S−C group. (SeCN)2 can be prepared similarly as a yellow powder which polymerizes to a red solid.

Thiocyanates and selenocyanates can be made by fusing the corresponding cyanide with S or Se. The SCN− and SeCN− ions are both linear, like OCN−. (See p. 779 for TeCN−) Treatment of KSCN with dry KHSO4 produces free isothiocyanic acid HNCS, a white crystalline solid which is stable below 0° but which decomposes rapidly at room temperatures to HCN and a yellow solid H2C2N2S3. Thiocyanic acid, HSCN, (like HOCN) has not been prepared

pure but compounds such as MeSCN and Se(SCN)$_2$ are known.

The thiocyanate ion has been much studied as an ambidentate ligand (in which either S or N is the donor atom); it can also act as a bidentate bridging ligand -SCN-, and even as a tridentate ligand >SCN-.(147,148,149) The ligands OCN$^-$ and SeCN$^-$ have been less studied but appear to be generally similar. A preliminary indication of the mode of coordination can sometimes be obtained from vibrational spectroscopy since N coordination raises both $\nu$(CN) and $\nu$(CS) relative to the values of the uncoordinated ion, whereas S coordination leaves $\nu$(CN) unchanged and increases $\nu$(CS) only somewhat. The bridging mode tends to increase both $\nu$(CN) and $\nu$(CS). Similar trends are noted for OCN$^-$ and SeCN$^-$ complexes. However, these “group vibrations” are in reality appreciably mixed with other modes both in the ligand itself and in the complex as a whole, and vibrational spectroscopy is therefore not always a reliable criterion. Increasing use is being made of $^{14}$N and $^{13}$C nmr data(150) but the most reliable data, at least for crystalline complexes, come from X-ray diffraction studies.(151) The variety of coordination modes so revealed is illustrated in Table 8.9, which is based on one by A. H. Norbury.(147) Phenomenologically it is observed that class a metals tend to be N-bonded whereas class b tend to be S-bonded (see below), though it should be stressed that kinetic and solubility factors as well as relative thermodynamic stability are sometimes implicated, and so-called ‘linkage isomerism’ is well established, e.g. [Co(NH$_3$)$_5$(NCS)]Cl$_2$ and [Co(NH$_3$)$_5$(SCN)]Cl$_2$. In terms of the a and b (or “hard” and “soft”) classification of ligands and acceptors it is noted that metals in Groups 3–8 together with the lanthanoids and actinoids tend to form –NCS complexes; in the later transition groups Co, Ni, Cu and Zn also tend to form –NCS complexes whereas their heavier congeners Rh, Ir; Pd, Pt; Au; and Hg are predominantly S-bonded. Ag and Cd are intermediate and readily form both types of complex. See also refs. 152, 153. The interpretation to be placed on these observations is less certain. Steric influences have been mentioned (N bonding, which is usually linear, requires less space than the bent M–S–CN mode). Electronic factors also play a role, though the detailed nature of the bonding is still a matter of debate and devotees of the various types of electronic influence have numerous interpretations to select from. Solvent effects (dielectric constant $\varepsilon$, coordinating power, etc.) have also been invoked and it is clear that these various explanations are not mutually exclusive but simply tend to emphasize differing aspects of an extremely complicated and delicately balanced situation. The interrelation of these various interpretations is summarized in Table 8.10.

$^{(a)}$Sometimes discussed in terms of “hard” and “soft” acids and bases.

Fewer data are available for SeCN$^-$ complexes but similar generalizations seem to hold. By contrast, OCN$^-$ complexes are not so readily discussed in these terms: in fact, very few cyanato

8.9 Organometallic Compounds

Compounds which contain direct M–C bonds comprise a vast field which spans the traditional branches of inorganic and organic chemistry. A general overview is given in Section 19.7.

---

(p. 924) and specific aspects are treated separately under the chemistry of each individual element, e.g. alkali metals (pp. 102–6), alkaline earth metals (pp. 127–38), Group 13 metals (pp. 257–67) etc. In addition to the references cited on p. 924, useful general accounts can be found in refs. 155–160.

Silicon shows a rich variety of chemical properties and it lies at the heart of much modern technology. Indeed, it ranges from such bulk commodities as concrete, clays and ceramics, through more chemically modified systems such as soluble silicates, glasses and glazes to the recent industries based on silicone polymers and solid-state electronics devices. The refined technology of ultrapure silicon itself is perhaps the most elegant example of the close relation between chemistry and solid-state physics and has led to numerous developments such as the transistor, printed circuits and microelectronics.

In its chemistry, silicon is clearly a member of Group 14 of the periodic classification but there are notable differences from carbon, on the one hand, and the heavier metals of the group on the other. Perhaps the most obvious questions to be considered are why the vast covalent chemistry of carbon and its organic compounds finds such pallid reflection in the chemistry of silicon, and why the intricate and complex structural chemistry of the mineral silicates is not mirrored in the chemistry of carbon-oxygen compounds.

Silica (SiO$_2$) and silicates have been intimately connected with the evolution of mankind from prehistoric times: the names derive from the Latin silex, gen. silicis, flint, and serve as a reminder of the simple tools developed in Paleolithic times (~500 000 years ago) and the shaped flint knives and arrowheads of the neolithic age which began some 20 000 years ago. The name of the element, silicon, was proposed by Thomas Thomson in 1817. Throughout this chapter we will notice important differences between the chemical behaviour of carbon and silicon, and one is reminded of Grant Ury's memorable words: "It is perhaps appropriate to chide the polysilane chemist for milking the horse and riding the cow in attempting to adapt the success of organic chemistry in the study of polysilanes. A valid argument can be made for the point of view that the most effective Chemistry of silicon arises from the differences with the chemistry of carbon compounds rather than the similarities" (see ref. 35 on p. 342).
§9.2.1  

Occurrence and distribution

1831, the ending on being intended to stress the analogy with carbon and boron.

The great affinity of silicon for oxygen delayed its isolation as the free element until 1823 when J. J. Berzelius succeeded in reducing $K_2SiF_6$ with molten potassium. He first made $SiCl_4$ in the same year, $SiF_4$ having previously been made in 1771 by C. W. Scheele who dissolved $SiO_2$ in hydrofluoric acid. The first volatile hydrides were discovered by F. Wöhler who synthesized $SiHCl_3$ in 1857 and $SiH_4$ in 1858, but major advances in the chemistry of the silanes awaited the work of A. Stock during the first third of the twentieth century. Likewise, the first organosilicon compound $SiEt_4$ was synthesized by C. Friedel and J. M. Crafts in 1863, but the extensive development of the field was due to F. S. Kipping in the first decades of this century. The unique properties and industrial potential of siloxanes escaped attention at that time and the dramatic development of silicone polymers, elastomers, and resins has occurred during the past 50 years (p. 365).

The solid-state chemistry of silicon has shown similar phases. The bizarre compositions derived by analytical chemistry for the silicates only became intelligible following the pioneering X-ray structural work of W. L. Bragg in the 1920s and the concurrent development of the principles of crystal chemistry by L. Pauling and of geochemistry by V. M. Goldschmidt. More recently the complex crystal chemistry of the silicides has been elucidated and the solid-state chemistry of doped semiconductors has been developed to a level of sophistication that was undreamt of even in the 1960s.

9.2 Silicon

9.2.1 Occurrence and distribution

Silicon (27.2 wt%) is the most abundant element in the earth's crust after oxygen (45.5%), and together these 2 elements comprise 4 out of every 5 atoms available near the surface of the globe. This implies that there has been a substantial fractionation of the elements during the formation of the solar system since, in the universe as a whole, silicon is only seventh in order of abundance after H, He, C, N, O and Ne (p. 4). Further fractionation must have occurred within the earth itself: the core, which has 31.5% of the earth's mass, is commonly considered to have a composition close to $Fe_{25}Ni_{20}Co_8; the mantle (68.1% of the mass) probably consists of dense oxides and silicates such as olivine $(Mg,Fe)_2SiO_4$, whereas the crust (0.4% of the mass) accumulates the lighter siliceous minerals which "float" to the surface. The crystallization of igneous rocks from magma (molten rock, e.g. lava) depends on several factors such as the overall composition, the lattice energy, mp and crystalline complexity of individual minerals, the rate of cooling, etc. This has been summarized by N. L. Bowen in a reaction series which gives the approximate sequence of appearance of crystalline minerals as the magma is cooled: olivine $[Mg_2SiO_4]$, pyroxene $[Mg_2Si_2O_6]$, amphibole $[M_2[(Al, Si)O_3]]_2OH], biotite mica $[(K, H)_{(2}(Mg, Fe)_{(2}(Al, Fe)_{(2}(SiO_3)]_2OH], orthoclase feldspar $[KA(Si_3O_8], muscovite mica $[KA(Si_3O_10(OH)]_2], quartz [SiO_2], zeolites and hydrothermal minerals. The structure of these mineral types is discussed later (p. 347), but it is clear that the reaction series leads to progressively more complex silicate structural units and that the later part of the series is characterized by the introduction of OH (and F) into the structures. Extensive isomorphous substitution among the metals is also possible. Subsequent weathering, transport and deposition leads to sedimentary rocks such as clays, shales and sandstones. Metamorphism at high temperatures and pressures can effect further
changes during which the presence or absence of water plays a vital role.\(^{(6,7)}\)

Silicon never occurs free: it invariably occurs combined with oxygen and, with trivial exceptions, is always 4-coordinate in nature. The \{Si\(_4\)\} unit may occur as an individual group or be linked into chains, ribbons, rings, sheets or three-dimensional frameworks (pp. 347–59).

### 9.2.2 Isolation, production and industrial uses

Silicon (96–99% pure) is now invariably made by the reduction of quartzite or sand with high purity coke in an electric arc furnace; the Si\(_2\)O\(_2\) is kept in excess to prevent the accumulation of SiC (p. 334):

\[
\text{SiO}_2 + 2\text{C} = \text{Si} + 2\text{CO};
\]

\[
2\text{SiC} + \text{SiO}_2 = 3\text{Si} + 2\text{CO}
\]

The reaction is frequently carried out in the presence of scrap iron (with low P and S content) to produce ferrosilicon alloys: these are used in the metallurgical industry to deoxidize steel, to manufacture high-Si corrosion-resistant Fe, and Si/steel laminations for electric motors. The scale of operations can be gauged from the 1980 world production figures which were in excess of 5 megatonnes. Consumption of high purity (semiconductor grade) Si leapt from less than 10 tonnes in 1955 to 2800 tonnes in 1980.

Silicon for the chemical industry is usually purified to \(\sim98.5\%\) by leaching the powdered 96–97% material with water. Very pure Si for semiconductor applications is obtained either from SiCl\(_4\) (made from the chlorination of scrap Si) or from SiHCl\(_3\) (a byproduct of the silicone industry, p. 338). These volatile compounds are purified by exhaustive fractional distillation and then reduced with exceedingly pure Zn or Mg; the resulting spongy Si is melted, grown into cylindrical single crystals, and then purified by zone refining. Alternative routes are the thermal decomposition of Si\(_4\)/H\(_2\) on a hot tungsten filament (cf. boron, p. 140), or the epitaxial growth of a single-crystal layer by thermal decomposition of SiH\(_4\). A one-step process has also been developed to produce high-purity Si for solar cells at one-tenth of the cost of rival methods. In this process Na\(_2\)SiF\(_6\) (which is a plentiful waste product from the phosphate fertilizer industry) is reduced by metallic Na; the reaction is highly exothermic and is self-sustaining without the need for external fuel.

Hyperfine Si is one of the purest materials ever made on an industrial scale: the production of transistors (p. 332) requires the routine preparation of crystals with impurity levels below 1 atom in \(10^{10}\), and levels below 1 atom in \(10^{12}\) can be attained in special cases.

### 9.2.3 Atomic and physical properties

Silicon consists predominantly of \(^{28}\text{Si}\) (92.23%) together with 4.67% \(^{29}\text{Si}\) and 3.10% \(^{30}\text{Si}\). No other isotopes are stable. The \(^{28}\text{Si}\) isotope (like the proton) has a nuclear spin \(I = \frac{1}{2}\), and is being increasingly used in nmr spectroscopy.\(^{(8)}\) \(^{31}\text{Si}\), formed by neutron irradiation of \(^{30}\text{Si}\), has \(t_{\frac{1}{2}}\) 2.62 h; it can be detected by its characteristic \(\beta^-\) activity (\(E_{\text{max}}\) 1.48 MeV) and is very useful for the quantitative analysis of Si by neutron activation. The radioisotope with the longest half-life (\(\sim 172\) y) is the soft \(\beta^-\) emitter \(^{32}\text{Si}\) (\(E_{\text{max}}\) 0.2 MeV).

In its ground state, the free atom Si has the electronic configuration [Ne]3s\(^2\)3p\(^2\). Ionization energies and other properties are compared with those of the other members of Group 14 on p. 372. Silicon crystallizes in the diamond

§9.2.4 Chemical properties

lattice (p. 275) with \( a_0 = 543.10204 \text{pm} \) at 25°, corresponding to an Si–Si distance of 235.17 pm and a covalent atomic radius of 117.59 pm. The density and lattice constant of pure single-crystal Si are now known sufficiently accurately to give a direct value of the Avogadro constant \( (N_A = 6.022 1363 \times 10^{23} \text{ mol}^{-1}) \) which is as precise as the best currently accepted value \( (6.022 1367 \times 10^{23} \text{ mol}^{-1}) \). There appear to be no allotropes of Si at ambient pressure but the 4-coordinate diamond lattice of Si–I transforms to several other modifications at higher pressures, of which distorted-diamond Si–II, primitive hexagonal Si–V and eventually hexagonal close packed Si–VII may be mentioned; the structural sequence corresponds to a systematic increase in coordination number:\(^{(10)}\)

\[
\begin{align*}
4(\text{Si–I}) & \xrightarrow{8.8 \text{ GPa}} 6(\text{Si–II}) \xrightarrow{16 \text{ GPa}} 8(\text{Si–V}) \xrightarrow{\sim 40 \text{ GPa}} 12(\text{Si–VII})
\end{align*}
\]

[1 GPa = 10 kbar \( \approx 9869 \text{ atm.} \)]

Physical properties are summarized in Table 9.1 (see also p. 373). Silicon is notably more volatile than C and has a substantially lower energy of vaporization, thus reflecting the smaller Si–Si bond energy. The element is a semiconductor with a distinct shiny, blue-grey metallic lustre; the resistivity decreases with increase of temperature, as expected for a semiconductor. The actual value of the resistivity depends markedly on purity but is \( \sim 40 \text{ ohm cm} \) at 25° for very pure material.

The immense importance of Si in transistor technology stems from the chance discovery of the effect in Ge at Bell Telephone Laboratories, New Jersey, in 1947, and the brilliant theoretical and practical development of the device by J. Bardeen, W. H. Brattain and W. Shockley for which they were awarded the 1956 Nobel Prize for Physics. A brief description of the physics and chemistry underlying transistor action in Si is given in the Panel (p. 332).

9.2.4 Chemical properties

Silicon in the massive, crystalline form is relatively unreactive except at high temperatures. Oxygen, water and steam all have little effect probably because of the formation of a very thin, continuous, protective surface layer of SiO\(_2\) a few atoms thick (cf. Al, p. 224). Oxidation in air is not measurable below 900°; between 950° and 1160° the rate of formation of vitreous SiO\(_2\) rapidly increases and at 1400° the N\(_2\) in the air also reacts to give SiN and Si\(_3\)N\(_4\). Sulfur vapour reacts at 600° and P vapour at 1000°. Silicon is also unreactive towards aqueous acids, though the aggressive mixture of conc HNO\(_3\)/HF oxidizes and fluorinates the element. Silicon dissolves readily in hot aqueous alkali due to reactions of the type Si + 4OH\(^-\) = SiO\(_4^{2-}\) + 2H\(_2\). Likewise, the thin film of SiO\(_2\) is no barrier to attack by halogens, F\(_2\) reacting vigorously at room temperature, Cl\(_2\) at \( \sim 300° \), and Br\(_2\), I\(_2\) at \( \sim 500° \). Even alkyl halides will react at elevated temperatures and, in the presence of Cu catalysts, this constitutes the preferred "direct" synthesis of organosilicon chlorides for the manufacture of silicones (p. 364).

In contrast to the relative inertness of solid Si to gaseous and liquid reagents, molten Si is an extremely reactive material: it forms alloys or

\(^{(a)}\) This is the "effective ionic radius" for 4-coordinate Si\(^{IV}\) in silicates, obtained by subtracting \( r(O^{II}) = 140 \text{ pm} \) from the observed Si–O distance. The value for 6-coordinate Si\(^{IV}\) is 40 pm. [R. D. Shannon, Acta Cryst. A32, 751–67 (1976).]

The Physics and Chemistry of Transistors

In ultrapure semiconductor grade Si there is an energy gap $E_g$ between the highest occupied energy levels (the valence band) and the lowest unoccupied energy levels (the conduction band). This is shown diagrammatically in Fig. a: the valence band is completely filled, the conduction band is empty, the Fermi level ($E_F$), which is the energy at which the chance of a state being occupied by an electron is $\frac{1}{2}$, lies approximately midway between these, and the material is an insulator at room temperature. If the Si is doped with a Group 15 element such as P, As or Sb, each atom of dopant introduces a superimposed electron and the impurity levels can act as a source of electrons which can be thermally or photolytically excited into the conduction band (Fig. b): the material is an n-type semiconductor with an activation energy $\Delta E_n$ (where n indicates negative current carriers, i.e. electrons). Conversely, doping with a Group 13 element such as B, Al or Ga introduces acceptor levels that can act as traps for electrons excited from the filled valence band (Fig. c): the material is a p-type semiconductor and the current is carried by the positive holes in the valence band.

When an n-type sample of Si is joined to a p-type sample, a p–n junction is formed having a common Fermi level as in Fig. d: electrons will flow from n to p and holes from p to n thereby producing a voltage drop $V_0$ across the space charge region. A p–n junction can thus act as a diode for rectifying alternating current, the current passing more easily in one direction than the other. In practice a large p–n junction might cover 10 mm$^2$, whereas in integrated circuits such a device might cover no more than $10^{-4}$ mm$^2$ (i.e. a square of side 10 $\mu$m).

A transistor, or n–p–n junction, is built up of two n-type regions of Si separated by a thin layer of weakly p-type (Fig. e). When the emitter is biased by a small voltage in the forward direction and the collector by a larger voltage in the reverse direction, this device acts as a triode amplifier. The relevant energy level diagram is shown schematically in Fig. f.

The large-scale reproducible manufacture of minute, electronically-stable, single-crystal transistor junctions is a triumph of the elegant techniques of solid-state chemical synthesis. The sequence of steps is illustrated in diagrams (i)–(v).

(i) A small wafer of single-crystal n-type Si is oxidized by heating it in O$_2$ or H$_2$O vapour to form a thin surface layer of SiO$_2$.

(ii) The oxide coating is covered by a photosensitive film called “photoresist”.

(iii) A mask is placed over the photoresist to confine the exposure to the desired pattern and the chip is exposed to ultraviolet light; the exposed photoresist is then removed by treatment with acid, leaving a tough protective layer over the parts of the oxide coating that are to be retained.

(iv) The unprotected areas of Si are etched away with hydrofluoric acid and the remaining photoresist is also removed.

(v) The surface is exposed to the vapour of a Group 13 element and the impurity atoms diffuse into the unprotected area to form a layer of p-type Si.

(vi) Steps (i)–(v) are repeated, with a different mask, and then the newly exposed areas are treated with the vapour of a Group 15 element to produce a patterned layer of n-type Si.

(vii) Finally, again with a different mask, the surface is reoxidized and then re-etched to produce openings into which metal is deposited so as to connect the n- and p-regions into an integrated circuit.

Each individual p–n diode or n–p–n transistor can be made almost unbelievably minute by these techniques; for example computer memory units storing over $10^5$ bits of information on a single small chip are routinely used. Further information can be obtained from textbooks of solid-state physics or electronic engineering.

Silicon does not form binary compounds with the heavier members of the group (Ge, Sn, Pb) but its compound with carbon, SiC, is of outstanding academic and practical interest, and is manufactured on a huge scale industrially (see Panel on p. 334). In the vast majority of its compounds Si is tetrahedrally coordinated but sixfold coordination also occurs, and occasional examples of other coordination geometries are known as indicated in Table 9.2 (p. 335). Unstable 2-coordinate Si has been known for many years but in 1994 the stable, colourless, crystalline silylene [:SiNBu'CH=CHNBu'], structure (1), p. 336, was

silicides with most metals (see below) and rapidly reduces most metal oxides because of the very large heat of formation of SiO$_2$ ($\sim$900 kJ mol$^{-1}$). This presents problems of containment when working with molten Si, and crucibles must be made of refractories such as ZrO$_2$ or the borides of transition metals in Groups 4–6 (p. 146).

Chemical trends within Group 14 are discussed on p. 373. Silicon does not form binary compounds with the heavier members of the group (Ge, Sn, Pb) but its compound with carbon, SiC,
Chemical properties

Fig. (a)-(f) mentioned in Panel opposite.

Steps (i)-(v) mentioned in Panel opposite.
Silicon Carbide, SiC\textsuperscript{11,12}

Silicon carbide was made accidentally by E. G. Acheson in 1891; he recognized its abrasive power and coined the name “carborundum” from carbo(n) and (co)rundum (Al\textsubscript{2}O\textsubscript{3}) to indicate that its hardness on the Mohs scale (9.5) was intermediate between that of diamond (10) and Al\textsubscript{2}O\textsubscript{3} (9). Within months he had formed the Carborundum Co. for its manufacture, and current world production approaches 1 million tonnes annually.

Despite its simple formula, SiC exists in at least 200 crystalline modifications based on hexagonal \(\alpha\)-SiC (wurtzite-type ZnS, p. 1210) or cubic \(\beta\)-SiC (diamond or zincblende-type, p. 1210). The complexity arises from the numerous stacking sequences of the \(a\) and \(b\) “layers” in the crystal.\textsuperscript{13} The \(\alpha\)-form is marginally the more stable thermodynamically. Industrially, \(\alpha\)-SiC is obtained as black, dark green or purplish iridescent crystals by reducing high-grade quartz sand with a slight excess of coke or anthracite in an electric furnace at 2000–2500°C:

\[
\text{SiO}_2 + 2\text{C} \rightarrow \text{Si} + 2\text{CO}; \quad \text{Si} + \text{C} \rightarrow \text{SiC}
\]

The dark colour is caused by impurities such as iron, and the iridescence is due to a very thin layer of SiO\textsubscript{2} formed by surface oxidation. Purer samples are pale yellow or colourless. Even higher temperatures (and vacuum conditions) are required to produce the \(\beta\)-form. Alternatively, very pure \(\beta\)-SiC can be obtained by heating grains of ultrapure Si with graphite at 1500° or by gas-phase plasma decomposition of Me\textsubscript{2}SiCl\textsubscript{2}, MeSiCl\textsubscript{3} or SiCl\textsubscript{4}/CH\textsubscript{4} mixtures. Fibres of SiC are made by the progressive pyrolysis of organosilicon polymers such as \(-\text{CH}_2\text{SiHMe}_2-\) or \(-\text{CH}_2\text{SiMe}_2-\). Lattice constants for \(\alpha\)-SiC are \(a = 307.39\) pm, \(c = 1006.1\) pm, \(c/a = 3.273\); for cubic \(\beta\)-SiC, \(a_0 = 435.02\) pm (cf. diamond 356.68, Si 543.10, mean 449.89 pm).

SiC has greater thermal stability than any other binary compound of Si and decomposition by loss of Si only becomes appreciable at \(\sim 2700^\circ\). It resists attack by most aqueous acids (including HF but not H\textsubscript{3}PO\textsubscript{4}) and is oxidized in air only above 1000° because of the protective layer of SiO\textsubscript{2}; this can be removed by molten hydroxides or carbonates and oxidation is much more rapid under these conditions, e.g.:

\[
\text{SiC} + 2\text{NaOH} + \text{O}_2 \rightarrow 2\text{Na}_2\text{SiO}_3 + \text{H}_2\text{O} + \text{CO}_2
\]

\(\text{Cl}_2\) attacks SiC vigorously, yielding SiCl\textsubscript{4} + C at 100° and SiCl\textsubscript{4} + CCl\textsubscript{4} at 1000°.

Technical interest in SiC originally stemmed from its excellence as an abrasive powder; this derives not only from the great intrinsic hardness of the compound but also from its peculiar fracture to give sharp cutting edges. As a refractory, \(\alpha\)-SiC combines great strength and chemical stability, with an extremely low thermal expansion coefficient (\(\sim 6 \times 10^{-6}\)) which shows no sudden discontinuities due to phase transitions. Pure \(\alpha\)-SiC is an intrinsic semiconductor with an energy band gap sufficiently large (1.90 ± 0.10 eV) to make it a very poor electrical conductor (\(\sim 10^{-13}\) ohm\textsuperscript{-1} cm\textsuperscript{-1}). However, the presence of controlled amounts of impurities makes it a valuable extrinsic semiconductor (10\textsuperscript{-2} – 3 ohm\textsuperscript{-1} cm\textsuperscript{-1}) with a positive temperature coefficient. This, combined with its mechanical and chemical stability, accounts for its extensive use in electrical heating elements. In recent years pure \(\beta\)-SiC has received much attention as a high-temperature semiconductor with applications in transistors, diode rectifiers, electroluminescent diodes, etc. (see p. 332). In fact, these various electrical and refractory uses account for only about 2% of the vast tonnages of SiC manufactured each year. About 43% is still used for its original application as an abrasive, and the remaining 55% is used in metallurgical processes, especially as a refining agent in the casting of iron and steel: the SiC reacts with free oxygen and with metal oxides to form CO and a siliceous slag.

\textsuperscript{13} Gmelin Handbook of Inorganic Chemistry, 8th edn., Springer-Verlag, Berlin, Silicon Suppl. B2, 1984, 312 pp. See also Suppl. B1, 1986, 545 pp. for further information on occurrence of SiC in nature, its manufacture, chemical reactions, applications, etc.

isolated,\textsuperscript{14} it distils without change at 85°C/0.1 torr and can be kept in solution in a sealed tube for several months at 150°C without apparent change. A recent example of pyramidal 3-coordinate Si is the Si\textsubscript{4}\textsuperscript{4-} anion (isoelectronic with the tetrahedral P\textsubscript{4} molecule, p. 479), which has been shown to occur in the long-known red silicide CsSi\textsubscript{4}.\textsuperscript{17} There has been much discussion about the possibility of planar 4-coordinate Si in orthosilicate esters of pyrocatechol (2) but this is

still far from being unequivocally established. Still, a 'one-sided' C₂ᵥ geometry for SiLi₄ (3) seems probable. Five-coordinate Si can be either trigonal bipyramidal or square pyramidal, e.g. (4), (5), etc. Numerous examples of octahedral 6-coordination are known. A single example of 7-coordinate Si has been identified, (6) and there are occasional examples of higher coordination numbers. Thus, Si has cubic 8-fold coordination in Mg₄Si which has the antifluorite structure, Si occupying the Ca sites and Mg the F sites of the fluorite lattice. The capped square antiprismatic structure of the anion [SiCo₉(CO)₁]²⁻ has essentially 9-fold coordination about the encapsulated Si atom (7), with Si–Co_base 231 pm, Si–Co_upper 228 pm and Si–Co_cap 252.7 pm; each of the four basal Co atoms has two terminal CO ligands, each of the other five Co atoms has one, and there are eight bridging CO groups. The coordination number 10 is found in the structures of several transition metal silicides and in decamethylsilicocene (8). The crystal structure of this latter compound reveals two types of molecular geometry; one-third of the molecules have the two rings parallel and staggered as in [Fe(C₅Me₅)₂] with Si–C 242 pm whereas the other two-thirds have non-parallel rings, implying a stereochemically active lone pair of electrons on the Si atom. The bent (C₂ᵥ) structure persists in the gas phase, the angle between the two C₅ planes being 22°.

### 9.3 Compounds

#### 9.3.1 Silicides

As with borides (p. 145) and carbides (p. 297) the formulae of metal silicides cannot be rationalized by the application of simple valency rules, and
the bonding varies from essentially metallic to ionic and covalent. Observed stoichiometries include $\text{M}_6\text{Si}$, $\text{M}_5\text{Si}$, $\text{M}_4\text{Si}$, $\text{M}_3\text{Si}_4$, $\text{M}_3\text{Si}$, $\text{M}_5\text{Si}_2$, $\text{M}_2\text{Si}$, $\text{M}_5\text{Si}_3$, $\text{M}_3\text{Si}_2$, $\text{M}_3\text{Si}_3$, $\text{M}_5\text{Si}_2$, $\text{MSi}$, $\text{M}_3\text{Si}_2$, $\text{MSi}_2$, $\text{MSi}_3$ and $\text{MSi}_6$. Silicon, like boron, is more electropositive than carbon, and structurally the silicides are more closely related to the borides than the carbides (cf. diagonal relation, p. 27). However, the covalent radius of Si (1 18 pm) is appreciably larger than for B (88 pm) and few silicides are actually isostructural with the corresponding borides. Silicides have been reported for virtually all elements in Groups 1–10 except Be, the greatest range of stoichiometries being shown by the transition metals in Groups 4–10 and uranium. No silicides are known for the metals in Groups 11–15 except Cu; most form simple eutectic mixtures, but the heaviest post-transition metals Hg, Tl, Pb and Bi are completely immiscible with molten Si.

Some metal-rich silicides have isolated Si atoms and these occur either in typical metal-like structures or in more polar structures. With increasing Si content, there is an increasing tendency to catenate into isolated $\text{Si}_2$ or $\text{Si}_4$, or into chains, layers or 3D networks of Si atoms. Examples are in Table 9.3 and further structural details are in refs. 24, 26 and 27.

Silicides are usually prepared by direct fusion of the elements but coreduction of SiO$_2$ and a metal oxide with C or Al is sometimes used. Heats of formation are similar to those of borides and carbides but mps are substantially lower; e.g. TiC 3140°, TiB$_2$ 2980°, TiSi$_2$ 1540°, and TaC 3800°, TaB$_2$ 3100°, TaSi$_2$ 1560°C. Few silicides melt as high as 2000–2500°, and above this temperature only SiC is solid (decomp ~2700°C).

Silicides of groups 1 and 2 are generally much more reactive than those of the transition elements (cf. borides and carbides). Hydrogen and/or silanes are typical products; e.g.:

\[
\text{Na}_2\text{Si} + 3\text{H}_2\text{O} \rightarrow \text{Na}_2\text{SiO}_3 + 3\text{H}_2 \\
\text{Mg}_2\text{Si} + 2\text{H}_2\text{SO}_4(\text{aq}) \rightarrow 2\text{MgSO}_4 + \text{SiH}_4
\]

Products also depend on stoichiometry (i.e. structural type). For example, the polar, non-conducting Ca$_2$Si (anti-PbCl$_2$ structure with isolated Si atoms) reacts with water to give Ca(OH)$_2$, SiO$_2$ (hydrated), and H$_2$, whereas CaSi (which features zigzag Si chains) gives silanes and the polymeric SiH$_2$. By contrast CaSi$_2$, which has puckered layers of Si atoms, does not react with pure water, but with dilute hydrochloric acid it yields a yellow polymeric solid of overall composition Si$_2$H$_5$O. Transition metal silicides
Silicon hydrides (silanes)

The great development which occurred in synthetic organic chemistry from the 1830s onward encouraged early speculations that a similar extensive chemistry might be generated based on Si. The first silanes were made in 1857 by F. Wöhler and H. Buff who reacted Al/Si alloys with aqueous HCl; the compounds prepared were shown to be SiH₄ and SiHCl₃ by C. Friedel and A. Ladenburg in 1867 but it was not until 1902 that the first homologue, Si₂H₆, was prepared by H. Moissan and S. Smiles from the protonolysis of magnesium silicide. The thermal instability and great chemical reactivity of the compounds precluded further advances until A. Stock developed his greaseless vacuum techniques and first began to study them as contaminants of his boron hydrides in 1916. He proposed the names silanes and boranes (p. 151) by analogy with the alkanes.

Silanes SiₙH₂ₙ₊₂ are now known as unbranched and branched chains (up to n = 8) and as cyclic compounds SiₙH₂ₙ (n = 5, 6). Silanes are colourless gases or volatile liquids; they are extremely reactive and spontaneously ignite or explode in air. Thermal stability decreases with increasing chain length and only SiH₄ is stable indefinitely at room temperature; Si₂H₆ decomposes very slowly (2.5% in 8 months), Si₃H₈ slowly and the tetrasilanes more rapidly, at room temperature. Some physical properties are in Table 9.4 from which it can be seen that silanes are less volatile than both the alkanes and boranes (p. 163) of similar formula, but more volatile than the corresponding germanes (p. 375).

There are three general types of preparative route to the silane and their derivatives. Early methods (pre-1945) treated materials such as metal silicides which contained negatively charged Si⁻ with a protonic reagent such as an aqueous acid. Concurrent hydrolysis of the products limited the yield but considerable improvement resulted from the use of nonaqueous systems such as NH₄Br/liq NH₃ (1934). The second general preparative route involves treatment of compounds such as SiX₄ (Si⁴⁺) with hydridic reagents such as LiH, NaH, LiAlH₄, etc., in ether solvents at low temperatures. This is now the preferred route: e.g. reaction of Si₃Cl₄⁺ (n = 1, 2, 3) with LiAlH₄ gives essentially quantitative

yields of SiH₄, Si₂H₆, and Si₃H₈. Organosilanes can be prepared similarly, e.g. Me₂SiCl₂ gives Me₂SiH₂. The third general method for preparing Si–H compounds involves direct reaction of HX or RX with Si or a ferrosilicon alloy in the presence of a catalyst such as Cu when necessary (p. 364), e.g.:

Si + 3HCl → SiHCl₃ + H₂
Si + 2MeCl → MeSiCl₂ + H₂ + C

Combination of these various methods has led to a vast number of derivatives in which H is progressively replaced by one or more monofunctional group such as F, Cl, Br, I, CN, R, Ar, OR, SH, SR, NH₂, NR₂, etc. The cyclic silanes Si₄H₁₀ and Si₆H₁₂ were prepared in the late 1970s via (SiPh)ₙ, which were themselves the first known homocyclic silane derivatives (F. S. Kipping, 1921):

Silanes are much more reactive than the corresponding C compounds. This has been ascribed to several factors including: (a) the larger radius of Si which would facilitate attack by nucleophiles, (b) the great polarity of Si–X bonds, and (c) the presence of low-lying d orbitals which permit the formation of 1:1 and 1:2 adducts, thereby lowering the activation energy of the reaction. The relative magnitude of the various bond energies is also an important factor in deciding which bonds will survive and which will be formed. Thus, it can be seen in Table 9.5, Si–Si < Si–C < C–C and Si–H < C–H, whereas for bonds for the other elements the energy C–X < Si–X. These data should

be used only for broad comparisons since the estimated bond energies depend markedly on the particular compounds being studied and also on the experimental technique employed and the method of computation.

The pyrolysis of silanes leads to polymeric species and ultimately to Si and H₂; indeed, pyrolysis of SiH₄ is a commercial route to ultrapure Si. The reactions occurring have been less studied than those of alkanes (and boranes, p. 164), but it is clear that there are significant differences. Thus the initial step in the thermal decomposition of alkanes is the cleavage of a C–H or C–C bond with formation of radical intermediates R₃C'. However, studies using deuterium-substituted compounds suggest that the initial step in the decomposition of polysilanes is the elimination of silenes :SiH₂ or :SiHR. Activation energies for this process (~210 kJ mol⁻¹) are substantially less than Si–Si and Si–H bond energies and the reaction appears to involve a 1,2-H shift with a 5-coordinate transition state.

Pure silanes do not react with pure water or dilute acids in silica vessels, but even traces of alkali dissolved out of glass apparatus catalyse the hydrolysis which is then rapid and complete (SiO₂·nH₂O + 4H₂). Solvolysis with MeOH can be controlled to give several products SiH₄₋ₙ⁻ (OMe)ₙ (n = 2, 3, 4). Si–H adds (with difficulty) to alkenes though the reaction occurs more readily with substituted silanes. Similarly, SiH₄ adds to Me₂CO at 450° to give C₃H₇OSiH₃, and it ring-opens ethylene oxide at the same temperature to give EtOSiH₃ and other products. Silanes explode in the presence of Cl₂ or Br₂ but the reaction with Br₂ can be moderated at −80° to give good yields of SiH₃Br and SiH₃Br₂. More conveniently, halogenosilanes SiH₃X can be made by the catalysed reaction of SiH₄ and HX in the presence of Al₂X₅, or by the reaction with solid AgX in a heated flow reactor, e.g.:

\[
\text{SiH}_4 + 2\text{AgCl} \xrightarrow{260°} \text{SiH}_3\text{Cl} + \text{HCl} + 2\text{Ag}
\]

SiH₃I in particular is a valuable synthetic intermediate and some of its reactions are summarized in Table 9.6. SiH₃I is a dense, colourless, mobile liquid, mp −57.0°, bp +45.4°, d(15°) 2.035 g cm⁻³.

Another valuable reagent is KSiH₃, a colourless crystalline compound with NaCl-type

\(^{(a)}\)See footnote \((a)\) to Table 9.6.

When hexamethyolphosphoramid, \((\text{NMe}_2)\)PO, is used as solvent only the second reaction occurs. The synthetic utility of KSiH$_3$ can be gauged from Table 9.7 which summarizes some of its reactions. In addition, PCl$_3$ gives polymeric (PH)$_x$, CO$_2$ gives CO plus HCO$_2$K (formate), and N$_2$O gives N$_2$ + H$_2$ (plus) some SiH$_4$ in each case.\(^{(32)}\)

The hypervalent silicon hydride anion, SiH$_5^-$ (cf. SiF$_5^-$ below), has been synthesized as a reactive species in a low-pressure flow reactor:\(^{(33)}\)

\[
\text{Et}_3\text{SiH} + \text{H}^+(g) \rightarrow \begin{cases} 
32\% & \text{SiH}_5^- + \text{Et}_3\text{SiH} \\
68\% & \text{SiH}_3^- + \text{Et}_3\text{SiH} + \text{H}_2
\end{cases}
\]

### 9.3.3 Silicon halides and related complexes

Silicon and silicon carbide both react readily with all the halogens to form colourless volatile reactive products SiX$_4$. SiCl$_4$ is particularly important and is manufactured on the multikilotonne scale for producing boron-free transistor grade Si, fumed silica (p. 345), and various silicon esters. When two different tetrahalides are heated together they equilibrate to form an approximately random distribution of silicon halides which, on cooling, can be separated and characterized:

\[
n\text{SiX}_4 + (4 - n)\text{SiY}_4 \rightleftharpoons 4\text{SiX}_n\text{Y}_{4-n}
\]

Mixed halides can also be made by halogen exchange reaction, e.g. by use of SbF$_3$ to successively fluorinate SiCl$_4$ or SiBr$_4$. The mps and bps of these numerous species are compared with those of the parent hydride and halides in Fig. 9.1. While there is a clear trend to higher mps and bps with increase in molecular weight, this is by no means always regular. More notable is the enormous drop in mp (bp) which occurs for the halides of Si when compared with Al and earlier elements in the same row of the periodic table, e.g.:

This is sometimes erroneously ascribed to a discontinuous change from “ionic” to “covalent” bonding, but the electronegativity and other bonding parameters of Al are fairly similar to those of Si and the difference is more convincingly seen merely as a consequence of the change from an infinite lattice structure (in which each Al is surrounded by 6 F) to a lattice of discrete SiF$_4$ molecules as dictated by stoichiometry and size. Several other examples of this effect will be noticed amongst compounds of the Group 14 elements. Another instructive trend is in the Si–F interatomic distance in binary Si/F species: in tetrahedral SiF$_4$(c) it is 154.0 pm; in trigonal bipyramidal SiF$_5^-$ it is 159.4 and 164.6 pm, respectively, for equatorial and axial bonds, and in SiF$_6^{2-}$ it is 168.5 pm. The trend is to longer distances with increase in coordination number, presumably reflecting a gradual decrease in bond order. The 3.3% increase in going from

---

equatorial to axial bonding in $\text{SiF}_5^-$ is also in the usual direction.

The reactions of $\text{SiX}_4$ are straightforward and call for little comment.$^{(1,2)}$

Higher homologues $\text{Si}_n\text{X}_{2n-2}$ are volatile liquids or solids and, contrary to the situation in carbon chemistry, catenation in Si compounds reaches its maximum in the halides rather than the hydrides. This has been ascribed to additional back-bonding from filled halogen $p_x$ orbitals into the Si $d_z$ orbitals which thus synergically compensates for electron loss from Si via $\sigma$ bonding to the electronegative halogens (cf. CO, pp. 926–8). Fluoropolysilanes up to $\text{Si}_{14}\text{F}_{30}$ and other series up to at least $\text{Si}_6\text{Cl}_{14}$ and $\text{Si}_4\text{Br}_{10}$ are known. Preparative routes are exemplified by the following reactions:

$\text{Si} + \text{SiF}_4 \xrightarrow{\text{low press. flow, system/1250°C}} 2\text{SiF}_2(g) \xrightarrow{\text{condense}} -196^\circ$  

$\text{(SiF}_2)_n \xrightarrow{\text{polymer}} \text{Si}_n\text{F}_{2n+2}$ mixture

$\text{Si} + \text{SiCl}_4 \xrightarrow{\text{red heat}} \text{Si}_2\text{Cl}_6$ plus higher homologues

$\text{Si}_2\text{Cl}_6 + \text{ZnF}_2 \xrightarrow{\text{}} \text{Si}_2\text{F}_6 + \text{ZnCl}_2$
minerals coesite and stishovite. Earthy forms are particularly prevalent as kieselguhr and diatomaceous earth.†

Vitreous SiO₂ occurs as tectites, obsidian and the rare mineral lechatelierite. Synthetic forms include keatite and W-silica. Opals are an exceedingly complex crystalline aggregate of partly hydrated silica.

The main crystalline modifications of SiO₂ consist of infinite arrays of corner-shared \{SiO₄\} tetrahedra. In α-quartz, which is thermodynamically the most stable form at room temperature, the tetrahedra form interlinked helical chains; there are two slightly different Si–O distances (159.7 and 161.7 pm) and the angle Si–O–Si is 144°. The helices in any one crystal can be either right-handed or left-handed so that individual crystals have non-superimposable mirror images and can readily be separated by hand. This enantiomorphism also accounts for the pronounced optical activity of α-quartz (specific rotation of the Na D-line 27.7°/mm). At 573°C α-quartz transforms into β-quartz which has the same general structure but is somewhat less distorted (Si–O–Si 155°): only slight displacements of the atoms are required so the transition is readily reversible on cooling and the “handedness” of the crystal is preserved throughout. This is called a non-reconstructive transformation. A more drastic structural change occurs at 867°C when β-quartz transforms into β-tridymite. This is a reconstructive transformation which requires the breaking of Si–O bonds to enable the \{SiO₄\}

9.3.4 Silica and silicic acids

Silica has been more studied than any other chemical compound except water. More than 22 phases have been described and, although some of these may depend on the presence of impurities or defects, at least a dozen polymorphs of “pure” SiO₂ are known. This intriguing structural complexity, coupled with the great scientific and technical utility of silica, have ensured continued interest in the compound from the earliest times. The various forms of SiO₂ and their structural interrelations will be described in the following paragraphs. By far the most commonly occurring form of SiO₂ is α-quartz which is a major mineral constituent of many rocks such as granite and sandstone; it also occurs alone as rock crystal and in impure forms as rose quartz, smoky quartz (red brown), morion (dark brown), amethyst (violet) and citrine (yellow). Poorly crystalline forms of quartz include chaledony (various colours), chrysoprase (leek green), carnelian (deep red), agate (banded), onyx (banded), jasper (various), heliotrope (bloodstone) and flint (often black due to inclusions of carbon). Less-common crystalline modifications of SiO₂ are tridymite, cristobalite and the extremely rare

---

tetrahedra to be rearranged into a simpler, more open hexagonal structure of lower density. For this reason the change is often sluggish and this enables tridymite to occur as a (metastable) mineral phase below the transition temperature. When $\beta$-tridymite is cooled to $\sim$120$^\circ$ it undergoes a fast, reversible, non-reconstructive transition to (metastable) $\alpha$-tridymite by slight displacements of the atoms. Conversely, when $\beta$-tridymite is heated to 1470$^\circ$ it undergoes a sluggish reconstructive transformation into $\beta$-cristobalite and this, in turn, can retain its structure as a metastable phase when cooled below the transition temperature; further slight displacements occur rapidly and reversibly in the temperature range 200–280$^\circ$ to give $\alpha$-cristobalite ($\text{Si-O}$ 161 pm, $\text{Si-O-Si}$ 147$^\circ$). These transitions are summarized below.

The $\alpha$-form of each of the three minerals can thus be obtained at room temperature and, because of the sluggishness of the reconstructive interconversions of the $\beta$-forms, it is even possible to melt $\beta$-quartz (1550$^\circ$) and $\beta$-tridymite (1703$^\circ$) if they are heated sufficiently rapidly. The bp of $\text{SiO}_2$ is not accurately known but is about 2800$^\circ$C.

Other forms of $\text{SiO}_2$ can be made at high pressure (Fig. 9.2). Coesite was first made by L. Coes in 1953 by heating dry $\text{Na}_2\text{SiO}_3$ and ($\text{NH}_4)_2\text{HPO}_4$ at 700$^\circ$ and 40 kbar, and was subsequently found in nature at Meteor Crater, Arizona (1960). Its structure consists of 4-connected networks of $\{\text{SiO}_4\}$ in which the smallest rings are 4- and 8-membered, and this compact structure explains its high density (Table 9.8). On being heated it rapidly converts to tridymite or cristobalite. At still higher pressures (40–120 kbar, 380–585$^\circ$) keatite is formed under hydrothermal conditions from amorphous silica and dilute alkali (P. P. Keat, 1959); the $\{\text{SiO}_4\}$ are connected into 5-, 7-, and 8-membered rings as in ice(III) (p. 624). The highest density form of $\text{SiO}_2$ was predicted in 1952 by J. B. Thompson who visualized 6-coordinate Si in a rutile structure (p. 961). It was first synthesized in S. M. Stishov's laboratory (1961) at 1200: 1400$^\circ$ and 160 180 kbar, and found to have the predicted structure. It was discovered in association with coesite at Meteor Crater in 1962: presumably both minerals were formed under transient shock pressures following meteorite impact and then preserved by rapid quenching from high temperature. The rapid melting and cooling of pre-existing silica phases also occurs during lightning strikes, and this leads to the formation of lechatelierite, a glassy or vitreous silica mineral.

Finally, a very low-density form of fibrous silica, W-$\text{SiO}_2$ has been made by the disproportionation of (metastable) crystalline $\text{SiO}$:

$$\text{SiO}_2 + \text{Si} \xrightarrow{1250\text{–}1300^\circ\text{C}, 10^{-3}\text{mmHg}} 2\text{SiO} \rightarrow \text{W-SiO}_2 + \text{Si}$$

W-$\text{SiO}_2$ features $\{\text{SiO}_4\}$ tetrahedra linked by sharing opposite edges to form infinite parallel chains analogous to $\text{SiS}_2$ and $\text{SiSe}_2$; this edge-sharing of pairs of O atoms between pairs of Si atoms is not observed elsewhere in Si–O chemistry where linking is by corner sharing of single O atoms. The configuration is unstable, and fibrous SiO$_2$ rapidly reverts to amorphous SiO$_2$ on heating or in the presence of traces of moisture. It has also recently been shown that reaction of ($\text{SiO}_2$) and O$_2$ in an argon matrix results in the formation of dimeric molecules.
of silica, \( \text{O} = \text{Si}(\mu - \text{O})_2 \text{Si} = \text{O} \). Interaction of molecular \( \text{SiO} \) with \( \text{Ag} \) atoms in an argon matrix gives cyclic \( \text{AgSiO} \) with the angle at \( \text{Si} \) being \( \leq 90^\circ \).\(^{37}\)

Silica is chemically resistant to all acids except HF but dissolves slowly in hot concentrated alkali and more rapidly in fused MOH or \( \text{M}_2\text{CO}_3 \) to give \( \text{M}_2\text{SiO}_3 \). Of the halogens only \( \text{F}_2 \) attacks \( \text{SiO}_2 \) readily, forming \( \text{SiF}_4 \) and \( \text{O}_2 \). Above 1000° \( \text{H}_2 \) and \( \text{C} \) also react. Several varieties of crystalline, cryptocrystalline and vitreous \( \text{SiO}_2 \) find extensive applications and these are noted in the Panel. In vitreous silica \{\text{SiO}_4\} tetrahedra are again linked by sharing corners with each \( \text{O} \) linked to 2\( \text{Si} \) but the extended three-dimensional network lacks the symmetry and periodicity of the crystalline forms. The \( \text{Si} - \text{O} \) distances are similar to those in other forms of \( \text{SiO}_2 \) (158–162 pm) but the \( \text{Si} - \text{O} - \text{Si} \) angles vary by as much as 15–20° on either side of the mean value of 153°.

The detailed reactions of \( \text{SiO}_2 \) with the oxides of the metals and semi-metals are of great importance in glass technology and ceramics.

§9.3.4 Silica and silicic acids

but will not be treated here.\(^1\) Suffice it to say that, in addition to innumerable crystalline compounds and vitreous phases, many water-soluble compositions are known and many of these find extensive commercial application.

Perhaps the best known are the soluble sodium (and potassium) silicates which are made by fusing sand with the appropriate carbonate in a glass-making furnace at \(\sim 1400^\circ\). The resulting soluble glass is dissolved in hot water under pressure and any insoluble glass or unreacted sand filtered off. The ternary phase diagram for \(\text{Na}_2\text{O} - \text{SiO}_2 - \text{H}_2\text{O}\) (Fig. 9.3) indicates that only certain limited regions are of commercial interest, e.g. the stable liquid materials (area 9) in the composition range

---

---

Some Uses of Silica\(^1\)

The main types of SiO\(_2\) used in industry are high-purity \(\alpha\)-quartz, vitreous silica, silica gel, fumed silica and diatomaceous earth. The most important application of quartz is as a piezoelectric material (p. 58); it is used in crystal oscillators and filters for frequency control and modulation, and in electromechanical devices such as transducers and pickups: tens of millions of such devices are made each year. There is insufficient natural quartz of adequate purity so it must be synthesized by hydrothermal growth of a seed crystal using dilute aqueous NaOH and vitreous SiO\(_2\) at 400°C and 1.7 kbar. The technique was first successfully employed by G. R. Spezia in 1905. (Crystal growth from molten SiO\(_2\) cannot be used — why?)

Vitreous silica combines exceptionally low thermal expansion\(^*\) and high thermal shock resistance with high transparency to ultraviolet light, good refractory properties, and general chemical inertness. As a glass it is hard to work because of its very high softening point, high viscosity, short liquid range and high volatility at forming temperatures. It is familiar in high-quality laboratory glassware, particularly for photolysis experiments and as sample cells in ultraviolet/visible spectroscopy; it is also much used as a protective sheath in the form of tubing or as thin films deposited from the vapour.

Silica gel is an amorphous form of SiO\(_2\) with a very porous structure, formed by acidification of aqueous solutions of sodium silicate; the gelatinous precipitate is washed free of electrolytes and then dehydrated either by roasting or spray drying. The properties of the resulting microporous material depend critically on the conditions of preparation, but typical samples have a pore diameter of 2200–2600 pm, a surface area of 750–800 m\(^2\) g\(^{-1}\), and an apparent bulk density of 0.67–0.75 g cm\(^{-3}\). Such material finds extensive use as a desiccant, selective absorbant, chromatographic support, catalyst substrate and insulator (thermal and sound). It can absorb more than 40% of its own weight of water and, when stained with cobalt salts such as the nitrate or (NH\(_4\))\(_2\)CoC\(_4\), is familiar as a self-indicating desiccant that can readily be regenerated by heating (anhydrous, blue; hydrated, pink). It is chemically inert, non-toxic and dimensionally stable, and finds a growing application in the food industry as an anticaking agent in cocoa, fruit juice powders, NaHCO\(_3\) and powdered sugar and spices. It is also used as a flattening agent to produce an attractive matte finish on lacquers, varnishes and paints, and on the surface of vinyl plastics and synthetic fabrics.

Another manufactured form of ultrafine powdered SiO\(_2\) is pyrogenic or fumed silica, formed by the high-temperature hydrolysis of SiCl\(_4\) in an oxyhydrogen flame in specially designed burners; the SiO\(_2\) is formed as a very fine white smoke which is collected on cooled rotating rollers. The bulk density is only 0.03–0.06 g cm\(^{-3}\) and the surface area 150–500 m\(^2\) g\(^{-1}\). Its main use is as a thixotropic thickening agent in the processing of epoxy and polyester resins and plastics, and as a reinforcing filler in silicone rubbers where, in contrast to carbon black fillers (p. 271), its chemical inertness does not interfere with the peroxide initiated cure (p. 365). Diatomaceous earth or kieselguhr (p. 342) is mined by open-cast methods on a very substantial scale, particularly in Europe and North America, which respectively account for 59% and 39% of the world production (1.8 million tonnes in 1977). The principal use is in filtration plants, and this accounts for about 60% of the supply; a further 20% is used in abrasives, fillers, light-weight aggregates and insulation material, and the remainder is used as an inert carrier, coating agent or in the manufacture of pozzolan.

\(^1\) The linear coefficient of thermal expansion of vitreous silica is \(\sim 0.25 \times 10^{-6}\). This can be compared with a value of \(\sim 100 \times 10^{-6}\) for ordinary soda-lime glasses (\(\sim 79%\) SiO\(_2\), \(\sim 12.5%\) Na\(_2\)O, \(\sim 8.5%\) CaO). Addition of B\(_2\)O\(_3\) (as in Pyrex) sharply reduces this value to \(3 \times 10^{-6}\) (typical laboratory glassware has a composition 83.9% SiO\(_2\), 10.6% B\(_2\)O\(_3\), 1.2% Al\(_2\)O\(_3\), 3.9% Na\(_2\)O, 0.4% K\(_2\)O).
30–40% SiO₂, 10–20% Na₂O, 60–40% H₂O, i.e. Na₂Si₂O₅·6H₂O. These find extensive use in industrial and domestic liquid detergents because they maintain high pH by means of their buffering ability and can saponify animal and vegetable oils and fats; they also emulsify mineral oils, defloculate dirt particles, and prevent redeposition of suspended dirt and soil. The more dilute solutions (area 10) are used in production of silica gels by acidification (pp. 345 and below). There are numerous other uses of soluble silicates including adhesives, glues and binders, especially for corrugated cardboard boxes, and as refractory acid-resistant cements and sealants. World production in 1981 was ~3.0 million tonnes of which the sodium silicates formed the major part. Price range from $220–450/tonne depending on composition.

Potassium silicate solutions are equally complex; for example, an aqueous solution prepared from KOH and SiO₂ in which the ratio K:Si is 1:1 contains 22 different discrete silicate anions as identified by ²⁹Si COSY nmr studies.³⁹

The system SiO₂–H₂O, even in the absence of metal oxides, is particularly complex and of immense geochemical and industrial importance.⁴⁰ The mp of pure SiO₂ decreases dramatically by as much as 800° on addition of 1–2% H₂O (at high pressure), presumably as a result of the structure-breaking effect of replacing Si–O–Si links by “terminal” Si–OH groups. With increasing concentrations of H₂O one obtains hydrated silica gels and colloidal dispersions of silica; there are also numerous hydrates and distinct silicic acids in very dilute aqueous solutions, but these tend to be rather insoluble and rapidly precipitate with further condensation when aqueous solutions of soluble silicates are acidified. Structural information is sparse, particularly for the solid state, but in solution evidence has been claimed for at least 5 species (Table 9.9). It is unlikely that any of these species exist in the solid state since precipitation is accompanied by further condensation and cross-linking to form “polysilicic acids” of indefinite and variable composition [SiO₄(OH)₄-k]n (cf B, Al, Fe, etc.). However, the crystal structure of [(−C₈H₁₁)₇Si₇O₉{O₃W(NMe₂)₃}₃] has been determined.⁴¹

Silicate minerals

§9.3.5 Silicate minerals

The earth's crustal rocks and their breakdown products — the various soils, clays and sands — are composed almost entirely (~95%) of silicate minerals and silica. This predominance of silicates and aluminosilicates is reflected in the abundance of O, Si and Al, which are the commonest elements in the crust (p. 329). Despite the great profusion of structural types and the widely varying stoichiometries which are unmatched elsewhere in chemistry, it is possible to classify these structures on the basis of a few simple principles. Almost invariably Si is coordinately tetrahedrally by 4 oxygen atoms and these \(\{\text{SiO}_4\}\) units can exist either as discrete structural entities or can combine by corner sharing of O atoms into larger units. The resulting O lattice is frequently close-packed, or approximately so, and charge balance is achieved by the presence of further cations in tetrahedral, octahedral, or other sites depending on their size. Typical examples are as follows (radii in pm):\(^1\)

\(\text{CN}\) refers to the coordination number of the cation. The quoted radii, which in turn depend on the CN, are the empirical "effective ionic radii" deduced by R. D. Shannon (and C. T. Prewitt)\(^{45}\) and do not imply full charge separation such as \(\{\text{Si}^{4+}\} \{\text{O}^{2-}\}_4\) etc. Note that \(\text{Al}^{3+}\) can occupy either 4- or 6-coordinate sites so that it can replace either Si or M in the lattice—this is particularly important in discussing the structures of the aluminosilicates. Several other cations can occupy sites of differing CN, e.g. \(\text{Li}^+(4\text{ and }6)\), \(\text{Na}^+(6\text{ and }8)\), \(\text{K}^+(6\text{–}12)\), though they are most commonly observed in the CN shown.

As with the borates (p. 205) and to a lesser extent the phosphates (p. 526), the \(\{\text{SiO}_4\}\) units can build up into chains, multiple chains (or ribbons), rings, sheets and three-dimensional networks as summarized below and elaborated in the following paragraphs.

### Silicates with discrete units

Discrete \(\{\text{SiO}_4\}\) units occur in the orthosilicates \(\text{M}_2\text{SiO}_4\) (\(\text{M} = \text{Be}, \text{Mg}, \text{Mn}, \text{Fe} \text{ and } \text{Zn}\)) and in \(\text{ZrSiO}_4\) as well as in the synthetic orthosilicates \(\text{Na}_4\text{SiO}_4\) and \(\text{K}_4\text{SiO}_4\).\(^{46}\) In phenacite, \(\text{Be}_2\text{SiO}_4\), both Be and Si occupy sites of CN 4 and the structure could equally well be described as a 3D network \(\text{M}_3\text{O}_4\). When octahedral sites are occupied, isomorphous replacement of \(\text{M}^{11}\) is often extensive as in olivine, \((\text{Mg,Fe,Mn})_2\text{SiO}_4\) which derives its name from its olive-green colour (Fe\(^{III}\)). In zircon, \(\text{ZrSiO}_4\), the stoichiometry

of the crystal and the larger radius of Zr (84 pm) dictate eightfold coordination of the cation. Another important group of orthosilicates is the garnets, $[\text{M}^{II}_3\text{M}^{III}_2(\text{Si}_2\text{O}_5)_3]$, in which $\text{M}^{II}$ are 8-coordinate (e.g. Ca, Mg, Fe) and $\text{M}^{III}$ are 6-coordinate (e.g. Al, Cr, Fe).\(^{(47)}\) Orthosilicates are also vital components of Portland cement (p. 252): p-Ca$\text{Si}_2\text{O}_4$ has discrete \{SO$_4$\} groups with rather irregularly coordinated Ca in sixfold and eightfold environments (the $\alpha$-form has the K$_2$SO$_4$ structure and the $\gamma$-form has the olivine structure). Again alite, Ca$_3$SiO$_5$, which is intimately involved in the “setting” process, has individual Ca, \{SiO$_4$\} and O as the structural units.

Disilicates, containing the discrete \{Si$_2$O$_6$\} unit, are rare. One example is the mineral thortveitite, Sc$_2$Si$_2$O$_7$, which features octahedral Sc$^{III}$ (75 pm) and a linear Si O Si bond between the two tetrahedra and the D$_{3d}$ (staggered) conformation, and (b) eclipsed (C$_{2v}$) conformation of the \{Si$_2$O$_5$\} unit in hemimorphite, [Zn$_2$Si$_2$O$_7$(OH)$_2$].H$_2$O.

Figure 9.4 (a) Two representations of the [Si$_2$O$_7$] unit in Sc$_2$Si$_2$O$_7$, showing the linear Si O Si link between the two tetrahedra and the D$_{3d}$ (staggered) conformation, and (b) eclipsed (C$_{2v}$) conformation of the [Si$_2$O$_5$] unit in hemimorphite, [Zn$_2$Si$_2$O$_7$(OH)$_2$].H$_2$O.

Disilicates, containing the discrete \{Si$_2$O$_7$\} unit, are rare. One example is the mineral thortveitite, Sc$_2$Si$_2$O$_7$, which features octahedral Sc$^{III}$ (75 pm) and a linear Si O Si bond between staggered tetrahedra (Fig. 9.4a). There is also a series of lanthanoid disilicates Ln$_2$Si$_2$O$_7$ in which the Si – O – Si angle decreases progressively from 180° to 133° and the CN of Ln increases from 6 through 7 to 8 as the size of Ln increases from 6-coordinated La$^{III}$ (86 pm) to 8-coordinated Nd$^{III}$ (111 pm). In the Zn mineral hemimorphite the angle is 150° but the conformation of the 2 tetrahedra is eclipsed (C$_{2v}$) rather than staggered (Fig. 9.4b); the mineral was originally formulated as Zn$_2$Si$_2$O$_4$.H$_2$O or H$_2$Zn$_2$SiO$_5$, but X-ray studies showed that the correct formula was [Zn$_4$(OH)$_2$Si$_2$O$_7$].H$_2$O, i.e. “2H$_2$Zn$_2$SiO$_5$”. Two further features of importance also emerged. The first was that there was no significant difference between the Si – O distances to “bridging” and “terminal” O atoms as would be expected for isolated [Si$_2$O$_7$]$^{5-}$ groups, and the structure is best considered as a 3D framework of [ZnO$_4$(OH)] and [SiO$_4$] tetrahedra linked in threes to form 6-atom rings Zn – O – Si – O – Zn – OH. The rings are linked into infinite sheets in the (010) planes which are themselves linked via Zn – O(H) – Zn or Si – O – Si bonds. The 3D framework so generated leaves large channels which open into large cavities that accommodate the removable H$_2$O molecules. The structure is thus very similar in principle to that of the framework aluminosilicates (p. 354) and its conventional description in terms of discrete Si$_2$O$_7$$^{5-}$ ions is rather misleading and uninformative.

Structures having triple tetrahedral units are extremely rare but they exist in aminoffite, Ca$_3$(BeOH)$_2$(Si$_3$O$_{10}$), and kinoite, Cu$_2$Ca$_2$(Si$_3$O$_{10}$).2H$_2$O. The first chain-tetrasilicate, [0$_4$Si$\text{(OSi}_2)_2$OSi$_3$]$_{10-}$, was synthesized as recently as 1979:\(^{(48)}\) Ag$_{18}$Si$_4$O$_{13}$ was prepared as stable vermilion crystals by heating AgO and SiO$_2$ for 1–3 days at 500–600°C under a pressure of 2–4.5 kbar of O$_2$. At lower temperatures (<470°C) the bright red mixed silicate [Ag$_{18}$(Si$_4$O$_{13}$)(Si$_3$O$_{13}$)] crystallizes.\(^{(49)}\)

When every [SiO$_4$] shares 2 O with contiguous tetrahedra, metasilicates of empirical
§9.3.5  Silicate minerals

formula SiO$_3^{2-}$ are formed. Cyclic metasilicates \([\text{SiO}_3]_{n}^{2-}\) having 3, 4, 6 or 8 linked tetrahedra are known, though 3 and 6 are the most common. These anions are shown schematically in Fig. 9.5 and are exemplified by the mineral benitoite \([\text{BaTi}][\text{Si}_3\text{O}_9]\), the synthetic compound \([\text{K}_4][\text{Si}_4\text{O}_6(\text{OH})_4]\), and by beryl \([\text{Be}_3\text{Al}_2][\text{Si}_6\text{O}_{18}]\) (p. 107) and murrite \([\text{Ba}_{10}[\text{Ca},\text{Mn},\text{Ti}]_4[\text{Si}_8\text{O}_{24}](\text{Cl},\text{OH},\text{O})_{12}]\cdot 4\text{H}_2\text{O}\).

Figure 9.5  Schematic representations of the structures of cyclic metasilicate anions with \(n = 3, 4, 6, \) and 8.

Silicates with chain or ribbon structures

Chain metasilicates \([\text{SiO}_3^{2-}]_{\infty}\) formed by corner-sharing of \([\text{SiO}_4]\) tetrahedra are particularly prevalent in nature and many important minerals have this basic structural unit (cf. polyphosphates, p. 528). Despite the apparent simplicity of their structure motif and stoichiometry considerable structural diversity is encountered because of the differing conformations that can be adopted by the linked tetrahedra. As a result, the repeat distance along the c-axis can be (1), 2, 3, .... 7, 9 or 12 tetrahedra \((T)\). as illustrated schematically in Fig. 9.6. The most common configuration for metasilicates is a repeat after every second tetrahedron \((2T)\) with the chains stacked parallel so as to provide sites of 6- or 8-coordination for the cations; e.g. the pyroxene minerals enstatite \([\text{Mg}_2\text{Si}_2\text{O}_6]\), diopside \([\text{CaMg}_2\text{Si}_2\text{O}_6]\), jadeite \([\text{NaAlSi}_2\text{O}_6]\), and spodumene \([\text{LiAlSi}_2\text{O}_6]\) (p. 69). The synthetic metasilicates \(\text{Li}_2\text{Si}_3\text{O}_5\) and \(\text{Na}_2\text{Si}_3\text{O}_5\) are similar; for the latter compound Si–O–Si is 134° and the Si O distance is 167 pm within the chain and 159 pm for the other two O. The minerals wollastonite \([\text{Ca}_3\text{Si}_3\text{O}_9]\) and pectolite \([\text{Ca}_2\text{Na}_2\text{Si}_3\text{O}_9]\) have a 3T repeat unit, kajalite \([\text{Sr}_2(\text{VO})\text{Si}_4\text{O}_{12}]\) is 4T, rhodonite \([\text{CaMn}_4\text{Si}_3\text{O}_{15}]\) has a 5T repeat, etc.\(^{(24,44)}\)

In the next stage of structural complexity the single \([\text{SiO}_3^{2-}]_{\infty}\) chains can link laterally to form double chains or ribbons whose stoichiometry depends on the repeat unit of the single chain (Fig. 9.7). By far the most numerous are the amphiboles or asbestos minerals which adopt the \([\text{Si}_2\text{O}_{11}^{6-}]\) double chain, e.g. tremolite \([\text{Ca}_2\text{Mg}_5(\text{Si}_4\text{O}_{11})_2(\text{OH})_2]\); the structure of this compound is very similar to that of diopside (above) except that the length of the b-axis of the unit cell is doubled. The fibrous nature of the asbestos minerals thus finds a ready interpretation on the basis of their crystal structures (see Panel on p. 351). In addition to these well-established double chains of linked \([\text{SiO}_4]\) tetrahedra, examples of infinite one-dimensional structures consisting of linked triple, quadruple and even sextuple chains have been discovered in nephrite jade by means of electron microscopy,\(^{(50)}\) and these form a satisfying link between the pyroxenes and amphiboles, on the one hand, and the sheet silicates (to be described in the next paragraph), on the other.

Silicates with layer structures

Silicates with layer structures include some of the most familiar and important minerals known to man, particularly the clay minerals (such as kaolinite (china clay), montmorillonite (bentonite, fuller’s earth), and vermiculite), the micas (e.g. muscovite, phlogopite, and biotite), and others such as chrysotile (white asbestos),

Figure 9.6 Schematic representation and examples of various chain metasilicates \([\text{SiO}_2^{\text{2-}}]_\infty\) with repeat distances (in pm) after 1, 2, ..., 7, 9 or 12 tetrahedra (T), ([ht]) high-temperature form; (hp) high-pressure form.

talc, soapstone, and pyrophyllite. The physical and chemical properties of these minerals, which have made many of them so valued for domestic and industrial use for several millennia (p. 328), can be directly related to the details of their crystal structure. The simplest silicate layer structure can be thought of as being formed either by the horizontal cross-linking of the 2T metasilicate chain \(\{\text{Si}_2\text{O}_6^{4-}\}\) in Fig. 9.6 or by the planar condensation of the \([\text{Si}_6\text{O}_{18}^{12-}]\) unit in Fig. 9.5 to give a 6T network of composition \(\{\text{Si}_5\text{O}_8^{2-}\}\) in which 3 of the 4 O atoms in each tetrahedron are shared; this is shown in both plan and elevation in Fig. 9.8. In fact, such a structure with a completely planar arrangement is extremely rare though closely related puckered 6T networks are found in \(\text{M}_2\text{Si}_2\text{O}_5\) (M = Li, Na, Ag, H) and in petalite (\(\text{LiAlSi}_4\text{O}_{10}\), p. 69). More complex arrangements are also found in which the 6T rings forming the network are replaced by alternate 4T and 8T rings, or by equal numbers of 4T, 6T, and 8T rings, or even by a network of 4T, 6T and 12T rings.

Double layers can be generated by sharing the fourth (apical) O atom between pairs of tetrahedra as in Fig. 9.9(a). This would give a stoichiometry \(\text{Si}_2\text{O}_5\) (since each O atom is shared between 2 Si atoms) but if half the Si\(^{IV}\) were replaced by
§9.3.5 Silicate minerals

Production and Uses of Asbestos

The fibrous silicate minerals known collectively as asbestos (Greek ἀσβεστος, unquenchable) have been used both in Europe and the Far East for thousands of years. In ancient Rome the wicks of the lamps of the vestal virgins were woven from asbestos, and Charlemagne astounded his barbarian guests by throwing the festive table cloth into the fire whence, being woven asbestos, it emerged cleansed and unburnt. Its use has accelerated during the past 100 years and it is now an important ingredient in over 3000 different products. Its desirable characteristics are high tensile strength, great flexibility, resistance both to heat and flame and also to corrosion by acids or alkalis, good thermal insulation properties and low cost.

Asbestos is derived from two large groups of rock-forming minerals — the serpentines and the amphiboles. Chrysotile, or white asbestos \(\text{Mg}_3(\text{Si}_2\text{O}_5)(\text{OH})_4\), is the sole representative of the serpentine layer silicate group (p. 352) but is by far the most abundant kind of asbestos and constitutes more than 98% of world production. The amphibole group includes the blue asbestos mineral crocidolite \([\text{Na}_2\text{Fe}^2\text{Fe}^3\text{Si}_8\text{O}_{22}(\text{OH})_2]\) (<1% of world production) and the grey-brown mineral amosite \([\text{Mg}_2\text{Si}_8\text{O}_{22}(\text{OH})_2]\). (<1%). Annual production in 1989 was 4.3 million tonnes having fallen from a maximum of 5 Mt in 1979. The main producing countries are Russia (55%), Canada (20%), South Africa (4.7%) and Zimbabwe, China, Italy and Brazil (3–4% each).

Asbestos-reinforced cements (~12.5% asbestos) absorb nearly two-thirds of the world's annual production of chrysotile: it is used in corrugated and flat roofing sheets, pressure pipes and ducts, and many other hard-wearing, weather-proof, long-lasting products. About 8% is used in asbestos papers and a further 7% is used for making vinyl floor tiles. Other important uses include composites for brake linings, clutch facings, and other friction products. Long-fibred chrysotile (fibre length >20 mm) is woven into asbestos textiles for fire-fighting garments and numerous fire-proofing and insulating applications.

Prolonged exposure to airborne suspensions of asbestos fibre dust can be very dangerous and there has been increasing concern at the incidence of asbestosis (non-malignant scarring of lung tissue) and lung carcinoma among certain workers in the industry. Unfortunately, there is an extended latent period (typically 20–30 y) before these diseases are manifest. Stringent precautions are now enforced in many countries and the incidence of the disease appears to be falling steadily. There is also general (though not universal) agreement that white asbestos (chrysotile), which is the overwhelmingly predominant type of asbestos in use, is not implicated in the incidence of asbestosis and lung carcinoma which seems to be confined mainly (perhaps exclusively) to the blue crocidolite and brown amosite amphibole varieties. Asbestosis is dose-related and the best form of control is to reduce the level of dust exposure in places where the mineral is mined, processed or fabricated.

Figure 9.7 Double chains of \(\{\text{Si}_4\text{O}_{10}\}\) tetrahedra: (a) the double chain based on the 1T metasilicate structure, stoichiometry \(\{\text{Si}_2\text{O}_5\}^{2-}\) — it is found in the aluminosilicate sillimanite \([\text{Al}(<\text{Si}\text{O}_3])\); (b) \(\{\text{Si}_4\text{O}_{10}\}^{4-}\) chain based on the 2T metasilicate occurs in the amphiboles (see text); and (c) the rare 3T double chain \(\text{Si}_6\text{O}_{17}^{10-}\) occurs in xonotlite \([\text{Ca}_6\text{Si}_6\text{O}_{24}(\text{OH})_2]\). More complex 3T, 4T and 6T double chains are also known.\(^{44}\)

Figure 9.8 Planar network formed by extended 2D condensation of rings of 6 \(\{\text{Si}_4\text{O}_{10}\}\) tetrahedra to give \(\{\text{Si}_2\text{O}_{5}\}^{2-}\). (a) Plan as seen looking down the O-Si direction, and (b) side elevation.

Figure 9.9  (a) Side elevation of double layers of formula \(\{\text{Al}_2\text{Si}_2\text{O}_8\}^+\) formed by sharing the fourth (apical) \(O\) in Fig. 9.9(b). Sites marked ● are occupied by equal numbers of \(\text{Al}\) and \(\text{Si}\) atoms. (b) Structure of \(\text{Ca}_3\text{Al}_2\text{Si}_2\text{O}_8\) formed by interleaving 6-coordinated \(\text{Ca}^{II}\) atoms between the double layers depicted in (a).

The gibbsite \(\text{Al(OH)}_3\) or brucite \(\text{Mg(OH)}_2\) structure (pp. 243–5, 121) which happen to have closely similar dimensions and can thus share \(O\) atoms with the silicate network. This leads to the china-clay mineral kaolinite \([\text{Al}_2(\text{OH})_4\text{Si}_2\text{O}_5]\) illustrated in Figs. 9.10(a) and 9.11(a). [The mineral was so-named in 1867 from “kaolin”, a corruption of the Chinese kaoling, or high-ridge, the name of the hill where this china clay was found some 300 miles north of Hong Kong.]

Repetition of the process on the other side of the \(\text{Al}/\text{O}\) layer leads to the structure of pyrophyllite \([\text{Al}_2(\text{OH})_2\text{Si}_4\text{O}_{10}]\) (Fig. 9.10b,c). Replacement of 2\(\text{Al}^{III}\) by 3\(\text{Mg}^{II}\) in kaolinite \([\text{Al}_2(\text{OH})_4\text{Si}_2\text{O}_5]\) gives the serpentine asbestos mineral chrysotile \([\text{Mg}_3(\text{OH})_4\text{Si}_2\text{O}_5]\) and a similar replacement in pyrophyllite gives talc \([\text{Mg}_3(\text{OH})_2\text{Si}_4\text{O}_{10}]\). The gibbsite series is sometimes called dioctahedral and the brucite series trioctahedral in obvious reference to the number of octahedral sites occupied in the “non-silicate” layer.

Alternative representations of the structures are given in Fig. 9.11, and it is well worth while looking carefully at these various diagrams since they have the pleasing property of becoming simpler and easier to understand the longer they are contemplated. It should be stressed that the formulae given are ideal limiting compositions and that \(\text{Al}^{III}\) or \(\text{Mg}^{II}\) can be replaced by several other cations of appropriate size. The stoichiometry is further complicated by the possibility that \(\text{Si}^{IV}\) can be partly replaced by \(\text{Al}^{III}\) in the tetrahedral sites thereby giving rise to charged layers. These layers can be interleaved with \(\text{M}^{I}\) or \(\text{M}^{II}\) cations to give the micas or by layers of hydrated cations to give montmorillonite. Alternatively, charge balance can be achieved by interleaving positively charged \((\text{Mg,Al})(\text{OH})_2\) layers as in the chlorites. These possibilities are shown schematically in Figs. 9.12 and 9.13 (p. 355) and elaborated in the following paragraphs.
Figure 9.10  (a) Schematic representation of the structure of kaolinite (side elevation) showing \([\text{SiO}_2\text{O}]\) tetrahedra (bottom) sharing common \(\text{O}\) atoms with \([\text{Al(OH)}_2\text{O}]\) to give a composite layer of formula \([\text{Al}_2(\text{OH})_2\text{Si}_2\text{O}_5]\). The double lines and double circles in the tetrahedra indicate bonds to 2 \(\text{O}\) atoms (one in front and one behind). (b) Similar representation of the structure of pyrophyllite, showing shared \([\text{SiO}_2\text{O}]\) tetrahedra above and below the \([\text{Al(OH)}_2\text{O}]\) layer to give a composite layer of formula \([\text{Al}_2(\text{OH})_2\text{Si}_4\text{O}_{10}]\). (c) Alternative representation of pyrophyllite to be compared with (b), and showing the stoichiometry of each layer.

The technological importance of the clay minerals is outlined in the Panel on p. 356.

Micas are formed when one-quarter of the \(\text{Si}^{IV}\) in pyrophyllite and talc are replaced by \(\text{Al}^{III}\) and the resulting negative charge is balanced by \(\text{K}^{I}\):

\[
\text{pyrophyllite } [\text{Al}_2(\text{OH})_2\text{Si}_4\text{O}_{10}] \rightarrow [\text{KAl}_2(\text{OH})_2(\text{Si}_3\text{AlO}_{10})] \text{ muscovite (white mica)}
\]

\[
\text{talc } [\text{Mg}_3(\text{OH})_2\text{Si}_4\text{O}_{10}] \rightarrow [\text{KMg}_3(\text{OH})_2(\text{Si}_3\text{AlO}_{10})] \text{ phlogopite}
\]

The \(\text{OH}\) can be partly replaced by \(\text{F}\) and, in phlogopite, partial replacement of \(\text{Mg}^{II}\) by \(\text{Fe}^{II}\) gives biotite (black mica) \([\text{K(Mg,Fe)}^{II}_3(\text{OH,F})_2(\text{Si}_3\text{AlO}_{10})]\). The presence of \(\text{K}^{I}\) between the layers makes the micas appreciably harder than pyrophyllite and talc but the layers are still a source of weakness and micas show perfect cleavage parallel to the layers. With further substitution of up to half the \(\text{Si}\) by \(\text{Al}\) charge balance can be restored by the more highly charged \(\text{Ca}^{II}\) and brittle micas result, such as margarite \([\text{CaAl}_2(\text{OH})_2(\text{Si}_2\text{AlO}_{10})]\) which is even harder than muscovite.

Another set of minerals, the montmorillonites, result if, instead of replacing tetrahedral \(\text{Si}^{IV}\) by \(\text{Al}^{III}\) in phlogopite, the octahedral \(\text{Al}^{III}\) is partially replaced by \(\text{Mg}^{II}\) (not completely as in talc). The resulting partial negative charge per unit formula can be balanced by incorporating hydrated \(\text{M}^{II}\) or \(\text{M}^{III}\) between the layers; this leads to the characteristic swelling, cation exchange and thixotropy of these minerals (see Panel, p. 356). A typical sodium montmorillonite might be formulated \(\text{Na}_{0.33}[\text{Mg}_{0.33}\text{Al}_{1.67}(\text{OH})_2(\text{Si}_2\text{O}_{10})]\), \(n\text{H}_2\text{O}\), but more generally they can be written as \(\text{M}_x[(\text{Mg,Al,Fe})_2(\text{OH})_2(\text{Si}_4\text{O}_{10})]n\text{H}_2\text{O}\) where \(M = \text{H}, \text{Na}, \text{K}, \frac{1}{2}\text{Mg}\) or \(\frac{1}{2}\text{Ca}\). Simultaneousivalent substitution in both the octahedral and tetrahedral sites in talc leads to the vermiculites
of which a typical formula is
\[
[Mg_{0.32}(H_2O)_{4-3.2}]^{0.64+} +
[(Mg_{2-3.6}Al_{0.46}Fe^{3+}_{0.48})(OH)_2(Si_{2.72}Al_{1.20}O_{10})]^{0.64-}
\]
\[
\text{total 3.00}
\]
When these minerals are heated they dehydrate in a remarkable way by extruding little worm-like structures as indicated by their name (Latin *vermiculus*, little worm); the resulting porous light-weight mass is much used for packing and insulation. The relationship between the various layer silicates is summarized with idealized formulae in Table 9.10 (on page 357).

Silicates with framework structures

The structural complexity of the 3D framework aluminosilicates precludes a detailed treatment here, but many of the minerals are of paramount importance. The group includes the feldspars (which are the most abundant of all minerals, and comprise ~60% of the earth’s crust), the zeolites (which find major applications as molecular sieves, desiccants, ion exchangers and water softeners), and the ultramarines which, as their name implies, often have an intense blue colour. All are constructed from SiO₄ units in which each O atom is shared by 2 tetrahedra (as in the various forms of SiO₂ itself), but up to one-half of the Si
§9.3.5 Silicate minerals

Figure 9.12 Schematic representation of the structures of muscovite mica, $[K_2Al_4(Si_6Al_2)O_{20}(OH)_4]$, hydrated montmorillonite, $[Al_4Si_8O_{20}(OH)_{12}]xH_2O$ and chlorite, $[Mg_{10}Al_2(Si_6Al_2)O_{20}(OH)_{16}]$, see text.

Figure 9.13 Alternative representations of muscovite and chlorite (after B. Mason and L. G. Berry(43)).
Clays are an essential component of soils, to which we owe our survival, and they are also the raw materials for some of mankind's most ancient and essential artefacts: pottery, bricks, tiles, etc. Clays are formed by the weathering and decomposition of igneous rocks and occur typically as very fine particles: e.g. kaolinite is formed as hexagonal plates of edge ~0.1-3 μm by the weathering of alkaline feldspars:

\[
2\text{KAlSi}_3\text{O}_8 + \text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{[Al}_2\text{(OH)}_2\text{Si}_2\text{O}_5] + 4\text{SiO}_2 + \text{K}_2\text{CO}_3
\]

When mixed with water, clays become soft, plastic and mouldable; the water of plasticity can be removed at ~100° and the clay then becomes rigid and brittle. Further heating (~500°) removes structural water of crystallization and results in the oxidation of any carbonaceous material or FeII (600-900°). Above about 950° mullite (\(\text{Al}_6\text{Si}_2\text{O}_13\)) begins to form and glassy phases appear. Common clay is mined on a huge scale (28 million tonnes in USA alone in 1991) and is used principally in the manufacture of bricks (12 Mt), portland cement (10 Mt) and concrete (2.4 Mt), as well as for paper filling and coating (3.7 Mt).

China clay or kaolin, which is predominantly kaolinite, is particularly valuable because it is essentially free from iron impurities (and therefore colourless). World production in 1991 was 24.7 Mt (USA 39%, UK 13%, Colombia, Korea and USSR ~7% each). In the USA over half of this vast tonnage is used for paper filling or paper coating and only 130 000 tonnes was used for china, crockery, and earthenware, which is now usually made from ball clay, a particularly fine-grained, highly plastic material which is predominantly kaolinite together with clay-mica and quartz. Some 800 000 tonnes of ball clay is used annually in the USA for white ware, table ware, wall and floor tiles, sanitary ware, and electrical porcelain.

Fuller's earth is a montmorillonite in which the principal exchangeable cation is calcium. It has a high absorptive and adsorptive capacity, and pronounced cation exchange properties which enable it to be converted to sodium-montmorillonite (bentonite). Nomenclature is confusing and, in American usage, the fibrous hydrated magnesium aluminosilicate attapulgite is also called fuller's earth. World production (1991) was 4.0 million tonnes (USA 68%, Germany 19%, UK 5%). Of the 2.74 Mt produced in the USA, two-thirds was used for what government statisticians coyly call "pet absorbant" and about one-eighth was for oil and grease absorbance.

Bentonite (sodium-montmorillonite) is extensively used as a drilling mud, but this apparently mundane application is based on the astonishing thixotropic properties of its aqueous suspensions. Thus, replacement of Ca by Na in the montmorillonite greatly enhances its ability to swell in one dimension by the reversible uptake of water; this effectively cleaves the clay particles causing a separation of the lamellar units to give a suspension of very finely divided, exceedingly thin plates. These plate-like particles have negative charges on the surface and positive charges on the edges and, even in a suspension of quite low solid content, the particles orient themselves negative to positive to give a jelly-like mass or gel; on agitation, however, the weak electrical bonds are broken and the dispersion becomes a fluid whose viscosity diminishes with the extent of agitation. This indefinitely reversible property is called thixotropy and is widely used in civil engineering applications, in oil-well drilling, and in non-drip paints. The plasticity of bentonite is also used in mortars, putties, and adhesives, in the pelletizing of iron ore and in foundry sands. World production was 9.3 Mt in 1991 (USA 37%, USSR 26%, Greece 11%).

Micas occur as a late crystallization phase in igneous rocks. Usually the crystals are 1-5 mm on edge but in pegmatites (p. 108) they may considerably exceed this to give the valuable block mica. Uses of muscovite mica depend on its perfect basal cleavage, toughness, elasticity, transparency, high dielectric strength, chemical inertness and thermal stability to 500°. Phlogopite (Mg-mica) is less used except when stability to 850-1000° is required. Sheet mica is used for furnace windows, for electrical insulation (condensers, heating elements, etc.) and in vacuum tubes. Ground mica is used as a filler for rubber, plastics and insulating board, for silver glitter paints, etc. World production (excluding China) was ~240 000 tonnes in 1974 (USA 53%, India 20%, USSR 17%).

Talc, unlike the micas, consists of electrically neutral layers without the interleaving cations. It is valued for its softness, smoothness and dry lubricating properties, and for its whiteness, chemical inertness and foliated structure. Its most important applications are in ceramics, insecticides, paints and paper manufacture. The more familiar uses include toilet preparations accounts for only 3% of world production which is about 5 Mt per annum. Half of this comes from Japan and the USA, and other major producers are Korea, the former Soviet Union, France and China. Talc and its more massive mineral form soapstone or steatite are widely distributed throughout the world and many countries produce it for domestic consumption either by open-cast or underground mining.

Most feldspars can be classified chemically as members of the ternary system \(\text{NaAlSi}_3\text{O}_8 - \text{KAlSi}_3\text{O}_8 - \text{CaAl}_2\text{Si}_2\text{O}_8\). This is illustrated in Fig. 9.14, which also indicates the names of the mineral phases. Particularly notable

Figure 9.14 Ternary phase diagram for feldspars. The precise positions of the various phase boundaries depend on the temperature of formation.

is the continuous plagioclase series in which Na\(^+\) (102 pm) is replaced by Ca\(^{2+}\) (100 pm) on octahedral sites, the charge-balance being maintained by a simultaneous substitution of Al\(^{3+}\) for Si\(^{4+}\) on the tetrahedral sites. K\(^{+}\) (138 pm) is too disparate in size to substitute for Ca\(^{2+}\) and 2-phase mixtures result, though orthoclase does form a continuous series of solid solutions with the Ba feldspar celsian [BaAl\(_2\)Si\(_2\)O\(_8\)] (Ba\(^{2+}\) 136 pm). Likewise, most of the alkaline feldspars are not homogeneous but tend to contain separate K-rich and Na-rich phases unless they have crystallized rapidly from solid solutions at high temperatures (above ~600°). Feldspars have tightly constructed aluminosilicate frameworks that generate large interstices in which the large M\(^{1+}\) or M\(^{2+}\) are accommodated in irregular coordination.\(^{(43)}\) Smaller cations, which are common in the chain and sheet silicates (e.g. Li\(^+\), Mg\(^{2+}\), Fe\(^{3+}\)), do not occur as major constituents in feldspars presumably because they are unable to fill the interstices adequately.

Pressure is another important variable in the formation of feldspars and at sufficiently high pressures there is a tendency for Al to increase its coordination number from 4 to 6 with consequent destruction of the feldspar lattice.\(^{†}\) For example:

\(^{†}\) In some compounds of course, octahedrally coordinated Al is stable at normal atmospheric pressure, e.g. in Al\(_2\)O\(_3\).
A. F. Cronstedt in 1756 (ζείν, to boil; λίθος, stone) because the mineral appeared to boil when heated in the blow-pipe flame. Zeolite structures are characterized by the presence of tunnels or systems of interconnected cavities; these can be linked either in one direction giving fibrous crystals, or more usually in two or three directions to give lamellar and 3D structures respectively. Figure 9.15a shows the construction of a single cavity from 24 linked \(\text{SiO}_4\) tetrahedra and Fig. 9.15b shows how this can be conventionally represented by a truncated cubo-octahedron formed by joining the Si atom positions. Several other types of polyhedron have also been observed. These are then linked in three dimensions to build the aluminosilicate framework. A typical structure is shown in Fig. 9.15c for the synthetic zeolite “Linde A” which has the formula \([\text{Na}_{12}(\text{Al}_{12}\text{Si}_{12}\text{O}_{48})] \cdot 27\text{H}_2\text{O}\).\(^{53}\) Other cavity frameworks are found in other zeolites such as faujasite, which has the idealized formula \([\text{NaCa}_{0.5}(\text{Al}_2\text{Si}_5\text{O}_{14})] \cdot 10\text{H}_2\text{O}\), and chabazite \([\text{Ca}(\text{Al}_2\text{Si}_4\text{O}_{12})] \cdot 6\text{H}_2\text{O}\). There is great current interest in this field since it offers scope for the reproducible synthesis of structures having cavities, tunnels and pores of precisely defined dimensions on the atomic scale.\(^{54}\) By

\[\begin{align*}
\text{Na}_2\text{Al}_3\text{Si}_3\text{O}_8 & \xrightarrow{\text{pressure}} \text{Na}_6\text{Al}_5\text{Si}_2\text{O}_{16} + \text{SiO}_2 \\
\text{Na}_2\text{Al}_3\text{Si}_3\text{O}_8 + \text{Na}_2\text{Si}_2\text{O}_5 & \xrightarrow{\text{pressure}} 2\text{Na}_4\text{Al}_5\text{Si}_2\text{O}_{16} \\
3\text{Ca}(\text{Al}_2\text{Si}_3\text{O}_8) & \xrightarrow{\text{pressure}} \text{Ca}_3(\text{Al}_2\text{Si}_3\text{O}_8)_2 + 2\text{Al}_2\text{Si}_2\text{O}_5 + \text{SiO}_2 \\
\text{Ca}(\text{Al}_2\text{Si}_2\text{O}_8) + \text{Ca}_2(\text{Al}_2\text{Si}_2\text{O}_7) + 3\text{CaSiO}_3 & \xrightarrow{\text{pressure}} 2\text{Ca}_3(\text{Al}_2\text{Si}_3\text{O}_8)_2
\end{align*}\]

Such reactions marking the disappearance of plagioclase feldspars may be responsible for the Mohorovicic discontinuity between the earth’s crust and mantle: this implies that the crust and mantle are iso-compositional, the crustal rocks above having phases characteristic of gabbro rock (olivine, pyroxene, plagioclase) whilst the mantle rocks below are an eclogite-containing garnet, Al-rich pyroxene and quartz. Not all geochemists agree, however.

Zeolites have much more open aluminosilicate frameworks than feldspars and this enables them to take up loosely bound water or other small molecules in their structure. Indeed, the name zeolite was coined by the mineralogist Al(OH)₃, and spinels such as MgAl₂O₄. Much higher pressures still are required to transform 4-coordinated Si to 6-coordinated (p. 343).

Figure 9.15 (a) 24 \(\text{SiO}_4\) tetrahedra linked by corner sharing to form a framework surrounding a truncated cubo-octahedral cavity; (b) conventional representation of the polyhedron in (a); and (c) space-filling arrangement of the polyhedra A which also generates larger cavities B.
appropriate design such molecular sieves can be used to selectively remove water or other small molecules, to separate normal from branched-chain paraffins, to generate highly dispersed metal catalysts, and to promote specific size-dependent chemical reactions. Zeolites are made commercially by crystallizing aqueous gels of mixed alkaline silicates and aluminates at 60–100°. Zeolite-A is being increasingly used as a detergent builder to replace sodium tripolyphosphate (p. 528).

The final group of framework aluminosilicates are the ultramarines which have alternate Si and Al atoms at the corners of the polyhedra shown in Fig. 9.15a and b and, in addition, contain substantial concentrations of anions such as Cl\textsuperscript{−}, SO\textsubscript{4}²⁻ or S\textsubscript{2}²⁻. These minerals tend to be anhydrous, like the feldspars, and in contrast to the even more open zeolites. Examples are sodalite (Na\textsubscript{8}Cl\textsubscript{2}\textsubscript{2}\textsubscript{3}\textsubscript{4})(Al\textsubscript{16}Si\textsubscript{6}O\textsubscript{24})), noselite (Na\textsubscript{8}(SO\textsubscript{4})(Al\textsubscript{16}Si\textsubscript{6}O\textsubscript{24}))), and ultramarine (Na\textsubscript{8}(S\textsubscript{2})(Al\textsubscript{16}Si\textsubscript{6}O\textsubscript{24}))). Sodalite is colourless if the supernumerary anions are all chloride, but partial replacement by sulfide gives the brilliant blue mineral lapiz lazuli. Further replacement gives ultramarine which is now manufactured synthetically as an important blue pigment for oil-based paints and porcelain, and as a “blueing” agent to mask yellow tints in domestic washing.

---

9.3.6 Other inorganic compounds of silicon

This section briefly considers compounds in which Si is bonded to elements other than hydrogen, the halogens or oxygen, especially compounds in which Si is bonded to S, N or P. Silicon burns in S vapour at 100° to give SiS\textsubscript{2} which can be sublimed in a stream of N\textsubscript{2} to give long, white, flexible, asbestos-like fibres, mp 1090°, sublimation 1250°C. The structure consists of infinite chains of edge-shared tetrahedra (like W-silica, p. 343) and these transform at high temperature and pressure to a (corner-shared) cristobalite modification. The structural complexity of SiO\textsubscript{2} is not repeated, however. SiS\textsubscript{2} hydrolyses rapidly to SiO\textsubscript{2} and H\textsubscript{2}S and is completely ammonolysed by liquid NH\textsubscript{3} to the imide

\[
\text{SiS}_2 + 4\text{NH}_3 \rightarrow \text{Si(NH)}_2 + 2\text{NH}_4\text{SH}
\]

Sulfides of Na, Mg, Al and Fe convert SiS\textsubscript{2} into metal thiosilicates, and ethanol yields “ethylsilicate” Si(OEt)\textsubscript{4} and H\textsubscript{2}S. † Volatile paper making, starch, etc. † The colour is due to the presence of the sulfur radical anions S\textsubscript{2}⁻ and S\textsubscript{3}⁻ and shifts from green to blue as the ratio S\textsubscript{3}⁻/S\textsubscript{2}⁻ increases; in ultramarine red the predominant species may be the neutral S\textsubscript{4} molecule though S\textsubscript{3}⁻ and S\textsubscript{2}⁻ are also present. 56

† According to H. Remy the artificial production of ultramarine was first suggested by J. W. von Goethe in his Italian Journey (1786–8); it was first accomplished by L. Gmelin in 1828 and developed industrially by the Meissen porcelain works in the following year. It can be made by firing kaolin and sulfur with sodium carbonate; various treatments yield greens, reds and violets, as well as the deep blue, the colours being reminiscent of the highly coloured species obtained in nonaqueous solutions of S, Se and Te (pp. 664, 759).

† Si(OEt)\textsubscript{4} is an important industrial chemical that is made on the kilotonne scale by the action of EtOH on SiCl\textsubscript{4}. It has mp −77°, bp 168.5°, and d\textsubscript{20} 0.9346 g/cm\textsuperscript{3}. Almost all uses depend on its controlled hydrolysis to produce silica in an adhesive or film-producing form. It is also a source of
thiohalides have been reported from the reaction of SiX4 with H2S at red heat; e.g. SiCl4 yields S(SiCl)2, cyclic Cl2Si(μ-S)2SiCl2 and crystalline (SiCl)4. The first normal thiocyanate derivative of Si, RMe2Si–SCN, [R = –C(SiMe3)2(SiMe2(OMe))] was prepared from the corresponding chloride by treatment with AgSCN; it is more readily solvolysed than its isothiocyanate isomer, RMe2Si–NCS.(57)

The elusive Si=S grouping has been synthesized by reaction between solid Si and H2S at 1200°C to give monomeric SiS; this high-temperature molecule can itself be reacted with Cl2 or HCl in an argon matrix to yield monomeric S=SiCl2 and S=SiHCl.(58) Synthesis of stable organosilanethiones, RR’Si=S has been achieved by using the strategem of imparting additional stabilization through intramolecular coordination via an amine function; e.g. [(α-naphthyl)(8-MezNCH;CloHg)Si=S] was prepared by heating the corresponding silane RR’SiH2 with S8; the Si=S distance of 201.3 pm was noticeably shorter than the normal single bond Si-S distance of 216 pm.(59)

The most important nitride of Si is Si3N4; this is formed by direct reaction of the elements above 1300° or more economically by heating SiO2 and coke in a stream of N2/H2 at 1500°. The compound is of considerable interest as an engineering material since it is almost completely inert chemically, and retains its strength, shape and resistance to corrosion and wear even above 1000°.(60) Its great hardness (Mohs 9), high
dissociation temperature (1900°, 1 atm) and high density (3.185 g cm−3) can all be related to its compact structure which resembles that of phenacite (Be2SiO4, p. 347). It is an insulator with a resistivity at room temperature ~ 6.6 × 1010 ohm cm. Another refractory, Si2N2O, is formed when Si + SiO2 are heated to 1450° in a stream of Ar containing 5% N2. The structure comprises puckered hexagonal nets of alternating Si and N atoms interlinked by nonlinear Si–O–Si bonds to similar nets on either side: the Si atoms are thus each 4-coordinate and the N atoms 3-coordinate.

Volatile silylamides are readily prepared by reacting a silyl halide with NH3, RNHz or R2NH in the vapour phase or in Et2O, e.g.:

\[
\begin{align*}
3\text{SiH}_3\text{Cl} + 4\text{NH}_3 & \rightarrow \text{N(SiH}_3\text{)}_3 + 3\text{NH}_4\text{Cl} \\
\text{SiH}_3\text{Br} + 2\text{Me}_2\text{NH} & \rightarrow \text{SiH}_3\text{NMMe}_2 + \text{Me}_2\text{NH}_3\text{Br} \\
4\text{SiH}_3\text{I} + 5\text{N}_2\text{H}_4 & \rightarrow (\text{SiH}_3\text{)}_2\text{NN(SiH}_3\text{)}_2 + 4\text{N}_2\text{H}_5\text{I}
\end{align*}
\]

Silicon-substituted derivatives may require the use of lithio or sodio reagents, e.g.:

\[
\begin{align*}
\text{Me}_3\text{SiCl} + \text{NaN(SiMe}_3\text{)}_2 & \rightarrow \text{N(SiMe}_3\text{)} + \text{NaCl} \\
\text{Ph}_3\text{SiLi} + \text{R}_2\text{NH} & \rightarrow \text{Ph}_3\text{SiNR}_2 + \text{LiH}
\end{align*}
\]

The N atom is always tertiary in these compounds and no species containing the SiH–NH group is stable at room temperature. Apart from this restriction, innumerable such compounds have been prepared including cyclic and polymeric analogues, e.g. [cyclo-{Me2SiN(SiMe3)2}] and [cyclo-(Me2SiNH)4]. Interest has focused on the stereochemistry of the N atom which is often planar, or nearly so.(61) Thus N(SiH3)3 features a planar N atom and this has been ascribed to p–dπ interaction between the “nonbonding” pair of electrons on N and the “vacant” dπ orbitals on Si as shown schematically in Fig. 9.16. Consistent with this trisilylamines are notably weaker ligands than their tertiary amine analogues though replacement of one or two SiH3 by CH3 enhances the donor power again; e.g. N(SiH3)3 forms no adduct with BH3 even at low temperature;
Organosilicon compounds and silicones

9.3.7 Organosilicon compounds and silicones

at 40° gives an 87% yield of the yellow bicyclo (Mes₂Si)₂P₂: this has a “butterfly” structure in which the “hinge” P atoms retain electron donor properties to give adducts such as the bis-W(CO)₅ complex (2) (P–P 234.2 pm; Si–P 224.4, 226.7 pm; P–W 256.0 pm; Si···Si 324.4 pm; angle Si–P–Si 91.9°). The now extensive field of phosphorus-rich silaphosphanes has been reviewed. Silaphosphenes, RR'Si=PAR are also known.

Figure 9.16 Symmetry relation between p₅ orbitals on N and d₅ orbitals on the 3 Si atoms in planar [NSi₃] compounds such as N(SiH₃)₃.

MeN(SiH₃)₂ forms a 1:1 adduct with BH₃ at −80° but this decomposes when warmed; Me₂N(SiH₃) gives a similar adduct which decomposes at room temperature into Me₂NBH₂ and SiH₄ (cf. the stability of Me₃NBH₃, p. 165). The linear skeleton of H₃SiNCO and H₃SiNCS has also been interpreted in terms of p₅–d₅ N=Si bonding.

Compounds containing an Si=N double bond are of very recent provenance. The first stable silanimine, Bu₂Si=N–SiBu₃, was prepared in 1986 as pale yellow crystals, mp 85° (decomp.), it features a short Si=N distance (156.8 pm, cf. Si–N 169.5 pm) and almost linear coordination about the N atom (177.8°), suggesting some electronic delocalization as described above. The compound was made by reacting the azidosilane Bu₂SiC₁(N₃) with NaSiBu₃ in Bu₂O at −78°. The related compound Pr²Si=NR (R = 2,4,6-Bu₃C₆H₂) forms stable orange crystals, mp 98°.

Unusual Si/P compounds are also beginning to appear, for example, the tetrasilahexaphosphadamantane derivative [(Pr₅Si₄)(PH)₆] (1), which is made by reacting Pr₅SiCl₃ with Li[Al(PH₃)₄]. Again, reaction of white phosphorus, P₄, with tetramesityldisilene, Mes₂Si=SiMes₂, in toluene

Well over 100,000 organosilicon compounds have been synthesized. Of these, during the past few decades, silicone oils, elastomers and resins have become major industrial products. Many organosilicon compounds have considerable thermal stability and chemical inertness; e.g. SiPh₄ can be distilled in air at its bp 428°, as can Ph₃SiCl (bp 378°) and Ph₂SiCl₂ (bp 305°). These, and innumerable similar compounds, reflect the considerable strength of the Si–C bond which is, indeed, comparable with that of the C–C bond (p. 338). A further illustration is the compound SiC which closely resembles diamond in its properties (p. 334). Catenation and the formation of multiple bonds are further similarities with carbon chemistry, though these features are less prominent in organosilicon chemistry and much of the work in these areas is of recent

---

origin (e.g. pp. 338 and below). For example, although the word "silicone" was coined by F. S. Kipping in 1901 to indicate the similarity in formula of Ph<sub>2</sub>SiO with that of the ketone benzophenone, Ph<sub>2</sub>CO, he stressed that there was no chemical resemblance between them and that Ph<sub>2</sub>SiO was polymeric. It is now recognized that the great thermal and chemical stability of the silicones derives from the strength both of the Si–C bonds and of the Si–O–Si linkages. Many general reviews of the vast subject of organosilicon chemistry are available (e.g. refs 1, 2, 69–74) and only some of the salient or topical features will be touched on here. An interesting subset comprises the carbosilanes, that is compounds with a skeleton of alternating C and Si atoms. These include chains, rings and polycyclic compounds, many of which can be made on a multigram or even larger scale by controlled thermolysis or by standard organometallic syntheses.

Transient reaction species containing Si=C bonds have been known since about 1966 and can be generated thermally, photolytically, or even chemically. A decade later Me<sub>2</sub>Si=CHMe was isolated in low-temperature matrices but, despite concerted and well-planned attempts over many years, it was not until 1981 that a stable silene was reported. A. G. Brook and his group prepared 2-adamantyl-2-trimethylsiloxo-1,1-bis(trimethylsilyl)-1-silaethene as very pale yellow needles, mp 92°:

\[
(\text{Me}_3\text{Si})_2\text{Si}=\text{C}(\text{OSiMe}_3)\text{(adamantyl)} \xrightarrow{\text{ether/hv}} (\text{Me}_3\text{Si})_2\text{Si}=\text{C}((\text{SiMe}_3)\text{MeBu}_2)\text{(adamantyl)}
\]

The solid silaethene was stable indefinitely at room temperature in the absence of air or other reagents but in solution it slowly reverted (over several days) to the isomeric acylsilane starting material. An X-ray analysis confirmed the structure and revealed a short >Si=C< bond (176.4 pm, cf. 187–191 pm for single-bonded Si=C) and a planar disposition of ipso atoms, the two planes being slightly twisted with respect to each other (14.6°). The use of bulky groups to enhance the stability of the silaethene is also notable, though this is not a necessary feature, at least at the Si centre, since Me<sub>2</sub>Si=C(SiMe<sub>3</sub>)(SiMeBu<sub>2</sub>) is stable as colourless crystals at room temperature (>Si=C< distance 170.2 pm, Si–C 189.0 pm and a planar C<sub>2</sub>Si=CSi<sub>2</sub> skeleton). The not unrelated planar heterocyclic compounds silabenzen, C<sub>5</sub>SiH<sub>5</sub>, and silatoluene, C<sub>5</sub>H<sub>5</sub>SiMe<sub>3</sub>, should also be recalled.

Disilenes, containing the grouping >Si=Si<, can be isolated as thermally stable yellow or orange crystalline compounds provided that the substituents are sufficiently large to prevent...
polymerization (e.g. mesityl, $t$-butyl, etc.)\(^{(79)}\) The first such compound, Si$_2$Mes$_4$, was isolated in 1981 as orange crystals, mp 176°, following photolysis of the trisilane SiMes$_3$(SiMe$_3$)$_2$..\(^{(80)}\) The Si–Si distance in several such compounds falls in the range 214–216 pm, which is about 10% shorter than the normal single-bonded Si–Si distance. Disilenes are chemically very reactive. Halogens and HX molecules give 1,2-addition products, e.g. Mes$_2$Si(Cl)Si(Cl)Mes$_2$, whilst aldehydes and ketones undergo [2+2] cyclo-addition reactions to give 1,2,3-oxadisilenanes, OSi(Mes)$_2$Si(Mes)$_2$CHR. Controlled oxidation gives predominantly the 1,2-dioxetane OSiR$_2$SiR$_2$O (80%), plus the 1,3-cyclodisiloxane OSiR$_2$O$\equiv$SiR$_2$ as a minor product. Numerous other novel heterocycles have been prepared by controlled reactions of disilenes with chalcogens, N$_2$O, P$_4$ and organic nitro-, nitroso-, azo- and azido-compounds.\(^{(81)}\) Transition metal complexes can give $\eta^2$-disilene adducts such as [Pt(PR$_3$)$_2$]($\eta^2$-Si$_2$Mes$_4$)].\(^{(79,82)}\)

Another fertile area of current interest is the synthesis of stable homocyclic polysilane derivatives.\(^{(83)}\) Typical examples are cyclo-(SiMe$_2$)$_7$,\(^{(84)}\) (cyclo-Si$_3$Me$_9$)-(SiMe$_2$)$_n$-(cyclo-Si$_3$Me$_9$), $n = 2–5$,\(^{(85)}\) and several new permethylated polycyclic silanes such as the colourless crystalline compounds bicyclo[3.2.1]-Si$_8$Me$_{14}$ (mp 245°), bicyclo[3.3.1]-Si$_9$Me$_{16}$ (mp ≥ 330°) and bicyclo[4.4.0]-Si$_{10}$Me$_{18}$ (mp 165°).\(^{(86)}\) Analogues of cubane and tetrahedrane have also been synthesized. Thus, the one-step condensation of Br$_2$RSiSiBr$_2$ or even RSiBr$_3$ with Na in toluene at 90° gave yields of up to 72% of the cubane (SiR)$_8$ (R = SiMe$_2$Bu$'$) as bright yellow, air-sensitive crystals which are stable up to at least 400°C.\(^{(87)}\) The synthesis of a molecular tetrasila-tetrahedrane has also finally been achieved by the following ingenious route (R = SiBu$'_3$):\(^{(88)}\)

\[
\begin{align*}
2\text{SiH}_2\text{Cl}_2 & \rightarrow 2\text{RSiH}_2\text{Cl} \rightarrow \text{RSiH}_2\text{SiH}_2\text{R} \\
2\text{RSiBr}_2\text{SiBr}_2\text{R} + 4\text{NaR} & \rightarrow \text{Si}_4\text{R}_4 + 4\text{RBr} + 4\text{NaBr}
\end{align*}
\]

The product, Si$_4$(SiBu$'_3$)$_4$, forms intensely orange crystals that are stable to heat, light, water and air, and do not melt below 350°. The Si–Si distances within the closo-Si$_4$ cluster are 232–234 pm and the exo Si–Si distances are slightly longer, 235–237 pm (cf. Si–Si 235.17 in crystalline Si). Comparison with the closo-anion Si$_4^{4-}$, which occurs in several metal silicides (p. 337) and is isoelectronic with the P$_4$ molecule, is also appropriate.

There are three general methods for forming Si–C bonds. The most convenient laboratory method for small-scale preparations is by the reaction of SiCl$_4$ with organolithium, Grignard or organoaluminium reagents. A second attractive route is the hydrosilylation of alkenes, i.e. the catalytic addition of Si-H across C=C double bonds; this is widely applicable except for the crucially important methyl and phenyl silanes. Industrially, organosilanes are made by the direct reaction of RX or ArX with a fluidized bed of Si in the presence of about 10% by weight of metallic Cu as catalyst (cf. the direct preparation of organo compounds of Si and P).
The method was patented by E. G. Rochow in 1945 and ensured the commercial viability of the now extensive silicone industry.\(^{(2,69,72)}\)

\[
\text{Cu powder} \quad 2\text{MeCl} + \text{Si} \rightarrow \text{Me}_2\text{SiCl}_2 \quad (70\% \text{ yield})
\]

By-products are \(\text{MeSiCl}_3\) (12\%) and \(\text{Me}_3\text{SiCl}\) (5\%) together with 1–2\% each of \(\text{SiCl}_4\), \(\text{SiMe}_4\), \(\text{MeSiHCl}_2\), etc. Relative yields can readily be altered by modifying the reaction conditions or by adding HCl (which increases \(\text{MeSiHCl}_2\) and drastically reduces \(\text{Me}_2\text{SiCl}_2\)). The overall reaction is exothermic and heat must be removed from the fluidized bed. Because of their very similar bps, careful fractionation is necessary if pure products are required: \(\text{Me}_3\text{SiCl} \quad 57.7^\circ\), \(\text{Me}_2\text{SiCl}_2 \quad 69.6^\circ\), \(\text{MeSiCl}_3 \quad 66.4^\circ\). Mixtures of ethylchlorosilanes or phenylchlorosilanes (or their bromo analogues) can be made similarly.

All these compounds are mobile, volatile liquids (except \(\text{Ph}_3\text{SiCl}\), mp 89\°, bp 378\°).

Innumerable derivatives have been prepared by the standard techniques of organic chemistry.\(^{(2,69–75)}\) The organosilanes tend to be much more reactive than their carbon analogues, particularly towards hydrolysis, ammonolysis, and alcoholysis. Further condensation to cyclic oligomers or linear polymers generally ensues, e.g.:

\[
\text{Ph}_2\text{SiCl}_2 \rightarrow \text{Ph}_2\text{Si(OH)}_2 \quad \text{white crystals}
\]

\(\text{mp} \sim 132^\circ\) (d)

\[
>100^\circ \rightarrow \tfrac{1}{n}\left(\text{Ph}_2\text{SiO}\right)_n + \text{H}_2\text{O}
\]

\(n = 3\) (cyclo), 4(cyclo), or \(\infty\)

\[
\text{Me}_2\text{SiCl}_2 \rightarrow \text{Me}_2\text{Si(NH}_2\text{)}_2 \quad \text{not isolated}
\]

\[
\tfrac{\text{NH}_2}{\text{H}_2\text{O}} \sim 35^\circ
\]

\[\text{[cyclo-(Me}_2\text{SiNH}]}_3 + \text{[cyclo-(Me}_2\text{SiNH}]}_4\]

For both economic and technical reasons, commercial production of such polymers is almost entirely restricted to the methyl derivatives (and to a lesser extent the phenyl derivatives) and hydrolysis of the various methyliclorosilanes has, accordingly, been much studied. Hydrolysis of \(\text{Me}_3\text{SiCl}\) yields trimethylsilanol as a volatile liquid (bp 99\°): it is noticeably more acidic than the corresponding Bu'OH and can be converted to its Na salt by aqueous NaOH (12M). Condensation gives hexamethyldisiloxane which has a very similar bp (100.8\°):

\[
2\text{Me}_3\text{SiCl} \xrightarrow{+2\text{H}_2\text{O}} 2\text{Me}_3\text{SiOH} \rightarrow \text{[O(SiMe}_3]}_2\]

Hydrolysis of \(\text{Me}_2\text{SiCl}_2\) usually gives high polymers, but under carefully controlled conditions leads to cyclic dimethylsiloxanes \(\{\text{Me}_2\text{SiO} \}_n\) \((n = 3, 4, 5, 6)\). Linear siloxanes have also been made by hydrolysing \(\text{Me}_2\text{SiCl}_2\) in the presence of varying amounts of \(\text{Me}_3\text{SiCl}\) as a “chain-stopping” group, i.e. \(\{\text{Me}_2\text{SiO}\}(\text{Me}_2\text{SiO})_x\text{SiMe}_3\) \((x = 0, 1, 2, 3, 4)\), etc. Cross-linking is achieved by hydrolysis and condensation in the presence of \(\text{MeSiCl}_3\) since this generates a third Si–O function in addition to the two required for polymerization:

\[
\text{Me}_3\text{SiCl} \rightarrow \text{Me}_3\text{Si–O–} \quad \text{terminal group}
\]

\[
\text{Me}_2\text{SiCl}_2 \rightarrow \quad \text{O–SiMe}_2–\text{O–}
\]

\[
\text{chain-forming group}
\]

\[
\text{MeSiCl}_3 \rightarrow \text{MeSi(–O–)}_3
\]

branching and bridging group

Comparison with the mineral silicates is instructive since there is a 1:1 correspondence between the two sets of compounds, the methyl groups in the silicones being replaced by the formally isoelectronic O\(^-\) in the silicates (see p. 366). This reminds us of the essentially covalent nature of the Si–O–Si linkage, but the analogy should not be taken to imply identity of structures in detail, particularly for the more highly condensed polymers. Some aspects of the technology of silicones are summarized in the concluding Panel.

While siloxanes and silicones are generally regarded as being unreactive, it is well to remember that they do indeed react with fluorinating agents and with concentrated hydroxide solutions. In certain cases they can even be employed as mild selective reagents for specific syntheses. For example, \((\text{Me}_3\text{Si})_2\text{O}\) is a useful reagent for the convenient high-yield
§9.3.7
Organosilicon compounds and silicones
365

Silicone Polymers

Silicones have good thermal and oxidative stability, valuable resistance to high and low temperatures, excellent water repellency, good dielectric properties, desirable antistick and antifoam properties, chemical inertness, prolonged resistance to ultraviolet irradiation and weathering, and complete physiological inertness. They can be made as fluids (oils), greases, emulsions, elastomers (rubbers) and resins. Silicone oils are made by shaking suitable proportions of \( \{\text{OSiMe}_2\} \) and \( \{\text{cyclo(Me}_2\text{SiO)}_3\} \) with a small quantity of 100% \( \text{H}_2\text{SO}_4 \); this randomizes the siloxane links by repeatedly cleaving the Si–O bonds to form \( \text{HSO}_4 \) esters and then reforming new Si–O bonds by hydrolysing the ester group:

\[
\begin{align*}
\text{Si–O–Si} & \quad \text{+ H}_2\text{SO}_4 \quad \text{→} \quad \text{Si–O–SO}_2\text{H} \quad \text{+ Si–OH} \\
\text{Si–OH} & \quad \text{+ H}_2\text{O} \quad \text{→} \quad \text{Si–O–Si} \quad \text{+ H}_2\text{SO}_4
\end{align*}
\]

The molecular weight of the resulting polymer depends only on the initial proportion of the chain-ending groups (Me3SiO– and Me3Si–) and the chain-building groups (–Me2SiO–) from the two components. Viscosity at room temperature is typically in the range 50–300 000 times that of water and it changes only slowly with temperature. These liquids are used as dielectric insulating media, hydraulic oils and compressible fluids for liquid springs. Pure methylsilicone oils are good lubricants at light loads but cannot be used for heavy-duty steel gears and shafts since they contain no polar film-forming groups and are too readily exuded under high pressure. The introduction of some phenyl groups improves performance, and satisfactory greases can be made by thickening methylphenylsilicone oil with \( \text{Li} \) soap. Other uses are as heat transfer media in heating baths and as components in car polish, sun-tan lotion, lipstick and other cosmetic formulations. Their low surface tension leads to their extensive use as antifoams in textile dyeing, fermentation processes and sewage disposal: about \( 10^{-2} \) to \( 10^{-4} \% \) is sufficient for these applications. Likewise their complete non-toxicity allows them to be used to prevent frothing in cooking oils, the processing of fruit juices and the production of potato crisps.

Silicone elastomers (rubbers) are reinforced linear dimethylpolysiloxanes of exceedingly high molecular weight \( \left( 5 \times 10^4 - 10^7 \right) \). The reinforcing agent, which differs from the viscous gum is useless, is usually fumed silica (p. 345). Polymerization can be acid-catalyzed but KOH produces a rubber with superior physical properties; in either case scrupulous care must be taken to avoid the presence of precursors of chain-blocking groups \( \text{Me}_3\text{Si-0-1} \). The reinforced silicone rubber composition can be "vulcanized" by oxidative cross-linking using \( 1-3\% \) of benzoyl peroxide or similar reagents; the mixture is heated to \( 150^\circ \) for 1 min at the time of pressing or moulding and then cured for \( 1-10 \text{h} \) at \( 250^\circ \). Alternatively, and more elegantly, the process can be achieved at room temperature or slightly above by incorporating a small controlled concentration of Si–H groups which can be catalytically added across pre-introduced Si–CH=CH2 groups in adjacent chains. Again, the cross-linking of 3-component silicone rubbers containing acetoxy groups can be readily effected at room temperature by exposure to moisture: Such rubbers generally have 1 cross-link for every 100-1000 Si atoms and are unmatched by any other synthetic or natural rubbers in retaining their inertness, flexibility, elasticity and strength up to \( 250^\circ \) and down to \( -100^\circ \). They find use in cable-insulation sleeving, static and rotary seals, gaskets, belting, rollers, diaphragms, industrial sealants and adhesives, electrical tape insulation, plug-and-socket connectors, oxygen masks, medical tubing, fabrication of heart-valve implants, etc. They are also much used for making accurate moulds and to give rapid, accurate and flexible impressions for dentures and inlays.

Silicone resins are prepared by hydrolysing phenyl substituted dichloro- and trichloro-silanes in toluene. The Ph groups increase the heat stability, flexibility, and processability of the resins. The hydrolysed mixture is washed with water to remove \( \text{HCl} \) and then partly polymerized or "bodied" to a carefully controlled stage at which the resin is still soluble. It is in this form that the resins are normally applied, after which the final cross-linking to a 3D silicone network is effected by heating to \( 200^\circ \) in the presence of a heavy metal or quaternary ammonium catalyst to condense the silanol groups. E.g.:
preparation of oxyhalide derivatives of Mo and W.\textsuperscript{(89)} Thus, in CH$_2$Cl$_2$ solution, (Me$_3$Si)$_2$O converts a suspension of WCl$_6$ quantitatively to red crystals of W(O)Cl$_4$ in less than 1h at room temperature, and W(O)Cl$_4$ can then itself be converted to yellow W(O)$_2$Cl$_2$ in 95% yield (light petroleum, 100°C, overnight). Likewise, Mo(O)Cl$_4$ when treated with (Me$_3$Si)$_2$O in CH$_2$Cl$_2$ gives Mo(O)$_2$Cl$_2$ in 97% yield at r.t. Even silicone high-vacuum grease has been found unexpectedly to react with the potassium salt of an organoindium hydride to give crystals of the pseudo-crown ether complex [cyclo-(Me$_2$SiO)$_7$K$^+$(K$^+$)$_3$[HIn(CH$_2$CMe$_3$)$_3$]$^-$_4].\textsuperscript{(90)}

10.1 Introduction

Germanium was predicted as the missing element of a triad between silicon and tin by J. A. R. Newlands in 1864, and in 1871 D. I. Mendeleev specified the properties that “ekasilicon” would have (p. 29). The new element was discovered by C. A. Winkler in 1886 during the analysis of a new and rare mineral argyrodite, Ag₈GeS₈; he named it in honour of his country, Germany.† By contrast, tin and lead are two of the oldest metals known to man and both are mentioned in early books of the Old Testament. The chemical symbols for the elements come from their Latin names stannum and plumbum. Lead was used in ancient Egypt for glazing pottery (7000–5000 BC); the Hanging Gardens of Babylon were floored with sheet lead to retain moisture and the Romans used lead extensively for water-pipes and plumbing; they extracted some 6–8 million tonnes in four centuries with a peak annual production of 60,000 tonnes. Production of tin, though equally influential, has been on a more modest scale and dates back to 3500–3200 BC. Bronze weapons and tools containing 10–15% Sn alloyed with Cu have been found at Ur, and Pliny described solder as an alloy of Sn and Pb in AD 79.

Germanium and Sn are non-toxic (like C and Si). Lead is now recognized as a heavy-metal poison; it acts by complexing with oxo-groups.

‡ The astonishing correspondence between the predicted and observed properties of Ge (p. 29) has tempted later writers to overlook the fact that Winkler thought he had discovered a metalloid like As and Sb and he originally identified Ge with Mendeleev’s (incorrectly) predicted “eka-stibium” between Sb and Bi; Mendeleev himself thought it was “eka-cadmium”, which he had (again incorrectly) predicted as a missing element between Cd and Hg. H. T. von Richter thought it was “eka-silicon”; so did Lothar Meyer, and they proved to be correct. This illustrates the great difficulties encountered by chemists working only 100 years ago, yet three decades before the rationale which stemmed from the work of Moseley and Bohr.

in enzymes and affects virtually all steps in the process of haem synthesis and porphyrin metabolism. It also inhibits acetylcholinesterase, acid phosphatase, ATPase, carbonic anhydrase, etc. and inhibits protein synthesis probably by modifying transfer-RNA. In addition to O complexation (in which it resembles Tl\textsuperscript{+}, Ba\textsuperscript{2+} and Ln\textsuperscript{3+}), Pb\textsuperscript{2+} also inhibits SH enzymes (though less strongly than Cd\textsuperscript{2+} and Hg\textsuperscript{2+}), especially by interaction with cysteine residues in proteins. Typical symptoms of lead poisoning are cholic, anaemia, headaches, convulsions, chronic nephritis of the kidneys, brain damage and central nervous-system disorders. Treatment is by complexing and sequestering the Pb using a strong chelating agent such as edta, \(-\text{CH}_2\text{N} (\text{CH}_2\text{CO}_2\text{H})_2\)\textsubscript{2}, or BAL i.e. British anti-Lewisite, HSCH\textsubscript{2}CH(SH)CH\textsubscript{2}OH.

10.2 The Elements

10.2.1 Terrestrial abundance and distribution

Germanium and Sn appear about half-way down the list of elements in order of abundance in crustal rocks, together with several other elements in the region of 1–2 ppm:

Germanium minerals are extremely rare but the element is widely distributed in trace amounts (like its neighbour Ga). Recovery has been achieved from coal ash but is now normally from the flue dusts of smelters processing Zn ores.

Tin occurs mainly as cassiterite, SnO\textsubscript{2}, and this has been the only important source of the element from earliest times. Julius Caesar recorded the presence of tin in Britain, and Cornwall remained the predominant supplier for European needs until the present century (apart from a minor flourish from Bohemia between 1400 and 1550).\textsuperscript{3} Today (1990s) world production approaches 200,000 tonnes per annum (see next section), of which the UK contributes less than 1%.\textsuperscript{4}

Lead (13 ppm) is by far the most abundant of the heavy elements, being approached amongst these only by thallium (8.1 ppm) and uranium (2.3 ppm). This abundance is related to the fact that 3 of the 4 naturally occurring isotopes of lead (206, 207 and 208) arise primarily as the stable end products of the natural radioactive series. Only \(^{204}\text{Pb}\) (1.4%) is non-radiogenic in origin. The variation in isotopic composition of Pb with its origin also accounts for the variability of atomic weight and the limited precision with which it can be quoted (p. 19). The most important Pb ore is the heavy black mineral galena, PbS. Other ore minerals are anglesite (PbSO\textsubscript{4}), cerussite (PbCO\textsubscript{3}), pyromorphite (Pb\textsubscript{5}(PO\textsubscript{4})\textsubscript{3}Cl) and mimetesite (Pb\textsubscript{5}(AsO\textsubscript{4})\textsubscript{3}Cl). Some 25 other minerals are known but are not economically important; all contain Pb\textsuperscript{2+} in contrast to tin minerals which are invariably Sn\textsuperscript{4+} compounds. Lead ores are widely distributed and commercial deposits are worked in over fifty countries. Primary production (from mines) was 3.3 million tonnes (as Pb) in 1991 of which four-fifths came from the half dozen main producers: Australia 17.4%, USA 14.3%, the former Soviet Union 13.8%, China 9.6%, Canada 8.3% and Peru 6.0%.\textsuperscript{4} Secondary production (from the resmelting of scrap) produces a further 5.6 Mtpa i.e. nearly two-thirds of the world’s supply in 1991. The average price in 1992 was £306.4/tonne ($542/t).

10.2.2 Production and uses of the elements

Recovery of Ge from flue dusts is complicated, not only because of the small concentration of Ge but also because its amphoteric properties are similar to those of Zn from which it is being separated.\(^5\) Leaching with H\(_2\)SO\(_4\), followed by addition of aqueous NaOH, results in the coprecipitation of the 2 elements at pH \(\sim 5\) and enrichment of Ge from \(\sim 2\) to 10%. GeO\(_2\) begins to precipitate at pH 2.4, is 90% precipitated at pH 3, and 98% precipitated at pH 5. Zn(OH)\(_2\) begins to precipitate at pH 4 and is completely precipitated at pH 5.5. The concentrate is heated with HCl/Cl\(_2\) to drive off GeCl\(_4\), bp 83.1° (cf. ZnCl\(_2\), bp 756°). After further fractionation of GeCl\(_4\), hydrolysis affords purified GeO\(_2\), which can be slowly reduced to the element by H\(_2\) at \(\sim 530^\circ\). Final purification for semiconductor-grade Ge is effected by zone refining. World production of Ge in 1991 was 80 000 kg (80 tonnes), about 10% less than a decade earlier. The largest use is in transistor technology and, indeed, transistor action was first discovered in this element (p. 331). This use is now diminishing somewhat whilst that in optics is growing — Ge is transparent in the infrared and is used in infrared windows, prisms and lenses. Magnesium germanate is a useful phosphor, and other small-scale applications are in special alloys, strain gauges and superconductors. Despite its spectacular increase in availability during the past few decades from a laboratory rarity to a general article of commerce Ge and its compounds are still relatively expensive. Zone-refined Ge was quoted at $850 per kg in 1991 and GeO\(_2\) at $500 per kg.

The ready reduction of SnO\(_2\) by glowing coals accounts for the knowledge of Sn and its alloys in the ancient world. Modern technology uses a reverberatory furnace at 1200–1300°.\(^6\) The main chemical problem in reducing SnO\(_2\) comes from the presence of Fe in the ores which leads to a hard product with unacceptable properties. Reference to Ellingham-type diagrams of the sort shown on p. 308 shows that \(-\Delta G(\text{SnO}_2)\) is very close to that for FeO/Fe\(_3\)O\(_4\) and only about 80 kJ mol\(^{-1}\) above the line for reducing FeO to Fe at 1000–2000°. It is therefore essential to reduce cassiterite/iron oxide ores at an oxygen pressure sufficiently high to prevent extensive reduction to Fe. This is achieved in a two-stage process, the impure molten Sn from the initial carbon reduction being stirred vigorously in contact with atmospheric O\(_2\) to oxidize the iron — a process that can be effected by “poling” with long billets of green wood — or, alternatively, by use of steam or compressed air. The price of tin was formerly regulated by The International Tin Council, but the market became progressively less stable and the suspension of buffer stock interventions in October 1985 precipitated on immediate collapse in the market from which it has not yet recovered. The ITC was superseded by The Association of Tin Producing Countries which attempts to limit production by the member countries. In 1991 there was an excess of tin on the world market for the 11th successive year and primary production was limited to 95 850 tonnes (Malaysia 29.8%, Indonesia 29.6%, Thailand 17.9%, Bolivia 13.2%, Australia 7.2%, Zaire 1.4%, Nigeria 0.9%). Additional production by China (43 000 t), the former USSR (13 500 t) and other countries brought the primary production of Sn in concentrates in 1991 to 196 700 tonnes. Prices hovered around $5700 per tonne, about half that of a few years earlier.\(^7\) The many uses of metallic tin and its alloys are summarized in the Panel overleaf.

Lead is normally obtained from PbS. This is first concentrated from low-grade ores by froth flotation then roasted in a limited supply of air

---

Uses of Metallic Tin and Its Alloys

Because of its low strength and high cost, Sn is seldom used by itself but its use as a coating, and as alloys, is familiar in a variety of domestic and technological applications. Tin-plate accounts for almost 27% of tin used—it provides a non-toxic corrosion-resistant cover for sheet steel and can be applied either by hot dipping in molten Sn or more elegantly and controllably by electrolytic tinning. The layer is typically 0.4–25 μm thick. In addition to extensive use in food packaging, tin-plate is used increasingly for distributing beer and other drinks. In the USA alone 35 000 million of the 130 000 million drink cans sold annually are tin-plate, the rest being Al: this is a staggering per capita consumption of 500 pa.

The main alloys of tin together with an indication of the percentage of total Sn production for these alloys in the USA (1991) are:

In either case the Pb contains numerous undesirable metal impurities, notably Cu, Ag, Au, Zn, Sn, As and Sb, some of which are clearly valuable in themselves. Copper is first removed by liqation: the Pb bullion is melted and held just above its freezing point when Cu rises to the surface as an insoluble solid which is skimmed off. Tin, As and Sb are next removed by preferential oxidation in a reverberatory furnace and skimming off the oxides; alternatively, the molten bullion is churned with an oxidizing flux of molten NaOH/NaNO₃ (Harris process). The softened Pb may still contain Ag, Au and perhaps Bi. Removal of the first two depends on their preferential solubility in Zn: the mixed metals are cooled slowly from 480° to below 420° when the Zn (now containing nearly all the Ag and Au) solidifies as a crust which is skimmed off; the
Uses of Lead Alloys and Chemicals

Although much lead is used as an inert material in cast, rolled or extruded form, a far greater tonnage is consumed as alloys. Its major application is in storage batteries where an alloy of 91% Pb, 9% Sb forms the supporting grid for the oxidizing agent (PbO₂) and the reducing agent (spongy Pb). Over 70% of this Pb is recovered and recycled. In addition, its use (with Sn) in solders, fusible alloys, bearing metals (babbitt) and type metals has been summarized on p. 370. Other mechanical as distinct from chemical applications are in ammunition, lead shot, lead weights and ballot.

The pattern of chemical usage of Pb compounds in a particular country depends very much on whether organolead compounds are allowed as antiknock additives in petrol for cars (gasoline for automobiles). In a growing number of developed countries such additives are considered to be wasteful, dangerous and unnecessary and environmental legislation is gradually achieving the elimination of PbEt₄ and PbMe₄ as antiknocks. The presence of Pb additives in petrol also interferes with the catalytic converters that are being developed to reduce or eliminate CO, NOₓ and hydrocarbons from exhaust fumes, and this has likewise encouraged the change to other antiknocks.

World production of mined lead was 3331 000 tonnes in 1991 and a further 5558 000 tonnes was refined by reprocessing. In the same year US consumption of Pb in metal products was 1125 000 tonnes (including 967 000 tonnes in storage batteries). In addition, some 57 250 tonnes of other oxides and 29 750 tonnes of miscellaneous Pb-containing products were consumed. The US market price of Pb dropped from $1.05/kg in 1990 to $0.40/kg in 1993 due in part to the collapse in use of PbEt₄ in petrol.

Lead pigments are widely used as rust-inhibiting priming paints for iron and steel. Red lead (Pb₃O₄) is the traditional primer but Ca₂PbO₄ is finding increasing use, particularly for galvanized steel. Lead chromate, PbCrO₄, is a strong yellow pigment extensively used in yellow paints for road markings and as an ingredient (with iron blues) in many green paints and coloured plastics. Other pigments include PbMoO₄ (red-orange), litharge PbO (canary yellow), and white lead, 2PbCO₃.Pb(OH)₂. Lead compounds are also used for ceramic glazes, e.g. PbSi₂O₅ (colourless), in crown glass manufacture, and as polyvinylchloride plastic stabilizers, e.g. “tribasic lead sulfate”, 3PbO.PbSO₄.H₂O. See also p. 386.

excess of dissolved Zn is then removed either by oxidation in a reverberatory furnace, or by preferential reaction with gaseous Cl₂, or by vacuum distillation. Final purification (which also removes any Bi) is by electrolysis using massive cast Pb anodes and an electrolyte of acid PbSiF₆ or a sulfamate; this yields a cathode deposit of 99.99% Pb which can be further purified by zone refining to <1 ppm impurity if required. Total world production figures and the current price were given at the end of the preceding section, and the various uses for lead alloys and chemicals are summarized in the Panel.

10.2.3 Properties of the elements

The atomic properties of Ge, Sn and Pb are compared with those of C and Si in Table 10.1. Trends noted in previous groups are again apparent. The pairwise similarity in the ionization energies of Si and Ge (which can be related to the filling of the 3d₁⁰ shell) and of Sn and Pb (which is likewise related to the filling of the 4f¹⁴ shell) are notable (Fig. 10.1). Tin has more stable isotopes than any other element (why?) and one of these, ¹¹⁹Sn (nuclear spin ½), is particularly valuable both for nmr experiments and for Mössbauer spectroscopy.

Some physical properties of the elements are compared in Table 10.2. Germanium forms brittle, grey-white lustrous crystals with the diamond structure; it is a metalloid with a similar electrical resistivity to Si at room temperature but with a substantially smaller band gap. Its mp, bp and associated enthalpy changes are also lower than for Si and this trend continues for Sn and Pb which are both very soft, low-melting metals.

Tin has two allotropes: at room temperature the stable modification is white, tetragonal...

\(\beta\)-Sn, but at low temperatures this transforms into grey \(\alpha\)-Sn which has the cubic diamond structure. The transition temperature is 13.2° but the transformation usually requires prolonged exposure at temperatures well below this.

The reverse transition from \(\alpha\rightarrow\beta\) involves a structural distortion along the c-axis and is remarkable for the fact that the density increases by 26% in the high-temperature form. This arises because, although the Sn-Sn distances increase in the \(\alpha\rightarrow\beta\) transition, the CN increases from 4 to 6 and the distortion also permits a closer approach of the 12 next-nearest neighbours:

A similar transformation to a metallic, tetragonal \(\beta\)-form can be effected in Si and Ge by subjecting them to pressures of \(\sim200\) and \(\sim120\) kbar respectively along the c-axis, and again the density increases by \(\sim25\%\) from the value at atmospheric pressure. Lead is familiar as a blue-grey, malleable metal with a fairly high density (nearly 5 times that of Si and twice those of Ge and Sn, but only half that of Os and Ir).

10.2.4 Chemical reactivity and group trends

Germanium is somewhat more reactive and more electropositive than Si; it dissolves slowly in hot concentrated H₂SO₄ and HNO₃ but does not react with water or with dilute acids or alkalis unless an oxidizing agent such as H₂O₂ or NaOCl is present; fused alkalis react with incandescence to give germanates. Germanium is oxidized to GeO₂ in air at red heat and both H₂S and gaseous S yield GeS₂; Cl₂ and Br₂ yield GeX₄ on moderate heating and HCl gives both GeCl₄ and GeHCl₃. Alkyl halides react with heated Ge (as with Si) to give the corresponding organogermanium halides.

Tin(13) is notably more reactive and electropositive than Ge though it is still markedly amphoteric in its aqueous chemistry. It is stable towards both water and air at ordinary temperatures but reacts with steam to give SnO₂ plus H₂ and with air or oxygen on heating to give SnO₂. Dilute HCl and H₂SO₄ show little, if any, reaction but dilute HNO₃ produces Sn(NO₃)₂ and NH₄NO₃. Hot concentrated HCl yields SnCl₂ and H₂ whereas hot concentrated H₂SO₄ forms SnSO₄ and SO₂. The occurrence of Sn²⁺ compounds in these reactions is notable. By contrast, the action of hot aqueous alkali yields hydroxostannate(IV) compounds, e.g.:

Sn + 2KOH + 4H₂O → K₂[Sn(OH)₆] + 2H₂

Tin reacts readily with Cl₂ and Br₂ in the cold and with F₂ and I₂ on warming to give SnX₄. It reacts vigorously with heated S and Se, to form Sn²⁺ and Sn⁴⁺ chalcogenides depending on the proportions used, and with Te to form SnTe.

Finely divided Pb powder is pyrophoric but the reactivity of the metal is usually greatly diminished by the formation of a thin, coherent, protective layer of insoluble product such as oxide, oxocarbonate, sulfate or chloride. This inertness has been exploited as one of the main assets of the metal since early times: e.g. a temperature of 600-800° is needed to form PbO in air and Pb is widely used for handling hot concentrated H₂SO₄. Aqueous HCl does, in fact, react slowly to give the sparingly soluble PbCl₂ (<1% at room temperature) and nitric acid reacts quite rapidly to liberate oxides of nitrogen and form the very soluble Pb(NO₃)₂ (~50 g per 100 cm³, i.e. 1.5 M). Organic acids such as acetic acid also dissolve Pb in the presence of air to give Pb(OAc)₂, etc.; this precludes contact with the metal when processing or storing wine, fruit juices and other drinks. The familiar soft metal protective caps covering the cork on quality wines is Pb-foil laminated between thin outer layers of non-toxic Sn metal to which coloured decorative finishes can be applied. Fluorine reacts at room temperatures to give PbF₂ and Cl₂ gives PbCl₂ on heating.

Molten Pb reacts with the chalcogens to give PbS, PbSe and PbTe.

The steady trend towards increasing stability of M\textsuperscript{II} rather than M\textsuperscript{IV} compounds in the sequence Ge, Sn, Pb is an example of the so-called "inert-pair effect" which is well established for the heavier post-transition metals. The discussion on p. 226 is relevant here. A notable exception is the organometallic chemistry of Sn and Pb which is almost entirely confined to the M\textsuperscript{IV} state (pp. 399–405).

Catenation is also an important feature of the chemistry of Ge, Sn and Pb though less so than for C and Si. The discussion on p. 341 can be extended by reference to the bond energies in Table 10.3 from which it can be seen that there is a steady decrease in the M–M bond strength. In general, with the exception of M–H bonds, the strength of other M–X bonds diminishes less noticeably, though the absence of Ge analogues of silicone polymers speaks for the lower stability of the Ge–O–Ge linkage.

The structural chemistry of the Group 14 elements affords abundant illustrations of the trends to be expected from increasing atomic size, increasing electropositivity and increasing tendency to form M\textsuperscript{II} compounds, and these will become clear during the more detailed treatment of the chemistry in the succeeding sections. The often complicated stereochemistry of M\textsuperscript{II} compounds (which arises from the presence of a nonbonding electron-pair on the metal) is particularly revealing as also is the propensity of Sn\textsuperscript{IV} to become 5- and 6-coordinate.\textsuperscript{14} The ability of both Sn and Pb to form polyatomic cluster anions of very low formal oxidation state, (e.g. M\textsubscript{2}\textsuperscript{2–}, M\textsubscript{9}\textsuperscript{4–}, etc.) reflects the now well-established tendency of the heavier post-transition elements to form chain, ring or cluster homopolyatomic ions:\textsuperscript{18} this was first established for the polyhalide anions and for Hg\textsubscript{2}\textsuperscript{2+} but is also prevalent in Groups 14, 15 and 16, e.g. Pb\textsubscript{9}\textsuperscript{5+} is isoelectronic with Bi\textsubscript{9}\textsuperscript{5+} (see Section 10.3.6, p. 391).

10.3 Compounds

10.3.1 Hydrides and hydrohalides

Germanes of general formula Ge\textsubscript{n}H\textsubscript{2n+2} are known as colourless gases or volatile liquids for \( n = 1–5 \) and their preparation, physical properties, and chemical reactions are very similar to those of silanes (p. 337). Thus GeH\textsubscript{4} was formerly made by the inefficient hydrolysis of Mg/Ge alloys with aqueous acids but is now generally made by the reaction of GeCl\textsubscript{4} with LiAlH\textsubscript{4} in ether or even more conveniently by the reaction of GeO\textsubscript{2} with aqueous solutions of NaBH\textsubscript{4}. The higher germanes are prepared by the action of a silent electric discharge on GeH\textsubscript{4}; mixed hydrides such as SiH\textsubscript{3}GeH\textsubscript{3} can be prepared similarly by circulating a mixture of SiH\textsubscript{4} and GeH\textsubscript{4} but no cyclic or unsaturated hydrides have yet been prepared. The germanes are all less volatile than the corresponding silanes (see Table) and, perhaps surprisingly, have partially filled d shells.

\( (a) \) These values often vary widely (by as much as 50–100 kJ mol\textsuperscript{−1}) depending on the particular compound considered and the method of computation used. Individual values are thus less significant than general trends. The data represent a collation of values for typical compounds gleaned from refs 15–17.

10.3.2 Halides and related complexes

### Property | GeH4 | Ge2H6
---|---|---
**Property** | MP/°C | -164.8 | -109
**Property** | BP/°C | -88.1 | 29
**Property** | Density (T/°C)/g cm⁻³ | 1.52 (-142°) | 1.98 (-109°)

noticeably less reactive. Thus, in contrast to SiH₄ and SnH₄, GeH₄ does not ignite in contact with air and is unaffected by aqueous acid or 30% aqueous NaOH. It acts as an acid in liquid NH₃ forming NH₄⁺ and GeH₃⁻ ions and reacts with alkali metals in this solvent (or in MeOC₂H₄-OMe) to give MGeH₃. Like the corresponding MSiH₃, these are white, crystalline compounds of considerable synthetic utility. X-ray diffraction analysis shows that KGeH₃ and RbGeH₃ have the NaCl-type structure, implying free rotation of GeH₃⁻, and CsGeH₃ has the rare TlI structure (p. 242). The derived “ionic radius” of 229 pm emphasizes the similarity to SiH₃⁻ (226 pm) and this is reinforced by the bond angles deduced from broad-line nmr experiments: SiH₃⁻ 94 ± 4° (cf. isoelectronic PH₃, 93.5°); GeH₃⁻ 92.5 ± 4° (cf. isoelectronic AsH₃, 91.8°).¹⁹

The germanium hydrohalides GeHₓX₄₋ₓ (X = Cl, Br, I; x = 1, 2, 3) are colourless, volatile, reactive liquids. Preparative routes include reaction of Ge, Geₓ or GeHₓ with HX. The compounds are valuable synthetic intermediates (cf. SiHₓ). For example, hydrolysis of GeHₓCl yields O(GeHₓ)₂, and various metatheses can be effected by use of the appropriate Ag salts or, more effectively, Pbᴵᴵ salts, e.g. GeHₓBr with PbO, Pb(OAc)₂, and Pb(NCS)₂ affords O(GeHₓ)₂, GeHₓ(OAc), and GeHₓ(SCN). Treatment of this latter compound with MeSH or [Mn(CO)₅H] yields GeHₓSMe and [Mn(CO)₅(GeHₓ)] respectively. An extensive phosphinogermane chemistry is also known, e.g. RₙGe(PH₂)₄₋ₙ, R = alkyl or H. The novel germinaine CF₃N=GeH₂ has been obtained as a colourless gas by reacting a 1:1 mixture of GeH₄ and CF₃NO in a sealed tube at 120° (the other product being H₂O). Addition of HI to the Ge=N double bond gave CF₃NHGeH₂I.²⁰

Binary Sn hydrides are much less stable. Reduction of SnCl₄ with ethereal LiAlH₄ gives SnH₄ in 80–90% yield; SnCl₂ reacts similarly with aqueous NaBH₄. SnH₄ (mp - 146°, bp -52.5°) decomposes slowly to Sn and H₂ at room temperature; it is unattacked by dilute aqueous acids or alkalis but is decomposed by more concentrated solutions. It is a potent reducing agent. Sn₃H₆ is even less stable, and higher homologues have not been obtained. By contrast, organotin hydrides are more stable, and catenation up to H(SnPh₂)₆H has been achieved by thermolysis of Ph₂SnH₂. Preparation of RₙSnH₄₋ₙ is usually by LiAlH₄ reduction of the corresponding organotin chloride.

PbH₄ is the least well-characterized Group 14 hydride and it is unlikely that it has ever been prepared except perhaps in trace amounts at high dilution; methods which successfully yield MH₄ for the other Group 14 elements all fail even at low temperatures. The alkyl derivatives R₂PbH₂ and R₃PbH can be prepared from the corresponding halides and LiAlH₄ reduction of the corresponding organotin chloride.

Bu₅PbX + Ph₃SnH → Bu₅PbH + Ph₃SnX
Me₃PbH (mp ~ -106°, decomp above -30°) and Et₃PbH (mp ~ -145°, decomp above -20°) readily add to alkenes and alkynes (hydroplumbation) to give stable tetraorganolead compounds.

10.3.2 Halides and related complexes

Germanium, Sn and Pb form two series of halides: MX₂ and MX₄. PbX₂ are more stable than PbX₄, whereas the reverse is

---

true for Ge, consistent with the steady increase in stability of the dihalides in the sequence \( \text{CX}_2 \ll \text{SiX}_2 < \text{GeX}_2 < \text{SnX}_2 < \text{PbX}_2 \). Numerous complex halides are also known for both oxidation states.

![Figure 10.2](image)

**Figure 10.2** Crystal structure of GeF\(_2\): (a) projection along the chains, and (b) environment of Ge (pseudo trigonal bipyramidal). The bond to the unshared F is appreciably shorter (179 pm) than those in the chain and there is a weaker interaction (257 pm) linking the chains into a 3D structure.

**Germanium halides**

GeF\(_2\) is formed as a volatile white solid (mp 110°) by the action of GeF\(_4\) on powdered Ge at 150–300°; it has a unique structure in which trigonal pyramidal \{GeF\(_3\)\} units share 2 F atoms to form infinite spiral chains (Fig. 10.2). Pale-yellow GeCl\(_2\) can be prepared similarly at 300° or by thermal decomposition of GeHCl\(_3\) at 70°. Typical reactions are summarized in the scheme:

![Scheme](image)

GeBr\(_2\) is made by reduction of GeBr\(_4\) or GeHBr\(_3\) with Zn, or by the action of HBr on an excess of Ge at 400°; it is a yellow solid, mp 122°, which disproportionates to Ge and GeBr\(_4\) at 150°, adds HBr at 40°, and hydrolyses to the unstable yellow Ge(OH)\(_2\). GeI\(_2\) is best prepared by reduction of GeI\(_4\) with aqueous H\(_2\)PO\(_3\) in the presence of HI to prevent hydrolysis; it sublimes to give bright orange-yellow crystals, is stable in dry air and disproportionates only when heated above ~550°. The structure of the lemon-yellow, monomeric, pyramidal 3-coordinate Ge\(^{II}\) complex \[\text{Ge(acac)}\] has been determined.\(^{21}\) GeI\(_2\) is oxidized to GeI\(_4\) in aqueous KI/HCl; it forms numerous adducts with nitrogen ligands, and reacts with C\(_2\)H\(_2\) at 140° to give a compound that was originally formulated as a 3-membered heterocycle \(\text{CH}||\rangle\text{GeI}_2\) but which was subsequently shown by mass spectroscopy to have the unusual dimeric structure (2).

The ternary Ge\(^{II}\) halides, MGeX\(_3\) (M = Rb, Cs; X = Cl, Br, I) are polymorphic with various distorted perovskite-like (p. 963) structures which reflect the influence of the "non-bonding" pair of electrons on the Ge\(^{II}\) centre.\(^{22}\) Thus, at room temperature, rhombohedral CsGeI\(_3\) has three Ge–I at 275 pm and three at 327 pm whereas in the high-temperature cubic form (above 277°C) there are six Ge–I distances at 320 pm as a result of position changes of the Ge atoms (reversible order–disorder transition). Again, RbGeI\(_3\) has a lemon-yellow, orthorhombic form below ~92°; an intermediate, bordeaux-red orthorhombic perovskite form (~92° to ~52°); a black rhombohedral form (~52° to ~29°); and

a black, cubic perovskite form between $-29^\circ$ and the decomposition temperature, $+61^\circ$. In the yellow form there is one Ge–I at 281 pm, four at 306 pm and one at 327 pm, whereas in the red form there are three Ge–I at 287 pm and three at 324 pm. All the compounds are readily made simply by heating Ge(OH)$_2$ with MX in aqueous HX solutions.

Germanium tetrahalides are readily prepared by direct action of the elements or via the action of aqueous HX on GeO$_2$. The lighter members are colourless, volatile liquids, but GeI$_4$ is an orange solid (cf. CX$_4$, SiX$_4$). All hydrolyse readily and GeCl$_4$ in particular is an important intermediate in the preparation of organogermainium compounds via LiR or RMgX reagents. Many mixed halides and hydrohalides are also known, as are complexes of the type GeF$_6^{2-}$, GeCl$_6^{2-}$, trans-L$_2$GeCl$_4$ and L$_4$GeCl$_4$ (L = tertiary amine or pyridine). The curious mixed-valency complex Ge$_5$F$_{12}$, i.e. [(GeF$_2$)$_4$GeF$_4$] has been shown to feature distorted square pyramids of [:Ge$^{II}$F$_4$] with the "lone-pair" of electrons pointing away from the 4 basal F atoms which are at 181, 195, 220, and 245 pm from the apical Ge$^{II}$; the Ge$^{IV}$ atom is at the centre of a slightly distorted octahedron (Ge$^{IV}$–F 171–180 pm, angle F–Ge–F 87.5–92.5$^\circ$) and the whole structure is held together by F bridges.$^{(23)}$

**Tin halides**

The structural chemistry of Sn$^{II}$ halides is particularly complex, partly because of the stereochemical activity (or non-activity) of the nonbonding pair of electrons and partly because of the propensity of Sn$^{II}$ to increase its CN by polymerization into larger structural units such as rings or chains. Thus, the first and second ionization energies of Sn (p. 372) are very similar to those of Mg (p. 111), but Sn$^{II}$ rarely adopts structures typical of spherically symmetrical ions because the nonbonding pair of electrons, which is 5s$^2$ in the free gaseous ion, readily distorts in the condensed phase; this can be described in terms of ligand-field distortions or the adoption of some "p character". Again, the "nonbonding" pair can act as a donor to vacant orbitals, and the "vacant" third 5p orbital and 5d orbitals can act as acceptors in forming further covalent bonds.

A good example of this occurs with the adducts [SnX$_2$(NM$_3$)$_2$] (X = Cl, Br, I): the Sn$^{II}$ atom, which has accepted a pair of electrons from the ligand NMe$_3$, can itself donate its own lone-pair to a strong Lewis acid to form a double adduct of the type [BF$_3$(tSnX$_2$(tNMe$_3$))] (X = Cl, Br, I). Further examples, including more complicated interactions, are described later in this subsection.

SnF$_2$ (which is obtained as colourless monoclinic crystals by evaporation of a solution of SnO in 40% aqueous HF) is composed of Sn$_4$F$_8$ tetramers interlinked by weaker Sn–F interactions,$^{(25)}$ the tetramers are puckered 8-membered rings of alternating Sn and F as shown in Fig. 10.3 and each Sn is surrounded by a highly distorted octahedron of F (1 Sn–F$_i$ at ∼205 pm, 2 Sn–F$_o$ at ∼218 pm, and 3 much longer Sn···F in the range 240–329 pm, presumably due to the influence of the nonbonding pair of electrons. In aqueous solutions containing F$^-$ the predominant species is the very stable pyramidal complex SnF$_3^-$ but crystallization is attended by further condensation. For example, crystallization of SnF$_2$ from aqueous solutions containing NaF does not give NaSnF$_3$ as previously supposed but

---

NaSn$_2$F$_5$ or Na$_4$Sn$_3$F$_{10}$ depending on conditions. The [Sn$_2$F$_5$] unit in the first compound can be thought of as a discrete ion [Sn$_2$F$_5$]$^-$ or as an F$^-$ ion coordinating to 2 SnF$_2$ molecules (Fig. 10.4a): each Sn is trigonal pyramidal with two close F$_n$, one intermediate F$_m$, and 3 more distant F at 253, 298, and 301 pm. By contrast the compound Na$_4$Sn$_3$F$_{10}$ features 3 corner-shared square-pyramidal [SnF$_4$] units (Fig. 10.4b) though the wide range of Sn–F distances could be taken to indicate incipient formation of a central SnF$_4^{2–}$ weakly bridged to two terminal SnF$_3^{–}$ groups. In the corresponding system with KF the compound

Figure 10.4 Structure of some fluoro-complexes of Sn$^n$. 
that crystallizes is KSnF$_3$·$rac{1}{2}$H$_2$O in which the bridging of square pyramids is extended to give infinite chain polymers (Fig. 10.4c). (The main commercial application of SnF$_2$ is in toothpaste and dental preparations where it is used to prevent demineralization of teeth and to lessen the development of dental caries.)

SnF$_3$ is described on p. 381. There are also some intriguing mixed valence compounds such as Sn$_3$F$_8$ (i.e. Sn$^{IV}$Sn$^{II}$F$_8$) which is formed when solutions of SnF$_2$ in anhydrous HF are oxidized at room temperature with F$_2$, O$_2$ or even SO$_2$; the structure features nearly regular [Sn$^{IV}$F$_6$] octahedra trans-bridged to [Sn$^{II}$F$_3$] pyramids which themselves form polymeric Sn$^{II}$F chains: Sn$^{IV}$–F 196 pm and Sn$^{II}$–F 210, 217, 225 pm with weaker Sn$^{II}$–F interactions in the range 255–265 pm.$^{(26)}$ Another example is α-Sn$_2$F$_6$ (i.e. Sn$^{III}$Sn$^{IV}$F$_6$) which transforms to β-Sn$_2$F$_6$ at 112° and to γ-Sn$_2$F$_6$ at 197°.

High-temperature neutron diffraction studies$^{(27)}$ have shown that this latter phase has the cubic ordered ReO$_3$-type structure (p. 1047) with octahedral coordination of both types of Sn atoms by F (Sn$^{II}$–F 229 pm, Sn$^{IV}$–F 186 pm). The β-phase also features octahedral coordination in a structure closely related to that of rhombohedral LiSbF$_6$.

Tin(II) chlorides are similarly complex (Fig. 10.5). In the gas phase, SnCl$_2$ forms bent molecules, but the crystalline material (mp 246°, bp 623°) has a layer structure with chains of corner-shared trigonal pyramidal {SnCl$_3$} groups. The dihydrate also has a 3-coordinated structure with only 1 of the H$_2$O molecules directly bonded to the Sn$^{II}$ (Fig. 10.5c); the neutral aquo complexes are arranged in double layers with the second H$_2$O molecules interleaved between them to form a two-dimensional H-bonded network.

---

with the coordinated H$_2$O (O—H···O 274, 279, and 280 pm).\(^{(28)}\) If the aquo ligand is replaced by Cl$^-$ the pyramidal SnCl$_3^-$ ion (isoelectronic with SbCl$_3$) is obtained, e.g. in CsSnCl$_3$ Fig. 10.5d). There seems little tendency to add a second ligand: e.g. the compound K$_2$SnCl$_4$.H$_2$O has been shown to contain pyramidal SnCl$_3^-$ and “isolated” Cl$^-$ ions, i.e. K$_2$[SnCl$_3$]Cl.H$_2$O with Sn–Cl 259 pm and the angle Cl–Sn–Cl ~85°. Again, reaction of [Co(en)$_3$]Cl$_3$ and SnCl$_2$.2H$_2$O in excess HCl gives [Co(en)$_3$]$^{3+}$[SnCl$_3^-$](Cl$^-$)$_2$. However, reaction of the closely related complex [Co(NH$_3$)$_6$]Cl$_3$ with SnCl$_2$ in aqueous HCl solution yields [Co(NH$_3$)$_6$]$^{3+}$[SnCl$_3^-$]$^{2-}$ in which the novel [SnCl$_3^-$]$^{2-}$ anion has a distorted pseudo-trigonal bipyramidal structure shown in Fig. 10.5e), the axial angle Cl–Sn–Cl being 164.7°.\(^{(29)}\) The bridged dinuclear anion [Sn$_2$Cl$_5$]$^-$ is also known, i.e. [Cl$_2$Sn($\mu$-Cl)SnCl$_2$]$^-$\(^{(30)}\) as in the corresponding [Sn$_2$F$_5$]$^-$ (Fig. 10.4a). The lone pair of electrons in SnCl$_3^-$ can itself act as a ligating bond: for example, SnCl$_3^-$ can replace PPh$_3$ from the central Au atom in the cluster cation [Au$_8$(PPh$_3$)$_3$]$^{2+}$ to give [Au$_8$(PPh$_3$)$_3$(SnCl$_3$)]$^+$.\(^{(31)}\) Another interesting system involves crown complexes (p. 96) such as [Sn(18-crown-6)Cl]$^+$[SnCl$_3^-$] in which the cation features 7-coordinate hexagonal-pyramidal Sn$^{II}$.\(^{(32)}\)

Apart from its structural interest, SnCl$_2$ is important as a widely used mild reducing agent in acid solution. The dihydrate is commercially available for use in electrolytic tin-plating baths, as a sensitizer in silvering mirrors and in the plating of plastics, and as a perfume stabilizer in toilet soaps. The anhydrous material can be obtained either by dehydration using acetic anhydride or directly by reacting heated Sn with dry HCl gas.

SnBr$_2$ is a white solid when pure (mp 216°, bp 620°); it has a layer-lattice structure but the details are unknown. It forms numerous hydrates (e.g. 3SnBr$_2$.H$_2$O, 2SnBr$_2$.H$_2$O, 6SnBr$_2$.5H$_2$O) all of which have a distorted trigonal prism of 6 Br about the Sn$^{II}$ with a further Br and H$_2$O capping one or two of the prism faces and leaving the third face uncapped (presumably because of the presence of the nonbonding pair of electrons in that direction).\(^{(33)}\) A similar pseudo-9-coordinate structure is adopted by 3PbBr$_2$.2H$_2$O. By contrast, NH$_4$SnBr$_3$.H$_2$O adopts a structure in which Sn$^{II}$ is coordinated by a tetragonal pyramid of 5 Br atoms which form chains by edge sharing of the 4 basal Br; the Sn$^{II}$ is slightly above the basal plane with Sn–Br 304–350 pm and Sn–Br$_{apex}$ 269 pm. The NH$_4^+$ and H$_2$O form rows between the chains.

SnI$_2$ forms as brilliant red needles (mp 316°, bp 720°) when Sn is heated with I$_2$ in 2 M hydrochloric acid. It has a unique structure in which one-third of the Sn atoms are in almost perfect octahedral coordination in rutile-like chains (2 Sn–I 314.7 pm, 4 Sn–I 317.4 pm, and no significant distortions of angles from 90°); these chains are in turn cross-linked by double chains containing the remaining Sn atoms which are themselves 7-coordinate (5 Sn–I all on one side at 300.4–325.1 and 2 more-distant I at 371.8 pm).\(^{(34)}\) There is an indication here of reduced distortion in the octahedral site and this has been observed more generally for compounds with the heavier halides and chalcogenides in which the nonbonding electron pair on Sn$^{II}$ can delocalize into a low-lying band of the crystal. Accordingly, SnTe is a metalloid with cubic NaCl structure. Likewise, CsSn$^{II}$Br$_3$ has the ideal cubic perovskite structure (p. 963);\(^{(35)}\) the compound forms black lustrous crystals with a semi-metallic

\(^{32}\) J. D. DONALDSON, J. SILVER, S. HADJIMINOLIS and S. D. ROSS, J. Chem. Soc., Dalton Trans., 1500–6 (1975) and
10.3.2 Halides and related complexes

conductivity of \( \sim 10^3 \text{ohm}^{-1} \text{cm}^{-1} \) at room temperature due to the population of a low-lying conduction band formed by the overlap of “empty” \( t_2 \) 5d orbitals on Br. In this connection it is noteworthy that Cs\(_2\)Sn\(^{IV}\)Br\(_6\) has a very similar structure to CsSn\(^{II}\)Br\(_3\) (i.e. Cs\(_2\)Sn\(^{II}\)Br\(_6\)) but with only half the Sn sites occupied — it is white and non-conducting since there are no high-energy nonbonding electrons to populate the conduction band which must be present. Similarly, yellow CsSn\(^{II}\)I\(_3\), CsSn\(^{II}\)Br\(_5\), Cs\(_4\)Sn\(^{II}\)Br\(_6\) and compositions in the system CsSn\(^{II}\)X\(_5\) (X = Cl, Br) all transform to black metallics on being warmed, and even yellow monoclinic CsSnCl\(_3\) (Fig. 10.5d) transforms at 90° to a dark-coloured cubic perovskite structure. In solutions of SnX\(_2\) in aqueous HX, however, the pyramidal SnX\(_3^-\) ions are formed and, by suitable mixtures of halides followed by extraction into Et\(_2\)O, all ten trihalogenostannate(I\(_1\)) anions \([\text{SnCl}_x\text{Br}_y\text{I}_z^-]^- (x + y + z = 3)\) have been observed and characterized by \(^{119}\text{Sn} \) nmr spectroscopy.\(^{36}\)

Tin(IV) halides are more straightforward. SnF\(_4\) (prepared by the action of anhydrous HF on SnCl\(_4\)) is an extremely hygroscopic, white crystalline compound which sublimes above 700°. The structure (unlike that of CF\(_4\), SiF\(_4\) and GeF\(_4\)) is polymeric with octahedral coordination about Sn: the \([\text{SnF}_6^-]\) units are joined into planar layers by edge-sharing of 4 equatorial F atoms (Sn-F, 202 pm) leaving 2 further (terminal) F in \textit{trans} positions above and below each Sn (Sn-F, 188 pm). The other SnX\(_4\) can be made by direct action of the elements and are unremarkable volatile liquids or solids comprising tetrahedral molecules. Similarities with the tetrahalides of Si and Ge are obvious. The compounds hydrolyse readily but definite hydrates can also be isolated from acid solution, e.g. SnCl\(_4\)·5H\(_2\)O, SnBr\(_4\)·4H\(_2\)O. Complexes with a wide range of organic and inorganic ligands are known, particularly the 6-coordinate \textit{cis}- and \textit{trans}-

Lead halides

Lead continues the trends outlined in preceding sections, PbX\(_2\) being much more stable thermally and chemically than PbX\(_4\). Indeed, the only stable tetrahalide is the yellow PbF\(_4\) (mp 600°); PbCl\(_4\) is a yellow oil (mp \(-15°\)) stable below 0° but decomposing to PbCl\(_2\) and Cl\(_2\) above 50°; PbBr\(_4\) is even less stable and PbI\(_4\) is of doubtful existence (cf. discussion on TI\(_3\), p. 239). Stability can be markedly increased by coordination: e.g.

direct chlorination of PbCl₂ in aqueous HCl followed by addition of an alkali metal chloride gives stable yellow salts M₂PbCl₆ (M = Na, K, Rb, Cs, NH₄) which can serve as a useful source of Pb⁴⁺. By contrast, PbX₂ are stable crystalline compounds which can readily be prepared by treating any water-soluble Pb²⁺ salt with HX or halide ions to precipitate the insoluble PbX₂. As with Sn, the first two ionization energies of Pb are very similar to those of Mg; moreover, the 6-coordinate radius of Pb²⁺ (1.19 pm) is virtually identical with that of Sr²⁺ (1.18 pm) and there is less evidence of the structurally distorting influence of the nonbonding pair of electrons. Thus α-PbF₂, PbCl₂, and PbBr₂ all form colourless orthorhombic crystals in which Pb²⁺ is surrounded by 9 X at the corners of a tricapped trigonal prism. There are, in fact, never 9 equidistant X neighbours but a range of distances in which one can discern 7 closer and 2 more distant neighbours. This (7 + 2)-coordination is also a feature of the structures of BaX₂ (X = Cl, Br, I), EuCl₂, CaH₂, etc.; see also hydrated tin(II) bromides, p. 380.

The high-temperature β-form of PbF₂ has the cubic fluorite (CaF₂) structure with 8-coordinated Pb²⁺. PbI₂ (yellow) has the CdI₂ hexagonal layer lattice structure. Like many other heavy-metal halides, PbCl₂ and PbBr₂ are photo-sensitive and deposit metallic Pb on irradiation with ultraviolet or visible light. PbF₂ is a photoconductor and decomposes on exposure to green light (λₘₐₓ 494.9 nm). Many mixed halides have also been characterized, e.g. PbFCl, PbFBr, PbFI, PbX₂, 4PbF₂, etc. Of these PbFCl₁ is an important tetragonal layer-lattice structure type frequently adopted by large cations in the presence of 2 anions of differing size; its sparing solubility in water (37 mg per 100 cm³ at 25°C) forms the basis of a gravimetric method of determining F. It is also interesting to note that PbF₂ was the first ionically conducting crystalline compound to be discovered (Michael Faraday, 1838).

Pb²⁺ apparently forms complexes with an astonishing range of stoichiometries, but structural information is frequently lacking. Cs₄PbX₆ (X = Cl, Br, I) have the K₄CdCl₆ structure with discrete [Pb⁴⁺X₆]₄⁻ units. CsPbI₃ also feature octahedral coordination (in perovskite-like structures, cf. p. 963) but there is sometimes appreciable distortion as in the yellow, low-temperature form of CsPbI₃ which adopts the NH₄CdCl₃ structure with three Pb-I distances, 301, 325, and 342 pm. Note also the orange-yellow crystalline compound of overall composition [Co(en)₃PbCl₅].₁₅H₂O which in fact features a novel chain anion [Pb₂Cl₉]₅⁻ and should be formulated [Co(en)₃]₂[Pb₂Cl₉]-Cl₃H₂O. There are also many ternary solid state compounds, e.g. PbI₃OlBr₆.

### 10.3.3 Oxides and hydroxides

GeO is obtained as a yellow sublimate when powdered Ge and GeO₂ are heated to 1000°C, and dark-brown crystalline GeO is obtained on further heating at 650°C. The compound can also be obtained by dehydrating Ge(OH)₂.

---

Oxides and hydroxides

(p. 376) but neither compound is particularly well characterized. Both are reducing agents and GeO disproportionates rapidly to Ge and GeO₂ above 700°. Much more is known about GeO₂ and there is an impressive resemblance between the oxide chemistry of GeIV and SiIV. Thus hexagonal GeO₂ has the 4-coordinated β-quartz structure (p. 342), tetragonal GeO₂ has the 6-coordinated rutile-like structure of stishovite (p. 343), and vitreous GeO₂ resembles fused silica. Similarly, Ge analogues of all the major types of silicates and aluminosilicates (pp. 347–59) have been prepared. Be₂GeO₄ and Zn₂GeO₄ have the phenacite and willemite structures with “isolated” \{GeO₄\} units; Sc₂Ge₅O₇ has the stishovite structure; BaTiGe₃O₉ has the same type of cyclic ion as benitoite, and CaMgGe₂O₆ has a chain structure similar to diopside. Further, the two crystalline forms of Ca₂GeO₄ are isostructural with two forms of Ca₂SiO₄, and Ca₃Ge₂O₇ crystallizes in no fewer than 4 of the known structures of Ca₃SiO₅. The reaction chemistry of the two sets of compounds is also very similar.

SnO exists in several modifications. The commonest is the blue-black tetragonal modification formed by the alkaline hydrolysis of SnII salts to the hydrous oxide and subsequent dehydration in the absence of air. The structure features square pyramids of \{SnO₄\} arranged in parallel layers with SnII at the apex and alternately above and below the layer of O atoms as shown in Fig. 10.6. The Sn–Sn distance between tin atoms in adjacent layers is 370 pm, very close to the values in β-Sn (p. 372). The structure can also be described as a fluorite lattice with alternate layers of anions missing. A metastable, red modification of SnO is obtained by heating the white hydrous oxide; this appears to have a similar structure and it can be transformed into the blue-black form by heating, by pressure, by treatment with strong alkali or simply by contact with the stable form. Both forms oxidize to SnO₂ with incandescence when heated in air to ~300° but when heated in the absence of O₂, the compound disproportionates like GeO. Various mixed-valence oxides have also been reported of which the best characterized is Sn₃O₄, i.e. SnIISnIVO₄.

SnO and hydrous tin(II) oxide are amphoteric, dissolving readily in aqueous acids to give SnII or its complexes, and in alkalis to give the pyramidal Sn(OH)₃⁺; at intermediate values of pH, condensed basic oxide–hydroxide species form, e.g. [(OH)₂SnOSn(OH)₂]²⁻ and [Sn₃(OH)₄]²⁺, etc. Analytically, the hydrous oxide frequently has a composition close to 3SnO.H₂O and an X-ray study shows it to

Figure 10.6 Structure of tetragonal SnO (and PbO) showing (a) a single square-based pyramid \{SnO₄\}, (b) the arrangement of the pyramids in layers, and (c) a plane view of a single layer.
contain pseudo-cubic \( \text{Sn}_8 \text{O}_8 \) clusters resembling \( \text{Mo}_6 \text{Cl}_8^{4+} \) (p. 1022) with 8 oxygen atoms centred above the faces of an \( \text{Sn}_6 \) octahedron and joined in infinite array by H bonds, i.e. \( \text{Sn}_6 \text{O}_8 \text{H}_4 \); the compound can be thought of as being formed by the deprotonation and condensation of \( 2[\text{Sn}_3(\text{OH})_4]^2^+ \) units as the pH is raised:

\[
2[\text{Sn}_3(\text{OH})_4]^2^+ + 4\text{OH}^- \rightarrow [\text{Sn}_6\text{O}_8\text{H}_4]^4^+ + 4\text{H}_2\text{O}
\]

(Hydrolysis of Pb\(^{11}\) salts leads to different structures, p. 395.) It seems unlikely that pure \( \text{Sn} (\text{OH})_2 \) itself has ever been prepared from aqueous solutions but it can be obtained as a white, amorphous solid by an anhydrous organometallic method: \(^{42}\)

\[
2\text{Me}_3\text{SnOH} + \text{SnCl}_2 \rightarrow \text{Sn(OH)}_2 + 2\text{Me}_3\text{SnCl}
\]

\( \text{SnO}_2 \), cassiterite, is the main ore of tin and it crystallizes with a rutile-type structure (p. 961): It is insoluble in water and dilute acids or alkalis but dissolves readily in fused alkali hydroxides to form "stannates" \( \text{M}_2\text{Sn} (\text{OH})_6 \). Conversely, aqueous solutions of tin(IV) salts hydrolyse to give a white precipitate of hydrous tin(IV) oxide which is readily soluble in both acids and alkalis thereby demonstrating the amphoteric nature of tin(IV). \( \text{Sn} (\text{OH})_2 \) itself is not known, but a reproducible product of empirical formula \( \text{SnO}_2 \cdot \text{H}_2\text{O} \) can be obtained by drying the hydrous gel at 110\(^\circ\), and further dehydration at temperatures up to 600\(^\circ\) eventually yields crystalline \( \text{SnO}_2 \). Similarly, thermal dehydration of \( \text{K}_2 [\text{Sn} (\text{OH})_6] \), i.e. "\( \text{K}_2\text{SnO}_3\cdot3\text{H}_2\text{O} \)", yields successively \( \text{K}_2\text{SnO}_3\cdot\text{H}_2\text{O} \), \( 3\text{K}_2\text{SnO}_3\cdot2\text{H}_2\text{O} \) and, finally, anhydrous \( \text{K}_2\text{SnO}_3 \); this latter compound also results when \( \text{K}_2\text{O} \) is heated directly with \( \text{SnO}_2 \), and variations in the ratio of the two reactants yield \( \text{K}_4\text{SnO}_4 \) and \( \text{K}_2\text{Sn}_3\text{O}_7 \).

The structure of \( \text{K}_2\text{SnO}_3 \) does not have 6-coordinate Sn\(^{IV}\) but chains of 5-coordinate Sn\(^{IV}\) of composition \( \{\text{SnO}_3\}_n \) formed by the edge sharing of tetragonal pyramids of \( \{\text{SnO}_3\}_n \) as shown in Fig. 10.7. The colourless compound \( \text{RbNa}_3\text{SnO}_4 \), formed by heating \( \text{RbSn} \) and \( \text{Na}_2\text{O}_2 \) at 750\(^\circ\) has tetrahedral \( \text{SnO}_4^{4-} \) units (Sn–O 196 pm); it is isotypic with \( \text{NaLi}_3\text{SiO}_4 \) and \( \text{NaLi}_3\text{GeO}_4 \). \(^{43}\) Some industrial uses of tin(IV) oxide systems and other tin compounds are summarized in the Panel (opposite).

Much confusion exists concerning the number, composition, and structure of the oxides of lead. PbO exists as a red tetragonal form (litharge) stable at room temperature and a yellow orthorhombic form (massicot) stable above 488\(^\circ\)C. Litharge (mp 897\(^\circ\), \( d \) 9.355 g cm\(^{-3} \)) is not only the most important oxide of Pb, it is also the most widely used inorganic compound of Pb (see Panel on p. 386); it is made by reacting molten Pb with air or \( \text{O}_2 \) above 600\(^\circ\) and has the SnO structure (p. 383, Pb–O 230 pm). Massicot (\( d \) 9.642 g cm\(^{-3} \)) has

Oxides and hydroxides

Figure 10.7 [SnO₃] chain in the structure of \(K₂SnO₃\) (and \(K₂PbO₃\)).

Figure 10.8 Portion of the crystal structure of Pb₃O₄ showing chains of edge-shared Pb⁴⁺O₆ octahedra joined by pyramids of Pb⁰O₃; the mean O–Pb°–O angle is 76° as in PbO.

A distorted version of the same structure. The mixed-valency oxide Pb₃O₄ (red lead, minium, \(d = 8.924\ \text{g cm}^{-3}\)) is made by heating PbO in air in a reverberatory furnace at 450–500° and is important commercially as a pigment and primer (see Panel on p. 386). Its structure (Fig. 10.8) consists of chains of Pb⁴⁺O₆ octahedra (Pb–O 214 pm) sharing opposite edges, these chains being linked by the Pb° atoms which themselves

Some Industrial Uses of Tin Compounds

Tin(IV) oxide is much used in the ceramics industry as an opacifier for glazes and enamels. Because of its insolubility (or, rather, slow solubility) in glasses and glazes it also serves as a base for pigments, e.g. SnO₂/V₂O₅ yellow, SnO₂/Sb₂O₅ blue-greys and SnO₂/Cr₂O₃ pinks. These latter, which can vary from a delicate pale pink to a dark maroon, probably involve substitutional incorporation of Cr°⁺ for Sn°⁺ with concomitant oxide-ion vacancies, i.e. \([\text{Sn}^{IV}_{1-\delta},\text{Cr}^{II}_{\delta}\text{O}_{2-\delta}]^{\delta-}\). The vanadium- and antimony-tin glazes, on the other hand, probably involve reductive substitution without vacant sites, e.g. \([\text{Sn}^{IV}_{1-\delta},\text{Sn}^{IV}_{\delta}\text{Sb}^{III}_{\delta}\text{O}_{2-\delta}]^{\delta-}\). Some 3500 tonnes of SnO₂ are consumed annually for ceramic glazes.

A related application is the use of SnCl₄ vapour to toughen freshly fabricated glass bottles by deposition of an invisible transparent film of SnO₂ (<0.1 \(\mu\text{m}\)) which is then incorporated in the surface structure of the glass. This increases the strength of the glass and improves its abrasion resistance so that bottles so treated can be made considerably lighter without loss of robustness. When the thickness of the SnO₂ film is similar to the wavelength of visible light (0.1–1.0 \(\mu\text{m}\)), then thin-film interference effects occur and the glass acquires an attractive iridescence. Still thicker films give electrically conducting layers which, after suitable doping with Sb or F ions, can be used as electrodes, electro-luminescent devices (for low-intensity light panels and display signs, aircraft, cinema, etc.), fluorescent lamps, antistatic cover-glasses, transparent tube furnaces, deiceable windshields (especially for aircraft, etc). Another property of these thicker films is their ability to reflect a high proportion of infrared (heat) radiation whilst remaining transparent to visible radiation — the application to heat insulation of windows is obvious.

Attention should be drawn to the use of tin oxide systems as heterogeneous catalysts. The oldest and most extensively patented systems are the mixed tin-vanadium oxide catalysts for the oxidation of aromatic compounds such as benzene, toluene, xylene and naphthalene in the synthesis of organic acids and acid anhydrides. More recently mixed tin-antimony oxides have been applied to the selective oxidation and amoxidation of propylene to acrolein, acrylic acid and acrylonitrile.

Homogeneous catalysis by tin compounds is also of great industrial importance. The use of SnCl₄ as a Friedel–Crafts catalyst for homogeneous acylation, alkylation and cyclization reactions has been known for many decades. The most commonly used industrial homogeneous tin catalysts, however, are the Sn(II) salts of organic acids (e.g. acetate, oxalate, oleate, stearate and octoate) for the curing of silicone elastomers and, more importantly, for the production of polyurethane foams. World consumption of tin catalysts for these last applications alone is over 1000 tonnes pa.

For uses of organotin compounds (i.e. compounds having at least one Sn–C bond), see p. 400.
The Oxides of Lead\(^9,10\)

PbO (red, orange or yellow depending on the method of preparation) is amphoteric and dissolves readily in both acids and alkalis. It is much used in glass manufacture since a high Pb content leads to greater density, lower thermal conductivity, higher refractive index (greater brilliance), and greater stability and toughness. The replacement of the very mobile alkali ions by Pb also leads to high electrical capacities, comparable with mica. PbO is also used to form stable ceramic glazes and vitreous enamels (see SnO\(_2\), p. 385). Electric storage batteries are the other major user of PbO (either as litharge or as “black oxide”, i.e. PbO + Pb). The plates of the battery consist of an inactive grid or support onto which is applied a paste of PbO/H\(_2\)SO\(_4\). The positive plates are activated by oxidizing PbO to PbO\(_2\) and the negative plates by reducing PbO to Pb. Another use of PbO is in the production of pigments (p. 371).

Red lead (Pb\(_3\)O\(_4\)) is manufactured on the 20000-tonne scale annually and is used primarily as a surface coating to prevent corrosion of iron and steel (check oxidation-reduction potentials). It is also used in the production of leaded glasses and ceramic glazes and, very substantially, as an activator, vulcanizing agent and pigment in natural and artificial rubbers and plastics.

PbO\(_2\) is a strong oxidizing agent and, in addition to its in situ production in storage batteries, it is independently manufactured for use as an oxidant in the manufacture of chemicals, dyes, matches and pyrotechnics. It is also used in considerable quantity as a curing agent for sulfide polymers and in high-voltage lightning arresters. Because of the instability of Pb\(^{IV}\), PbO\(_2\) tends to give salts of Pb\(^{II}\) with liberation of O\(_2\) when treated with acids, e.g.

\[
PbO_2 + H_2SO_4 \xrightarrow{\text{warm}} PbSO_4 + H_2O + \frac{1}{2}O_2 *
\]

Warm HCl reacts similarly but in the cold PbCl\(_4\) is obtained. PbO\(_2\) is produced commercially by the oxidation of Pb\(_2\)O\(_4\) in alkaline slurry with Cl\(_2\) and the technical product is marketed in 90-kg drums.

Mixed oxides of Pb\(^{IV}\) with other metals find numerous applications in technology and industry. They are usually made by heating PbO\(_2\) (or PbO) in air with the appropriate oxide, hydroxide or oxoacid salt, the product formed being dependent on the stoichiometry used, e.g. M\(^{III}\)Pb\(^{IV}\)O\(_3\), M\(^{II}\)Pb\(^{IV}\)O\(_4\) (M\(^{III}\) = Ca, Sr, Ba). CaPbO\(_2\) in particular is increasingly replacing Pb\(_3\)O\(_4\) as a priming pigment to protect steel against corrosion by salt water. Mixed oxides of Pb\(^{III}\) are also important. Ferrimagnetic oxides of general formula PbO\(_n\)Fe\(_{2}O\(_3\) (n = 6.5, 2.5, 1, 0.5) can be prepared by direct reaction but have not proved to be as attractive, commercially, as the hard ferrite BaFe\(_{12}O_{19}\). By contrast, the ferroelectric behaviour (p. 57) of several mixed oxides with Pb\(^{III}\) has excited considerable interest. Many of these compounds have a distorted perovskite-type structure (p. 963); e.g. yellow PbTiO\(_3\) (ferroelectric below 490°C, colourless PbZrO\(_3\) (230°C), and PbHFeO\(_3\) (215°C, antiferroelectric)). Others have a tetragonal tungsten-bronce-type structure (p. 1016), e.g. PbNb\(_2\)O\(_6\) (ferroelectric up to 560°C), PbTi\(_2\)O\(_6\) (\(\sim 215°C\)). The mode of action and uses of hard ferroelectrics has been discussed on p. 58, and the high Curie temperature of many Pb\(^{III}\) ferroelectrics makes them particularly useful for high-temperature applications.

are pyramidally coordinated by 3 oxygen atoms (2 at 218 pm and 1 at 213 pm). The dioxide normally occurs as the maroon-coloured PbO\(_2\)(I) which has the tetragonal, rutile structure (Pb\(^{IV}\)–O 218 pm, d 9.643 g cm\(^{-3}\)), but there is also a high-pressure, black, orthorhombic polymorph, PbO\(_2\)(II) (d 9.773 g cm\(^{-3}\)).

When PbO\(_2\) is heated in air it decomposes as follows:\(^{44}\)

\[
PbO_2 \xrightarrow{293^\circ} Pb_{12}O_{19} \xrightarrow{351^\circ} Pb_{12}O_{17} \xrightarrow{374^\circ} Pb_3O_4 \xrightarrow{605^\circ} PbO
\]

In addition, a sesquioxide Pb\(_2\)O\(_3\) can be obtained as vitreous black monoclinic crystals (d 10.046 g cm\(^{-3}\)) by decomposing PbO\(_2\) (or PbO) at 580–620° under an oxygen pressure of 1.4 kbar: in this compound the Pb\(^{III}\) atoms are situated between layers of distorted Pb\(^{IV}\)O\(_6\) octahedra (mean Pb\(^{IV}\)–O 218 pm) with 3 Pb\(^{II}\)–O in the range 231–246 pm and 3 in the range 264–300 pm. The monoclinic compound Pb\(_{12}\)O\(_{19}\) (i.e. PbO\(_{1.58}\)) forms dark-brown or black crystals which have a pseudocubic defect-fluorite structure with 10 ordered anion vacancies according to the formulation [Pb\(_{2}\)O\(_{3}\)(\(\square\))\(_{10}\)] and no detectable variability of composition. It will be recalled that PbO can be considered as a defect fluorite structure in which each alternate layer

of O atoms in the (001) direction is missing (p. 383), i.e. \([\text{Pb}_2\text{O}_{24}(\square...)_{24}]\); it therefore seems reasonable to suppose that the anion vacancies in \([\text{Pb}_{24}\text{O}_{38}(\square...)_{10}]\) are also confined to alternate layers, though it is not clear why this structure should show no variability in composition. Further heating above 350° (or careful oxidation of PbO) yields Pb_{12}O_{17} (i.e. PbO_{1.417}) which is also a stoichiometric ordered defect fluorite structure \([\text{Pb}_{24}\text{O}_{34}(\square...)_{14}]\). However, oxidation of this phase under increasing oxygen pressure leads to a nonstoichiometric phase of variable composition between PbO_{1.42} and PbO_{1.57} in which there appears to be a quasi-random array of anion vacancies.\(^{45}\)

Lead does not appear to form a simple hydroxide, Pb(OH)$_2$, [cf. Sn(OH)$_2$, p. 384]. Instead, increasing the pH of solutions of Pb$^{II}$ salts leads to hydrolysis and condensation, see [Pb$_6$(OH)$_6$]$^{4+}$ (p. 395).

### 10.3.4 Derivatives of oxoacids

Oxoacid salts of Ge are usually unstable, generally uninteresting, and commercially unimportant. The tetraacetate Ge(OAc)$_4$ separates as white needles, mp 156°, when GeCl$_4$ is treated with TiOAc in acetic anhydride and the resulting solution is concentrated at low pressure and cooled. An unstable sulfate Ge(SO$_4$)$_2$ is formed in a curious reaction when GeCl$_4$ is heated with SO$_3$ in a sealed tube at 160°:

\[
\text{GeCl}_4 + 6\text{SO}_3 \rightarrow \text{Ge(SO}_4)_2 + 2\text{S}_2\text{O}_5\text{Cl}_2
\]

Numerous oxoacid salts of Sn$^{II}$ and Sn$^{IV}$ have been reported and several basic salts are also known. Anhydrous Sn(NO$_3$)$_2$ has not been prepared but the basic salt Sn$_3$(OH)$_4$(NO$_3$)$_3$ can be made by reacting a paste of hydrous tin(II) oxide with aqueous HNO$_3$; the compound may well contain the oligomeric cation [Sn$_3$(OH)$_4$]$^{2+}$ illustrated on p. 384. Sn(NO$_3$)$_3$ can be obtained in anhydrous reactions of SnCl$_4$ with N$_2$O$_5$, ClNO$_3$ or BrNO$_3$; the compound readily oxidizes or nitrates organic compounds, probably by releasing reactive NO$_3$ radicals. Many phosphates and phosphato complexes have been described: typical examples for Sn$^{II}$ are Sn$_3$(PO$_4$)$_2$, SnHPO$_4$, Sn(H$_2$PO$_4$)$_2$, Sn$_2$P$_2$O$_7$ and Sn(P$_2$O$_7$)$_2$. Examples with Sn$^{IV}$ are Sn$_2$O(SO$_4$)$_2$, Sn$_2$O$_2$(PO$_4$)$_2$, 10H$_2$O, SnP$_4$O$_7$, KSn(P$_2$O$_7$)$_3$, KSnOP$_4$ and Na$_2$Sn(SO$_4$)$_2$. One remarkable compound is tin(IV) hypophosphite, Sn$_2$P$_2$O$_7$ which contains Sn$^{IV}$ in the presence of the strongly reducing hypophosphorous anion; it has been suggested that the isolation of Sn$_2$P$_2$O$_7$ (colourless crystals) by bubbling O$_2$ through a solution of SnO in hypophosphorous acid, [H$_3$P(OH)$_4$], may be due to a combination of kinetic effects and the low solubility of the product.

Treatment of SnO$_2$ with hot dilute H$_2$SO$_4$ yields the hygroscopic dihydrate Sn(SO$_4$)$_2$.2H$_2$O. In the Sn$^{II}$ series SnSO$_4$ is a stable, colourless compound which is probably the most convenient laboratory source of Sn$^{II}$ uncontaminated with Sn$^{IV}$; it is readily prepared by using metallic Sn to displace Cu from aqueous solutions of CuSO$_4$. SnSO$_4$ was at one time thought to be isostructural with BaSO$_4$ but this seemed unlikely in view of the very different sizes of the cations and the known propensity of Sn$^{II}$ to form distorted structures; it is now known to consist of {SO$_4$} groups linked into a framework by O—Sn—O bonds in such a way that Sn is pyramidal coordinated by 3 O atoms at 226 pm (O—Sn—O angles 77–79°); other Sn—O distances are much larger and fall in the range 295–334 pm.\(^{46}\) A basic sulfate and oxosulfate are also known:

\[
3\text{Sn}^{II}\text{SO}_4(\text{aq}) + 3\text{NH}_3(\text{aq}) \rightarrow [\text{Sn}_3^{II}(\text{OH})_2\text{O(SO}_4)_2]\n
\rightarrow [\text{Sn}_3^{III}\text{O}_2\text{SO}_4]
\]

The crystal structures of the oxalates SnC$_2$O$_4$ and K$_2$Sn(C$_2$O$_4$)$_2$.H$_2$O show interesting features.\(^{47}\)

---

reminiscent of tetragonal SnO (Fig. 10.6). The organotin(IV) sulfate (Me₃Sn)₂SO₄·2H₂O has trigonal bipyramidal Sn with trans-O₅SnMe₃ stereochemistry, i.e. [H₂O-SnMe₃-(μ-OSO₂O)-SnMe₃-OH₂]; H-bonding between the two non-bridging O-atoms of the sulfate group and water molecules in neighbouring units produces a three-dimensional network.\(^{(48)}\) In general, the product obtained by the thermal decomposition of Sn⁺⁺ oxoacid salts depends on the coordinating strength of the oxoacid anion. For strong ligands such as formate, acetate and phosphite, other Sn⁺⁺ compounds are formed (often SnO), whereas for less-strongly coordinating ligands such as the sulfate or nitrate internal oxidation to SnO₂ occurs, e.g.:

**Strong ligands:**

\[
\begin{align*}
2\text{Sn(HCO}_2\text{)}_2 & \rightarrow 2\text{SnO} + \text{H}_2\text{CO} + \text{CO}_2 \\
\text{Sn(MeCO}_2\text{)}_2 & \rightarrow \text{SnO} + \text{Me}_2\text{CO} + \text{CO}_2 \\
5\text{SnHPO}_3 & \rightarrow \text{Sn}_{1/2}\text{P}_2\text{O}_7 + \text{Sn}_{1/2}\text{(PO}_4\text{)}_2 \\
2\text{SnHPO}_4 & \rightarrow \text{Sn}_{1/2}\text{P}_2\text{O}_7 + \text{H}_2\text{O}
\end{align*}
\]

**Weak ligands:**

\[
\begin{align*}
2\text{SnO} & \rightarrow 3\text{SnO}_2 + \text{Sn} \\
\text{SnSO}_4 & \rightarrow \text{SnO}_2 + \text{SO}_2 \\
\text{Sn}_3\text{(OH)}_4\text{(NO}_3\text{)}_2 & \rightarrow 3\text{SnO}_2 + 2\text{NO} \\
& \quad + 2\text{H}_2\text{O}
\end{align*}
\]

Most oxoacid derivatives of lead are Pb⁺⁺ compounds, though Pb(OAc)₄ is well known and is extensively used as a selective oxidizing agent in organic chemistry.\(^{(49)}\) It can be obtained as colourless, moisture-sensitive crystals by treating Pb₃O₄ with glacial acetic acid. Pb(SO₄)₂ is also stable when dry and can be made by the action of conc H₂SO₄ on Pb(OAc)₄ or by electrolysis of strong H₂SO₄ between Pb electrodes. PbSO₄ is familiar as a precipitate for the gravimetric determination of sulfate (solubility 4.25 mg per 100 cm³ at 25°C); PbSeO₄ is likewise insoluble. By contrast Pb(NO₃)₂ is very soluble in water (37.7 g per 100 cm³ at 0°, 127 g at 100°). The diacetate is similarly soluble (19.7 and 221 g per 100 cm³ at 0° and 50° respectively). Both compounds find wide use in the preparation of Pb chemicals by wet methods and are made simply by dissolving PbO in the appropriate aqueous acid. A large number of basic nitrates and acetates is also known. The thermal decomposition of anydrous Pb(NO₃)₂ above 400° affords a convenient source of N₂O₄ (see p. 456).

Other important Pb⁺⁺ salts are the carbonate, basic carbonate, silicates, phosphates and perchlorate, but little new chemistry is involved. PbCO₃ occurs as cerussite; the compound is made as a dense white precipitate by treating the nitrate or acetate with CO₂ in the presence of (NH₄)₂CO₃ or Na₂CO₃, care being taken to keep the temperature low to avoid formation of the basic carbonate \(\sim 2\text{Pb(CO}_3\text{)}\cdot\text{Pb(OH)}_2\). These compounds were formerly much used as pigments (white lead) but are now largely replaced by other white pigments such as TiO₂ which has higher covering power and lower toxicity. The highly soluble perchlorate [and even more the tetrafluoroborate Pb(BF₄)₂] are much used as electrolytic plating baths for the deposition of Pb to impart corrosion resistance or lubricating properties to various metal parts. Throughout the chemistry of the oxoacid salts of Pb⁺⁺ the close correlation between anionic charge and aqueous solubility is apparent.

The complex coordination chemistry of Pb⁺⁺ is also beginning to be actively explored and some unusual stereochemistries are emerging. Thus, the mononuclear (η²-nitrate)bis(phenanthroline)(N-thiocyanato) complex \([\text{Pb(phen)}_2(\text{NCS})(\eta²-\text{NO}_3)]\) has 7-coordinate Pb⁺⁺ with a large vacancy.
in the coordination sphere, possibly indicating a stereochemically active lone pair.\(^{50}\) Again, \([\text{Pb(phen)}_4(\text{OCIO}_3)]\text{ClO}_4\) features 9-fold, capped square antiprismatic coordination about Pb,\(^{51}\) whereas in \([\text{Pb(tpy)}_3]\text{ClO}_4\text{Cl}_2\) (tpy = 2,2':6',2"-terpyridine) there is an unusual \(D_3\) 9-coordinate environment around the Pb\(^{II}\) centre.\(^{52}\)

10.3.5 Other inorganic compounds

Few of the many other inorganic compounds of Ge, Sn and Pb call for special comment. Many pseudo-halogen derivatives of Sn\(^{IV}\), Pb\(^{IV}\) and Pb\(^{II}\) have been reported, e.g. cyanides, azides, isocyanates, isothiocyanates, isoselenocyanates and alkoxides.\(^{39,53}\)

All 9 chalcogenides MX are known (X = S, Se, Te). GeS and SnS are interesting in having layer structures similar to that of the iso electronic black-P (p. 482). The former is prepared by reducing a fresh precipitate of GeS\(_2\) with excess H\(_3\)PO\(_2\) and purifying the resulting amorphous red-brown powder by vacuum sublimation. SnS is usually made by sulfide precipitation from Sn\(^{II}\) salts. PbS occurs widely as the black opaque mineral galena, which is the principal ore of Pb (p. 368). In common with PbSe, PbTe and SnTe, it has the cubic NaCl-type structure. Pure PbS can be made by direct reaction of the elements or by reaction of Pb(OAc)\(_2\) with thiourea; the pure compound is an intrinsic semiconductor which, in the presence of impurities or stoichiometric imbalance, can develop either n-type or p-type semiconducting properties (p. 332). It is also a photoconductor (like PbSe and PbTe) and is one of the most sensitive detectors of infrared radiation; the photovoltaic effect in these compounds is also widely used in photoelectric cells, e.g. PbS in photographic exposure meters. The three compounds are also unusual in that their colour diminishes with increasing molecular weight: PbS is black, PbSe grey, and PbTe white.

Of the selenides, GeSe (mp 667\(^\circ\)) forms as a dark-brown precipitate when H\(_2\)Se is passed into an aqueous solution of GeCl\(_2\). SnSe (mp 861\(^\circ\)) is a grey-blue solid made by direct reaction of the elements above 350\(^\circ\). PbSe (mp 1075\(^\circ\)) can be obtained by volatilizing PbCl\(_2\) with H\(_2\)Se, by reacting PbEt\(_4\) with H\(_2\)Se in organic solvents, or by reducing PbSeO\(_4\) with H\(_2\) or C in an electric furnace; thin films for semiconductor devices are generally made by the reaction of Pb(OAc)\(_2\) with selenourea, (NH\(_2\))\(_2\)CSe. The tellurides are best made by heating Ge, Sn or Pb with the stoichiometric amount of Te.

Other chalcogenides that have been described include GeS\(_2\), GeSe\(_2\), Sn\(_2\)S\(_3\) and SnSe\(_2\), but these introduce no novel chemistry or structural principles. Of more interest, perhaps, is the polymeric anion [Sn\(_5\)S\(_{12}\)\(^{4-}\)]\(_\infty\) (1) which occurs in Cs\(_4\)Sn\(_5\)S\(_{12}\)\(_2\)H\(_2\)O and which contains both trigonal bipyramidal and octahedral Sn\(^{IV}\).\(^{54}\)

The compound was prepared by hydrothermal reaction of Cs\(_2\)CO\(_3\) with SnS\(_2\) at 150\(^\circ\)C. A similar reaction between Rb\(_2\)CO\(_3\) and SnS\(_2\) in saturated aqueous H\(_2\)S solution at 190\(^\circ\)C afforded Rb\(_2\)Sn\(_3\)S\(_7\)H\(_2\)O in which the polymeric [Sn\(_3\)S\(_7\)\(^{2-}\)]\(_\infty\) anion (2) features both Sn\(_4\) tetrahedra and Sn\(_6\) octahedra.\(^{55}\) Another new structural form, in which a common Sn atom joins a double cube, is found in the discrete [Sn\(_7\)S\(_8\)O\(_2\)] cluster core (3) of [[Bu'Sn(S)L\(_3\)]\(_2\)Sn; the diphosphinate ligand L = \(\mu-\eta^2\)O\(_2\)PPh\(_2\) bridges the three non-commo Sn atoms in each of the cubes.\(^{56}\) Examples of
square-pyramidal 5-coordinate Sn\textsuperscript{IV} (57,58) and pentagonal bipyramidal 7-coordinate Sn\textsuperscript{IV} (59) have also been recently established in various thio-organotin complexes.

![Diagrams of Sn complexes](image)

The discrete anions [Sn\textsubscript{2}Se\textsubscript{6}]\textsuperscript{4-} and [Sn\textsubscript{2}Te\textsubscript{6}]\textsuperscript{4-} have the B\textsubscript{3}H\textsubscript{6}-type structure (p. 154) and are known in Rb\textsubscript{4}(Sn\textsubscript{2}Se\textsubscript{6})\textsuperscript{4-} (55) [enH\textsubscript{2}]\textsubscript{2}[Sn\textsubscript{2}Se\textsubscript{6}]\textsuperscript{4-} (60) and [NMe\textsubscript{4}]\textsubscript{4}[Sn\textsubscript{2}Te\textsubscript{6}]\textsuperscript{4-} (61). By contrast, [enH\textsubscript{2}]\textsuperscript{2}[Sn\textsubscript{2}Se\textsubscript{7}].\textsubscript{2}en features a sheet polymeric anion [Sn\textsubscript{3}Se\textsubscript{7}\textsuperscript{2-}]\textsubscript{\textinfty} (4) in which the basic elements are SnSe\textsubscript{5} trigonal bipyramids. (60) The adamantane-like anion [Ge\textsubscript{4}Te\textsubscript{10}]\textsuperscript{4-} was identified by X-ray diffraction analysis of the black crystalline salt [NEt\textsubscript{4}]\textsubscript{4}[Ge\textsubscript{4}Te\textsubscript{10}], prepared in 72% yield by extraction of the alloy of composition K\textsubscript{4}Ge\textsubscript{4}Te\textsubscript{10} with ethylene diamine in the presence of Et\textsubscript{4}NB\textsubscript{r}.\textsuperscript{(61a)}

The first sulfide halide of Ge was made by the apparently straightforward reaction:

\[ 4\text{GeBr}_4 + 6\text{H}_2\text{S} \xrightarrow{\text{CS}_2/\text{Al}_2\text{Br}_6} \text{Ge}_4\text{S}_6\text{Br}_4 + 12\text{HBr} \]

The unexpectedly complex product was isolated as an almost colourless air-stable powder, and a single-crystal X-ray analysis showed that it had the molecular adamantane-like structure (5).\textsuperscript{(62)} This is very similar to the structure of the "iso-electronic" compound P\textsubscript{4}O\textsubscript{10} (p. 504).

There has been growing interest in the detailed structure and reaction chemistry of monomeric and [NMe\textsubscript{4}]\textsubscript{4}[Sn\textsubscript{2}Te\textsubscript{6}]\textsuperscript{4-} by contrast. [enH\textsubscript{2}]\textsuperscript{2}[Sn\textsubscript{2}Se\textsubscript{7}].\textsubscript{2}en features a sheet polymeric anion [Sn\textsubscript{3}Se\textsubscript{7}\textsuperscript{2-}]\textsubscript{\textinfty} (4) in which the basic elements are SnSe\textsubscript{5} trigonal bipyramids. (60) The adamantane-like anion [Ge\textsubscript{4}Te\textsubscript{10}]\textsuperscript{4-} was identified by X-ray diffraction analysis of the black crystalline salt [NEt\textsubscript{4}]\textsubscript{4}[Ge\textsubscript{4}Te\textsubscript{10}], prepared in 72% yield by extraction of the alloy of composition K\textsubscript{4}Ge\textsubscript{4}Te\textsubscript{10} with ethylene diamine in the presence of Et\textsubscript{4}NB\textsubscript{r}.\textsuperscript{(61a)}

The first sulfide halide of Ge was made by the apparently straightforward reaction:

\[ 4\text{GeBr}_4 + 6\text{H}_2\text{S} \xrightarrow{\text{CS}_2/\text{Al}_2\text{Br}_6} \text{Ge}_4\text{S}_6\text{Br}_4 + 12\text{HBr} \]

This is very similar to the structure of the "iso-electronic" compound P\textsubscript{4}O\textsubscript{10} (p. 504).

There has been growing interest in the detailed structure and reaction chemistry of monomeric forms of two-coordinate derivatives of Ge\textsuperscript{II}, Sn\textsuperscript{II} and Pb\textsuperscript{II} since the first examples were unequivocally established in 1980.\textsuperscript{(63,64)} Thus, treatment of the corresponding chlorides MCl\textsubscript{2} with lithium di-tert-butyl phenoxide derivatives in thf affords a series of yellow (Ge\textsuperscript{II}, Sn\textsuperscript{II}) and red (Pb\textsuperscript{II}) compounds M(OAr)\textsubscript{2} in high yield.\textsuperscript{(63)} The O–M–O bond angle in M(OC\textsubscript{6}H\textsubscript{2}Me-4-Bu\textsubscript{2}-2,6)\textsubscript{2} was 92° for Ge and 89° for Sn. Similar reactions.

\[ 4\text{GeBr}_4 + 6\text{H}_2\text{S} \xrightarrow{\text{CS}_2/\text{Al}_2\text{Br}_6} \text{Ge}_4\text{S}_6\text{Br}_4 + 12\text{HBr} \]

The unexpectedly complex product was isolated as an almost colourless air-stable powder, and a single-crystal X-ray analysis showed that it had the molecular adamantane-like structure (5).\textsuperscript{(62)} This is very similar to the structure of the "iso-electronic" compound P\textsubscript{4}O\textsubscript{10} (p. 504).

There has been growing interest in the detailed structure and reaction chemistry of monomeric forms of two-coordinate derivatives of Ge\textsuperscript{II}, Sn\textsuperscript{II} and Pb\textsuperscript{II} since the first examples were unequivocally established in 1980.\textsuperscript{(63,64)} Thus, treatment of the corresponding chlorides MCl\textsubscript{2} with lithium di-tert-butyl phenoxide derivatives in thf affords a series of yellow (Ge\textsuperscript{II}, Sn\textsuperscript{II}) and red (Pb\textsuperscript{II}) compounds M(OAr)\textsubscript{2} in high yield.\textsuperscript{(63)} The O–M–O bond angle in M(OC\textsubscript{6}H\textsubscript{2}Me-4-Bu\textsubscript{2}-2,6)\textsubscript{2} was 92° for Ge and 89° for Sn. Similar reactions.
of MCl₂ with LiNBu₃yielded the (less stable) monomeric di-tert-butylamide, Ge(NBU₃)₂ (orange), and Sn(NBu₃)₂ (maroon); the more stable related bis(tetramethylpiperidino) compound [Ge{NCMe₂(CH₂)₃CMe₂}₂] was found to have a somewhat larger bond angle at Ge (N-Ge-N = 111°) and a rather long Ge–N bond (189 pm). More recent examples are [Ge[N(SiMe₃)₂]₂](65) and [GeN(Bu')CH=CHN=Ge(NBu₃)].(66) The first monomeric prochiral Sn²⁺ complexes, [Sn[N(SiMe₃)₂]X], have also been reported, where X is a bulky substituted phenoxy group or a tetramethylpiperidino moiety.(67) These are but illustrative examples of a large and burgeoning field.(68)

Turning finally to compounds with bonds from the heavier Group 14 elements to heavier Group 15 elements we may note compounds such as [Sn(C(PMe₂)₃)] which has the pseudo trigonal bipyramidal structure (6). This complex, which has Sn bonded exclusively to four P atoms, is formed as yellow crystals by the reaction of SnCl₂ with 2Li[C(PMe₂)₃] in Et₂O at −78°C.(69) A notable feature of the structure is the substantial difference between the equatorial and axial Sn–P distances (260 pm vs 279 and 284 pm, respectively) and the small chelate bite angle of 62.9° at the Sn atom. The compound is fluxional in solution even at −90°C due to pseudorotation (p. 499) which equilibrates the axial and equatorial positions. Several similar compounds are known.(69) Germanium analogues of (6) such as the stable crystalline complexes [Ge{C(PMe₂)₃}]₂ and [Ge{C(PMe₂)₂(SiMe₃)}₂] can be made by similar procedures, starting from GeCl₂-dioxane:(70) see also next section.

A range of shiny metallic compounds featuring trigonal planar anions SnX₃⁻ (X = As, Sb, Bi) have been characterized with composition Mₓ(SnX₃)O₀.₅ (M = Rb, Cs); the Sn and X atoms in SnX₃⁻ (isostuctural with CO₃⁻) are coordinated by trigonal prisms of 6M⁺, and the O⁻ ions occupy octahedral sites in the M⁺ lattice.(70a)

Rather different is the X-ray structural characterization of the ‘bare’ Sn²⁺ ion in [Sn²⁺][SbF₆]⁻₂.2AsF₃ (prepared by treating the product of the direct reaction between SnF₂ and SbF₅ with AsF₃). The crystal packing is such that each Sn²⁺ is surrounded by nine F atoms (tricapped trigonal prism) and the average Sn–F distance is 257 pm (cf. the sum of the ionic radii, 251 pm). The Mössbauer spectrum (p. 371) shows zero quadrupole splitting and the highest known chemical shift for any tin(II) species, consistent with the ‘bare ion’ formulation.

10.3.6 Metal–metal bonds and clusters

The catenation of Group 14 elements has been discussed on pp. 337–42 and 374–5,
and further examples are in Section 10.3.7. In addition, when the reaction of GeCl₂-dioxane with 2Li[Cl{(PMe₂)₂X}₂] (mentioned above(70)) is varied by using a higher proportion of GeCl₂, concurrent redox disproportionation occurs to yield a mixture of [Ge⁺V{(PMe₂)₂X}₂Cl⁻](7) and [Ge⁺I{(PMe₂)₂X}₂Cl⁻](8) according to the optimized stoichiometry:(72)

3GeCl₂.diox + 4Li[Cl{(PMe₂)₂X}₂] = (7) + (8) + 4LiCl + 3C₄H₈O₂

where X = SiMe₃ (or PMe₂). The Ge–Ge distance in (8) is 254 pm, i.e. about 10 pm longer than in polygermanes. The stereochemically active lone pairs of electrons on Ge⁺ in (8) can be used as electron-pair donors to a further GeCl₂ moiety to form the homonuclear (germanediyl donor)–(germanediyl acceptor) complex [Ge₂{µ-(PMe₂)₂CX}₂]GeCl₂ which features a mixed-valent Ge₅ chain as shown schematically in (9). The Ge–Ge distances along the Ge⁺–Ge⁺–Ge⁺–Ge⁺–Ge⁺ chain are 249.2, 255.4, 256.2 and 248.5 pm, respectively.

Heteroatomic metal-metal bonds can be formed by a variety of synthetic routes as illustrated below for tin:

**Insertion:** SnCl₂ + Co₂(CO)₈ → SnCl₂ + (CO)₄Sn–Co(CO)₄

**Elimination:** SnCl₂ + [Fe(η⁵-C₅H₅)(CO)₂HgCl] → CO

**Oxidative addition:** SnCl₄ + [Ir(CO)Cl(PPh₃)₂] → SnCl₃ + [((PPh₃)₂IrCl₂]

Some representative examples, all featuring tetrahedral Sn, are in Fig. 10.9.(53) Several reactions are known in which the Sn–M bond remains intact, e.g.:

Ph₃SnMn(CO)₅ + 3Cl₂ → Cl₃SnMn(CO)₅ + 3PhCl

Cl₅Sn(CO)₄Cl₂ + 2RMgX → R₂Sn(CO)₄Cl₂ + 2MgClX

Others result in cleavage, e.g.:

Me₃SnCo(CO)₄ + I₂ → Me₃SnI + Co(CO)₄I

Me₃SnMn(CO)₅ + Ph₂PCl → Me₃SnCl + ½[Ph₂PMn(CO)₄]₂ + CO

Me₃SnMn(CO)₅ + C₂F₄ → Me₃SnCF₂CF₂Mn(CO)₄

---

A similar though less extensive range of Pb–M compounds has been established;\(^{(39)}\) e.g. [Ph₂Pb[Mn(CO)₅]₂], [Ph₃PbRe(CO)₅], [Ph₂Pb-[Co(CO)₄]₂], [(PPh₃)₂Pt(PbPh₃)₄], [(CO)₃Fe(PbEt₃)]₂, and the cyclic dimer [(CO)₄Fe-PbEt₂].

Reaction of these compounds with halogens results in fission of the Pb–M bonds. In the unique case of [Pb[Mn(η⁵-C₅H₅)(CO)₂]] the linear central MnPbMn core (177.2°) and short Mn–Pb distance (246.3 pm) suggest that this is the first example of multiple bonding between Pb and a transition metal, Mn=Pb=Mn.\(^{(73)}\)

The compound is obtained in 20% yield as air-stable reddish-brown crystals by the reaction of PbCl₂ with the substitutionally labile complex [Mn(η⁵-C₅H₅)(CO)₂(thf)].

It has been known since the early 1930s that reduction of Ge, Sn and Pb by Na in liquid ammonia gives polyatomic Group 14 metal anions, and crystalline compounds can be isolated using ethylenediamine, e.g. [Na₄(en)₅Ge₉] and [Na₄(en)₅Sn₉]. A dramatic advance was achieved\(^{(74)}\) in the 1970s by means of the polydentate cryptand ligand [N{(C₂H₅)O(C₂H₅)-O(C₂H₅)}₃N] (p. 98). Thus, reaction of cryptand in ethylenediamine with the alloys NaSn₁₋₁.₇ and NaPb₁₋₂ gave red crystalline salts [Na(crypt)]₂[Sn₅]²⁻ and [Na(crypt)]₂[Pb₅]²⁻ containing the D₅h cluster anions illustrated in Fig. 10.10. If each Sn or Pb atom is thought to have 1 nonbonding pair of electrons then the

---

Figure 10.10 The structure of polystannide and polyplumbide anions: (a) the slightly distorted $D_{3h}$ structure of $\text{[Sn}_5\text{I}_2^-$, (b) the $D_{3h}$ structure of $\text{[Pb}_5\text{I}_2^-$, and (c) the unique $C_{4v}$ structure of $\text{[Sn}_9\text{I}_4^-$: all Sn–Sn distances are in the range 295–302 pm except those in the slightly longer upper square (1,3,6,4) which are in the range 319–331 pm; the angles within the two parallel squares are all 90° ($\pm 0.8^\circ$).

M$_5^{2-}$ clusters have 12 framework bonding electrons as has $\text{[B}_5\text{H}_5\text{I}_2^-$(p. 161); the anions are also isoelectronic with the well-known cation $\text{[B}_5\text{I}_5]^{3+}$. Similarly, the alloy NaSn$-2.25$ reacts with cryptand in ethylenediamine to give dark-red crystals of $\text{[Na(crypt)]}_6^+\text{[Sn}_9\text{I}_4^{4-}$; the anion is the first example of a $C_{4v}$ unicapped Archimedian antiprism (Fig. 10.10c) and differs from the $D_{3h}$ structure of the isoelectronic cation $\text{[B}_9\text{I}_6]^{5+}$ which, in the salt $\text{Bi}^+\text{[B}_9\text{I}_6]^{5+}[\text{HfCl}_6]^{2-}$(p. 591), features a tricapped trigonal prism, as in $\text{[B}_9\text{H}_9\text{I}_2^-$(p. 153). The emerald green species $\text{[Pb}_9\text{I}_4^-$, which is stable in liquid NH$_3$ solution, has not so far proved amenable to isolation via cryptand-complexed cations.

The influence of electron-count on cluster geometry has been very elegantly shown by a crystallographic study of the deep-red compound $\text{[K(crypt)]}_6^+\text{[Ge}_9\text{I}_2^-[\text{Ge}_9]^{4-}$–2.5en, prepared by the reaction of KGe with cryptand in ethylenediamine. $\text{[Ge}_9]^{4-}$ has the $C_{4v}$ uncapped square-antiprismic structure (10.10c) whereas $\text{[Ge}_9]^{2-}$, with 2 less electrons, adopts a distorted $D_{3h}$ structure which clearly derives from the tricapped trigonal prism (p. 153). The field is one of great interest and activity, as evidenced by papers describing the synthesis of and structural studies on tetrahedral Ge$_4^{2-}$ and Sn$_4^{2-}$ (76) tricapped trigonal-prismatic TlSn$_9^{3-}$ (77) bicapped square-antiprismatic TlSn$_9^{3-}$ (77) and the two nido-series Sn$_{9-x}$Ge$_x^{4-}$ ($x = 0$–9) and Sn$_{9-x}$Pb$_x^{4-}$ ($x = 0$–9). (78) Other theoretical studies on many of these polymetallic-cluster anions have also been published. (79) Recent synthetic and structural work includes the characterization of the octahedral $\text{closo-[Ge}_2\text{Co}_4]$ grouping in $[1,6-(\text{CO})_2\text{COGe}]_2\text{Co}_4(\text{CO})_11$. (80)

---

the closo-10 vertex cluster \([\text{Sn}_4\text{Cr}(\text{CO})_3]^{4-}\) and encapsulated Ge and Sn atoms (E) in species such as \([\text{Ni}_{12}(\mu_2-E)(\text{CO})_{22}]^{2+}\) and \([\text{Ni}(\mu_{10}-\text{Ge})(\text{CO})_{20}]^{2-}\). The polymeric cluster compound \([\text{Sn}_6\text{O}_4-(\text{OH})_4]\) formed by hydrolysis of \(\text{Sn}^{II}\) compounds has been mentioned on p. 384. Hydrolysis of \(\text{Pb}^{II}\) compounds also leads to polymerized species; e.g. dissolution of \(\text{PbO}\) in aqueous \(\text{HClO}_4\) followed by careful addition of base leads to \([\text{Pb}_6\text{O}(\text{OH})_6]^{4+}[\text{ClO}_4]_2\cdot \text{H}_2\text{O}\). The cluster cation (Fig. 10.11a) consists of 3 tetrahedra of \(\text{Pb}\) sharing faces; the central tetrahedron encompasses the unique O atom and the 6 OH groups lie on the faces of the 2 end tetrahedra. The extent of direct \(\text{Pb}-\text{Pb}\) interaction within the overall cluster has not been established but it is noted that the distance between "adjacent" \(\text{Pb}\) atoms falls in the range 344–409 pm (average 381 pm) which is appreciably larger than in the \(\text{Pb}_5^{2-}\) anion. The distance from the central O to the 4 surrounding \(\text{Pb}\) atoms is 222–235 pm and the other \(\text{Pb}-\text{O(H)}\) distances are in the range 218–267 pm. The structure should be compared with the \([\text{Sn}_6\text{O}_4(\text{OH})_4]\) cluster (p. 384), which also has larger \(\text{Sn}-\text{Sn}\) distances than in the polystannide anions in Fig. 10.10.

Another polycyclic structure in which a unique O atom is surrounded tetrahedrally by 4 \(\text{Pb}^{II}\) atoms is the colourless adamantane-like complex \([\text{Pb}_4\text{O}(\text{OSiPh}_3)_6]\), obtained as a 1:1 benzene solvate by reaction of \(\text{Ph}_3\text{SiOH}\) with \([\text{Pb}(_5\text{C}_5\text{H}_5)_2]\) (p. 404). The local geometry about \(\text{Pb}^{II}\) is also noteworthy: it comprises pseudo-trigonal bipyramidal coordination in which the bridging \(\text{OSiPh}_3\) groups occupy the equatorial sites whilst the apical sites are occupied by the unique O atom and axially directed lone pairs of electrons. The first heterometallic oxoalkoxide, \([\text{Pb}_6\text{Nb}_4\text{O}_4(\text{OEt})_{24}]\), has also been prepared, by reacting \([\text{Pb}_4\text{O}(\text{OEt})_6]\) and \([\text{Nb}_2(\text{OEt})_{10}]\) in ethanol at room temperature. X-ray structural analysis shows an octahedral \(\text{Pb}_6\) framework, four of whose faces are capped by a \(\mu_4\)-oxo ligand connected to 3\(\text{Pb}\) atoms and an \{\(\text{Nb}(\text{OEt})_5\}\} moiety; the remaining

---

**Figure 10.11** (a) The three face-sharing tetrahedra of \(\text{Pb}\) atoms in the \(\text{Pb}_6\text{O}(\text{OH})_6^{4+}\) cluster; only the unique 4-coordinate O atom at the centre of the central tetrahedron is shown (in white). (b) The adamantane-like structure of \([\text{Pb}_4\text{O}(\text{OSiPh}_3)_6]\) showing the fourfold coordination about the central O atom.
four faces of the Pb₆ octahedron are capped by \((\mu₃-OEt)\) groups. This leads, to the overall detailed formulation of the compound as 
\[
[\text{Pb}_6(\mu_4-O)]_4\{\text{Nb}(\text{OEt})_2\}_4(\mu_3-OEt)_4(\mu_2-OEt)]_{12}.
\]
Alternatively the complex can be described as a tetradentate oxo ligand donating to 4\{\text{Nb}(\text{OEt})_2(\mu_2-OEt)\}_3\} \text{i.e.} [\text{Pb}_6\text{O}_4(\text{OEt})_4_{\cdot\cdot\cdot}\{\text{Nb}(\text{OEt})_2\}_3].

### 10.3.7 Organometallic compounds

**Germanium**

Organogermanium chemistry closely resembles that of Si though the Ge compounds tend to be somewhat less thermally stable. They are also often rather more chemically reactive than their Si counterparts, e.g. in ligand scrambling reactions, Ge–C bond cleavage and hydrogermylation. However, GeR₄ compounds themselves are rather inert chemically and R₄GeX₄–ₙ tend to be less prone to hydrolysis and condensation reactions than their Si analogues. Again, following expected group trends, germynes (R₂Ge:) are more stable than silylenes. The table of comparative bond energies on p. 374 indicates that the Ge–C and Ge–H bonds are weaker than the corresponding bonds involving Si but are nevertheless quite strong; Ge–Ge is noticeably weaker. The electronegativity of both Si and Ge are similar to that of H, though the reactivity pattern towards organolithium reagents suggests a slight hydridic character \((H^{3−})\) for \(\text{Ph}_3\text{SiH}\) and some protic character \((H^{5+})\) for \(\text{Ph}_3\text{GeH}\):

\[
\text{Ph}_3\text{Si}^{-} + \text{LiR} \rightarrow \text{Ph}_3\text{Si}^{-} \cdot \text{R} + \text{LiH}
\]

**(metathesis)**

\[
\text{Ph}_3\text{Ge}^{-} + \text{LiR} \rightarrow \text{Ph}_3\text{Ge}^{-} \cdot \text{Li} + \text{RH}
\]

**(metallation)**

In fact, the polarity of the Ge–H bond can readily be reversed (umpolung) by an appropriate choice of constituents, e.g.:

\[
\text{Et}_3\text{Ge}^{5+} - \text{H}^{5+} + >\text{C} = \text{O} \rightarrow \text{H}^- \cdot \text{C} = \text{O} \cdot \text{GeEt}_3
\]

\((\text{germoxane})\)

\[
\text{Cl}_3\text{Ge}^{5+} - \text{H}^{5+} + >\text{C} = \text{O} \rightarrow \text{Cl}_3\text{Ge}^- \cdot \text{C} = \text{OH}
\]

\((\text{germylcarbinol})\)

Preparative routes to organogermanium compounds parallel those for organosilicon compounds (p. 363) and most of the several thousand known organogermanes can be considered as derivatives of \(\text{R}_n\text{GeX}_{4−n}\) or \(\text{Ar}_n\text{GeX}_{4−n}\) where \(X = \text{hydrogen, halogen, pseudohalogen, OR, etc.}\) The compounds are colourless, volatile liquids, or solids. Attempts to prepare \((-\text{R}_2\text{GeO})_n\) analogues of the silicones (p. 364) show that the system is different: hydrolysis of \(\text{Me}_2\text{GeCl}_2\) is reversible and incomplete, but extraction of aqueous solutions of \(\text{Me}_2\text{GeCl}_2\) with petrol leads to the cyclic tetramer \([\text{Me}_2\text{GeO}]_4\), mp 92°; the compound is monomeric in water. Organodigermanes and -polygermanes have also been made by standard routes, e.g.:

\[
2\text{Me}_2\text{GeBr} + 2\text{K} \overset{\text{reflux}}{\longrightarrow} 2\text{KBr} + \text{Ge}_2\text{Me}_6
\]

\((\text{mp} −40°, \text{bp} 140°)\)

\[
\text{Et}_3\text{GeBr} + \text{NaGePh}_3 \overset{\text{liq NH}_3}{\longrightarrow} \text{NaBr} + \text{Et}_3\text{GeGePh}_3(\text{mp} 90°)
\]

\[
2\text{Ph}_3\text{GeBr} + 2\text{Na} \overset{\text{boiling xylene}}{\longrightarrow} 2\text{NaBr} + \text{Ge}_2\text{Ph}_6
\]

\((\text{mp} 340°)\)

\[
\text{Ph}_2\text{GeCl}_2 + 2\text{NaGePh}_3 \overset{\text{boiling xylene}}{\longrightarrow} 2\text{NaCl} + \text{Ge}_3\text{Ph}_8
\]

\((\text{mp} 248°)\)

In general, the Ge–Ge bond is readily cleaved by \(\text{Br}_2\) either at ambient or elevated temperatures but the compounds are stable to thermal cleavage at moderate temperatures. Ge₂R₆ compounds can even be distilled unchanged in air (like Si₂R₆ but unlike the more reactive Sn₂R₆) and are stable towards hydrolysis and ammonolysis.
Considerable recent attention has focused on the preparation, structure and stability of germenes (>Ge=C<), germylenes (R₂Ge:), cyclo and polyhedral oligopolygermanes, and Ge" species with coordination numbers greater than 4 (especially 5 and 10). Thus, evidence for fugitive germene species has been known for some 20 years but stable germenes, R₂Ge=CR'₂, were first reported only in 1987, the stabilization being achieved by use of bulky groups both on Ge [e.g. R = mesityl or -N(SiMe₃)₂] and on C [e.g. R' = -B(Bu')₂C(SiMe₃)₂B(Bu')₂ or CR' = fluorenylidene]. Numerous other stable germenes have since been characterized.

The first germylene, R₂Ge: [R = (SiMe₃)₂], was reported in 1976. It can now be conveniently prepared from GeCl₂.diox and Grignard-type derivatives of the bulky bis(trimethylsilyl)methyl R group in Et₂O (e.g. ether complexes of RMgCl or MgR₂); gas-phase electron diffraction at 155°C shows it to be a V-shaped monomer with the angle CGeC = 107°. In the solid phase the compound forms bright yellow crystals (mp 182°C) of the centrosymmetric dimer Ge₂₂ with a fold angle θ of 32° and a Ge–Ge distance of 235 pm. By contrast, reductive coupling reactions of R₂GeX₂ with a mixture of Mg/MgBr₂ in thf affords colourless crystals of cyclotrigermanes or cyclotetragermanes in moderate or good yield.

Bulky R groups such as mesityl, xylol or 2,6-diethylbenzil lead to Ge₃ rings whereas sterically less demanding groups such as Pr, Ph or Me₃SiCH₂ yield Ge₄ rings. Note that the compounds (Ge₃R₂)n feature Ge with the coordination number 2, 3 or 4 depending on whether n = 1, 2, or ≥3, respectively. Mixed derivatives can also be made: e.g., reductive coupling of Mes(Bu)GeCl₂ at room temperature affords [{Ge(Mes)Bu₃}], mp 201°C. Thermolysis of [{Ge(Mes)₂}], (a) in the presence of Et₃SiH at 105°C yields a mixture of dimesityltris(dimethylsilyl)germane (b) and tetramesityltris(dimethylsilyl)germane (c) according to the subjoined scheme.

Polyhedral oligogermanes of varying complexity can be made by careful choice of the organo R group and the metal reductive coupling agent. Thus, treatment of [{Me₃Si(CH₂)GeCl₃} with Li metal in thf gave thermochoic yellow-orange crystals of the hexamer [Ge₆(CH(SiMe₃)₂)]₆ which were unexpectedly stable to atmospheric exposure.

---

O₂ and moisture. X-ray analysis revealed a prismatic structure (Fig. 10.12a) rather than a monocyclic benzenoid structure. The Ge–Ge distances within the two triangular faces (258 pm) are, perhaps surprisingly, longer than those in the prism quadrilateral edges (252 pm) and all the Ge–Ge distances are significantly longer than in other polygermanes (237–247 pm). Again, treatment of GeBr₄ with LiBut yields a mixture of Bu₃GeBr₂ and Bu₃Br₂Ge–GeBr₂Bu', and treatment of this latter with an excess of Li/naphthalene afforded the polycyclic octagermane, Ge₈Bu₂Br₂, in 50% yield. As shown in Fig. 10.12b, the molecule is chiral with C₂ skeletal symmetry. The octagermacubane [Ge₈(CHMeEt₂)₈] (Fig. 10.12c) was obtained as yellow crystals (mp > 215°C) by a simple coupling reaction of R₃GeCl with Mg₂Br₂, and numerous other cyclic, ladder and cluster polygermanes have been described.

The coordination number of Ge in organogermanes is not limited to 2, 3 or 4, and higher coordination numbers are well documented. Examples are 5-coordinate Ge⁺ in the cation of \([\text{Ge}([\eta^5-\text{C}_5\text{Me}_3])^+]\text{[BF}_4^-\) (10), and 6-coordinate Ge⁺ in the corresponding chloride \([\eta^5-\text{C}_5\text{Me}_5]\text{GeCl}\) (11) and 10-coordinate Ge⁺ in \([\text{Ge}([\eta^5-\text{C}_5\text{H}_5])^+]\) (12) and its \([\eta^5-\text{C}_5\text{R}_5]\) analogues. These species can now readily be prepared by standard reactions, and structural details are in the leading references cited. Thus, reaction of NaC₅H₅ with GeCl₂·diox in thf gives a 60% yield of (12) as colourless crystals, mp 78°C. The angle of aperture between the two C₅H₅ planes in (12) is 50.4° compared with 45.9° or 48.4° for stannocene. By contrast, 5-coordinate Ge⁺ adopts a structure midway between trigonal bipyramidal and rectangular pyramidal in phenyl-substituted anionic germanates such as \([\text{PhGe}([\eta^2-\text{C}_6\text{H}_4\text{O}_2])^-\) (13), the precise geometry being dictated by the co-cation, e.g. \([\text{NEt}_4]^+, [\text{N}(\text{Et})_3\text{H}]^+\) or \([\text{AsPh}_₃]^+\).

Finally, brief mention should be made of the growing range of heterocyclic organogermanium compounds. Compounds with 3–13(+) atoms in the ring have recently been reviewed.

6-coordinate Ge⁺ in the corresponding chloride \([\eta^5-\text{C}_5\text{Me}_5]\text{GeCl}\) (11) and 10-coordinate Ge⁺ in \([\text{Ge}([\eta^5-\text{C}_5\text{H}_5])^+]\) (12) and its \([\eta^5-\text{C}_5\text{R}_5]\) analogues. These species can now readily be prepared by standard reactions, and structural details are in the leading references cited. Thus, reaction of NaC₅H₅ with GeCl₂·diox in thf gives a 60% yield of (12) as colourless crystals, mp 78°C. The angle of aperture between the two C₅H₅ planes in (12) is 50.4° compared with 45.9° or 48.4° for stannocene. By contrast, 5-coordinate Ge⁺ adopts a structure midway between trigonal bipyramidal and rectangular pyramidal in phenyl-substituted anionic germanates such as \([\text{PhGe}([\eta^2-\text{C}_6\text{H}_4\text{O}_2])^-\) (13), the precise geometry being dictated by the co-cation, e.g. \([\text{NEt}_4]^+, [\text{N}(\text{Et})_3\text{H}]^+\) or \([\text{AsPh}_₃]^+\).

Finally, brief mention should be made of the growing range of heterocyclic organogermanium compounds. Compounds with 3–13(+) atoms in the ring have recently been reviewed.

Organometallic compounds

§10.3.7

Organotin compounds have been much more extensively investigated than those of Ge and, as described in the Panel, many have important industrial applications.\(^{(108)}\) Syntheses are by standard techniques (pp. 134, 259, 363) of which the following are typical:

\[
\text{Grignard: } \text{SnCl}_4 + 4\text{RMgCl} \rightarrow \text{SnR}_4 \\
+ 4\text{MgCl}_2 \text{ (also with ArMgCl)}
\]

\[
\text{Organo Al: } 3\text{SnCl}_4 + 4\text{AlR}_3 \rightarrow 3\text{SnR}_4 \\
+ 4\text{AlCl}_3 \text{ (alkyl only)}
\]

Direct (Rochow)\(\dagger\) \(\text{Sn} + 2\text{RX} \rightarrow \text{R}_2\text{SnX}_2\) (and \(\text{R}_n\text{SnX}_{4-n}\)) (alkyl only).

All three routes are used on an industrial scale and the Grignard route (or the equivalent organo-Li reagent) is convenient for laboratory scale. Rather less used is the modified Wurtz-type reaction \((\text{SnCl}_4 + 4\text{RCl} \rightarrow \text{SnR}_4 + 8\text{NaCl})\).

Conversion of \(\text{SnR}_4\) to the partially halogenated species is readily achieved by scrambling reactions with \(\text{SnCl}_4\). Reduction of \(\text{R}_n\text{SnX}_{4-n}\) with \(\text{LiAlH}_4\) affords the corresponding hydrides and hydrostannation (addition of \(\text{Sn-H}\)) to \(\text{C-C}\) double and triple bonds is an attractive route to unsymmetrical or heterocyclic organotin compounds.

Most organotin compounds can be regarded as derivatives of \(\text{R}_n\text{SnIVX}_{4-n}\) \((n = 1-4)\) and even compounds such as \(\text{SnR}_2\) or \(\text{SnAr}_2\) are in fact cyclic oligomers \((\text{SnIVR}_2)_n\) \((p. 402)\). The physical properties of tetraorganostannanes closely resemble those of the corresponding hydrocarbons or tetraorganosilanes but with higher densities, refractive indices, etc. They are colourless, monomeric, volatile liquids or solids. Chemically they resist hydrolysis or oxidation under normal conditions though when

\(\dagger\) For example, with \(\text{MeCl}\) at 175\(^\circ\) in the presence of catalytic amounts of \(\text{CH}_3\text{I}\) and \(\text{NEt}_3\), the yields were \(\text{Me}_2\text{SnCl}_2\) (39\%), \(\text{MeSnCl}_3\) (6.6\%), \(\text{Me}_3\text{SnCl}\) (4.6\%).
Uses of Organotin Compounds

Tin is unsurpassed by any other metal in the multiplicity of applications of its organometallic compounds. The first organotin compound was made in 1849 but large-scale applications have developed only recently; indeed, world production figures for organotin compounds increased more than 700-fold between 1950 and 1980:

<table>

The largest application for organotin compounds (75% by weight) is as stabilizers for PVC plastics; in their absence halogenated polymers are rapidly degraded by heat, light or oxygen to give discoloured, brittle products. The most effective stabilizers are $R_2SnX_2$, where $R$ is an alkyl residue (typically $n$-octyl) and $X$ is laurate, maleate, etc. For food packaging the cis-butenedioate polymer, $[Oct_3Sn-OC(O)CH=CHC(O)O]_2$, and the $S,S'$-bis-($iso$-octyl mercaptoethanoate), $Oct_2Sn(SCH_2C(O)OOct')_2$ have been approved and are used when colourless non-toxic materials with high transparency are required. The compounds are thought to be such effective stabilizers because (i) they inhibit the onset of dehydrochlorination by exchanging their anionic groups $X$ with reactive Cl sites in the polymer, (ii) they react with and hence scavenge the HCl which is produced and which would otherwise catalyse further elimination, and (iii) they act as antioxidants and thereby prevent breakdown of the polymer initiated by atmospheric $O_2$.

Another major use of organotin compounds is as curing agents for the room temperature “vulcanization” of silicones; the 3 most commonly used compounds are $Bu_3SnX_2$, where $X$ is acetate, 2-ethylhexanoate or laurate. The same compounds are also used to catalyse the addition of alcohols to isocyanates to produce polyurethanes.

The next major use of organotin compounds (15–20%) is as agricultural biocides and here triorganotins are the most active materials; the importance of this application can readily be appreciated since, at present, over one-third of the world’s food crops are lost annually to pests such as fungi, bacteria, insects or weeds. The great advantage of organotin compounds in these applications is that their toxic action is selective and there is little danger to higher (mammalian) life; furthermore, their inorganic degradation products are completely non-toxic. $Bu_3SnOH$ and $Ph_3SnOAc$ control fungal growths such as potato blight and related infections of sugar-beet, peanuts, and rice. They also eradicat red spider mite from apples and pears. Other $R_3SnX$ are effective in controlling insects, either by acting as chemosterilants or by killing the larvae. Again, $O(SnBu_3)_2$ is an excellent wood preserver, and derivatives of $Ph_3Sn$- and $(cyclohexyl)_3Sn$- are also used for this. Related applications are as marine antifouling agents for timber-hulled boats; paints containing $Bu_3Sn$- or $Ph_3Sn$- derivatives slowly release these groups and provide long-term protection against attachment of barnacles or attack by Teredo woodworm borers. Cellulose and woollen fabrics are likewise protected against fungal attack or destruction by mites. $R_3SnX$ are also used as bacteriostats to control slime in paper and wood-pulp manufacture.

$Me_2SnCl_2$ is now used as an alternative to SnCl$_4$ for coating glass with a thin film of SnO$_2$ since it is a non-corrosive solid which is easier to handle. The glass (or ceramic) surface is treated with Me$_2$SnCl$_2$ vapour at temperatures above 450° and, depending on the thickness of the oxide film produced, the glass is toughened and the surface can be rendered scratch-resistant, lustrous, or electroconductive (p. 385).

Organotin reagents and intermediates are finding increasing use in organic syntheses.\(^{109}\)

---

which thereby raise the coordination number of Sn to 5, 6 or even 7. As expected, F is more effective in this role than the other halogens (why?). For example, Ph₃SnF is a strictly linear polymer with 5-coordinate trigonal bipyramidal geometry about Sn; the angles Sn−F−Sn and F−Sn−F are both 180° and the Sn−F distances in the chain are identical (214.6 pm). By contrast, Me₃SnF has a zig-zag chain structure (Fig. 10.13) with unequal Sn−F distances and a pronounced bend at F (~140°). The volatile chlorine analogue (Me₃SnCl; mp 39.5°, bp 154°) also has a zig-zag chain structure with angle Sn−Cl−Sn 151° and essentially linear Cl−Sn−Cl (177°); The two Sn−Cl distances in the chain are 243 and 326 pm but even this longer distance is substantially shorter than the sum of the van der Waals radii (385 pm). On the other hand crystalline Ph₃SnCl and Ph₃SnBr feature monomeric molecules with 4-coordinate Sn atoms.

Me₂SnF₂ has a layer structure with octahedral Sn and trans-Me groups above and below the F-bridged layers as in SnF₄ (p. 381). The weaker Cl bridging in Me₂SnCl₂ leads to the more distorted structure shown in Fig. 10.13b. The O atom is an even more effective ligand than F and, amongst the numerous compounds R₂SnOR and R₂Sn(OR')₂ that have been studied by X-ray crystallography, the only ones with 4-coordinate tin (presumably because of the bulky ligands) are 1,4-(Et₃SnO)₂C₆Cl₄ and [Mn(CO)₃(η⁵-C₅H₄SnPh₃)].

The converse of polymerization is heterolytic bond scission leading either to R₃Sn⁺ or R₃Sn⁻ species. Tricoordinate organotin(IV) cations can readily be synthesized at room temperature by hydride or halide abstraction reactions in benzene or other solvents. For example, with R = Me, Bu or Ph:

\[
\begin{align*}
R₃SnH + Ph₃CClO₄ & \longrightarrow [R₃Sn]^+ [ClO₄]^- + Ph₃CH \\
R₃SnCl + AgClO₄ & \longrightarrow [R₃Sn]^+ [ClO₄]^- + AgCl \\
R₃SnH + B(C₆F₅)₃ & \longrightarrow [R₃Sn]^+ [B(C₆F₅)₃]^- 
\end{align*}
\]

The highly ionic nature of these (presumably planar) species is revealed by cryoscopy, electrical conductance and the diagnostically large downfield Sn nmr chemical shift. Salts of the corresponding anionic species Ph₃Sn⁻ are easily generated by heating either Ph₃SnH or Sn₂Ph₆.

---

Footnotes:

with alkali metal, and an X-ray crystal structure of the crown ether complex (p. 97) [K(18-crown-6)][[Pt₃Sn]⁻] revealed a naked pyramidal anion with Sn–C 222.4 pm (cf. 212 pm in SnPh₂) and the angle C–Sn–C 96.9°.¹¹⁴ Seven-coordinate pentagonal bipyramidal organotin(IV) complexes are exemplified by [SnEt₂(η⁵-dapt)] in which the two Et groups are axial and the planar 5-fold ligation (η⁵-N₃O₂) is provided by the ligand (dapt), (H₂dapt = 2,6-diacetylpyridinebis(2-thenoylhydrazone)).¹¹⁵

Catenaion is well established in organotin chemistry and distannane derivatives can be prepared by standard methods (see Ge, p. 396). The compounds are more reactive than organodi-germanes; e.g. Sn₂Me₆ (mp 23°) inflames in air at its bp (182°) and absorbs oxygen slowly at room temperature to give (Me₂Sn)₂O. Typical routes to higher polystananes are:

\[
\text{2Me₃SnBr + NaMe₂SnSnMe₂Na} \xrightarrow{\text{liq NH₃}} \text{Me₃Sn(SnMe₂)₂SnMe₃ (oil)}
\]

Unbranched chains up to at least Sn₆ are known, e.g. Ph₃Sn(Bu₃Sn)₄, SnPh₃ (n = 0–4).¹¹⁶ Cyclo-diaryl stannanes(IV) can also be readily prepared, e.g. reaction of Me₂SnCl₂ with Na/liq NH₃ yields cyclo-(SnMe₂)₆ together with acyclic X(SnMe₂)₆X (n = 12–20). Yellow crystalline cyclo-(SnEt₂)₆ is obtained almost quantitatively when Et₂SnH₂, dissolved in toluene/pyridine, is catalytically dehydrogenated at 100° in the presence of a small amount of Et₂SnCl₂. Similarly, under differing conditions, the following have been prepared:³⁴ (SnEt₂)₆, (SnEt₂)₇, (SnBu₂)₄, (SnBu₂)₄, (SnBu₂)₆, and (SnPh₂)₅. The compounds are highly reactive yellow or red oils or solids. A crystal structure of the colourless hexamer (SnPh₂)₆ shows that it exists in the chair conformation (I) with Sn–Sn distances very close to the value of 280 pm in α-Sn (p. 372). Small rings are also known, e.g. [cyclo-(SnR₂)₃] where R = 2,4,6-triisopropylphenyl.,¹¹⁷ and even the propellane [1.1.1]-Sn₃R₆ (structure II, R = 2,6-C₆H₃Et₂).¹¹⁸ This latter compound was formed in 13% yield as dark blue-violet crystals by the thermolysis of cyclo-Sn₃R₆ in xylene at 200°. The axial Sn–Sn distance of 337 pm is substantially longer than the previously known longest Sn–Sn bond (305 pm) and may indicate significant siglel diradical character).

True monomeric organotin(II) compounds have proved rather elusive. The cyclopentadienyl compound [Sn(η⁵-C₅H₅)]₂ (which is obtained as white crystals mp 105° from the reaction of NaC₅H₅ and SnCl₂ in thf) has a structure similar to that of germanocene (12 pp. 398–9) with the angle subtended at Sn by the midpoints of the C₅ rings 147.7° and 148.0° in the two independent molecules.¹¹⁹ Interestingly, the mean value of 146° is 1° larger than the value for [Sn(η⁵-C₅Me₅)]₂, suggesting that the angle is governed predominantly by electronic rather than steric factors. However, with the much more demanding η⁵-C₅Ph₅ ligand, the two planar C₅ rings are exactly parallel and staggered, the opposed canting of the phenyl rings with respect to the C₅ rings giving overall

Organometallic compounds

S\textsubscript{10} symmetry.\(^\text{120}\) Heterostannocenes such as the pyrrole analogue, [Sn(\(\eta^5\)-C\textsubscript{5}Bu\textsubscript{5}H\textsubscript{2}N\textsubscript{2})], (in which a CH group has been replaced by the isoelectronic N atom) have also been reported, the angle subtended by the ring centres at Sn being 142.5\(^\circ\) in this case.\(^\text{121}\) The related “half-sandwich” cation, nido-[(\(\eta^5\)-C\textsubscript{5}Me\textsubscript{5})Sn\textsuperscript{+}]\(^\text{\textmd{122}}\) which is isostructural with nido-B\textsubscript{6}H\textsubscript{10} (p. 154), can be made in moderate yield by treating [Sn(\(\eta^5\)-C\textsubscript{5}Me\textsubscript{5})\textsubscript{2}] with an ethereal solution of HBF\textsubscript{4}. The product, [(Sn\textsubscript{3}-C\textsubscript{5}Me\textsubscript{5})]BF\textsubscript{4}, forms colourless crystals which are somewhat sensitive to air and moisture.\(^\text{122}\) As its trifluoromethanesulfonate salt (X\textsuperscript{-} = CF\textsubscript{3}SO\textsubscript{3}\textsuperscript{-}), the cation undergoes a remarkable reaction with BI\textsubscript{3} which results in replacement of the apical Sn atom with the {BI} group to give a pentacarba analogue of nido-B\textsubscript{6}H\textsubscript{10}:\(^\text{123}\)

\begin{align*}
nido-[(\eta^5-C\textsubscript{5}Me\textsubscript{5})Sn]^+ + X^- + BI_3 &\rightarrow \\
nido-[(\eta^5-C\textsubscript{5}Me\textsubscript{5})BI]^+ + X^- + SnI_2
\end{align*}

The stabilization of \(\sigma\)-bonded dialkyltin(II) compounds, R\textsubscript{2}Sn, (and also those of Ge and Pb) can be achieved by the use of bulky R groups. The first such compound, [Sn(CH(SiMe\textsubscript{3})\textsubscript{2}]\textsubscript{2}], was prepared by direct reaction of LiCH(SiMe\textsubscript{3})\textsubscript{2} with SnCl\textsubscript{2} or [Sn(N(SiMe\textsubscript{3})\textsubscript{2}] in ether, and was obtained as air-sensitive red crystals (mp 136\(^\circ\)).\(^\text{124,125}\) It is monomeric in the gas phase and in benzene solution, and behaves chemically as a “stannylene”, displacing CO from M(CO)\textsubscript{6} to give orange [Cr(CO)\textsubscript{5}(SnR\textsubscript{2})] and yellow [Mo(CO)\textsubscript{5}(SnR\textsubscript{2})].\(^\text{124,126}\) However, a crystal structure determination showed that the compound dimerizes in the solid state, perhaps by donation of the lone-pair of electrons on each Sn centre into the “vacant” orbital of its neighbour, to give a weak bent double bond as indicated schematically below.\(^\text{125,127}\) This would interpret the orientation of the four \{-CH(SiMe\textsubscript{3})\textsubscript{2}\} groups.

A synthetic strategy which ensures retention of the monomeric form of SnR\textsubscript{2} even in the crystalline state is to use functionalized R groups which contain a chelating substituent, e.g. by replacing the H atom in \{-CH(SiMe\textsubscript{3})\textsubscript{2}\} with a 2-pyridyl group.\(^\text{128}\) Stable stannaethanethes, >C=Sn<,\(^\text{129}\) and stannaphosphenes, >Sn=P<,\(^\text{130}\) have been reported and these, again, exploit the use of bulky groups to prevent oligomerization.

The organic chemistry of Pb is much less extensive than that of Sn, though over 2000 organolead compounds are known and PbEt₄ has been produced on a larger tonnage than any other single organometallic compound (p. 371). The most useful laboratory-scale routes to organoleads involve the use of LiR, RMgX, or AlR₃ on lead(II) compounds such as PbCl₂, or lead(IV) compounds such as R₂PbX₂, R₃PbX, or K₂PbCl₆. On the industrial scale the reaction of RX on a Pb/Na alloy is much used; an alternative is the electrolysis of RMgX, M²BR₄, or M³AlR₄ using a Pb anode. The simple tetraalkyls are volatile, monomeric molecular liquids which can be steam-distilled without decomposition; PbPh₄ (mp 227–228°) is even more stable thermally: it can be distilled at 240° (15–20 mmHg) but decomposes above 270°. Diplumbanes Pb₂R₆ are much less stable and higher polyplumbanes are unknown except for the thermally unstable, reactive red solid, Pb(PbPh₃)₄.

The decreasing thermal stability of Group 14 organometallics with increasing atomic number of M reflects the decreasing M–C and M–M bond energies. This in turn is related to the increasing size of M and the consequent increasing interatomic distance (see table).

Parallel with these trends and related to them is the increase in chemical reactivity which is further enhanced by the increasing bond polarity and the increasing availability of low-lying vacant orbitals for energetically favourable reaction pathways.

It is notable that the preparation of alkyl and aryl derivatives from Pb¹⁺ starting materials always results in Pb¹⁺ organometallic compounds. The only well-defined examples of Pb¹⁺ organometallics are purple compound Pb[CH-(SiMe₃)₂]₂ (see refs on p. 403) and the cyclopentadienyl compound Pb(η⁵-C₅H₅)₂ and its ring-methyl derivative. Like the Sn analogue (p. 402) Pb(η⁵-C₅H₅)₂ features non-parallel cyclopentadienyl rings in the gas phase, the angle subtended at Pb being 135 ± 15°. Two crystalline forms are known and the orthorhombic polymorph has the unusual chain-like structure shown in Fig. 10.14: one C₅H₅ is between 2 Pb and perpendicular to the Pb–Pb vector whilst the other C₅H₅ is bonded (more closely) to only 1 Pb. The chain polymer can be thought to arise as a result of the interaction of the lone-pair of electrons on a given Pb atom with a neighbouring (chain) C₅H₅ ring; a 3-centre bond is constructed by overlapping 2 opposite sp² hybrids on 2 successive Pb atoms in the chain with the σMO (A'₂) of the C₅H₅ group: this forms one bonding, one nonbonding, and one antibonding MO of which the first 2 are filled and the third empty. By contrast, the deep red crystalline compound [Pb(η⁵-C₅Me₅)₂] (mp 100–105°) is monomeric; the angle subtended by the ring centres at Pb is 151° (i.e. even larger than in the Sn analogue) and there is a slight ring slippage.

---

C₆H₆ in which Pb⁺⁺ is in a distorted pentagonal bipyramidal site with 1 axial Cl and the other axial site occupied by the centre of the benzene ring (Fig. 10.15). The other C₆H₆ is a molecule of solvation far removed from the metal. One {AlCl₄} group chelates the Pb in an axial-equatorial configuration and the other {AlCl₄} chelates and bridges neighbouring Pb atoms to form a chain. There is a similar Sn⁺⁺ compound with the same structure. The original paper should be consulted for a discussion of the bonding.¹³³

The coordination chemistry of Pb⁺⁺ with conventional ligands from groups 14–16 and with macrocyclic ligands has recently been reviewed.¹³⁴

Figure 10.15 Schematic diagram of the chain structure of [Pb⁺⁺(AlCl₄)₂(η⁶-C₆H₆)]₆C₆H₆; Pb–Cl varies from 285–322 pm, Pb–C₆H₆ (bound) 311 pm, Pb-centre of C₆H₆ (bound) 277 pm.

which leads to a range of Pb–C distances (269–290 pm) to the pentahapto rings.

Another unusual organo-Pb⁺⁺ compound is the η⁶-benzene complex [Pb⁺⁺(AlCl₄)₂(η⁶-C₆H₆)].

11
Nitrogen

11.1 Introduction

Nitrogen is the most abundant uncombined element accessible to man. It comprises 78.1% by volume of the atmosphere (i.e. 78.3 atom% or 75.5 wt%) and is produced industrially from this source on the multimegatonne scale annually. In combined form it is essential to all forms of life, and constitutes, on average, about 15% by weight of proteins. The industrial fixation of nitrogen for agricultural fertilizers and other chemical products is now carried out on a vast scale in many countries, and the number of moles of anhydrous ammonia manufactured exceeds that of any other compound. Indeed, of the top fifteen "high-volume" industrial chemicals produced in the USA, five contain nitrogen (Fig. 11.1).(1)

This has important consequences, predominantly beneficial but occasionally detrimental, since of all man's recent interventions in the cycles of nature the industrial fixation of nitrogen is by far the most extensive. These aspects will be discussed further in later sections.

The "discovery" of nitrogen in 1772 is generally credited to Daniel Rutherford, though the gas was also isolated independently about the same time by both C. W. Scheele and H. Cavendish.(2) Rutherford (at the suggestion of his teacher Joseph Black who had earlier discovered CO\textsubscript{2}, p. 269) was studying the properties of the residual "air" left after carbonaceous substances were burned in a limited supply of air; he removed the CO\textsubscript{2} by means of KOH and so obtained nitrogen which he thought was ordinary air that had taken up phlogiston from the combusted material. The elementary nature of nitrogen was disputed by some even as late as 1840 despite the work of A. L. Lavoisier. The name "nitrogen" was suggested by Jean-Antoine-Claude Chaptal in 1790 when it was realized that the element was a constituent of nitric acid and nitrates (Greek νυτρоν, nitron; γεννάω, to form). Lavoisier preferred azote (Greek ἀζωτικός, no life) because

---

§11.2.1 Abundance and distribution

of the asphyxiating properties of the gas, and this name is still used in the French language and in such forms as azo, diazo, azide, etc. The German name Stickstoff refers to the same property (sticken, to choke or suffocate).

Compounds of nitrogen have an impressive history. Ammonium chloride was first mentioned in the Historia of Herodotus (fifth century BC) and ammonium salts, together with nitrates, nitric acid and aqua regia, were well known to the early alchemists. Some important dates in the subsequent development of the chemistry of nitrogen are given in the Panel on p. 408. Exciting discoveries are still being made at the present time and, indeed, the detailed mechanisms by which bacteria fix nitrogen at ambient temperatures and pressures is still an active area of research. Several recent reviews, monographs, and proceedings of symposia have been published.

11.2 The Element

11.2.1 Abundance and distribution

Despite its ready availability in the atmosphere, nitrogen is relatively unabundant in the crustal rocks and soils of the earth. At 19 ppm it is equal 33rd with Ga in the order of abundance, and similar to Nb (20 ppm) and Li (18 ppm). The only major minerals are KNO₃ (nitre, saltpetre) and NaN₃ (sodanitre, Chile saltpetre). Both occur widespread, usually in small amounts as evaporites in arid regions, often as an efflorescence on soils or in caverns. KNO₃ is isomorphous with calcite (p. 109) whereas NaN₃ is isomorphous with aragonite (p. 109), thus reflecting the similar size of NO₃⁻ and CO₃²⁻, and the fact that K⁺ is considerably larger than Na⁺ and Ca²⁺. Major deposits of KNO₃ occur in India and there are smaller amounts in Bolivia, Italy, Spain and the former Soviet Union. There are vast deposits of NaN₃ in the desert regions of northern Chile where it occurs with other evaporites such as NaCl, Na₂SO₄ and

---

Note: Because of the very low m.wt of NH₃, the number of moles of this compound produced (1.06 × 10¹¹) is 2.4 times greater than that of H₂SO₄ (0.448 × 10¹¹). Similarly the number of moles of N₂ produced (1.30 × 10¹²) is 2.9 times that of H₂SO₄.

</table>

The continuous interchange of nitrogen between the atmosphere and the biosphere is called the nitrogen cycle. Global estimates are difficult to obtain and there are frequently regional and local impacts which vary greatly from the mean. However, some indication of the size of the various “reservoirs” of nitrogen in the atmosphere, on land, and in the seas is
§11.2.2 Production and uses of nitrogen

given in Fig. 11.2 together with the estimated annual rate of transfer between these various pools.\(^7\)\(^8\) Estimates frequently vary by a factor of 3 or more. Atmospheric nitrogen is fixed by biological action (p. 1035), industrial processes (p. 421), and to a significant extent by fires, lightning and other atmospheric discharges which produce NO\(_x\). There is also a minute production (on the global scale) of NO\(_x\) from internal combustion engines and from coal-burning, though the local concentration in some urban environments can be very high and extremely unpleasant.\(^9\)\(^-\)\(^11\) Absorption of fixed nitrogen by both terrestrial and aquatic plants leads to protein synthesis followed by death, decay, oxidation and denitrification by bacterial and other action which eventually returns the nitrogen to the seas and the atmosphere as N\(_2\). An alternative sequence involves the digestion of plants by animals, the synthesis of animal proteins, excretion of nitrogenous material, and, again, ultimate death, decay and denitrification. Figure 11.2 indicates that the greatest anthropogenic impact on the cycle arises from the industrial fixation of nitrogen by the Haber and other processes. Much of this is used beneficially as fertilizers but the leaching of excess nitrogenous material can lead to eutrophication in freshwater systems, and the increased nitrate concentration in waters used for human consumption can pose a health hazard. Nevertheless, there is no doubt that the high yields of agriculture necessary to maintain even the present human population of the world cannot be achieved without the judicious application of manufactured nitrogenous fertilizers. Concern has also been expressed that increasing levels of N\(_2\)O following denitrification may eventually impoverish the ozone layer in the stratosphere. Much more data are required and the subject is being actively pursued by several international agencies as well as by national and local governments and individual scientists.

11.2.2 Production and uses of nitrogen

The only important large-scale process for producing N\(_2\) is the liquefaction and fractional distillation of air\(^12\) (see Panel on p. 411). Production has grown remarkably during the past few years, partly as a result of the increasing demand for its coproduct O\(_2\) for steelmaking. For example, US domestic production has increased 250-fold in the past 25 y from 0.12 million tonnes in 1955 to 30 million tonnes in 1980. In 1991 world production was 56 million tonnes (USA 47%; Europe 35%; Asia 15%). Commercial N\(_2\) is a highly purified product, typically containing less than 20 ppm O\(_2\). Specially purified “oxygen-free” N\(_2\), containing less than 2 ppm, is available commercially, and “ultrapure” N\(_2\) (99.999%) containing less than 10 ppm Ar is also produced on the multitonne per day scale.

Laboratory routes to highly purified N\(_2\) are seldom required. Thermal decomposition of sodium azide at 300°C under carefully controlled conditions is one possibility:

\[
2\text{NaN}_3 \rightarrow 2\text{Na} + 3\text{N}_2
\]

Hot aqueous solutions of ammonium nitrite also decompose to give nitrogen though small amounts of NO and HNO\(_3\) are also formed (p. 434) and must be removed by suitable absorbents such as dichromate in aqueous sulfuric acid:

\[
\text{NH}_4\text{NO}_2 \xrightarrow{\text{aq}} \text{N}_2 + 2\text{H}_2\text{O}
\]

Other routes are the thermal decomposition of (NH\(_4\))\(_2\)Cr\(_2\)O\(_7\), the reaction of NH\(_3\) with bromine water, or the high-temperature reaction of NH\(_3\)
Figure 11.2  Distribution of nitrogen in the biosphere and annual transfer rates can be estimated only within broad limits. The two quantities known with high confidence are the amount of nitrogen in the atmosphere and the rate of industrial fixation. The inventories (within the boxes) are expressed in terms of $10^9$ tonnes of N; the transfers (indicated by arrows) are in $10^6$ tonnes of N. Taken from ref. 7 with some adjustments for more recent data.
Industrial Gases from Air

Air is the source of six industrial gases, N₂, O₂, Ne, Ar, Kr and Xe. As the mass of the earth’s atmosphere is approximately \(5 \times 10^9\) million tonnes, the supply is unlimited and the annual industrial production, though vast, is insignificant by comparison. The composition of air at low altitudes is remarkably constant, the main variable component being water vapour which ranges from \(~4\%\) by volume in tropical jungles to very low values in cold or arid climates. Other minor local variations result from volcanism or human activity. The main invariant part of the air has the following composition (% by volume, bp in parentheses):

<p>| | | | | |</p>

</tbody>
</table>

Details of the production and uses of O₂ (p. 604) and the noble gases (p. 889) are in later chapters.

About two-thirds of the N₂ produced industrially is supplied as a gas, mainly in pipes but also in cylinders under pressure. The remaining one-third is supplied as liquid N₂ since this is also a very convenient source of the dry gas. The main use is as an inert atmosphere in the iron and steel industry and in many other metallurgical and chemical processes where the presence of air would involve fire or explosion hazards or unacceptable oxidation of products. Thus, it is extensively used as a purge in petrochemical reactors and other chemical equipment, as an inert diluent for chemicals, and in the float glass process to prevent oxidation of the molten tin (p. 370). It is also used as a blanketing gas in the electronics industry, in the packaging of processed foods and pharmaceuticals, and to pressurize electric cables, telephone wires, and inflatable rubber tyres, etc.

About 10% of the N₂ produced is used as a refrigerant. Typical of such applications are (a) freeze grinding of normally soft or rubbery materials, (b) low-temperature machining of rubbers, (c) shrink fitting and assembly of engineering components, (d) the preservation of biological specimens such as blood, semen, etc., and (e) as a constant low-temperature bath (~196°C). Liquid N₂ is also frequently used for convenience in applications where a very low temperature is not essential such as (a) food freezing (and hamburger meat grinding), (b) in-transit refrigeration, (c) freeze branding of cattle, (d) pipe-freezing for stopping flow in the absence of valves, and (e) soil-freezing for consolidating unstable ground in tunnelling or excavation.

The cost of N₂, like that of O₂, is particularly dependent on electricity costs, though plant maintenance and transport costs also obtrude. Typical prices in 1992 for N₂ in the USA were about $32 per tonne for bulk liquid (exclusive of transportation and handling charges). Costs for small-scale users of N₂ from gas cylinders are proportionately much higher.

with CuO; overall equations can be written as:

\[(\text{NH}_4)_2\text{Cr}_2\text{O}_7 \rightarrow \text{N}_2 + \text{Cr}_2\text{O}_3 + 4\text{H}_2\text{O}\]

\[8\text{NH}_3 + 3\text{Br}_2 \xrightarrow{\text{aq}} \text{N}_2 + 6\text{NH}_4\text{Br(aq)}\]

\[2\text{NH}_3 + 3\text{CuO} \rightarrow \text{N}_2 + 3\text{Cu} + 3\text{H}_2\text{O}\]

11.2.3 Atomic and physical properties

Nitrogen has two stable isotopes \(^{14}\text{N}\) (relative atomic mass 14.00307, abundance 99.634%) and \(^{15}\text{N}\) (15.00011, 0.366%); their relative abundance (272:1) is almost invariant in terrestrial sources and corresponds to an atomic weight of 14.00674(7). Both isotopes have a nuclear spin and can be used in nmr experiments.\(^{13}\) though the sensitivity at constant field is only one-thousandth that of \(^{1}\text{H}\). The \(^{14}\text{N}\) nucleus has a spin quantum number of 1 and, in consequence, the spectra are broadened by quadrupole effects. The \(^{15}\text{N}\) nucleus with spin \(\frac{1}{2}\) does not have this difficulty though its low abundance poses problems.\(^{14}\) Interestingly, the first chemical shift ever to be observed in nmr spectroscopy ("as an annoying ambiguity in the magnetic moment of \(^{14}\text{N}\)") was in 1950 in an aqueous solution of NH₄NO₃.\(^{15}\) Nowadays \(^{14}\text{N}\) and \(^{15}\text{N}\) nmr chemical shifts are widely used to probe the

---

nature of bonding in N-containing compounds, to study structural features (e.g. linear, bent, encapsulated N), to determine the site of coordination or protonation, to follow kinetically the course of chemical reactions and to detect new species.

Isotopic enrichment of $^{15}$N is usually effected by chemical exchange, and samples containing up to 99.5% $^{15}$N have been obtained from the 2-phase equilibrium

$$^{15}\text{NO}(g) + ^{14}\text{NO}_3^-(aq) \rightleftharpoons ^{14}\text{NO}(g) + ^{15}\text{NO}_3^-(aq)$$

Other exchange reactions that have been used are:

$$^{15}\text{NH}_3(g) + ^{14}\text{NH}_4^+(aq) \rightleftharpoons ^{14}\text{NH}_3(g) + ^{15}\text{NH}_4^+(aq)$$

$$^{15}\text{NO}(g) + ^{14}\text{NO}_2(g) \rightleftharpoons ^{14}\text{NO}(g) + ^{15}\text{NO}_2(g)$$

Fractional distillation of NO provides another effective route and, as the heavier isotope of oxygen is simultaneously enriched, the product has a high concentration of $^{15}$N$^{18}$O. Many key nitrogen compounds are now commercially available with $^{15}$N enriched to 5%, 30% or 95%, e.g. N$_2$, NO, NO$_2$, NH$_3$, HNO$_3$ and several ammonium salts and nitrates. Fortunately the use of these compounds in tracer experiments is simplified by the absence of exchange with atmospheric N$_2$ under normal conditions, in marked contrast with labelled H, C and O compounds where contract with atmospheric moisture and CO$_2$ must be avoided.

The ground state electronic configuration of the N atom is $1s^22s^22p^1$ with three unpaired electrons ($^3S$). The electronegativity of N (~3.0) is exceeded only by those of F and O. Its "single-bond" covalent radius (~70 pm) is slightly smaller than those of B and C, as expected; the nitride ion, N$^3-$, is much larger and has been assigned a radius in the range 140–170 pm. Ionization energies and other properties are compared with those of the other Group 15 elements (P, As, Sb and Bi) on p. 550.

Molecular N$_2$, i.e. dinitrogen (see p. 34), (mp -210°C, bp -195.8°C) is a colourless, odourless, tasteless, diamagnetic gas. The short interatomic distance (109.76 pm) and very high dissociation energy (945.41 kJ mol$^{-1}$) are both consistent with multiple bonding. The free-energy change for the equilibrium N$_2 \rightleftharpoons 2$N is $\Delta G = 911.13$ kJ mol$^{-1}$ from which it is clear that the dissociation constant $K_p = [N]^2/[N_2]$ atm is negligible under normal conditions; it is $1.6 \times 10^{-24}$ atm at 2000 K and still only $1.3 \times 10^{-12}$ atm at 4000 K. Detailed tabulations of other physical properties of nitrogen are available.$^{16}$

### 11.2.4 Chemical reactivity

Gaseous N$_2$ is rather inert at room temperature presumably because of the great strength of the N≡N bond and the large energy gap between the highest occupied molecular orbitals (HOMO) and the lowest unoccupied molecular orbitals (LUMO). Further contributory factors are the very symmetrical electron distribution in the molecule and the absence of bond polarity — when these are modified, as in the isoelectronic analogues CO, CN$^-$ and NO$^+$, the reactivity is considerably enhanced. Nitrogen reacts readily with Li at room temperature (p. 76) and with several transition-element complexes (p. 414).

Reactivity increases rapidly with rising temperature and the element combines directly with Be, the alkaline earth metals, and B, Al, Si and Ge to give nitrides (p. 417); hydrogen yields ammonia (p. 421), and coke yields cyanogen, (CN)$_2$, when heated to incandescence (p. 320). Many finely divided transition metals also react directly at elevated temperatures to give nitrides of general formula MN (M = Sc, Y, lanthanoids; Zr, Hf; V; Cr, Mo, W; Th, U, Pu). Although not always directly preparable from N$_2$(g), many other nitrides are known (p. 417) and, indeed, nitrides as a class include some of the most stable compounds in the whole of chemistry. Nitrogen forms bonds with almost all elements in the periodic table, the only exceptions apparently being the noble gases (other than Xe and Kr, pp. 902, 904). A wide range of stereochemistries is observed and

</table>

(a) For coordination numbers 1, 2, and 3 the CN is sometimes increased in the condensed phase as a result of H bonding (p. 52), e.g. HCN, NH₂⁻, NH₃, N₂H₄, NH₂(OH), NO₂⁻, (OH). Typical examples of coordination numbers 0, 1, 2, 3, 4, 5, 6, and 8 are given in Table 11.1.

A particularly reactive form of nitrogen can be obtained by passing an electric discharge through N₂(g) at a pressure of 0.1–2 mmHg.Atomic N is formed, and the process is accompanied by a peach-yellow emission which persists as an afterglow, often for several minutes after the discharge.

11.2.4 Chemical reactivity

---

Nitrogen

has been stopped. Atoms of N in their ground state \(^4S\) have a relatively long lifetime since recombination involves either a 3-body collision on the surface of the vessel (first-order reaction in N at pressures below \(\sim 3\) mmHg) or a termolecular homogeneous association reaction (second order in N at pressures above \(\sim 3\) mmHg):

\[
N(4S) + N(4S) \xrightarrow{\text{M}} N_2^* \rightarrow N_2 + h\nu (\text{yellow}) \quad (1)
\]

The molecules of \(N_2^*\) so formed are in an excited state \((B^3\Pi_g)\) and give rise to the emission of the first positive band system of the spectrum of molecular \(N_2\) in returning to the ground state \((A^3\Sigma_g^+)\).

Several elements react with the N atoms in active nitrogen to form nitrides. The excited \(N_2\) molecules are also highly reactive and can cause the dissociation of molecules that are normally stable to attack either by ordinary \(N_2\) or even N atoms, e.g.:

\[
N_2^* + CO_2 \rightarrow N_2 + CO + O(3P) \\
N_2^* + H_2O \rightarrow N_2 + OH(2\Pi) + H(2S).
\]

One of the most dramatic developments in the chemistry of \(N_2\) during the past 30 years was the discovery by A. D. Allen and C. V. Senoff in 1965 that dinitrogen complexes such as [Ru(NH\(_3\))\(_5\)(N\(_2\))]\(^{2+}\) could readily be prepared from aqueous RuCl\(_3\) using hydrazine hydrate in aqueous solution.\(^{28}\) Since that time virtually all transition metals have been found to give dinitrogen complexes and several hundred such compounds are now characterized.\(^{29,30}\)

Three general preparative methods are available:

(a) Direct replacement of labile ligands in metal complexes by \(N_2\): such reactions proceed under mild conditions and are often reversible, e.g.:

\[
[Ru(NH\(_3\))\(_5\)(H\(_2\)O)]^{2+} + N_2 \xrightleftharpoons{\text{H}_{2}O} \xrightarrow{\text{EtOH}} [Ru(NH\(_3\))\(_5\)(N\(_2\))]^{2+} \text{pale yellow}
\]

\[
[CoH\(_3\)(PPh\(_3\))] + N_2 \xrightleftharpoons{\text{H}_{2}O} \xrightarrow{\text{EtOH}} \text{H}_2
\]

\[
[CoH(N\(_2\))(PPh\(_3\))] \text{orange-red}
\]

\[
2[Cr(C\(_6\)Me\(_6\))(CO)\(_3\)] + N_2 \rightarrow 2\text{CO}
\]

\[
+ [(Cr(C\(_6\)Me\(_6\))(CO)\(_2\))]_{2}N_2 \text{red-brown}
\]

(b) Reduction of a metal complex in the presence of an excess of a suitable coligand under \(N_2\), e.g.:

\[
[\text{MoCl\(_4\)}(PMe\(_2\)Ph)\(_2\)] + 2N\(_2\) \rightarrow \text{cis-[Mo(N\(_2\))\(_2\)](PMe\(_2\)Ph)\(_4\)\]
\]

\[
[\text{WCl\(_4\)}(PMe\(_2\)Ph)\(_2\)] + 2N\(_2\) \rightarrow \text{cis-[W(N\(_2\))\(_2\)](PMe\(_2\)Ph)\(_4\)\]
\]

\[
[\text{FeClH(depe)\(_2\)] + N\(_2\) \rightarrow \text{trans-[Fe(depe)\(_2\)]H(N\(_2\))\]
\]

\[
[\text{Ni(acac)\(_2\)] + 4PCy\(_3\) + N\(_2\) \rightarrow [\text{Ni(N\(_2\))}2(\text{PCy\(_3\))2]\]
\]

\[
\text{Mg/therm} \rightarrow \text{cis-[Mo(N\(_2\))\(_2\)](PMe\(_2\)Ph)\(_4\)\]
\]

(c) Conversion of a ligand with \(N-N\) bonds into \(N_2\); in the early development of \(N_2\) complex chemistry this was the most successful and widely used route, e.g.:

\[
[\text{Mn(}\eta^1\text{-C}_3\text{H}_5\text{(CO)\(_2\)](N\(_2\)H\(_4\))] + 2\text{H}_2\text{O}
\]

\[
\xrightarrow{\text{Ca}^{11}\text{therm} - 40^\circ} 4\text{H}_2\text{O}
\]

\[
+ [\text{Mn(}\eta^1\text{-C}_3\text{H}_5\text{(CO)\(_2\)](N\(_2\))\]
\]

\[
\text{red-brown}
\]

---

\(^{28}\) A. D. ALLEN and C. V. SENOFF, Chem. Commun., 1965, 621–2. The unprecedented nature of the reaction can be gauged from the fact that this paper was rejected for publication by J. Am. Chem. Soc. on the grounds that it was impossible, before being accepted by Chem. Commun., See also H. TAUBE, The researches of A. D. Allen — an appreciation, Coord. Chem. Rev. 26, 1–5 (1978).

Chemical reactivity 415

\[
\begin{align*}
\text{(PPh}_3)_2\text{Cl}_2\text{Re} & \rightarrow \text{N}=\text{N} \rightarrow \text{CPh} + 2\text{PPh}_3 \\
\text{MeOH} & \rightarrow \text{HCl} + \text{PhCO}_2\text{Me} \\
+ \text{trans-}[\text{ReCl}(\text{N}_2)(\text{PPh}_3)_4] & \text{yellow} \\
[\text{RuCl}(\text{das})_2(\text{N}_3)]PF_6 + \text{NOPF}_6 & \rightarrow \\
[\text{RuCl}(\text{das})_2(\text{N}_3)] & \text{white, plus byproducts} \\
\text{trans-}[\text{Ir}(\text{CO})\text{Cl}(\text{PPh}_3)_2] & + \text{PhCON}_3 \\
\text{CHCl}_3/\text{O}^* & \rightarrow \text{trans-}[\text{IrCl}(\text{N}_2)(\text{PPh}_3)_2] \text{yellow}
\end{align*}
\]

A related example is the reaction of NbCl\(_5\) and thf with \((\text{Me}_3\text{Si})_2\text{NN(SiMe}_3)_2\) in CH\(_2\text{Cl}_2\) to give an 80% yield of \([\mu-\text{N}_2](\text{NbCl}_3(\text{thf})_2)_2]\).\(^{31}\) Occasionally an N≡N triple bond can be formed within a metal complex, e.g. by reaction of coordinated NH\(_3\) with HNO\(_2\), but this method is of limited application, e.g.:

\[
[\text{Os}(\text{N}_2)(\text{NH}_3)_3]^{2+} + \text{HNO}_2 \rightarrow 2\text{H}_2\text{O} \\
+ \text{cis-}[\text{Os}(\text{N}_2)_2(\text{NH}_3)_4]
\]

Frequently dinitrogen complexes have colours in the range white-yellow-orange-red-brown but other colours are known, e.g. \([\text{Ti}(\eta^5-\text{C}_5\text{H}_5)_2\text{N}(\eta^1-\text{N}_2)]\) is blue.

Dinitrogen might coordinate to metals in at least 4 ways,\(^{32}\) but only the end-on modes, structures (1) and (2), are well established as common bonding modes by numerous well-defined examples:

\[
\begin{align*}
(1) & \text{N} \equiv \text{N} & (2) & \mu(\text{bis-}\eta^1) \\
(3) & \mu(\text{bis-}\eta^2) & (4) & \eta^2
\end{align*}
\]

The side-on structure (3) has been established in two dinickel complexes which have very complicated structures involving lithium atoms also in association with the bridging N\(_2\).\(^{33}\) It also occurs in the first fully characterized N\(_2\) complex of a lanthanide element, \([\mu-\eta^2-\eta^2-\text{N}_2][\text{Sm}(\eta^5-\text{C}_5\text{Me}_5)_2]_2]\).\(^{34}\) The “side-on” \(\eta^2\) mode (structure 4) was at one time thought to be exemplified by the rhodium(I) complex \([\text{RhCl}(\text{N}_2)(\text{PPh}_3)_2])\) but a reinvestigation of the X-ray structure by another group\(^{35}\) showed conclusively that the N\(_2\) ligand was coordinated in the “end-on” mode (1) — an instructive example of mistaken conclusions that can initially be drawn from this technique. The side on structure (4) has been postulated for the zirconium(III) complex \([\text{Zr}(\eta^5-\text{C}_5\text{H}_5)(\text{N}_2)]\) on the basis of its \(\text{^{15}N}\) nmr spectrum.\(^{36}\) A unique triply-coordinated bridging mode \((\mu-3-\text{N}_2)\) has also recently been established by X-ray crystallography.\(^{37}\)

Complexes are known which feature more than one N\(_2\) ligand, e.g. cis-\([\text{W}(\text{N}_2)_2(\text{PMe}_3\text{Ph})_4]\) and trans-\([\text{W}(\text{N}_2)_2(\text{diphos})_2]\) (where diphos = Ph\(_2\text{PCH}_2\text{CH}_2\text{PPh}_2\)) and some complexes feature more than one bonding mode, e.g.:\(^{38}\)

\[
[\text{Zr}(\eta^5-\text{C}_5\text{Me}_5)_2(\eta^1-\text{N}_2)][\text{Zr}(\eta^1-\text{N}_2)-\eta^2-\text{C}_5\text{Me}_5]_2]
\]

The first example of a tris-N₂ complex is the yellow crystalline compound mer-[Mo(η¹-N₂)₃(PPr₃Ph)₃].

X-ray structural studies have shown that for N₂ complexes with structure (I), the M–N–N group is linear or nearly so (172–180°); the N–N internuclear distance is usually in the range 110–113 pm, only slightly longer than in gaseous N₂ (109.8 pm). Such complexes have a strong sharp, infrared absorption in the range 1900–2200 cm⁻¹, corresponding to the Raman-active band at 2331 cm⁻¹ in free N₂. Similarly, in complexes with structure (2), when both transition metals have a closed d-shell, the N–N distance falls in the range 112–120 pm and v(N–N) often occurs near 2100 cm⁻¹, i.e. little altered from that of the corresponding complexes of structure (1). On the other hand, if one of the M is a transition metal with a closed d-shell and the other is either a main-group metal such as Al in AlMe₃ or an open-shell transition metal such as Mo in MoCl₄, then the N–N bond is greatly lengthened and the N–N stretching frequency is lowered even to 1600 cm⁻¹. Compounds with structure (3) have N–N ~134–136 pm, and this very substantial lengthening has been attributed to interaction with the Li atoms in the structure.

As implied above, N₂ is isoelectronic with both CO and C₂H₂, and the detailed description of the bonding in structures 1–4 follows closely along the lines indicated on pp. 927 and 932 though there are some differences in the detailed sequences of orbital energies. Crystallographic and vibrational spectroscopic data have been taken to indicate that N₂ is weaker than CO in both its σ-donor and π-acceptor functions. Theoretical studies suggest that σ donation is more important for the formation of the M–N bond than is π back-donation, which mainly contributes to the weakening of the N–N bond, and end-on (η¹) donation is more favourable than side-on (η²).

The chemical reactivity of coordinated N₂ has been extensively studied because of its potential relevance to the catalytic and biological fixation of N₂ to NH₃ (p. 1035). For other recent work on the reactions of coordinated dinitrogen see refs. 41–44.

To conclude this section on the chemical reactivity of nitrogen it will be helpful to compare the element briefly with its horizontal neighbours C and O, and also with the heavier elements in Group 15, P, As, Sb and Bi. The diagonal relationship with S is vestigial. Nitrogen resembles oxygen in its high electronegativity and in its ability to form H bonds (p. 52) and coordination complexes (p. 198) by use of its lone-pair of electrons. Catenation is more limited than for carbon, the longest chain so far reported being the N₈ unit in PhN—N—N(Ph)—N═N—N(Ph)—N═NPh.

Nitrogen shares with C and O the propensity for multiple bonding via pₓ–pₓ interactions both with another N atom or with a C or O atom. In this it differs sharply from its Group 15 congeners which have no analogues of the oxides of nitrogen, nitrites, nitrates, nitro-, nitroso-, azo- and diazo-compounds, azides, cyanates, thiocyanates or imino-derivatives. Conversely, there are no nitrogen analogues of the various oxoacids of phosphorus (p. 510).

### 11.3 Compounds

This section deals with the binary compounds that nitrogen forms with metals, and then describes the extensive chemistry of the hydrides, halides, pseudohalides, oxides and oxoacids of the element. The chemistry of P–N compounds is deferred until Chapter 12 (p. 531) and S–N...

---

compounds are discussed in Chapter 15 (p. 721). Compounds with B (p. 207) and C (p. 319) have already been treated.

11.3.1 Nitrides, azides and nitrido complexes

Nitrogen forms binary compounds with almost all elements of the periodic table and for many elements several stoichiometries are observed, e.g. MnN, Mn$_6$N$_5$, Mn$_3$N$_2$, Mn$_2$N, Mn$_4$N and Mn$_x$N ($9.2 < x < 25.3$). Nitrides are frequently classified into 4 groups: "salt-like", covalent, "diamond-like" and metallic (or "interstitial"). The remarks on p. 64 concerning the limitations of such classifications are relevant here. The two main methods of preparation are by direct reaction of the metal with N$_2$ or NH$_3$ (often at high temperatures) and the thermal decomposition of metal amides, e.g.:

$$3\text{Ca} + \text{N}_2 \rightarrow \text{Ca}_3\text{N}_2$$

$$3\text{Mg} + 2\text{NH}_3 \rightarrow 900^\circ \text{Mg}_3\text{N}_2 + 3\text{H}_2$$

$$3\text{Zn(NH}_2)_2 \rightarrow \text{Zn}_3\text{N}_2 + 4\text{NH}_3$$

Common variants include reduction of a metal oxide or halide in the presence of N$_2$ and the formation of a metal amide as an intermediate in reactions in liquid NH$_3$:

$$\text{Al}_2\text{O}_3 + 3\text{C} + \text{N}_2 \rightarrow 2\text{AlN} + 3\text{CO}$$

$$2\text{ZrCl}_4 + \text{N}_2 + 4\text{H}_2 \rightarrow 2\text{ZrN} + 8\text{HCl}$$

$$3\text{Ca} + 6\text{NH}_3 \rightarrow 3\text{Ca(NH}_2)_2$$

$$\quad \rightarrow \text{Ca}_3\text{N}_2 + 4\text{NH}_3$$

Metal nitrides have also been prepared by adding KNH$_2$ to liquid-ammonia solutions of the appropriate metal salts in order to precipitate the nitride, e.g. Cu$_3$N, Hg$_3$N$_2$, AlN, Tl$_3$N and BiN.

"Salt-like" nitrides are exemplified by Li$_3$N (mp 548°C, decomp) and M$_3$N$_2$ (M = Be, Mg, Ca, Sr, Ba). It is possible to write ionic formulations of these compounds using the species $\text{N}^{3-}$ though charge separation is unlikely to be complete, particularly for the corresponding compounds of Groups 11 and 12, i.e. Cu$_3$N, Ag$_3$N, and M$_3$N$_2$ (M = Zn, Cd, Hg). The $\text{N}^{3-}$ ion has been assigned a radius of 146 pm, slightly larger than the value for the isoelectronic ions $\text{O}^{2-}$ (140 pm) and $\text{F}^{-}$ (133 pm), as expected. Stability varies widely; e.g. Be$_3$N$_2$ melts at 2200°C whereas Mg$_3$N$_2$ decomposes above 271°C. The existence of Na$_3$N is doubtful and the heavier alkali metals appear not to form analogous compounds, perhaps for steric reasons (p. 76). However the azides NaN$_3$ and KN$_3$ are well characterized as colourless crystalline salts which can be melted with little decomposition; they feature the symmetrical linear $\text{N}^{3-}$ group as do Sr(N$_3$)$_2$ and Ba(N$_3$)$_2$. The corresponding "B subgroup" metal azides such as Ag(N$_3$)$_2$, Cu(N$_3$)$_2$, and Pb(N$_3$)$_2$ are shock-sensitive and detonate readily; they are far less ionic and have more complex structures. Further discussion of azides is on p. 433. Other stoichiometries are also known, e.g. Ca$_3$N (anti-CdCl$_2$ layer structure), Ca$_3$N$_4$, and Ca$_{11}$N$_8$.

The covalent binary nitrides are more conveniently treated under the appropriate element. Examples include cyanogen (CN)$_2$ (p. 320), P$_3$N$_5$ (p. 531), S$_2$N$_2$ (p. 725) and S$_4$N$_4$ (p. 722). The Group 13 nitrides MN (M = B, Al, Ga, In, Tl) are a special case since they are isoelectronic with graphite, diamond, SiC, etc., to which they are structurally related (p. 255). Their physical properties suggest a gradation of bond-type from covalent, through partially ionic, to essentially metallic as the atomic number increases. Si$_3$N$_4$ and Ge$_3$N$_4$ are also known and have the phenacite (Be$_2$SiO$_4$)-type structure. Si$_3$N$_4$, in particular, has excited considerable interest in recent years as a ceramic material with extremely desirable properties: high strength and wear resistance, high decomposition temperature and oxidation resistance, excellent thermal-shock properties and resistance to corrosive environments, low coefficient of friction, etc. Unfortunately it is extremely difficult to fabricate and sinter suitably shaped components, and considerable efforts have therefore been spent on developing related nitrogen ceramics by forming
solid solutions between Si$_3$N$_4$ and Al$_2$O$_3$ to give the “sialons” (SiAlON) of general formula Si$_6-x$Al$_{6x}$O$_x$N$_{8-x}$ (0 < x < 6).\(^{45}\)

The most extensive group of nitrides are the metallic nitrides of general formulae MN, M$_2$N, and M$_4$N in which N atoms occupy some or all of the interstices in cubic or hcp metal lattices (examples are in Table 11.1, p. 413). These compounds are usually opaque, very hard, chemically inert, refractory materials with metallic lustre and conductivity and sometimes having variable composition. Similarities with borides (p. 145) and carbides (p. 297) are notable. Typical mps (°C) are:

<table>

Hardness on the Mohs scale is often above 8 and sometimes approaches 10 (diamond). These properties commend nitrides for use as crucibles, high-temperature reaction vessels, thermocouple sheaths and related applications. Several metal nitrides are also used as heterogeneous catalysts, notably the iron nitrides in the Fischer-Tropsch hydriding of carbonyls. Few chemical reactions of metal nitrides have been studied; the most characteristic (often extremely slow but occasionally rapid) is hydrolysis to give ammonia or nitrogen:

\[
2\text{AlN} + (n + 3)\text{H}_2\text{O} \rightarrow \text{Al}_2\text{O}_3\cdot n\text{H}_2\text{O} + 2\text{NH}_3
\]

\[
2\text{VN} + 3\text{H}_2\text{SO}_4 \rightarrow \text{V}_2(\text{SO}_4)_3 + \text{N}_2 + 3\text{H}_2
\]

The crystal chemistry of metal nitrides has been reviewed\(^{45a}\) and there have recently been some intriguing developments in our understanding of the stoichiometries and structures of ternary and quaternary metal nitrides.\(^{45b}\)

The nitride ion N$_3^-$ is an excellent ligand, particularly towards second- and third-row transition metals.\(^{46}\) It is considered to be by far the strongest π donor known, the next strongest being the iso-electronic species O$_2^-$. Nitrido complexes are usually prepared by the thermal decomposition of azides (e.g. those of phosphine complexes of V$^V$, Mo$^VI$, W$^VI$, Ru$^VI$, Re$^V$) or by dehydration of NH$_3$ (e.g. [OsO$_2$→O$\text{S}$O$_3$$^-$N$^-$]). Most involve a terminal [≡N]$_3^-$ group as in [VCl$_3$N]$^-$, [MoO$_3$N]$^-$, [WC$_5$N]$^{2^-}$, [ReN(PR$_3$)$_3$X$_2$] and [RuN(OH$_2$)$_4$]$^{4^-}$. The M–N distance is much shorter (by 40–50 pm) than the “normal” σ-(M–N) distance, consistent with strong multiple bonding. Other bonding modes feature linear symmetrical bridging as in [(H$_2$O)$_4$Cr–N–RuC$(O$_2$H$_2$)]$^{3^-}$, trigonal planar μ$_3$ bridging as in [(H$_2$O)(SO$_4$)$_2$IrN]$^{4^-}$, and tetrahedral coordination as in [(Me$_2$H$_2$)$_4$N]$^{1^-}$ (Fig. 11.3). The nitrido ligand has a strong trans influence, e.g. in [Os$^{VI}$NCl$_5$]$^{2^-}$ (p. 1085); likewise, in the octahedral complex. [Tc$^V$NCl$_2$(PMe$_2$Ph)$_3$], the Tc–Cl distance trans to N is 266.5 pm whereas that cis to N is only 244.1 pm.\(^{47}\)

Azidotrifluoromethylmethane, CF$_3$N$_3$, (mp $-152^\circ$, bp $-285^\circ$) is a colourless gas which is thermally stable at room temperature. It can be prepared in 90% yield by reacting CF$_3$NO with hydrazine in MeOH at $-78^\circ$ and then treating the product with HCl gas.\(^{48}\)

\[
\text{CF}_3\text{NO} + \text{H}_2\text{NNH}_2 \rightarrow \text{CF}_3\text{N} = \text{NNH}_2
\]

The molecule has an almost linear N$_3$ group and an angle C–N–N of 112.4° (Fig. 11.4a).\(^{49}\) The (linear) azide ion, N$_3^-$, is iso-electronic with N$_2$O, CO$_2$, OCN$^-$, etc. and forms numerous coordination complexes by standard ligand replacement reactions. Various coordination modes have been established, including end-on η$^1$, bridging

1.3.1 Nitrides, azides and nitrido complexes

Figure 11.3 Structures of some nitrido complexes.\(^{(24)}\)

\(\mu,\eta^1\) and bridging \(\mu,\eta^1 : \eta^1\) (Fig. 11.4).\(^{(50,51)}\)
The binuclear complex \([\text{Mo}_2\text{Cl}_2\text{N}_20]\)^{2-} features a terminal nitrido ligand, \(N\equiv\), as well as terminal and bridging azido ligands, i.e. \([(\text{MoCl}(\eta^1 - \text{N}_3)\text{Cl}_2(\mu,\eta^1 - \text{N}_3))\text{Cl}_2]^2\)^{2-}.\(^{(52)}\)

Concatenations larger than \(N_3\) are rare. The planar bridging \(N_4^{4-}\) occurs in the binuclear \(W^{VI}\) dianion, \([\text{Cl}_3\text{W}(\mu,\eta^1 : \eta^1 - \text{N}_4)\text{WCl}_3]\)^{2-}; this is formed during the thermolytic interconversion of \([\text{W(N}_3\text{Cl}_3]\) to the corresponding nitrido complex \(\text{WNC}_1\text{Cl}_3\) in the presence of \(\text{Ph}_4\text{AsCl}\), the nitride reacting as it is formed with unreacted azide still present according to the simple stoichiometry.\(^{(53)}\)

It will be noted that \(N_4^{4-}\) is isosteric with the tetraeprotonated urea molecule, \((\text{H}_2\text{N})_2\text{C} = \text{O}\), and is also isoelectronic and isostructural with \(\text{CO}_3^{2-}\) and \(\text{NO}_3^-\). An X-ray analysis of the red single crystals shows that \(\text{N}(\text{central}) - \text{N}\)), is long (149 pm) and that \(\text{N}(\text{central}) - \text{N}_1\) is short (123 pm). Unbranched \(\text{N}-\text{cationation}\) is observed in 2-tetrazenes such as \((\text{Me}_3\text{Si})_2\text{N} - \text{N} = \text{N} - \text{N}(\text{SiMe}_3)_2\) (mp 46\(^\circ\)) and its derivatives, e.g.

\[\text{Me}_3\text{Si} - \text{N} = \text{N} - \text{N} - \text{N}(\text{SiMe}_3)_2\quad (\text{mp} 46\^\circ)\]

and \((\text{Me}_3\text{Si})_2\text{N} - \text{N} = \text{N} - \text{N}(\text{SiMe}_3)_2\) \(^{(54)}\)

\[\text{SiMe}_2\]

\[\text{SiMe}_2\]

---

11.3.2 Ammonia and ammonium salts

NH₃ is a colourless, alkaline gas with a unique, penetrating odour that is first perceptible at concentrations of about 20–50 ppm. Noticeable irritation to eyes and the nasal passages begins at about 100–200 ppm, and higher concentrations can be dangerous. NH₃ is prepared industrially in larger amounts (number of moles) than any other single compound (p. 407) and the production of synthetic ammonia is of major importance for several industries (see Panel).

In the laboratory NH₃ is usually obtained from cylinders unless isotopically enriched species such as ¹⁵NH₃ or ND₃ are required. Pure dry ¹⁵NH₃ can be prepared by treating an enriched ¹⁵NH₄⁺ salt with an excess of KOH and drying the product gas over metallic Na. Reduction of ¹⁵NO₃⁻ or ¹⁵NO₂⁻ with Devarda’s alloy (50% Cu, 45% Al, 5% Zn) in alkaline solution provides an alternative route as does the hydrolysis of a nitride, e.g.:

\[
3\text{Ca} + ¹⁵\text{N}_2 \rightarrow \text{Ca}_3¹⁵\text{N}_2 + 6\text{H}_2\text{O} \rightarrow 2¹⁵\text{NH}_3 + 3\text{Ca(OH)}_2
\]

ND₃ can be prepared similarly using D₂O, e.g.:

\[
\text{Mg}_3\text{N}_2 + 6\text{D}_2\text{O} \rightarrow 2\text{ND}_3 + 3\text{Mg(OD)}_2
\]

---

§11.3.2  Ammonia and ammonium salts

Industrial Production of Synthetic Ammonia

The first industrial production of NH₃ began in 1913 at the BASF works in Ludwigshaven-Oppau, Germany. The plant, which had a design capacity of 30 tonnes per day, involved an entirely new concept in process technology; it was based on the Haber-Bosch high-pressure catalytic reduction of N₂ with H₂ obtained by electrolysis of water. Modern methods employ the same principles for the final synthesis but differ markedly in the source of hydrogen, the efficiency of the catalysts, and the scale of operations, many plants now having a capacity of 1650 tonnes per day or more. Great ingenuity has been shown not only in plant development but also in the application of fundamental thermodynamics to the selection of feasible chemical processes. Except where electricity is unusually cheap, reduction by electrolytic hydrogen has now been replaced either by coke/H₂O or, more recently, by natural gas (essentially CH₄) or naphtha (a volatile aliphatic petrol-like fraction of crude oil). The great advantages of modern hydrocarbon reduction methods over coal-based processes are that, comparing plant of similar capital costs, they occupy one-third the land area, use half the energy, and require one-tenth the manpower, yet produce 4 times the annual tonnage of NH₃.

The operation of a large synthetic ammonia plant based on natural gas involves a delicately balanced sequence of reactions. The gas is first desulfurized to remove compounds which will poison the metal catalysts, then compressed to ~30 atm and reacted with steam over a nickel catalyst at 750°C in the primary steam reformer to produce H₂ and oxides of carbon:

\[
\begin{align*}
\text{Ni/750°C} & : \quad \text{CH}_4 + \text{H}_2\text{O} \rightarrow \text{CO} + 3\text{H}_2; \\
\text{Ni/750°C} & : \quad \text{CH}_4 + 2\text{H}_2\text{O} \rightarrow \text{CO}_2 + 4\text{H}_2
\end{align*}
\]

Under these conditions the issuing gases contain some 9% of unreacted methane; sufficient air is injected via a compressor to give a final composition of 1 : 3 N₂ : H₂ and the air burns in the hydrogen thereby heating the gas to ~1100°C in the secondary reformer:

\[
\begin{align*}
\text{Ni/1100°C} & : \quad 2\text{H}_2 + (\text{O}_2 + 4\text{N}_2) \rightarrow 2\text{H}_2\text{O} + 4\text{N}_2; \\
\text{Ni/1100°C} & : \quad \text{CH}_4 + \text{H}_2\text{O} \rightarrow \text{CO} + 3\text{H}_2
\end{align*}
\]

The emerging gas, now containing only 0.25% CH₄, is cooled in heat exchangers which generate high-pressure steam for use first in the turbine compressors and then as a reactant in the primary steam reformer. Next, the CO is converted to CO₂ by the shift reaction which also produces more H₂:

\[
\text{CO} + \text{H}_2\text{O} \rightarrow (a \text{ (a)) + (b)) \rightarrow \text{CO}_2 + \text{H}_2
\]

Maximum conversion occurs by equilibration at the lowest possible temperature so the reaction is carried out sequentially on two beds of catalyst: (a) iron oxide (400°C) which reduces the CO concentration from 11% to 3%; (b) a copper catalyst (200°C) which reduces the CO content to 0.3%. Removal of CO₂ (~18%) is effected in a scrubber containing either a concentrated alkaline solution of K₂CO₃ or an amine such as ethanolamine:

\[
\text{CO}_2 + \text{H}_2\text{O} + \text{K}_2\text{CO}_3 \rightarrow \text{absorption} \rightarrow 2\text{KHCO}_3
\]

Absorption (heat)

Remaining trace quantities of CO (which would poison the iron catalyst during ammonia synthesis) are converted back to CH₄ by passing the damp gas from the scrubbers over a Ni methanation catalyst at 325°C: CO + 3H₂ \rightarrow \text{CH}_4 + \text{H}_2\text{O}. This reaction is the reverse of that occurring in the primary steam reformer. The synthesis gas now emerging has the approximate composition H₂ 74.3%, N₂ 24.7%, CH₄ 0.8%, Ar 0.3%, CO 1–2 ppm. It is compressed in three stages from 25 atm to ~200 atm and then passed over a promoted iron catalyst at 380–450°C:

\[
\text{Fe/400°C/200 atm} : \quad \text{N}_2 + 3\text{H}_2 \rightarrow \text{2NH}_3
\]

The gas leaving the catalyst beds contains about 15% NH₃; this is condensed by refrigeration and the remaining gas mixed with more incoming synthesis gas and recycled. Variables in the final reaction are the synthesis pressure.

Panel continues

synthesis temperature, gas composition, gas flow rate and catalyst composition and particle size. Since the earliest days the "promoted" Fe catalysts have been prepared by fusing magnetite (Fe₃O₄) on a table with KOH in the presence of a small amount of mixed refractory oxides such as MgO, Al₂O₃ and SiO₂; the solidified sheet is broken up into chunks 5–10 mm in size. These chunks are then reduced inside the ammonia synthesis converter to give the active catalyst which consists of Fe crystallites separated by the amorphous refractory oxides and partly covered by the alkali promotor which increases its activity by at least an order of magnitude.

World production of synthetic ammonia has increased dramatically particularly during the period 1950–80. Production in 1950 was little more than 1 million tonnes; though this was huge when compared with the production of most other compounds, it is dwarfed by today’s rate of production which exceeds 120 million tonnes pa. In 1990 world production capacity was 119.6 million tonnes distributed as follows: Asia 35.4%, the former Soviet Union 21.5%, North America 13.8%, Western Europe 11.3%, Eastern Europe 9.7%, Latin America 5.3%, Africa 3.0%. The price of NH₃ (FOB Gulf Coast plants, USA) was $107/tonne in 1990.

The applications of NH₃ are dominated (over 85%) by its use in various forms as a fertilizer. Of these, direct application is the most common (28.7%), followed by urea (22.4%), NH₄NO₃ (15.8%), ammonium phosphates (14.6%), and (NH₄)₂SO₄ (3.4%). Industrial uses include (a) commercial explosives such as NH₄NO₃, nitroglycerine, TNT and nitrocellulose, which are produced from NH₃ via HNO₃ — and (b) fibres/plastics e.g. in the manufacture of caprolactam for nylon-6, hexamethylenediamine for nylon-6,6, polyamides, rayon and polyurethanes. Other uses include a wide variety of applications in refrigeration, wood pulping, detinning of scrap-metal and corrosion inhibition; it is also used as a rubber stabilizer, pH controller, in the manufacture of household detergents, in the food and beverage industry, pharmaceuticals, water purification and the manufacture of numerous organic and inorganic chemicals. Indeed, synthetic ammonia is the key to the industrial production of most inorganic nitrogen compounds, as indicated in the subjoined Scheme.

The chemical fixation of N₂ to NH₃ under less extreme conditions than those used industrially is a continuing area of active research and considerable progress has been made in elucidating mechanisms involving N₂ coordinated to Mo, W, V and other centres.  

Some physical and molecular properties of NH₃ are in Table 11.2. The influence of H

---

bonding on the bp and other properties has already been noted (p. 53). It has been estimated that 26% of the H bonding in NH₃ breaks down on melting, 7% on warming from the mp to the bp, and the final 67% on transfer to the gas phase at the bp. The low density, viscosity and electrical conductivity, and the high dielectric constant of liquid ammonia are also notable. Liquid NH₃ is an excellent solvent and a valuable medium for chemical reactions (p. 424); its high heat of vaporization (23.35 kJ mol⁻¹ at the bp) makes it relatively easy to handle in simple vacuum flasks. The molecular properties call for little comment except to note that the rapid inversion frequency with which the N atom moves through the plane of the 3 H atoms has a marked effect on the vibrational spectrum of the molecule. The inversion itself occurs in the microwave region of the spectrum at 23.79 GHz (corresponding to a wavelength of 1.260 cm) and was, in fact, the first microwave absorption spectrum to be detected (C. E. Cleeton and N. H. Williams, 1934). The associated energy (hν) is 0.7935 cm⁻¹ i.e. 9.49 J mol⁻¹. Inversion also occurs in ND₃ at a frequency of 1.591 GHz, i.e. less than for NH₃ by a factor of 14.95. The inversion can be stopped in NH₃ by increasing the pressure to ~2 atm. The corresponding figure for ND₃ is ~90 mmHg (i.e. again a factor of about 15).

Ammonia is readily absorbed by H₂O with considerable evolution of heat (~37.1 kJ per mol of NH₃ gas). Aqueous solutions are weakly basic due to the equilibrium

\[
\text{NH}_3(aq) + \text{H}_2\text{O} \rightleftharpoons \text{NH}_4^+(aq) + \text{OH}^-(aq);
\]

\[K_{298.2} = [\text{NH}_4^+][\text{OH}^-]/[\text{NH}_3] = 1.81 \times 10^{-5} \text{ mol}^{-1}\]

The equilibrium constant at room temperature corresponds to pK_b = 4.74 and implies that a 1 mol aqueous solution of NH₃ contains only 4.25 mmol ⁻¹ of NH₄⁺ (or OH⁻). Such solutions do not contain the undissociated “molecule” NH₄OH, though weakly bonded hydrates have been isolated at low temperature:

\[
\text{NH}_3\cdot\text{H}_2\text{O} \text{ (mp 194.15 K) and 2NH}_3\cdot\text{H}_2\text{O} \text{ (mp 194.32 K)}
\]

These hydrates are not ionically dissociated but contain chains of H₂O molecules cross-linked by NH₃ molecules into a three-dimensional H-bonded network.

Ammonia burns in air with difficulty, the flammable limits being 16–25 vol%. Normal combustion yields nitrogen but, in the presence of a Pt or Pt/Rh catalyst at 750–900°C, the reaction proceeds further to give the thermodynamically less-favoured products NO and NO₂:

\[
4\text{NH}_3 + 3\text{O}_2 \xrightarrow{\text{burn}} 2\text{N}_2 + 6\text{H}_2\text{O}
\]

\[
4\text{NH}_3 + 5\text{O}_2 \xrightarrow{\text{Pt/800°}} 4\text{NO} + 6\text{H}_2\text{O}
\]

\[
2\text{NO} + \text{O}_2 \xrightarrow{\text{Pt/800°}} 2\text{NO}_2
\]
These reactions are very important industrially in the production of HNO₃ (p. 466). See also the industrial production of HCN by the Andrussov process (p. 321): 2NH₃ + 3O₂ + 2CH₄ → 2HCN + 6H₂O.

Gaseous NH₃ burns with a greenish-yellow flame in F₂ (or ClF₃) to produce NF₃ (p. 439). Chlorine yields several products depending on conditions: NH₄Cl, NH₂Cl, NHCl₂, NC1₃, NCl₃, NH₃, N₂ and even small amounts of N₂H₄. The reaction to give chloramine, NH₂Cl, is important in urban and domestic water purification systems. Reactions with other non-metals and their halides or oxides are equally complex and lead to a variety of compounds, many of which are treated elsewhere (pp. 497, 501, 506, 535, 723, etc.). At red heat carbon reacts with NH₃ to give NH₄CN + H₂, whereas phosphorus yields PH₃ and N₂, and sulfur gives H₂S and N₄S₄. Metals frequently react at higher temperature to give nitrates (p. 417). Of particular importance is the attack on Cu in the presence of oxygen (air) at room temperature since this precludes the use of this metal and its alloys in piping and valves for handling either liquid or gaseous NH₃. Corrosion of Cu and brass by moist NH₃/air mixtures and by air-saturated aqueous solutions of NH₃ is also rapid. Contact with Ni and with polyvinylchloride plastics should be avoided for the same reason.

**Liquid ammonia as a solvent**

Liquid ammonia is the best-known and most widely studied non-aqueous ionizing solvent. Its most conspicuous property is its ability to dissolve alkali metals to form highly coloured, electrically conducting solutions containing solvated electrons, and the intriguing physical properties and synthetic utility of these solutions have already been discussed (p. 77). Apart from these remarkable solutions, much of the chemistry in liquid ammonia can be classified by analogy with related reactions in aqueous solutions. Accordingly, we briefly consider in turn, solubility relationships, metathesis reactions, acid-base reactions, amphoteric solvates and solvolysis, redox reactions and the preparation of compounds in unusual oxidation states. Comparison of the physical properties of liquid NH₃ (p. 423) with those of water (p. 623) shows that NH₃ has the lower mp, bp, density, viscosity, dielectric constant and electrical conductivity; this is due at least in part to the weaker H bonding in NH₃ and the fact that such bonding cannot form cross-linked networks since each NH₃ molecule has only 1 lone-pair of electrons compared with 2 for each H₂O molecule. The ionic self-dissociation constant of liquid NH₃ at -50°C is \( \sim 10^{-33} \text{ mol}^2 \text{ l}^{-2} \).

Most ammonium salts are freely soluble in liquid NH₃ as are many nitrates, nitrites, cyanides and thiocyanates. The solubilities of halides tend to increase from the fluoride to the iodide; solubilities of salts of multivalent ions are generally low suggesting that (as in aqueous systems) lattice-energy and entropy effects outweigh solvation energies. The possibility of H-bond formation also influences solubility and, in the case of NH₄I, an X-ray single-crystal analysis of the monosolvate shows the presence of an H-bonded cation N₂H₄⁺ with an N–H⋯N distance of 269 ± 5 pm. Some typical solubilities at 25°C expressed as g per 100 g solvent are: NH₄OAc 253.2, NH₄NO₃ 389.6, LiNO₃ 243.7, NaNO₃ 97.6, KNO₃ 10.4, NaF 0.35, NaCl 3.0, NaBr 138.0, NaI 161.9, NaSCN 205.5. Some of these solubilities are astonishingly high, particularly when expressed as the number of moles of solute per 10 mol

---

NH₃, e.g.: NH₄NO₃ 8.3, LiNO₃ 6.1, NaSCN 4.3. Further data at 25° and other temperatures are in ref. 69.

Metathesis reactions are sometimes the reverse of those in aqueous systems because of the differing solubility relations. For example because AgBr forms the complex ion [Ag(NH₃)₂]⁺ in liquid NH₃ it is readily soluble, whereas BaBr₂ is not, and can be precipitated:

\[
\text{Ba(NO}_3\text{)}_2 + 2\text{AgBr} \rightarrow \text{BaBr}_2\downarrow + 2\text{AgNO}_3
\]

Reactions analogous to the precipitation of AgOH and of insoluble oxides from aqueous solution are:

\[
\text{AgNO}_3 + \text{KNH}_2 \rightarrow \text{AgNH}_2\downarrow + \text{KNO}_3
\]

Acid-base reactions in many solvent systems can be thought of in terms of the characteristic cations and anions of the solvent (see also p. 831)

solvent \(\leftrightarrow\) characteristic cation (acid) + characteristic anion (base)

\[
2\text{H}_2\text{O} \leftrightarrow \text{H}_3\text{O}^+ + \text{OH}^-
\]

\[
2\text{NH}_3 \leftrightarrow \text{NH}_4^+ + \text{NH}_2^-
\]

On this basis NH₄⁺ salts can be considered as solvo-acids in liquid NH₃ and amides as solvo-bases. Neutralization reactions can be followed conductimetrically, potentiometrically or even with coloured indicators such as phenolphthalein:

\[
\text{NH}_4\text{NO}_3 + \text{KNH}_2 \rightarrow \text{KNO}_3 + 2\text{NH}_3\;
\]\n
solvo-acid solvo-base salt solvent

Likewise, amphoteric behaviour can be observed. For example Zn(NH₂)₂ is insoluble in liquid NH₃ (as is Zn(OH)₂ in H₂O), but it dissolves on addition of the solvo-base KH₂ due to the formation of K₂[Zn(NH₂)₂]; this in turn is decomposed by NH₄⁺ salts (solvo-acids) with reprecipitation of the amide:

\[
\text{K}_2[\text{Zn(NH}_2\text{)}_2] + 2\text{NH}_4\text{NO}_3 \rightarrow \text{Zn(NH}_2\text{)}_2 + 2\text{KNO}_3 + 4\text{NH}_3
\]

Solvates are perhaps less prevalent in compounds prepared from liquid ammonia solutions than are hydrates precipitated from aqueous systems, but large numbers of ammines are known, and their study formed the basis of Werner’s theory of coordination compounds (1891–5). Frequently, however, solvolysis (ammonolysis) occurs (cf. hydrolysis).(65) Examples are:

\[
\text{M}^1\text{H} + \text{NH}_3 \rightarrow \text{MNH}_2 + \text{H}_2
\]

\[
\text{M}^1\text{O} + \text{NH}_3 \rightarrow \text{MNH}_2 + \text{MOH}
\]

\[
\text{SiCl}_4 \rightarrow \text{[Si(NH}_2\text{)}_4] \rightarrow \text{Si(NH)(NH}_2\text{)}_2
\]

\[
\text{Si}_3\text{N}_4
\]

Amides are one of the most prolific classes of ligand and the subject of metal and metalloid amides has been extensively reviewed.(70)

Redox reactions are particularly instructive. If all thermodynamically allowed reactions in liquid NH₃ were kinetically rapid, then no oxidizing agent more powerful than N₂ and no reducing agent more powerful than H₂ could exist in this solvent. Using data for solutions at 25°:(64)

\[
\text{Acid solutions (1 M NH}_4\text{⁺)}
\]

\[
\text{NH}_4^+ + \text{e}^- = \text{NH}_3 + \frac{1}{2}\text{H}_2\quad E^\circ = 0.0 \text{V}
\]

\[
3\text{NH}_4^+ + \frac{1}{2}\text{N}_2 + 3\text{e}^- = 4\text{NH}_3\quad E^\circ = -0.04 \text{V}
\]

\[
\text{Basic solutions (1 M NH}_2\text{⁻)}
\]

\[
\text{NH}_3 + \text{e}^- = \text{NH}_2^- + \frac{1}{2}\text{H}_2\quad E^\circ = 1.59 \text{V}
\]

\[
2\text{NH}_3 + \frac{1}{2}\text{N}_2 + 3\text{e}^- = 3\text{NH}_2^-\quad E^\circ = 1.55 \text{V}
\]

Obviously, with a range of only 0.04 V available very few species are thermodynamically stable. However, both the hydrogen couple and the nitrogen couple usually exhibit “overvoltages” of ~1 V, so that in acid solutions the practical range of potentials for solutes is from +1.0 to −1.0 V. Similarly in basic solutions the practical range...

---

extends from 2.6 to 0.6 V. It is thus possible to work in liquid ammonia with species which are extremely strong reducing agents (e.g. alkali metals) and also with extremely strong oxidizing agents (e.g. permanganates, superoxides and ozonides; p. 609). For similar reasons the NO$_3^-$ ion is effectively inert towards NH$_3$ in acid solution but in alkaline solutions N$_2$ is slowly evolved:

$$3K^+ + 3NH_2^- + 3NO_3^- \rightarrow 3KOH^- + N_2$$

$$+ 3NO_2^- + NH_3$$

The use of liquid NH$_3$ to prepare compounds of elements in unusual (low) oxidation states is exemplified by the successive reduction of K$_2$[Ni(CN)$_4$] with Na/Hg in the presence of an excess of CN$: the dark-red dimeric Ni$^{I}$ complex K$_4$[Ni$_2$(CN)$_6$] is first formed and this can be further reduced to the yellow Ni$^{II}$ complex K$_4$[Ni(CN)$_4$]. The corresponding complexes [Pd(CN)$_4$]$^{2-}$ and [Pt(CN)$_4$]$^{2-}$ can be prepared similarly, though there is no evidence in these latter systems for the formation of the M$^{II}$ dimer. A ditertiaryphosphine complex of Pd$^{0}$ has also been prepared:

$$[Pd(1,2-(PEt$_2$)$_2$C$_6$H$_4$)$_2]$Br$_2$,$^\text{Na/NH}_3$ $\rightarrow$ $[Pd(1,2-(PEt$_2$)$_2$C$_6$H$_4$)$_2]$ + 2NaBr$$

[Co$^{III}$$(CN)$_6$]$^{3-}$ yields the pale-yellow complex [Co$(CN)_4$]$^{3-}$ and the brown-violet complex [Co$^0$(CN)$_8$]$^{8-}$ (cf. the dimeric carbonyl [Co$_2$(CO)$_8$]).

Liquid NH$_3$ is also extensively used as a preparative medium for compounds which are unstable in aqueous solutions, e.g.:

$$2Ph_2GeNa + Br(CH_2)_2Br$$

$$\text{liq NH}_3$$

$$\rightarrow Ph_3Ge(CH_2)_2GePh_3$$

$$+ 2NaBr$$

$$\text{Me}_3SnX + NaPEt$_2$$$

$$\text{liq NH}_3$$

$$\rightarrow \text{Me}_3SnPEt$_2$ + 2NaX$$

Alkali metal acetylides M$_2$C$_2$, MCCH and MCCR can readily be prepared by passing C$_2$H$_2$ or C$_2$HR into solutions of the alkali metal in liquid NH$_3$, and these can be used to synthesize a wide range of transition-element acetylides,$^{(71)}$ e.g.:

$$\text{Ni(SCN)$_2$.6NH}_3 + 5\text{KC}_2\text{Ph} \rightarrow$$

$$K_4[\text{Ni(C}_2\text{Ph})_4].2\text{NH}_3 + 2\text{KSCN} + 4\text{NH}_3$$

$^\text{vac}$

$$K_2[\text{Ni(C}_2\text{Ph})_4].2\text{NH}_3$$

$$\rightarrow K_2[\text{NiII}(\text{C}_2\text{Ph})_4] + 2\text{NH}_3$$

yellow

Other examples are orange-red K$_3$[C$_{III}$(C$_2$H)$_6$], rose-pink Na$_2$[Mn$^{II}$(C$_2$Me)$_4$], dark-green Na$_4$-[Co$^{II}$(C$_2$Me)$_6$], orange K$_4$[Ni$^0$(C$_2$H)$_4$], yellow K$_6$[Ni$_2$(C$_2$Ph)$_6$]. Such compounds are often explosive, though the analogues of Cu$^I$ and Zn$^{II}$ are not, e.g. yellow Na[Cu(C$_2$Me)$_2$], colourless K$_2$[Cu(C$_2$H)$_3$], and colourless K$_2$[Zn(C$_2$H)$_4$].

Ammonium halides have been used as versatile reagents in low-temperature solid-state redox and acid-base reactions.$^{(72)}$ For example, direct reaction with the appropriate metal at 270–300$^\circ$ yields the ammonium salts of ZnCl$_4^{-}$, LaCl$_3^{-}$, YCl$_6^{-}$, YBr$_6^{-}$, CuCl$_3^{-}$, etc., whereas Y$_2$O$_3$ yields either (NH$_4$)$_3$YOBr or YOBr depending on the stoichiometric ratio of the reagents. Solid-state reactions of ammonium sulfate, nitrate, phosphates and carbonate have also been studied.

### 11.3.3 Other hydrides of nitrogen

Nitrogen forms more than 20 binary compounds with hydrogen$^{(73)}$ of which ammonia (NH$_3$, p. 420), hydrazine (N$_2$H$_4$, p. 427) and hydrogen azide (N$_3$H, p. 432) are by far the most important. Hydroxylamine, NH$_2$(OH), is closely related in structure and properties to both ammonia, NH$_2$(H), and hydrazine, NH$_2$(NH$_2$) and it will be convenient to discuss this compound in the present section also (p. 431). Several protonated cationic species such as NH$_4^+$, N$_2$H$_5^+$, etc, and deprotonated anionic species such as NH$_2^-$, N$_2$H$_3^-$, etc. also exist but ammonium hydride, NH$_3$, is unknown. Among

$^{71}$ R. NAST and coworkers; for summary of results and detailed refs., see pp. 568–71 of ref. 65.

the less familiar (and less stable) neutral radicals which have been well characterized are the imidogen (NH), amidogen (NH₂), diazenyl (N₂H) and hydrazyl (N₂H₃) radicals. Such species are important in atmospheric chemistry and in combustion reactions. Of the neutral compounds the following can be mentioned:(73)

N₂H₂: trans-diazene, HN—NH (yellow), and its 1:1 isomer, H₂N＝N
N₃H: hydrogen azide (p. 432) and cyclo-triazene (triaza­rine). N＝N＝NH
N₃H₃: triazene, HN＝N－NH₂ and cyclotri­azane (triaziridene) c(NH)₃
N₃H₅: triazane (aminohydrazine), H₂N(NH)-NH₂
N₄H₄: trans-2-tetrazene, H₂N－N＝N－NH₂, (colourless, low-melting crystals, N－N 143 pm, N＝N 121 pm). and am­monium azide, NH₄N₃ (white crystals, subl. 133°C, d 1.350 g cm⁻³)
N₄H₆: tetrazane, H₂NN(H)N(H)NH₂, (bright yellow solid)
N₅H₅: hydrazinium azide, N₂H₅N₅, (explosive white crystals)
N₆H₂: Probably a cyclic dimer of N₃H
N₇H₉: hydrazinium azide monohydrazinate, N₂H₅N₃N₂H₄
N₉H₃: cyclic trimer of N₃H, i.e. 1,3,5-N₆(NH)₃

Hydrazine(74)

Anhydrous N₂H₄ is a fuming, colourless liquid with a faint ammoniacal odour which is first detectable at a concentration of 70–80 ppm. Many of its physical properties (Table 11.3) are remarkably similar to those of water (p. 623); comparisons with NH₃ (p. 423) H₂O₂ (p. 634) are also instructive, and the influence of H bonding is apparent. In the gas phase four conformational isomers are conceivable (Fig. 11.5) but the large dipole (1.85 D) clearly eliminates the staggered trans-conformation; electron diffraction data (and infrared) indicate the gauche-conformation with an angle of rotation of 90–95° from the eclipsed position.

The most effective preparative routes to hydrazine are still based on the process introduced by F. Raschig in 1907: this involves the reaction of ammonia with an alkaline solution of sodium hypochlorite in the presence of gelatin or glue. The overall reaction can be written as

\[
2\text{NH}_3 + \text{NaOCl} \xrightarrow{\text{aqueous alkali}} \text{N}_2\text{H}_4 + \text{NaCl} + \text{H}_2\text{O} \tag{1}
\]

but it proceeds in two main steps. First there is a rapid formation of chloramine which proceeds to completion even in the cold:

\[
\text{NH}_3 + \text{OCl}^- \xrightarrow{\text{fast}} \text{NH}_2\text{Cl} + \text{OH}^- \tag{2}
\]

The chloramine then reacts further to produce N₂H₄ either by slow nucleophilic attack of NH₃ (3a) and subsequent rapid neutralization (3b), or by preliminary rapid formation of the chloramide ion (4a) followed by slow nucleophilic attack of NH₃ (4b):

\[
\text{NH}_2\text{Cl} + \text{NH}_3 \xrightarrow{\text{slow}} \text{N}_2\text{H}_5^+ + \text{Cl}^- \tag{3a}
\]
\[
\text{N}_2\text{H}_5^+ + \text{OH}^- \xrightarrow{\text{fast}} \text{N}_2\text{H}_4 + \text{H}_2\text{O} \tag{3b}
\]

---

Figure 11.5 Possible conformations of $\text{N}_2\text{H}_4$ with pyramidal $\text{N}$. Hydrazine adopts the gauche $C_2$ form with $\text{N} \cdot \text{N} 145\, \text{pm}$, $\text{H} \cdot \text{N} \cdot \text{H} 108^\circ$, and a twist angle of $95^\circ$ as shown in the lower diagram.

When ignited, $\text{N}_2\text{H}_4$ burns rapidly and completely in air with considerable evolution of heat (see Panel):

$$\text{N}_2\text{H}_4(\text{l}) + \text{O}_2(\text{g}) \rightarrow \text{N}_2(\text{g}) + 2\text{H}_2\text{O};$$
$$\Delta H = -621.5 \, \text{kJ mol}^{-1}$$

In solution, $\text{N}_2\text{H}_4$ is oxidized by a wide variety of oxidizing agents (including $\text{O}_2$) and it finds use as a versatile reducing agent because of the variety of reactions it can undergo. Thus the thermodynamic reducing strength of $\text{N}_2\text{H}_4$ depends on whether it undergoes a 1-, 2-, or 4-electron oxidation and whether this is in acid or alkaline solution. Typical examples in acid solution are as follows:\textsuperscript{†}

1-electron change (e.g. using $\text{Fe}^{\text{III}}$, $\text{Ce}^{\text{IV}}$, or $\text{MnO}_4^{-}$):

\textsuperscript{†} See p. 435 for discussion of standard electrode potentials and their use. It is conventional to write the half-reactions as (oxidized form) + $n\text{e}^-$ = (reduced form). Since $\Delta G = nF\overline{E}$ at unit activities, it follows that the reactions will occur spontaneously in the reverse direction to that written when $\overline{E}$ is negative, i.e. hydrazine is oxidized by the reagents listed.

\begin{align*}
\text{NH}_2\text{Cl} + \text{OH}^- & \xrightarrow{\text{fast}} \text{NHCl}^- + \text{H}_2\text{O} \quad (4a) \\
\text{NHCl}^- + \text{NH}_3 & \xrightarrow{\text{slow}} \text{N}_2\text{H}_4^- + \text{Cl}^- \quad (4b)
\end{align*}

In addition there is a further rapid but undesirable reaction with chloramine which destroys the $\text{N}_2\text{H}_4$ produced:

$$\text{N}_2\text{H}_4 + 2\text{NH}_2\text{Cl} \xrightarrow{\text{fast}} 2\text{NH}_4\text{Cl} + \text{N}_2 \quad (5)$$

This reaction is catalysed by traces of heavy metal ions such as $\text{Cu}^{\text{II}}$ and the purpose of the gelatin is to suppress reaction (5) by sequestering the metal ions; it is probable that gelatin also assists the hydrazine-forming reactions between ammonia and chloramine in a way that is not fully understood. The industrial preparation and uses of $\text{N}_2\text{H}_4$ are summarized in the Panel.

At room temperature, pure $\text{N}_2\text{H}_4$ and its aqueous solutions are kinetically stable with respect to decomposition despite the endothermic nature of the compound and its positive free energy of formation:

$$\text{N}_2(\text{g}) + 2\text{H}_2(\text{g}) \rightarrow \text{N}_2\text{H}_4(\text{l}); \Delta H_f = 50.6 \, \text{kJ mol}^{-1}$$
$$\Delta G_f = 149.2 \, \text{kJ mol}^{-1}$$
Industrial Production and Uses of Hydrazine\(^{(75)}\)

Hydrazine is usually prepared in a continuous process based on the Raschig reaction. Solutions of ammonia and sodium hypochlorite (30:1) are mixed in the cold with a gelatin solution and then passed rapidly under pressure through a reactor at 150° (residence time 1 s). This results in a 60% conversion based on hypochlorite and produces a solution of \(\sim0.5\%\) by weight of \(\text{N}_2\text{H}_4\). The excess of \(\text{NH}_3\) and steam are stripped off in stages and the solution finally distilled to give pure hydrazine hydrate \(\text{N}_2\text{H}_4\cdot\text{H}_2\text{O}\) (mp \(-51.7\^\circ\), bp 118.5°, \(d\ 1.0305\text{~g~cm}^{-3}\) at 21°). In the Olin Mathieson variation of this process, \(\text{NH}_2\text{Cl}\) is preformed from \(\text{NH}_3\) and \(\text{NaOCl}\) (3:1), and then anhydrous \(\text{NH}_3\) is injected to a ratio of \(\sim30:1\); this simultaneously raises the temperature and pressure in the reactor. An alternative industrial route, which is economical only for smaller plants, uses urea instead of ammonia in a process very similar to Raschig's:

\[
\begin{align*}
\text{(NH}_2\text{)}_2\text{CO} + \text{NaOCl} + 2\text{NaOH} &\rightarrow \text{N}_2\text{H}_4\cdot\text{H}_2\text{O} + \text{NaCl} + \text{Na}_2\text{CO}_3
\end{align*}
\]

Hydrazine hydrate contains 64.0% by weight of \(\text{N}_2\text{H}_4\) and is frequently preferred to the pure compound not only because it is cheaper but also because its much lower mp avoids problems of solidification. Anhydrous \(\text{N}_2\text{H}_4\) can be obtained from concentrated aqueous solutions by distillation in the presence of dehydrating agents such as solid \(\text{NaOH}\) or \(\text{KOH}\). Alternatively, hydrazine sulfate can be precipitated from dilute aqueous solutions using dilute \(\text{H}_2\text{SO}_4\) and the precipitate treated with liquid \(\text{NH}_3\) to liberate the hydrazine:

\[
\text{N}_2\text{H}_4\text{(aq)} + \text{H}_2\text{SO}_4\text{(aq)} \rightarrow \text{N}_2\text{H}_6\text{SO}_4 \rightarrow 2\text{NH}_3 \rightarrow \text{N}_2\text{H}_4 + (\text{NH}_4)_2\text{SO}_4
\]

World production capacity of hydrazine solutions in 1995 (expressed as \(\text{N}_2\text{H}_4\)) was about 40,000 tonnes, predominantly in USA 16,500 t, Germany 6,400 t, Japan 6,600 t and France 6,100 t. In addition some 3,200 t of anhydrous \(\text{N}_2\text{H}_4\) was manufactured in USA for rocket fuels.

The major use (non-commercial) of anhydrous \(\text{N}_2\text{H}_4\) and its methyl derivatives \(\text{MeNHNNH}_2\) and \(\text{Me}_2\text{NNH}_2\) is as a rocket fuel in guided missiles, space shuttles, lunar missions, etc. For example the Apollo lunar modules were decelerated upon landing and powered on blast-off by the oxidation of a 1:1 mixture of \(\text{MeNHNNH}_2\) and \(\text{Me}_2\text{NNH}_2\) with liquid \(\text{N}_2\text{O}_4\); the landing required some 3 tonnes of fuel and 4.5 tonnes of oxidizer, and the relaunching about one-third of this amount. Other oxidants used are \(\text{O}_2\), \(\text{H}_2\text{O}_2\), \(\text{HNO}_3\), or even \(\text{F}_2\). Space vehicles propelled by anhydrous \(\text{N}_2\text{H}_4\) itself include the Viking Lander on Mars, the Pioneer and Voyager interplanetary probes and the Giotto space probe to Halley's comet.

The major commercial applications of hydrazine solutions are as blowing agents (~40%), agricultural chemicals (~25%), medicinals (~5%), and increasingly — in boiler water treatment now as much as 20%. The detailed pattern of usage, of course, depends to some extent on the country concerned.

Aqueous solutions of \(\text{N}_2\text{H}_4\) are versatile and attractive reducing agents. They have long been used to prepare silver (and copper) mirrors, to precipitate many elements (such as the platinum metals) from solutions of their compounds, and in other analytical applications. A major application as noted above is now in the treatment of high-pressure boiler water: this was first introduced in about 1945 and has the following advantages over the previously favoured \(\text{Na}_2\text{SO}_3\):

(a) \(\text{N}_2\text{H}_4\) is completely miscible with \(\text{H}_2\text{O}\) and reacts with dissolved \(\text{O}_2\) to give merely \(\text{N}_2\) and \(\text{H}_2\text{O}\):

\[
\text{N}_2\text{H}_4 + \text{O}_2 \rightarrow \text{N}_2 + 2\text{H}_2\text{O}
\]

(b) \(\text{N}_2\text{H}_4\) does not increase the dissolved solids (cf. \(\text{Na}_2\text{SO}_3\)) since \(\text{N}_2\text{H}_4\) itself and all its reaction and decomposition products are volatile.

(c) These products are either alkaline (like \(\text{N}_2\text{H}_4\)) or neutral, but never acidic.

(d) \(\text{N}_2\text{H}_4\) is also a corrosion inhibitor (by reducing \(\text{Fe}_2\text{O}_3\) to hard, coherent \(\text{Fe}_3\text{O}_4\)) and it is therefore useful for stand-by and idle boilers.

The usual concentration of \(\text{O}_2\) in boiler feed water is \(~0.01\text{~ppm}\) so that, even allowing for a twofold excess, \(1\text{~kg}\ \text{N}_2\text{H}_4\) is sufficient to treat 50,000 tonnes of feed water (say \(~4\text{~days'}\) supply at the rate of 500 tonnes per hour).

Hydrazine and its derivatives find considerable use in the synthesis of biologically active materials, dyestuff intermediates and other organic derivatives. Reactions of aldehydes to form hydrazides (\(\text{RCH}=\text{NNH}_2\)) and azines (\(\text{RCH}=\text{NN}=\text{CHR}\)) are well known in organic chemistry, as is the use of hydrazine and its derivatives in the synthesis of heterocyclic compounds.

Nitrogen

\[
\text{NH}_4^+ + \frac{1}{2}\text{N}_2 + \text{H}^+ + e^- = \text{N}_2\text{H}_5^+; \quad E^o = -1.74 \text{ V}
\]

2-electron change (e.g. using \(\text{H}_2\text{O}_2\) or \(\text{HNO}_2\)):

\[
\frac{1}{2}\text{NH}_4^+ + \frac{1}{2}\text{HN}_3 + \frac{5}{2}\text{H}^+ + 2e^- = \text{N}_2\text{H}_5^+; \quad E^o = +0.11 \text{ V}
\]

4-electron change (e.g. using \(\text{IO}_3^-\) or \(\text{I}_2\)):

\[
\text{N}_2 + 5\text{H}^+ + 4e^- = \text{N}_2\text{H}_5^+; \quad E^o = -0.23 \text{ V}
\]

For basic solutions the corresponding reduction potentials are:

\[
\text{NH}_3 + \frac{1}{2}\text{N}_2 + \text{H}_2\text{O} + e^- = \text{N}_2\text{H}_4 + \text{OH}^-; \quad E^o = -2.42 \text{ V}
\]

\[
\frac{1}{2}\text{NH}_3 + \frac{1}{2}\text{N}_3^- + \frac{5}{2}\text{H}_2\text{O} + 2e^- = \text{N}_2\text{H}_4 + \frac{5}{2}\text{OH}^-; \quad E^o = -0.92 \text{ V}
\]

\[
\text{N}_2 + 4\text{H}_2\text{O} + 4e^- = \text{N}_2\text{H}_4 + 4\text{OH}^-; \quad E^o = -1.16 \text{ V}
\]

In the 4-electron oxidation of acidified \(\text{N}_2\text{H}_4\) to \(\text{N}_2\), it has been shown by the use of \(\text{N}_2\text{H}_4\) isotopically enriched in \(^{15}\text{N}\) that both the \(\text{N}\) atoms of each molecule of \(\text{N}_2\) originated in the same molecule of \(\text{N}_2\text{H}_4\). This reaction is also the basis for the most commonly used method for the analytical determination of \(\text{N}_2\text{H}_4\) in dilute aqueous solution:

\[
\text{N}_2\text{H}_4 + \text{KIO}_3 + 2\text{HCl} \xrightarrow{\text{H}_2\text{O}/\text{CCl}_4} \text{N}_2 + \text{KCl} + \text{ICl} + 3\text{H}_2\text{O}
\]

The \(\text{IO}_3^-\) is first reduced to \(\text{I}_2\) which is subsequently oxidized to ICl by additional \(\text{IO}_3^-\); the end-point is detected by the complete discharge of the iodine colour from the \(\text{CCl}_4\) phase.

As expected, \(\text{N}_2\text{H}_4\) in aqueous solutions is somewhat weaker as a base than is ammonia (p. 423):

\[
\text{N}_2\text{H}_4(\text{aq}) + \text{H}_2\text{O} = \text{N}_2\text{H}_5^+ + \text{OH}^-; \quad K_{25^\circ} = 8.5 \times 10^{-7} \text{ mol}^{-1}
\]

\[
\text{N}_2\text{H}_5^+(\text{aq}) + \text{H}_2\text{O} = \text{N}_2\text{H}_6^{2+} + \text{OH}^-; \quad K_{25^\circ} = 8.9 \times 10^{-16} \text{ mol}^{-1}
\]

The hydrate \(\text{N}_2\text{H}_4.\text{H}_2\text{O}\) is an H-bonded molecular adduct and is not ionically dissociated. Two series of salts are known, e.g. \(\text{N}_2\text{H}_3\text{Cl}\) and \(\text{N}_2\text{H}_6\text{Cl}_2\). (It will be noticed that \(\text{N}_2\text{H}_6^{2+}\) is isoelectronic with ethane.) H bonding frequently influences the crystal structure and this is particularly noticeable in \(\text{N}_2\text{H}_6\text{F}_2\) which features a layer lattice similar to \(\text{CdI}_2\) though the structure is more open and the fluoride ions are not close packed. Sulfuric acid forms three salts, \(\text{N}_2\text{H}_4.\text{H}_2\text{SO}_4\) (\(n = \frac{1}{2}, 1, 2\)), i.e. \([\text{N}_2\text{H}_5]_2\text{SO}_4\), \([\text{N}_2\text{H}_6]\text{SO}_4\) and \([\text{N}_2\text{H}_6][\text{HSO}_4]_2\).

Hydrazido(2−)-complexes of Mo and W have been prepared by protonating dinitrogen complexes with concentrated solutions of HX and by ligand exchange.\(^{76}\) For example several dozen complexes of general formulae \([\text{MX}_2(\text{NNH}_2)L_3]\) and \(\text{trans-[MX(\text{NNH}_2)L_4]}\) have been characterized for \(\text{M} = \text{Mo} ; \text{X} = \text{halogen}; \text{L} = \text{phosphine or heterocyclic-N donor. Similarly, cis-[W(\text{N}_2)_2(\text{PM}_{2}\text{Ph}))_4]\) afforded \(\text{trans-[WF(\text{NNH}_2)(\text{PM}_{2}\text{Ph})_4][BF}_4]\) when treated with \(\text{HF/MeOH}\) in a borosilicate glass vessel. Side-on coordination of a phenylhydrazido(1−) ligand has also been established in compounds such as the dark-red \([\text{W}(\eta^3-\text{C}_5\text{H}_5)_2(\eta^2-\text{H}_2\text{NNPh})]-[\text{BF}_4]_2\).\(^{77}\) these are synthesized by the ready isomerization of the first-formed yellow \(\eta^1-\)arylhydrazido(2−) tungsten hydride complex above −20° (X = \(\text{BF}_4, \text{PF}_6\)):

\[
[ \text{[N}_2\text{H}_6[\text{HSO}_4]_{12}^-] \quad ]^{\text{Yellow}} \quad [ \text{[N}_2\text{H}_6[\text{HSO}_4]_{12}^-] \quad ]^{\text{Dark red}}
\]

In these reactions \(\text{R} = \text{Ph}, \text{p-MeOC}_6\text{H}_4, \text{p-MeC}_6\text{H}_4\) or \(\text{p-FC}_6\text{H}_4\). Further bonding modes are as an isodiazene (i.e. \(\text{M} \leftrightarrow \text{N}=\text{NMe}_2\) rather than \(\text{M} \leftrightarrow \text{N} \leftrightarrow \text{NMe}_2\))\(^{78}\) and as a bridging diimido

group (M...N=N...M). Both hydrazine itself and its dianion, HNNH$_2^-$, act as bridging ligands in the pale yellow dinuclear tungsten(VI) complex shown in Fig. 11.6. A selection of further recent work on the various coordination modes of substituted hydrazido, diazenido and related ligands is appended.

Figure 11.6 Structure of [[W(NPh)Me$_3$]$_2$(μ-H$_2$N=NH)$_2$ MeN$_2$H$_2$]$_2$.

**Hydroxylamine**

Anhydrous NH$_2$OH is a colourless, thermally unstable hygroscopic compound which is usually handled as an aqueous solution or in the form of one of its salts. The pure compound (mp 32.05°C, d 1.204 g cm$^{-3}$ at 33°C) has a very high dielectric constant (77.63-77.85) and a vapour pressure of 10 mmHg at 47.2°C. It can be regarded as water in which 1 H has been replaced by OH. Aqueous solutions are less basic than either ammonia or hydrazine:

\[
\text{NH}_2\text{OH(aq)} + \text{H}_2\text{O} = \text{NH}_2\text{OH}^+ + \text{OH}^-;
\]

\[
K_{25^\circ} = 6.6 \times 10^{-9} \text{ mol l}^{-1}
\]

Hydroxylamine can be prepared by a variety of reactions involving the reduction of nitrites, nitric acid or NO, or by the acid hydrolysis of nitroalkanes. In the conventional Raschig synthesis, an aqueous solution of NH$_4$NO$_2$ is reduced with HSO$_4$-SO$_2$ at 0° to give the hydroxylamido-$N,N$-disulfate anion which is then hydrolysed stepwise to hydroxylammonium sulfate:

\[
\text{NH}_4\text{NO}_2 + 2\text{SO}_2 + \text{NH}_3 + \text{H}_2\text{O} \longrightarrow \text{[NH}_4\text{][N(OH)(OSO}_2\text{)]}\text{[H(NOS)}\text{][HOSO}_2\text{]}\text{[NH}_3\text{][HOSO}_2\text{]}\text{[NSO}_4\text{]}\text{[NH}_3\text{][HOSO}_2\text{]}
\]

Aqueous solutions of NH$_2$OH can then be obtained by ion exchange, or the free compound can be prepared by ammonolysis with liquid NH$_3$; insoluble ammonium sulfate is filtered off and the excess of NH$_3$ removed under reduced pressure to leave solid NH$_2$OH.

Alternatively, hydroxylammonium salts can be made either (a) by the electrolytic reduction of aqueous nitric acid between amalgamated lead electrodes in the presence of H$_2$SO$_4$/HCl or (b) by the hydrogenation of nitric oxide in acid solutions over a Pt/charcoal catalyst:

(a) HNO$_3$(aq) + 6H$_3$O$_2$(aq) \[\text{6e}^-\] $\longrightarrow$ 2H$_2$O + NH$_2$OH

(b) 2NO(g) + 3H$_2$(g) + H$_2$SO$_4$(aq) $\longrightarrow$ [NH$_3$(OH)Cl]Cl(s)

A convenient laboratory route involves the reduction of an aqueous solution of nitrous acid or potassium nitrite with bisulfite under carefully

---

controlled conditions: The hydroxylamidodisulfate first formed, though stable in alkaline solution, rapidly hydrolyses to the monosulfate in acid solution and this can then subsequently be hydrolysed to the hydroxylammonium ion by treatment with aqueous HCl at 100° for 1 h:

\[
\text{HNO}_2 + 2\text{HSO}_3^- \longrightarrow \text{[NH(OH)(OSO_2)_2]}^{2^-} + \text{H}_2\text{O} \\
\text{fast} \quad \longrightarrow \quad \text{[NH(OH)(OSO_2)]}^- + \text{[HSO_4]}^- \\
\text{[NH(OH)(OSO_2)]}^- + \text{H}_3\text{O}^+ \quad \begin{array}{c}100°/1\text{h} \\ \longrightarrow \quad \text{[NH}_3\text{(OH)}\text{]}^+ + \text{[HSO}_4]\text{]}^- \end{array}
\]

Anhydrous NH₂OH can be prepared by treating a suspension of hydroxylammonium chloride in butanol with NaOBu:

\[
\text{[NH}_3\text{(OH)}\text{]}\text{Cl} + \text{NaOBu} \longrightarrow \text{NH}_2\text{OH} \\
\quad + \text{NaCl} + \text{BuOH}
\]

The NaCl is removed by filtration and the NH₂OH precipitated by addition of Et₂O and cooling.

NH₂OH can exist as 2 configurational isomers (cis and trans) and in numerous intermediate gauche conformations as shown in Fig. 11.7. In the crystalline form, H bonding appears to favour packing in the trans conformation. The N–O distance is 147 pm consistent with its formulation as a single bond. Above room temperature the compound decomposes (sometimes explosively) by internal oxidation-reduction reactions into a complex mixture of N₂, NH₃, N₂O and H₂O. Aqueous solutions are much more stable, particularly acid solutions in which the compound is protonated, [NH₃(OH)]⁺. Such solutions can act as oxidizing agents particularly when acidified but are more generally used as reducing agents, e.g. as antioxidants in photographic developers, stabilizers of monomers, and for reducing Cu²⁺ to Cu¹ in the dyeing of acrylic fibres. Comparisons with the redox chemistry of H₂O₂ and N₂H₄ are also instructive (see, for example, pp. 272–3 of ref. 69). The ability of NH₂OH to react with N₂O, NO and N₂O₄ under suitable conditions (e.g. as the sulfate adsorbed on silica gel) makes it useful as an absorbent in combustion analysis. However, the major use of NH₂OH, which derives from its ability to form oximes with aldehydes and ketones, is in the manufacture of caprolactam, a key intermediate in the production of polyamide-6 fibres such as nylon. This consumes more than 97% of world production of NH₂OH, which is at least 650 000 tonnes per annum.

The extensive chemistry of the hydroxylamides of sulfuric acid is discussed later in the context of other H–N–O–S compounds (pp. 740–6).

**Hydrogen azide**

Aqueous solutions of HN₃ were first prepared in 1890 by T. Curtius who oxidized aqueous hydrazine with nitrous acid:

\[
\text{N}_2\text{H}_5^+ + \text{HNO}_2 \longrightarrow \text{HN}_3 + \text{H}^+ + 2\text{H}_2\text{O}
\]

Other oxidizing agents that can be used include nitric acid, hydrogen peroxide, peroxydisulfate, chlorate and the pervanadyl ion. The anhydrous

---

*Figure 11.7* Configurations of NH₂OH.
compound is extremely explosive and even dilute solutions should be treated as potentially hazardous. Pure HN₃ is best prepared by careful addition of H₂SO₄ to NaN₃; it is a colourless liquid or gas (mp ~ -80°C, estimated bp 35.7°C, d 1.126 g cm⁻³ at 0°C). Its large positive enthalpy and free energy of formation emphasize its inherent instability: ΔHᵢ(1, 298 K) = 269.5 kJ mol⁻¹, ΔGᵢ(1, 298 K) = 327.2 kJ mol⁻¹. It has a repulsive, intensely irritating odour and is a deadly (though non-cumulative) poison; even at concentrations less than 1 ppm in air it can be dangerous. In the gas phase the 3N atoms are (almost) colinear, as expected for a 16 valence-electron species, and the angle HNN is 109°; the two N–N distances are appreciably different, as shown in structure (1). The structure and dimensions of the isomeric molecule cyclotriazene are given in (2) for comparison; the N–H bond is tilted out of the plane of the N₃ ring by 74°.

![Structure diagrams](image)

Similar differences are found for organic azides (e.g. MeN₃). In ionic azides (p. 417) the N₃⁻ ion is both linear and symmetrical (both N–N distances being 116 pm) as befits a 16-electron species isoelectronic with CO₂ (cf. also the cyanamide ion NCN²⁻, the cyanate ion NCO⁻, the fulminate ion CNO⁻ and the nitronium ion NO₂⁺).

Aqueous solutions of HN₃ are about as strongly acidic as acetic acid:

\[ \text{HN}_3(aq) = \text{H}^+(aq) + \text{N}_3^-(aq); \quad K_a = 1.8 \times 10^{-5}, \]
\[ \text{p}K_a = 4.77 \text{ at } 298 \text{ K} \]

Numerous metal azides have been characterized (p. 417) and covalent derivatives of non-metals are also readily preparable by simple metathesis using either NaN₃ or aqueous solutions of HN₃. In these compounds the N₃ group behaves as a pseudohalogen (p. 319) and, indeed, the unstable compounds FN₃, ClN₃, BrN₃, IN₃ and NCN₃ are known, though potential allotropes of nitrogen such as N₃-N₃ (analogous to Cl₂) and N(N₃)₃ (analogous to NCl₃) have not been isolated. More complex heterocyclic compounds are, however, well established, e.g. cyanuric azide \{-NC(N₃)₃\}, B,B,B-triazidoborazine \{-NB(N₃)₃\} and even the azidophosphazene derivative \{-NP(N₃)₃\}.

Most preparative routes to HN₃ and its derivatives involve the use of NaN₃ since this is reasonably stable and commercially available. NaN₃ can be made by adding powdered NaN₃ to fused NaNH₂ at 175°C or by passing N₂O into the same molten amide at 190°C:

\[ \text{NaN}_3 + 3\text{NaNH}_2 \rightarrow \text{NaN}_3 + 3\text{NaOH} + \text{NH}_3 \]

The latter reaction is carried out on an industrial scale using liquid NH₃ as solvent; a variant uses Na/NH₃ without isolation of the NaNH₂:

\[ 3\text{N}_2\text{O} + 4\text{Na} + \text{NH}_3 \rightarrow \text{Na}_3\text{N}_3 + 3\text{NaOH} + 2\text{N}_2 \]

A remarkable new covalent azide is the pale yellow nitrosyl NNNNO, prepared by reacting gaseous NOCl (p. 441) with solid NaN₃ at low temperature. NNNN(SO₂F)₂ has also very recently been made by a similar route from (SO₂F)₂NCl; it is a volatile yellow liquid which sometimes decomposes explosively.

The major use of inorganic azides exploits the explosive nature of heavy metal azides. Pb(N₃)₂ in particular is extensively used in detonators because of its reliability, especially in damp conditions; it is prepared by metathesis between Pb(NO₃)₂ and NaN₃ in aqueous solution.

---

82 pp. 276–93 of ref. 69.
11.3.4 Thermodynamic relations between N-containing species

The ability of N to exist in its compounds in at least 10 different oxidation states from −3 to +5 poses certain thermodynamic and mechanistic problems that invite systematic treatment. Thus, in several compounds N exists in more than one oxidation state, e.g. \([\text{N}^{\text{III}}\text{H}_4]^+ [\text{N}^{\text{III}}\text{O}_2]^-\), \([\text{N}^{\text{III}}\text{H}_4]^+ [\text{N}^{\text{V}}\text{O}_3]^-\), \([\text{N}^{\text{II}}\text{H}_5]^+ [\text{N}^{\text{V}}\text{O}_3]^-\), \([\text{N}^{\text{III}}\text{H}_4]^+ [\text{N}^{\frac{1}{3}}\text{I}_3]^-\), etc. Furthermore, we have seen (p. 423) that, under appropriate conditions, \(\text{NH}_3\) can be oxidized by \(\text{O}_2\) to yield \(\text{N}_2\), \(\text{NO}\) or \(\text{N}_2\text{O}_2\), whereas oxidation by \(\text{OCl}^-\) yields \(\text{N}_2\text{H}_4\) (p. 427). Likewise, using appropriate reagents, \(\text{N}_2\text{H}_4\) can be oxidized either to \(\text{N}_2\) or to \(\text{HN}_3\) (in which the "average" oxidation number of N is \(-\frac{1}{3}\)).

The thermodynamic relations between these various hydrido and oxo species containing N can be elegantly codified by means of their standard reduction potentials, and these can be displayed pictorially using the concept of the "volt equivalent" of each species (see Panel).

The standard reduction potentials in acidic aqueous solution are given in Table 11.4; these are shown diagrammatically in Fig. 11.8 (p. 437) which also includes the corresponding data for alkaline solutions. The reduction potentials are readily converted to volt equivalents (by multiplying by the appropriate oxidation state) and these are plotted against oxidation state in Fig. 11.9. This latter diagram is particularly valuable in giving a visual representation of the redox chemistry of the element. Thus, it follows from the definition of "volt equivalent" that the reduction potential of any couple is the slope of the line joining the two points: the greater the positive slope the stronger the oxidizing potential and the greater the negative slope the stronger the reducing power. Any pair of points can be joined. For example in acid solution \(\text{N}_2\text{H}_4\) is a...
Standard Reduction Potentials and Volt Equivalents

Chemical reactions can often formally be expressed as the sum of two or more “half-reactions” in which electrons are transferred from one chemical species to another. Conventionally these are now almost always represented as equilibria in which the forward reaction is a reduction (addition of electrons):

\[(\text{oxidized form}) + n\text{e}^- \rightleftharpoons (\text{reduced form})\]

The electrochemical reduction potential (\(E\) volts) of such an equilibrium is given by

\[E = E^\circ - \frac{2.3026RT}{nF} \log_{10} \frac{a(\text{red})}{a(\text{ox})}\]  

(1)

where \(E^\circ\) is the “standard reduction potential” at unit activity \(a\), \(R\) is the gas constant \((8.3144 \text{ J mol}^{-1} \text{ K}^{-1})\), \(T\) is the absolute temperature, \(F\) is the Faraday constant \((96485 \text{ C mol}^{-1})\) and 2.3026 is the constant \(\ln 10\) required to convert from natural to decadic logarithms. At 298.15 K \((25^\circ \text{C})\) the factor \(2.3026RT/F\) has the value 0.05916 V and, replacing activities by concentrations, one obtains the approximate expression

\[E \approx E^\circ - \frac{0.05916}{n} \log_{10} \frac{[\text{red}]}{[\text{ox}]}\]  

(2)

By convention, \(E^\circ\) for the half-reaction \((3)\) is taken as zero, i.e. \(E^\circ(\text{H}^+/\text{H}_2) = 0.0\) V:

\[\text{H}^+(\text{aq}, a = 1) + \text{e}^- \rightleftharpoons \frac{1}{2}\text{H}_2(\text{g}, 1 \text{ atm})\]  

(3)

Remembering that \(\Delta G = -nEF\), it follows that the standard free energy change for the half reaction is \(\Delta G^\circ = -nE^\circ F\), e.g.:

\[\text{Fe}^{3+}(\text{aq}) + \text{e}^- \rightleftharpoons \text{Fe}^{2+}(\text{aq}); \quad E^\circ(\text{Fe}^{3+}/\text{Fe}^{2+}) = 0.771 \text{ V}\]  

(4)

\[\Delta G^\circ = -74.4 \text{ kJ mol}^{-1}\]

Coupling the half-reactions \((3)\) and \((4)\) gives the reaction \((5)\) [i.e. \((4) - (3)\)] which, because \(\Delta G\) is negative, proceeds spontaneously from left to right as written:

\[\text{Fe}^{3+}(\text{aq}) + \frac{1}{2}\text{H}_2(\text{g}) \rightleftharpoons \text{Fe}^{2+}(\text{aq}) + \text{H}^+(\text{aq}); \quad E^\circ = 0.771 \text{ V}\]  

(5)

\[\Delta G^\circ = -74.4 \text{ kJ mol}^{-1}\]

Again, \(E^\circ(\text{Zn}^{2+}/\text{Zn}) = -0.763 \text{ V}\), hence reaction \((6)\) occurs spontaneously in the reverse direction:

\[\text{Zn}^{2+}(\text{aq}) + \text{H}_2(\text{g}) \rightleftharpoons \text{Zn(s)} + 2\text{H}^+(\text{aq}); \quad E^\circ = -0.763 \text{ V}\]  

\[\Delta G^\circ = +147.5 \text{ kJ mol}^{-1} \text{ (note the factor of 2 for } n)\]  

(6)

In summary, at pH 0 a reaction is spontaneous from left to right if \(E^\circ > 0\) and spontaneous in the reverse direction if \(E^\circ < 0\). At other H-ion concentrations eqn. (2) indicates that the potential of the H electrode \((3)\) will be

\[E = -0.05916 \log \frac{[\text{H}_2(\text{atm})]^\frac{1}{2}}{[\text{H}^+(\text{aq})]/\text{mol}^{-1}} \text{ V}\]

and, in general, the potential of any half-reaction changes with the concentration of the species involved according to the Nernst equation (7):

\[E = E^\circ - \frac{0.05916}{n} \log Q\]  

(7)

where \(Q\) has the same form as the equilibrium constant but is a function of the actual activities of the reactants and products rather than those of the equilibrium state. Note also that the potential is independent of the coefficients of the half-reaction whereas the free energy is directly proportional to these, e.g.:
It is vital to remember that, when half-reactions are added or subtracted, one should not add or subtract the corresponding $E^\circ$ values but rather $nE^\circ$. (We shall return to this point later.)

Lists of standard reduction potentials are given in many books and are extensively quoted throughout this text. Almost all lists now use the IUPAC sign conventions employed above, though some earlier American books (including, unfortunately, the classic early text on the subject) use the opposite sign convention. When standard reduction potentials are listed in sequence from the most negative to the most positive the strongest reducing agents are at the top of the list and a reducing agent should, in principle, be capable of reducing all oxidizing agents lying below it in the table. Conversely, the oxidizing agents are listed in order of increasing strength and a given oxidizing agent should be able to oxidize all reducing agents lying above it in the table. Such lists are an extremely compact way of summarizing a great deal of predictive information. For example a list of 100 independent reduction potentials enables the free energy change for 100 x 99/2 = 4950 reactions to be calculated and indicates the direction in which a hypothetical reaction would occur under appropriate conditions (which might involve the use of a catalyst).

When an element can exist in several oxidation states it is sometimes convenient to display the various reduction potentials diagrammatically, the corresponding half-reactions under standard conditions being implied. Thus, in acidic aqueous solutions

$$\frac{1}{2}I_2 + e^- \rightarrow I^-; \quad E^\circ = 0.536 \text{ V}; \quad \Delta G^\circ = -51.5 \text{ kJ mol}^{-1}$$

$$I_2 + 2e^- \rightarrow 2I^-; \quad E^\circ = 0.536 \text{ V}; \quad \Delta G^\circ = -103.0 \text{ kJ mol}^{-1}$$

Note that the value of $E^\circ$ (Fe$^{3+}$/Fe) = -0.44 V is equivalent to [((2 x -0.44) + 0.77)/3. Because the quantity $nE^\circ$ is used in these calculations (rather than $E$) it is convenient to define the “volt equivalent” of a species; the volt equivalent of a compound or ion is the reduction potential of the species relative to the element in its standard state multiplied by the oxidation state of the element in the compound (including its sign). The oxidation state is the number of electrons that must be added to an atom of an element to regain electroneutrality when all other atoms in the compound (ion) have been removed as their “normal” ions. For example the oxidation state of Fe is +6 in FeO$_4^{2-}$:

$$\text{FeO}_4^{2-} \rightarrow \text{Fe}^{6+} + 6e^-$$

It follows that, in the above example, the volt equivalents of Fe$^{2+}$ and Fe$^{3+}$ are -0.88 and -0.11 respectively and that of FeO$_4^{2-}$ is +0.49 (i.e. (2 x -0.44) + 0.77 + (3 x 2.20)). This leads to $E^\circ$ (FeO$_4^{2-}$/Fe) = +1.08 V.

The power of these various concepts in codifying and rationalizing the redox chemistry of the elements is illustrated for the ease of nitrogen in the present section. Standard reduction potentials and plots of volt equivalents against oxidation state for other elements are presented in later chapters.

It also follows that, when three (or more) oxidation states lie approximately on a straight line in the volt-equivalent diagram, they tend to form an equilibrium mixture rather than a reaction going to completion (provided that the attainment of thermodynamic equilibrium is not hindered kinetically). This is because the slopes joining the several points are almost the same, so that $E^\circ$ for the various couples (and hence $\Delta G^\circ$) are the same; there is consequently approximately zero change in free energy and a balanced
Figure 11.8  Oxidation states of nitrogen showing standard reduction potentials in volts: (a) in acid solution at pH 0, and (b) in basic solution at pH 14.

equilibrium is maintained between the several species. Indeed, the volt-equivalent diagram is essentially a plot of free energy versus oxidation state (as indicated by the right-hand ordinate of Fig. 11.9).

Two further points follow from these general considerations:

(a) a compound will tend to disproportionate into a higher and a lower oxidation state if it lies above the line joining the 2 compounds in these oxidation states, i.e. disproportionation is accompanied by a decrease in free energy and will tend to occur spontaneously if not kinetically hindered. Examples are the disproportionation of hydroxylamine in acidic solutions (slow) and alkaline solutions (fast):

$$4\text{NH}_3\text{OH}^+ \rightarrow \text{N}_2\text{O} + 2\text{NH}_4^+ + 3\text{H}_2\text{O} + 2\text{H}^+$$

$$3\text{NH}_2\text{OH} \rightarrow \text{N}_2 + \text{NH}_3 + 3\text{H}_2\text{O}$$

(b) Conversely, a compound can be formed by conproportionation of compounds in which the element has a higher and lower oxidation state if it lies below the line joining these two states. A particularly important example is the synthesis of HN$_7^-$ by reacting N$_2^{12}$H$_5^+$ and HN$^{13}$O$_2$ (p. 432). It will be noted that the reduction potential of HN$_3$ (-3.09 V) is more negative than that of any other reducing agent in acidic aqueous solution so it is thermodynamically impossible to synthesize HN$_3$ by reduction of N$_2$ or any of its compounds in such media unless the reducing agent itself contains N (as does hydrazine).
Figure 11.9  Plot of volt equivalent against oxidation state for various compounds or ions containing N in acidic aqueous solution. Note that values of $-\Delta G$ refer to $N_2$ as standard (zero) but are quoted per mol of N atoms and per mol of $N_2$; they refer to reactions in the direction $(\text{ox}) + ne^- \rightarrow \text{(red)}$. Slopes corresponding to some common oxidizing and reducing agents are included for comparison.

In basic solutions a different set of redox equilibria obtain and a different set of reduction potentials must be used. For example:

\[
\begin{align*}
N_2 + 4H_2O + 2e^- & = 2NHzOH + 2OH^- & E^\circ/V & = -3.04 \\
N_2 + 4H_2O + 4e^- & = N_2H_4 + 4OH^- & E^\circ/V & = -1.16 \\
N_2O + 5H_2O + 4e^- & = 2NH_2OH + 4OH^- & E^\circ/V & = -1.05 \\
N_2O_2^- + 6H_2O + 4e^- & = 2NH_2OH + 6OH^- & E^\circ/V & = -0.73 \\
NO_3^- + H_2O + 2e^- & = NO_2^- + 2OH^- & E^\circ/V & = +0.01 \\
N_2H_4 + 4H_2O + 2e^- & = 2NH_4^+ + 4OH^- & E^\circ/V & = +0.11 \\
2NH_2OH + 2e^- & = N_2H_4 + 2OH^- & E^\circ/V & = +0.73
\end{align*}
\]

A more complete compilation is summarized in Fig. 11.8. It is instructive to use these data to derive a plot of volt equivalent versus oxidation state in basic solution and to compare this with Fig. 11.9 which refers to acidic solutions.

11.3.5 Nitrogen halides and related compounds\(^{(69)}\)

It is a curious paradox that NF\(_3\), the most stable binary halide of N, was not prepared until 1928, more than 115 y after the highly unstable
NCl₃ was prepared in 1811 by P. L. Dulong (who lost three fingers and an eye studying its properties). Pure NBr₃ explodes even at −100° and was not isolated until 1975(87) and NI₃ has not been prepared, though the explosive adduct NI₃.NH₃ was first made by B. Courtois in 1813 and several other amines are known. In all, there are now 5 binary fluorides of nitrogen (NF₃, N₂F₄, cis- and trans-N₂F₂ and N₃F) and these, together with the cations NF₄⁺ and N₂F₃⁺ and various mixed halides, hydride halides and oxohalides are discussed in this section.

NF₃ was first prepared by Otto Ruff's group in Germany by the electrolysis of molten NH₄F/HF and this process is still used commercially. An alternative is the controlled fluorination of NH₃ over a Cu metal catalyst.

\[
4\text{NH}_3 + 3\text{F}_2 \xrightarrow{\text{Cu}} \text{NF}_3 + 3\text{NH}_4\text{F}
\]

NF₃ is a colourless, odourless, thermodynamically stable gas (mp −206.8°, bp −129.0°, \(\Delta G_{298}^\circ = 83.3\text{ kJ mol}^{-1}\)). The molecule is pyramidal with an F−N−F angle of 102.5°, but the dipole moment (0.234 D) is only one-sixth of that of NH₃ (1.47 D) presumably because the N−F bond moments act in the opposite direction to that of the lone-pair moment:

\[
\text{NF}_3 + 2\text{F}_2 + \text{SbF}_3 \xrightarrow{200°/100\text{ atm}} [\text{NF}_4]^+ [\text{SbF}_6]^- \\
2\text{NF}_3 + \text{O}_2 \xrightarrow{\text{electric discharge}} -196° 2\text{ONF}_3
\]

ONF₃ was discovered independently by two groups in 1966.(89) Although isoelectronic with BF₄⁻, CF₄ and NF₄⁺ it has excited interest because of the short N−O distance (115.8 pm), which implies some multiple bonding, and the correspondingly long N−F distances (143.1 pm). Similar partial double bonding to O and highly polar bonds to F have also been postulated for the analogous ion [OCF₃]⁺ in Cs[OCF₃].(90)

FN₃ is one of the most explosive and thermally unstable covalent azides known. It can be prepared by reacting HN₃ with F₂ and is best handled as a gas at low pressure.(91) The molecular parameters (microwave) are N−F 144.4 pm, Nα−Nβ 125.3 pm, Nα−Nα 113.2 pm, and angles FNN 103.8°, NNN 170.9° (cf HN₃ p. 433) The species NF is known only as a ligand, in the octahedral complex [ReF₅(NF)](92) the complex is made by treating ReF₄N or ReF₃N with XeF₂ and X-ray structural analysis revealed a linear Re−N−F group (178°) with N−F 126 pm.

Dinitrogen tetrafluoride, N₂F₄, is the fluorine analogue of hydrazine and exists in both the staggered (trans) \(C_{2h}\) and gauche \(C_2\) conformations.

---

It was discovered in 1957 and is now made either by partial defluorination of NF₃ (see above) or by quantitative oxidation of NF₂H with alkaline hypochlorite:

\[
\text{(NH₂)₂CO(aq)} \overset{\text{conc H₂SO₄, NaOCl (pH 12)}}{\rightarrow} \text{NH₂CONF₂}
\]

\[
\text{F}²/\text{N}² \rightarrow \text{NF₂H} \rightarrow \text{NF₄}²⁻ \quad (70\% \text{ yield})
\]

\[
\text{NF₂H} \rightarrow \text{NF₄}²⁻ \quad (100\% \text{ yield})
\]

\[
\text{NF₄}²⁻ \quad \text{a colourless reactive gas (mp } -164.5°, \text{ bp } -73°, \Delta G_{298}^{\circ} + 81.2 \text{ kJ mol}⁻¹ \text{) which acts as a strong fluorinating agent towards many substances, e.g.:}
\]

\[
\text{SiH₄} + \text{NF₂F } \overset{\text{25°}}{\rightarrow} \text{SiF₄} + \text{N₂} + 2\text{H₂}
\]

\[
\text{10Li} + \text{NF₂F } \overset{-80 \text{ to } +250°}{\rightarrow} 4\text{LiF} + 2\text{Li₃N}
\]

\[
\text{S} + \text{NF₂F } \overset{110-140°}{\rightarrow} \text{SF₄} + \text{SF₅NF₂} + \ldots
\]

It forms adducts with strong fluoride-ion acceptors such as AsF₅ which can be formulated as salts, e.g. \([\text{NF₃}]⁺[\text{AsF₅}]⁻\). However, its most intriguing property is an ability to dissociate at room temperature and above to give the free radical NF₂. Thus, when NF₂F is frozen out from the warm gas at relatively low pressures the solid is dark blue whereas when it is frozen out from the cold gas at moderate pressures it is colourless. At 150°C the equilibrium constant for the dissociation \(\text{NF}_2\text{F} \rightleftharpoons 2\text{NF}_2\) is \(K = 0.03 \text{ atm}\) and the enthalpy of dissociation is 83.2 kJ mol⁻¹. Such a dissociation, which interprets much of the reaction chemistry of \(\text{N}_2\text{F}_4\), is reminiscent of the behaviour of \(\text{N}_3\text{O}_4\) (p. 455) but is not paralleled in the chemistry of \(\text{N}_2\text{H}_3\):

Dinitrogen difluoride, \(\text{N}_2\text{F}_2\), was first identified in 1952 as a thermal decomposition product of the azide \(\text{N}_3\text{F}\) and it also occurs in small yield during the electrolysis of \(\text{NH}_4\text{F}/\text{HF}\) (p. 439), and in the reactions of \(\text{NF}_3\) with \(\text{Hg}\) or with \(\text{NF}_3\) in a \(\text{Cu}\) reactor (p. 439). Fluorination of \(\text{NaF}_3\) gives good yields on a small scale but the compound is best prepared by the following reaction sequence:

\[
\text{KF} + \text{NF}_2\text{H} \overset{-80°}{\rightarrow} \text{KF.NF}_2\text{H}
\]

\[
\overset{20°}{\sim 100\% \text{ yield}} \rightarrow \text{N}_2\text{F}_2 + \text{KHF}_2
\]

All these methods give mixtures of the \textit{cis-} and \textit{trans-} isomers; these are thermally interconvertible but can be separated by low-temperature fractionation. The \textit{trans-} form is thermodynamically more unstable than the \textit{cis-} form but it can be stored in glass vessels whereas the \textit{cis-} form reacts completely within 2 weeks to give \(\text{SiF}_4\) and \(\text{N}_2\text{O}\). \(\text{Trans-N}_2\text{F}_2\) can be prepared free of the \textit{cis-} form by the low-temperature reaction of \(\text{N}_2\text{F}_4\) with \(\text{AlCl}_3\) or \(\text{MCl}_3\) (\(M = \text{Mn, Fe, Co, Ni, Sn}\)); thermal isomerization of \(\text{trans-N}_2\text{F}_2\) at 70–100°C yields an equilibrium mixture containing \(\sim 90\% \text{ cis-N}_2\text{F}_2\) \((\Delta H_\text{isom} 12.5 \text{ kJ mol}⁻¹\)). Pure \textit{cis-N}_2\text{F}_2 can be obtained by selective complexation with \(\text{AsF}_5\); only the \textit{cis-} form reacts at room temperature to give \([\text{N}_2\text{F}]⁺[\text{AsF}_6]⁻\) and this, when treated with \(\text{NaF}/\text{HF}\), yields pure \textit{cis-N}_2\text{F}_2.

Some characteristic properties are listed below.

Several mixed halides and hydrohalides of nitrogen are known but they tend to be unstable, difficult to isolate pure, and of little interest. Examples are NClF2, NCl2F, NBrF2, NF2H, NCl2H and NClH2. The cation NH2F2+ has also been prepared as its salts with AsF6− and SbF6−.\(^{(95)}\)

The well known compound NCl3 is a dense, volatile, highly explosive liquid (mp \(-40^\circ\), bp \(+71^\circ\), \(d(20^\circ)\) 1.65 g cm\(^{-3}\), \(\mu\) 0.6 D) with physical properties which often closely resemble those of CCl4 (p. 301). It is much less hazardous as a dilute gas and, indeed, is used industrially on a large scale for the bleaching and sterilizing of flour; for this purpose it is prepared by electrolyzing an acidic solution of NH4Cl at pH 4 and the product gas is swept out of the cell by means of a flow of air for immediate use. NCl3 is rapidly hydrolysed by moisture and in alkaline solution can be used to prepare ClO2:

\[
\text{NCl}_3 + 3\text{H}_2\text{O} \rightarrow \text{NH}_3 + 3\text{HOCI} \text{ (bleach, etc.)}
\]

\[
\text{NCl}_3 + 3\text{H}_2\text{O} + 6\text{NaClO}_2 \rightarrow 6\text{ClO}_2 + 3\text{NaCl} + 3\text{NaOH} + \text{NH}_3
\]

\[
2\text{NCl}_3 + 6\text{NaClO}_2 \rightarrow 6\text{ClO}_2 + 6\text{NaCl} + N_2
\]

The elusive NBr3 was finally prepared as a deep-red, very temperature-sensitive, volatile solid by the low-temperature bromination of bistrimethylsilylbromamine with BrCl:

\[
\text{(Me}_3\text{Si})_2\text{NBr} + 2\text{BrCl} \rightarrow \text{NBr}_3 + 2\text{MeSiCl _ pentafluoro-87^\circ}
\]

It reacts instantly with NH3 in CH2Cl2 solution at \(-87^\circ\) to give the dark-violet solid NBrH2; under similar conditions I2 yields the red-brown solid NBrI. The ligands NCl and NBr have been characterized in the purple complexes [ReF5(NCl)] (mp \(\sim\)80°, N–Cl 156 pm, angle Re–N–Cl 177°) and [ReF5(NBr)] (mp \(\sim\)140°); The preparation parallels that of [ReF5(NF)] (p. 439), the reagent XeF2 being replaced by ClF3 and BrF3, respectively.\(^{(92)}\) The complexes [VCl3(NX)] (X = Cl, Br, I) have also been characterized.\(^{(96)}\)

Pure N13 has not been isolated, but the structure of its well-known extremely shock-sensitive adduct with NH3 has been elucidated — a feat of considerable technical virtuosity.\(^{(97)}\) Unlike the volatile, soluble, molecular solid NCl3, the involatile, insoluble compound [N13.NH3]\(_n\) has a polymeric structure in which tetrahedral N14 units are corner-linked into infinite chains of \(-\text{N}–\text{I}–\text{N}–\text{I}–\) (215 and 230 pm) which in turn are linked into sheets by I–I interactions (336 pm) in the c-direction; in addition, one I of each N14 unit is also loosely attached to an NH3 (253 pm) that projects into the space between the sheets of tetrahedra. The structure resembles that of the linked SiO4 units in chain metasilicates (p. 349). A further interesting feature is the presence of linear or almost linear N–I–N groupings which suggest the presence of 3-centre, 4-electron bonds (pp. 63, 64) characteristic of polyhalides and xenon halides (pp. 835–8, 897).

Nitrogen forms two series of oxohalides — the nitrosyl halides XNO and the nitryl halides XN02. There are also two halogen nitrites FONO2 (bp \(-46^\circ\)) and ClONO2 (bp 22.3°), but these do not contain N–X bonds and can be considered as highly reactive derivatives of nitric acid, from which they can be prepared by direct halogenation:

\[
\text{HNO}_3 + F_2 \rightarrow \text{FONO}_2 + HF
\]

\[
\text{HNO}_3 + \text{ClF} \rightarrow \text{ClONO}_2 + HF
\]

The nitrosyl halides are reactive gases that feature bent molecules; they can be made by direct halogenation of NO with X2, though fluorination of NO with AgF2 has also been used and ClNO can be more conveniently made by passing N2O4 over moist KCl:

\[
2\text{NO} + X_2 \rightarrow 2X\text{NO}
\]

NO + AgF₂ \rightarrow FNO + AgF
N₂O₄ + KCl \rightarrow ClNO + KNO₃

Some physical properties are in Table 11.5. FNO is colourless, ClNO orange-yellow and BrNO red. The compounds, though generally less reactive than the parent halogens, are nevertheless extremely vigorous reagents. Thus FNO fluorinates many metals (nFNO + M \rightarrow MFₙ + nNO) and also reacts with many fluorides to form salt-like adducts such as NOAsF₆, NOVF₆, and NOBF₄. ClNO acts similarly and has been used as an ionizing solvent to prepare complexes such as NOAICl₄, NOFeCl₄, NOsBCl₆, and (NO)₂SnCl₆. Aqueous solutions of XNO are particularly potent solvents for metals (like aqua regia, HNO₃/HCl) since the HNO₂ formed initially, reacts to give HNO₃:

XNO + H₂O \rightarrow HNO₂ + HX
3HNO₂ \rightarrow HNO₃ + 2NO + H₂O

Alkaline solutions contain a similar mixture:
4XNO + 3H₂O \rightarrow HNO₃ + HNO₂ + 2NO + 4HX
4XNO + 6NaOH \rightarrow NaNO₃ + NaNO₂ + 2NO + 4NaX + 3H₂O

With alcohols, however, the reaction stops at the nitrite stage:

XNO + ROH \rightarrow RONO + HX

Nitryl fluoride and chloride, XNO₂, like their nitrosyl analogues, are reactive gases; they feature planar molecules, analogous to the isoelectronic nitrate anion, NO₃⁻. Some physical properties are in Table 11.6. FNO₂ can be prepared by direct reaction of F₂ with NO₂ or NaN₂O₂ or by fluorination of NO₂ using CoF₃ at 300°. CINO₂ cannot be made by direct chlorination of NO₂ but is conveniently synthesized in high yield by reacting anhydrous nitric acid with chlorosulfuric acid at 0°C:

HNO₃ + CISO₃H \rightarrow CINO₂ + H₂SO₄
Reactions of XNO₂ often parallel those of XNO; e.g. FNO₂ readily fluorinates many metals and reacts with the fluorides of non-metals to give nitryl “salts” such as NO₂BF₄, NO₂PF₆, etc. Likewise, CINO₂ reacts with many chlorides in liquid Cl₂ to give complexes such as NO₂SbCl₆. Hydrolysis yields aqueous solutions of nitric and hydrochloric acids, whereas ammonolysis in liquid ammonia yields chloramine and ammonium nitrite:

CINO₂ + H₂O \rightarrow [HOCICl + HNO₂] \rightarrow HNO₃ + HCl
CINO₂ + 2NH₃ \rightarrow ClNH₂ + NH₄NO₂

11.3.6 Oxides of nitrogen

Nitrogen is unique among the elements in forming no fewer than 8 molecular oxides, 3 of which are paramagnetic and all of which are thermodynamically unstable with respect to decomposition into N₂ and O₂. In addition there is evidence for fugitive species such as nitryl azide, N₃NO₂, but this decomposes rapidly below room temperature(99) and will not be considered further. Three of the oxides (N₂O, NO and NO₂) have been known for over 200 y and were, in fact, amongst the very first gaseous compounds to be isolated and identified (J. Priestley and others in the 1770s). The most recent addition, nitrosyl azide N₄O (p. 433), was isolated in 1993 as a pale yellow solid whose vibration spectrum at −110° is consistent with the optimized computed structure (3).(84)

The physiological effects of N₂O (laughing gas, anaesthetic) and NO₂ (acrid, corrosive fumes) have been known from the earliest days, and the environmental problems of “NOₓ” from automobile exhaust fumes and as a component in photochemical smog are well known in all industrial countries.(100,101) NO is now recognized as a key neuro transmitter in humans and other animals and its biologically triggered synthesis is implicated in cardiovascular pharmacology, hypertension, impotence, immunology and other vital functions.(102) NO and NO₂ are important in

the commercial production of nitric acid (p. 466) and nitrate fertilizers and N₂O₄ has been used extensively as the oxidizer in rocket fuels for space missions (p. 429).

The oxides of nitrogen played an important role in exemplifying Dalton’s law of multiple proportions which led up to the formulation of his atomic theory (1803–8), and they still pose some fascinating problems in bonding theory. Their formulae, molecular structure, and physical appearance are briefly summarized in Table 11.7 and each compound is discussed in turn in the following sections.

Nitrous oxide (Dinitrogen monoxide), N₂O

Nitrous oxide can be made by the careful thermal decomposition of molten NH₄NO₃ at about 250°C:

\[
\text{NH}_4\text{NO}_3 \xrightarrow{\Delta} \text{N}_2\text{O} + 2\text{H}_2\text{O}
\]

Although the reaction has the overall stoichiometry of a dehydration it is more complex than this and involves a mutual redox reaction between N⁻ and N⁷. This is at once explicable in terms of the volt-equivalent diagram in Fig. 11.9 which also interprets why NO and N₂ are formed simultaneously as byproducts. It is probable that the mechanism involves dissociation of NH₄NO₃ into NH₃ and HNO₃, followed by autoprolysis of HNO₃ to give NO₂⁺, which is the key intermediate:

\[
\text{NH}_4\text{NO}_3 \leftrightarrow \text{NH}_3 + \text{HNO}_3
\]

\[
2\text{HNO}_3 \leftrightarrow \text{NO}_2^+ + \text{H}_2\text{O} + \text{NO}_3^-
\]

\[
\text{NH}_3 + \text{NO}_2^+ \rightarrow (\text{H}_3\text{NNO}_2)^+
\]

\[
\rightarrow \text{NNO} + \text{H}_3\text{O}^+, \text{etc.}
\]

Consistent with this ¹⁵NNO can be made from ¹⁵NH₄NO₃ and ¹⁵NNO from NH₄¹⁵NO₃. Alternative preparative routes (Fig. 11.9) are the reduction of aqueous nitrous acid with either hydroxylamine or hydrogen azide:

HNO₂ + NH₂OH $\xrightarrow{aq}$ N₂O + 2H₂O

HNO₂ + HN₃ $\xrightarrow{aq}$ N₂O + N₂ + H₂O

Thermal decomposition of nitramide, H₂NNO₂, or hyponitrous acid H₂N₂O₂ (both of which have the empirical formula N₂O.H₂O) have also been used. The mechanisms of these and other reactions involving simple inorganic compounds of N have been reviewed.\(^{(103)}\)

However, though N₂O can be made in this way it is not to be regarded as the anhydride of hyponitrous acid since H₂N₂O₂ is not formed when N₂O is dissolved in H₂O (a similar relation exists between CO and formic acid).

Nitrous oxide is a moderately unreactive gas comprised of linear unsymmetrical molecules, as expected for a 16-electron triatomic species (p. 433). The symmetrical structure N–O–N is precluded on the basis of orbital energetics. Some physical properties are in Table 11.8: it will be seen that the N–N and N–O distances are

...both short and calculations⁴⁰⁴ give the bond orders as N–N 2.73 and N–O 1.61. N₂O is thermodynamically unstable and when heated above ~600°C it dissociates by fission of the weaker bond (N₂O → N₂ + ½O₂). However, the reaction is much more complex than this simple equation might imply and the process involves a “forbidden” singlet-triplet transition in which electron spin is not conserved.⁴⁰⁵ The activation energy for the process is high (~250 kJ mol⁻¹) and at room temperature N₂O is relatively inert: e.g. it does not react with the halogens, the alkali metals or even ozone. At higher temperatures reactivity increases markedly: H₂ gives N₂ and H₂O; many other non-metals (and some metals) react to form oxides, and the gas supports combustion. Perhaps its most remarkable reaction is with molten alkali metal amides to yield azides, the reaction with NaNH₂ being the commercial route to NaN₃ and hence all other azides (p. 433):

\[
\text{NaNH}_2(1) + N_2O(g) \stackrel{200°}{\longrightarrow} \text{NaN}_3 + H_2O(g)
\]

\[
\text{NaNH}_2 + H_2O \longrightarrow \text{NaOH} + NH_3(g)
\]

It is also notable that N₂O (like N₂ itself) can act as a ligand by displacing H₂O from the aquo complex [Ru(NH₃)₅(H₂O)]²⁺:⁴⁰⁶

\[
[Ru(NH₃)₅(H₂O)]²⁺ + N₂O(aq) \longrightarrow [Ru(NH₃)₅(N₂O)]²⁺ + H₂O
\]

The formation constant \( K \) is 7.0 mol⁻¹ for N₂O and 3.3 \( \times 10^4 \) mol⁻¹ for N₂.

Notwithstanding the fascinating reaction chemistry of N₂O it is salutory to remember that its largest commercial use is as a propellant and aerating agent for “whipped” ice-cream — this depends on its solubility under pressure in vegetable fats coupled with its non-toxicity in small concentrations and its absence of taste. It was also formerly much used as an anaesthetic.

**Nitric oxide (Nitrogen monoxide), NO**

Nitric oxide is the simplest thermally stable odd-electron molecule known and, accordingly, its electronic structure and reaction chemistry have been very extensively studied.⁴⁰⁷ The compound is an intermediate in the production of nitric acid and is prepared industrially by the catalytic oxidation of ammonia (p. 466). On the laboratory scale it can be synthesized from aqueous solution by the mild reduction of acidified nitrites with iodide or ferrocyanide or by the disproportionation of nitrous acid in the presence of dilute sulfuric acid:

\[
\text{KNO}_2 + \text{KI} + H_2SO₄ \rightarrow NO + K_2SO₄ + H_2O + \frac{1}{2}I_2
\]

\[
\text{KNO}_2 + K_4[\text{Fe(CN)}₆] + 2\text{MeCO}_2\text{H} \rightarrow
\]

\[
\text{NO} + K_3[\text{Fe(CN)}₆] + H₂O + 2\text{MeCO}_2\text{K}
\]

\[
6\text{NaN}_2O₂ + 3\text{H}_2\text{SO}_₄ \rightarrow 4\text{NO} + 2\text{HNO}_₃ + 2\text{H}_2\text{O} + 3\text{Na}_2\text{SO}_₄
\]

The dry gas has been made by direct reduction of a solid mixture of nitrite and nitrate with chromium(III) oxide (3KNO₂ + KNO₃ + Cr₂O₃ → 4NO + 2K₂CrO₄) but is now more conveniently obtained from a cylinder.

Nitric oxide is a colourless, monomeric, paramagnetic gas with a low mp and bp (Table 11.9). It is thermodynamically unstable and decomposes into its elements at elevated temperatures (1100–1200°C), a fact which militates against its direct synthesis from N₂ and O₂. At high pressures and moderate temperatures...

(-50°) it rapidly disproportionates:

$$3\text{NO} \rightarrow \text{N}_2\text{O} + \text{NO}_2; \quad -\Delta H = 3 \times 51.8 \text{kJ mol}^{-1}$$

$$-\Delta G = 3 \times 34.7 \text{kJ mol}^{-1}$$

However, when the gas is occluded by zeolites the disproportionation takes a different course:

$$4\text{NO} \rightarrow \text{N}_2\text{O} + \text{N}_2\text{O}_3; \quad -\Delta H = 4 \times 48.8 \text{kJ mol}^{-1}$$

$$-\Delta G = 4 \times 25.7 \text{kJ mol}^{-1}$$

The molecular orbital description of the bonding in NO is similar to that in N$_2$ or CO (p. 927) but with an extra electron in one of the $\pi^*$ antibonding orbitals. This effectively reduces the bond order from 3 to ~2.5 and accounts for the fact that the interatomic N–O distance (115 pm) is intermediate between that in the triple-bonded NO$^+$ (106 pm) and values typical of double-bonded NO species (~120 pm). It also interprets the very low ionization energy of the molecule (9.25 eV, compared with 15.6 eV for N$_2$, 14.0 eV for CO, and 12.1 eV for O$_2$). Similarly, the notable reluctance of NO to dimerize can be related both to the geometrical distribution of the unpaired electron over the entire molecule and to the fact that dimerization to O=N–N=O leaves the total bond order unchanged ($2 \times 2.5 = 5$). When NO condenses to a liquid, partial dimerization occurs, the cis-form being more stable than the trans-. The pure liquid is colourless, not blue as sometimes stated: blue samples owe their colour to traces of the intensely coloured N$_2$O$_3$.\(^{108}\) Crystalline nitric oxide is also colourless (not blue) when pure,\(^{108}\) and X-ray diffraction data are best interpreted in terms of weak association into dimeric units. It seems probable that the dimers adopt the *cis*-(C$_{2v}$) structure\(^{109}\) rather than the rectangular C$_{2h}$ structure which was at one time favoured,\(^{110}\) i.e.:

In either case each dimer has two possible orientations, and random disorder between these accounts for the residual entropy of the crystal (6.3 J mol$^{-1}$ of dimer). More recently\(^{111}\) an asymmetric dimer has been characterized; this forms as a red species when NO is condensed in the presence of polar molecules such as HCl or SO$_2$, or Lewis acids such as BX$_3$, SiF$_4$, SnCl$_4$ or TiCl$_4$. Reaction of NO with either [Pt(PPh$_3$)$_3$] or [Pt(PPh$_3$)$_4$] yields [Pt(NO)$_2$(PPh$_3$)$_2$] which has been shown by X-ray diffraction analysis to be an unstable planar *cis*-hyponitrite complex, \([\text{PPh}_3]_2\text{Pt}=-\text{ON}=-\text{NO}\), with an N=O distance of 121 pm and N–O 132 and 139 pm.\(^{112}\)

The reactivity of NO towards atoms, free radicals, and other paramagnetic species has been much studied, and the chemiluminescent reactions with atomic N and O are important in assaying atomic N (p. 414). NO reacts rapidly with molecular O$_2$ to give brown NO$_2$, and this gas is the normal product of reactions which produce NO if these are carried out in air. The oxidation is unusual in following third-order reaction kinetics and, indeed, is the classic

example of such a reaction (M. Bodenstein, 1918). The reaction is also unusual in having a negative temperature coefficient, i.e. the rate becomes progressively slower at higher temperatures. For example the rate drops by a factor of 2 between room temperature and 200°C. This can be accounted for by postulating that the mechanism involves the initial equilibrium formation of an unstable dimer which then reacts with oxygen:

\[ 2\text{NO} \rightleftharpoons \text{N}_2\text{O}_2 \xrightarrow{\text{O}_2} 2\text{NO}_2 \]

As the equilibrium concentration of \( \text{N}_2\text{O}_2 \) decreases rapidly with increase in temperature the decrease in rate is explained. However alternative mechanisms have also been suggested.\(^{(107)}\)

Nitric oxide reacts with the halogens to give XNO (p. 441). Some other facile reactions are listed below:

- \( \text{ClNO}_2 + \text{NO} \rightarrow \text{ClNO} + \text{NO}_2 \)  
  (?Cl transfer or O transfer)
- \( \text{NCl}_3 + 2\text{NO} \rightarrow \text{ClINO} + \text{N}_2\text{O} + \text{Cl}_2 \)  
  (stepwise at \(-150^\circ\))
- \( \text{XeF}_2 + 2\text{NO} \rightarrow 2\text{FNO} + \text{Xe} \)  
  (occurs stepwise; also with \( \text{XeF}_4 \))
- \( \text{I}_2\text{O}_5 + 5\text{NO} \rightarrow 5\text{N}_2\text{O}_4 + \text{I}_2 \)  
  \( \text{N}_2\text{O}_5 \) is also produced

Reactions with sulfides, polysulfides, sulfur oxides and the oxoacids of sulfur are complex and the products depend markedly on reaction conditions (see also p. 745 for blue crystals in chamber acid). Some examples are:

- \( \text{SO}_2 + 2\text{NO} \rightarrow \text{N}_2\text{O} + \text{SO}_3 \)
- \( 2\text{SO}_3 + \text{NO} \rightarrow (\text{SO}_3)_2\text{NO} \)
- \( 2\text{H}_2\text{SO}_3 + 2\text{NO} \rightarrow 2\text{H}_2\text{SO}_3\text{NO} \rightarrow \text{H}_2\text{SO}_3(\text{NO})_2 \rightarrow \text{N}_2\text{O} + \text{H}_2\text{SO}_4 \)

\[ \text{K}_2\text{SO}_3(\text{aq}) + \text{NO} \rightarrow \text{K}_2[\text{ONSO}_3] \]
\[ \text{radical anion} \]
\[ \text{NO white crystals} \]

Under alkaline conditions disproportionation reactions predominate. Thus with \( \text{Na}_2\text{O} \) the dioxonitrate(II) first formed, disproportionates into the corresponding nitrite(III) and dioxodinitrate(\(\text{N}-'\text{N}')(I)\) : 

\[ 4\text{Na}_2\text{O} + 4\text{N}^{\text{III}}\text{O} \xrightarrow{100^\circ\text{C}} 4\text{Na}_2\text{N}^{\text{II}}\text{O}_2 \]
\[ 2\text{Na}_2\text{O} + 2\text{Na}^{\text{III}}\text{O}_2 + \text{Na}_2\text{N}^{\text{II}}\text{O}_2 \]

With alkali metal hydroxides, both \( \text{N}_2\text{O} \) and \( \text{N}_2 \) are formed in addition to the nitrite:

\[ 2\text{MOH} + 4\text{N}^{\text{III}}\text{O} \rightarrow 2\text{MN}^{\text{III}}\text{O}_2 + \text{N}_2\text{O}_4 + \text{H}_2\text{O} \]
\[ 4\text{MOH} + 6\text{N}^{\text{III}}\text{O} \rightarrow 4\text{MN}^{\text{III}}\text{O}_2 + \text{N}_2(0) + 2\text{H}_2\text{O} \]

**Nitric oxide complexes.** NO readily reacts with many transition metal compounds to give nitrosyl complexes and these are also frequently formed in reactions involving other oxo-nitrogen species. Classic examples are the "brown-ring" complex \( [\text{Fe}(\text{H}_2\text{O})_5\text{NO}]^{2+} \) formed during the qualitative test for nitrates, Roussin’s red and black salts (p. 1094), and sodium nitroprusside, \( \text{Na}_2[\text{Fe(CN)}_5\text{NO}]\cdot2\text{H}_2\text{O} \). The field has been extensively reviewed\(^{(113-115)}\) and only the salient features need be summarized here. A variety of preparative routes is available (see Panel). Most nitrosyl complexes are highly coloured — deep reds, browns, purples, or even black. Apart from the intrinsic interest in the structure and bonding of these compounds there

Synthetic Routes to NO Complexes

The coordination chemistry of NO is often compared to that of CO but, whereas carbonyls are frequently prepared by reactions involving CO at high pressures and temperatures, this route is less viable for nitrosyls because of the thermodynamic instability of NO and its propensity to disproportionate or decompose under such conditions (p. 446). Nitrosyl complexes can sometimes be made by transformations involving pre-existing NO complexes, e.g. by ligand replacement, oxidative addition, reductive elimination or condensation reactions (reductive, thermal or photolytic). Typical examples are:

- $[\text{Mn(CO)}]_3(NO)(\text{PPh}_3) + \text{PPh}_3 \rightarrow [\text{Mn(CO)}]_2(NO)(\text{PPh}_3)_2 + \text{CO}$
- $2[\text{Cr}(\eta^5-\text{C}_5\text{H}_5)\text{Cl}(\text{NO})_2] \xrightarrow{\text{BH}_3} [\text{Mn}(\eta^5-\text{C}_5\text{H}_5)(\text{NO})_2]_2$
- $2[\text{Mn}(\text{CO})_4(\text{NO})] \xrightarrow{\text{hv}} [\text{Mn}_2(\text{CO})_7(\text{NO})_2]$
- $[[\text{Mn}(\eta^5-\text{C}_5\text{H}_5)(\text{CO})(\text{NO})_2]]_2 \xrightarrow{\text{hv}} [\text{Mn}_3(\eta^5-\text{C}_5\text{H}_5)_3(\text{NO})_4]$

Syntheses which increase the number of coordinated NO molecules can be classified into more than a dozen types, of which only the first three use free NO gas.

1. Addition of NO to coordinatively unsaturated complexes:
   - $[\text{CoCl}_2L_2] + \text{NO} \rightarrow [\text{CoCl}_2L_2(\text{NO})]$
   - $[\text{Co(OPPh}_3)_2X_2] + 2\text{NO} \rightarrow [\text{Co(NO)}(\text{OPP}_3)_2X_2]$

2. Substitution (ligand replacement)
   Very frequently in these reactions 2NO replace 3CO. Alternatively, 1NO can replace 2CO with simultaneous formation of a metal-metal bond, or 1NO can replace CO + a halogen atom:
   - $[\text{Co(CO)}]_3(\text{NO}) + 2\text{NO} \rightarrow [\text{Co(NO)}]_3 + 3\text{CO}$
   - $[\text{Fe(CO)}]_5 + 2\text{NO} \rightarrow [\text{Fe(CO)}]_2(NO)_2 + 3\text{CO}$
   - $[\text{Cr(CO)}]_6 + 4\text{NO} \rightarrow [\text{Cr(NO)}_4] + 6\text{CO}$
   - $[\text{Co}(\eta^5-\text{C}_5\text{H}_5)(\text{CO})_2] + \text{NO} \rightarrow \frac{1}{2}[\text{[Co}(\eta^5-\text{C}_5\text{H}_5)(\text{NO})_2] + 2\text{CO}$
   - $[\text{Mn}(\text{CO})_5I] + 3\text{NO} \rightarrow [\text{Mn}(\text{CO})_2(NO)_3] + 4\text{CO} + [\text{I}]$
   - $\frac{1}{2}[\text{[Mn}(\text{CO})_4I)_2] + 3\text{NO} \rightarrow [\text{Mn}(\text{CO})_2(NO)_3] + 3\text{CO} + [\text{I}]$

3. Reductive nitrosylation (cf. MF₆ + NO → NO⁺MF₆⁻ for Mo, Tc, Ru, Os, Ir, Pt)
   - $\text{CoCl}_2 + 3\text{NO} + \text{B} + \text{ROH} \rightarrow \frac{1}{2}[\text{[CoCl(NO)]_2}_2] + \text{BH}^+ + \text{RONO}$
   where B is a proton acceptor such as an alkoxide or amine.

4. Addition of or substitution by NO⁺
   This method uses NOBF₄, NOPF₆, or NO[HSO₄] in MeOH or MeCN, e.g.:
   - $[\text{Rh(CNR)}]_2^+ + \text{NO}^+ \rightarrow [\text{Rh(CNR)}]_2(\text{NO})^2^+^$
   - $[\text{Ir(CO)}]_2\text{Cl}_2 + \text{NO}^+ \rightarrow [\text{Ir(CO)}]_2\text{Cl}_2(NO)^+$
   - $[\text{Ni}(\text{CO})_2L_2] + \text{NO}^+ \rightarrow [\text{Ir(CO)}]_2L_2(NO)^+ + \text{CO}$
   - $[\text{Cr(CO)}]_4(\text{diphos}) + 2\text{NO}^+ \rightarrow [\text{Cr}(\text{NO})_2(\text{MeCN})_4]^{2^-} + 4\text{CO} + \text{diphos}$

5. Oxidative addition of XNO
   The reaction may occur with either coordinatively unsaturated or saturated complexes, e.g.:
   - $[\text{PtX}_4]^{2^-} + \text{CINO} \rightarrow [\text{PtCl(NO)}(\text{X})_4]^{2^-} (\text{X} = \text{Cl, CN, NO}_2)$

Panel continues.
§11.3.6 Oxides of nitrogen

\[ \text{[Ni(PPh₃)₄] + ClNO} \rightarrow \text{[Ni(Cl)(NO)(PPh₃)₂] + 2PPh₃} \]

6. Reaction of metal hydride complexes with N-nitrosoamides, e.g. N-methyl-N-nitrosourea:

\[ \text{[Mn(CO)₅H] + MeN(NO)CONHz} \rightarrow \text{[Mn(CO)₄(NO)] + CO + MeNHCONHz} \]

7. Transfer of coordinated NO (especially from dimethylglyoximate complexes)

\[ \text{Co(dmg)₂(NO)} + \text{[MCIL₉]} \rightarrow \text{[CoCl(dmg)₂] + [M(NO)L₉]} \]

\[ \text{[Ru(NO)₂(PPh₃)₂] + [RuCl₂(PPh₃)₃]} \xrightarrow{\text{Zn dust}} 2\text{[Ru(Cl(NO)(PPh₃)₂] + PPh₃} \]

8. Use of NH₂OH in basic solution (especially for cyano complexes)

The net transformation can be considered as the replacement of CN⁻ (or X⁻) by NO⁻ and the reaction can be formally represented as

\[ 2\text{NH₂OH} \rightarrow \text{NH₃ + H₂O + [NOH]} \rightarrow \text{NO⁻ + H}⁺(\text{removed by base}) \]

Examples are:

\[ \text{[Ni(CN)₄]²⁻ + 2NH₂OH} \xrightarrow{\text{MOH}} \text{[Ni(CN)₃(NO)]²⁻ + NH₃ + 2H₂O + MCN} \]

\[ \text{[Cr(CN)₆]³⁻ + 2NH₂OH} \xrightarrow{\text{MOH}} \text{[Cr(CN)₅(NO)]³⁻ + NH₃ + 2H₂O + MCN} \]

9. Use of acidified nitrites (i.e. NO₂⁻ + 2H⁺) e.g.:

\[ \text{K[Fe(CO)₃(NO)] + KNO₂ + CO₂ + H₂O} \rightarrow \text{[Fe(CO)₂(NO)₂] + 2KHCO₃} \]

\[ \text{Na[Fe(CO)₄H] + 2NaNO₂ + 3MeCO₂H} \rightarrow \text{[Fe(CO)₂(NO)₂] + 2CO + 2H₂O + 3MeCO₂Na} \]

10. Use of (acidified) nitrites RONO (i.e. RONO + H⁺) e.g.:

\[ \text{[Fe(CO)₃(PPh₃)₈] + RONO + H⁺} \rightarrow \text{[Fe(CO)₂(NO)(PPh₃)₂]⁺ + CO + ROH} \]

Alternatively in aprotic solvents such as benzene:

\[ \text{[Mn(CO)₅(PPh₃)₉]} \xrightarrow{\text{RONO}} 2\text{[Mn(CO)₄(NO)(PPh₃)₂] + 2CO} \]

11. Use of concentrated nitric acid (i.e. 2HNO₃) e.g.:

Some of these reactions result, essentially, in the oxidative addition of NO⁺NO₃⁻ to coordinatively unsaturated metal centres whereas in others ligand replacement by NO⁺ occurs — this is a favoured route for producing “nitroprusside”, i.e. nitrosylpentacyanoferrate(II):

\[ \text{[Pt(en)₂]²⁺ + HNO₃} \rightarrow \text{[Pt(en)₂(NO)(NO₃)]²⁺} \]

\[ \text{[Fe(CN)₆]³⁻ + HNO₃} \rightarrow \text{[Fe(CN)₅(NO)]²⁻} \]

12. Oxide ion abstraction from coordinated NO₂, i.e.

\[ \text{ML₄(NO₂)₂} \xrightarrow{\text{2H⁺}} \text{ML₄(NO)⁴⁺ + OH⁻} \]

\[ \text{cis-[Ru(bipy)₂(NO₂)X]} \xrightarrow{\text{2OH⁻}} \text{cis-[Ru(bipy)₂(NO)X]²⁺ + H₂O} \]

\[ \text{[Fe(CN)₅(NO₂)₄⁻} \xrightarrow{\text{2H⁺}} \text{[Fe(CN)₅(NO)]²⁻ + H₂O} \]

13. Oxygen atom abstraction

\[ \text{[Fe(CO)₅] + KNO₂} \rightarrow \text{K[Fe(CO)₅(NO)] + CO + CO₂} \]

Many variations on these synthetic routes have been devised and the field is still being actively developed. The reactions of NO coordinated to transition metals have been extensively reviewed.\(^{114}\)
is much current interest in their potential use as homogeneous catalysts for a variety of chemical reactions.\(^{115}\) See also p. 443.\(^{102}\)

NO shows a wide variety of coordination geometries (linear, bent, doubly bridging, triply bridging and quadruply bridging — see p. 453) and sometimes adopts more than one mode within the same complex. NO has one more electron than CO and often acts as a 3-electron donor — this is well illustrated by the following isoelectronic series of compounds in which successive replacement of CO by NO is compensated by a matching decrease in atomic number of the metal centre:

<table>
<thead>
<tr>

</tbody>
</table>

For the same reason 3CO can be replaced by 2NO; e.g.:

\[
[\text{Co(NO)}_3] \rightarrow [\text{Co(NO)}_3]_3 \\
[\text{Fe(NO)}_3] \rightarrow [\text{Fe(NO)}_2]_2 \\
[\text{Mn(NO)}_4] \rightarrow [\text{Mn(NO)}_3]_2 \\
[\text{Cr(NO)}_6] \rightarrow [\text{Cr(NO)}_3]_4
\]

In these and analogous compounds the M–N–O group is linear or nearly so, the M–N and N–O distances are short, and the N–O infrared stretching modes usually occur in the range 1650–1900 cm\(^{-1}\). The bonding in such compounds is sometimes discussed in terms of the preliminary transfer of 1 electron from NO to the metal and the coordination of NO\(^+\) to the reduced metal centre as a “2-electron σ donor, 2-electron π acceptor” analogous to CO (p. 926). This formal scheme, though useful in emphasizing similarities and trends in the coordination behaviour of NO\(^+\), CO and CN\(^-\), is unnecessary even for the purpose of “book-keeping” of electrons; it is also misleading in implying an unacceptably large separation of electronic charge in these covalent complexes and in leading to uncomfortably low oxidation states for many metals. e.g. Cr(–IV) in [Cr(NO)\(_4\)], Mn(–III) in [Mn(NO)(NO)\(_3\)], etc. Many physical techniques (such as ESCA, Mössbauer spectroscopy, etc.) suggest a much more even distribution of charge and there is accordingly a growing trend to consider linear NO complexes in terms of molecular orbital energy level schemes in which an almost neutral NO contributes 3 electrons to the bonding system via orbitals of σ and π symmetry.\(^{116}\) Nitrogen-15 nmr spectroscopy has also been developed as a powerful tool for characterizing and distinguishing between linear and bent nitrosyl complexes and, where appropriate for studying their interconversion.\(^{117}\)

Compounds in which the (M–N–O) group is nominally linear often feature a slightly bent coordination geometry and M–N–O bond angles in the range 165–180° are frequently encountered. However, another group of compounds is known in which the angle M–N–O is close to 120°. The first example, [Co(NO)(SCNMe)\(_2\)], appeared in 1962\(^{118}\) though there were problems in refining the structure, and a second example was found in 1968\(^{119}\) when the cationic complex [Ir(CO)Cl(NO)(PPh\(_3\))\(_2\)]\(^+\) was found to have a bond angle of 124° (Fig. 11.10); values in the range 120–140° have since been observed in several other compounds (Table 11.10). The related complex [RuCl(NO)(PPh\(_3\))\(_2\)]\(^+\), in which the CO ligand has been replaced by a second NO molecule, is interesting in having both

Figure 11.10  Complexes containing bent NO groups: (a) $[\text{Ir}(\text{CO})\text{Cl(NO)}(\text{PPh}_3)_2]^+$, and (b) $[\text{RuCl(NO)}_2(\text{PPh}_3)_2]^+$. This latter complex also has a linearly coordinated NO group. The diagrams show only the coordination geometry around the metal (the phenyl groups being omitted for clarity).

Table 11.10  Some examples of “linear” and “bent” coordination of nitric oxide

$\text{mnt} = \text{maleonitriledithiolate, diars} = 1,2\text{-bis(dimethylarsino)benzene, diptos} = \text{Ph}_2\text{PCH}_2\text{CH}_2\text{PPh}_2$.

$^{(a)}$ Value imprecise because of crystal twinning (see ref. 118).
linear and bent \{M–NO\} groups: as can be seen in Fig. 11.10 the nonlinear coordination is associated with a lengthening of the Ru–N and N–O distances. This is consistent with a weakening of these bonds and it is significant that the N–O infrared stretching mode in such compounds tends to occur at lower wave numbers (1525–1690 cm\(^{-1}\)) than for linearly coordinated NO (1650–1900 cm\(^{-1}\)). In such systems neutral NO can be thought of as a 1-electron donor, as in the analogous (bent) nitrosyl halides, XNO (p. 442); it is unnecessary to consider the ligand as an NO\(^{-}\) 2-electron donor. The implication is that the other pair of electrons on NO is placed in an essentially non-bonding orbital on N (which is thus approximately described as an sp\(^2\) hybrid) rather than being donated to the metal as in the linear, 3-electron-donor mode (Fig. 11.11). Consistent with this, non-linear coordination is generally observed with the later transition elements in which the low-lying orbitals on the metal are already filled, whereas linear coordination tends to occur with earlier transition elements which can more readily accommodate the larger number of electrons supplied by the ligand. However, the energetics are frequently finely balanced and other factors must also be considered — a good example is supplied by the two “isoelectronic” complexes shown in Fig. 11.12: \([\text{Co(diars)}_2(\text{NO})]^{2+}\) has a linear NO equatorially coordinated to a trigonal bipyramidal cobalt atoms whereas \([\text{IrCl}_2(\text{NO})(\text{PPh}_3)_2]\) has a bent NO axially coordinated to a square-pyramidal iridium atom, even though both Co and Ir are in the same group in the periodic table. Indeed, the complex cation \([\text{Ir}(\eta^3-C_5H_5)(\text{NO})(\text{PPh}_3)_2]^+\) shows a facile equilibrium (in CH\(_2\)Cl\(_2\) or MeCN solutions) between the linear and the bent NO modes of coordination and, with appropriate counter anions, either the linear \(\text{--NO}\) (light brown) or bent \(\text{--NO}\) (red-brown) isomer can be crystallized.\(^{\text{120}}\) Some further examples of the two coordination geometries are in Table 11.10.

Figure 11.11 Schematic representation of the bonding in NO complexes. Note that bending would withdraw an electron-pair from the metal centre to the N atom thus creating a vacant coordination site: this may be a significant factor in the catalytic activity of such complexes.\(^{\text{115,121}}\)

Figure 11.12 Comparison of the coordination geometries of \([\text{Co(diars)}_2(\text{NO})]^{2+}\) and \([\text{IrCl}_2(\text{NO})(\text{PPh}_3)_2]\); diars = 1,2-bis(di-methylarsino)benzene.

Like CO, nitric oxide can also act as a bridging ligand between 2 or 3 metals. Examples are the Cr and Mn complexes in Fig. 11.13. In \([\{\text{Cr}(\eta^5-C_5H_5)(\text{NO})(\mu_2-\text{NO})\}_2]\) the linear terminal NO has an infrared band at 1672 cm\(^{-1}\) whereas for the doubly bridging NO the vibration drops to 1505 cm\(^{-1}\). In both geometries NO can be considered as a 3-electron donor and there is also a Cr–Cr bond thereby completing an 18-electron configuration around each Cr atom. In \([\text{Mn}_3(\eta^5-C_5H_5)_3(\mu_2-\text{NO})_3(\mu_3-\text{NO})]\) the 3 Mn

§11.3.6 Oxides of nitrogen

Figure 11.13 Structures of polynuclear nitrosyl complexes: (a) \([\text{Cr}(\eta^7-C_5H_5)(NO)]_2(\mu_2-NH_2)(\mu_2-NO)\) showing linear-terminal and doubly bridging NO; and (b) \([\text{Mn}_3(\eta^5-C_5H_5)_3(\mu_2-NO)]_2(\mu_3-NO)\) showing double-and triply-bridging NO; the molecule has virtual \(C_3v\) symmetry and the average Mn–Mn distance is 250 pm (range 247–257 pm).

form an equilateral triangle each edge of which is bridged by an NO group (\(\nu 1543, 1481 \text{ cm}^{-1}\)); the fourth NO is normal to the MN\(_3\) plane and bridges all 3 Mn to form a triangular pyramid; the N–O stretching vibration moves to even lower wave numbers (1328 cm\(^{-1}\)). Again, each metal is associated with 18 valency electrons if each forms Mn–Mn bonds with its 2 neighbours and each NO is a 3-electron donor.

An unprecedented quadruply bridging mode for NO has been established in the violet cluster anion \([\text{Re}_3(\mu-H)_3(CO)_{10}]_2(\mu_4-\eta^7-\text{NO})\] (see Fig. 11.14a).\(^{122}\) The complex was isolated as its \([\text{NEt}_4]^+\) salt after its formation by reaction of NOBF\(_4\) with the trinuclear hydrido anion \([\text{Re}_3(\mu-H)_3(CO)_{10}]^-\). The rather long N–O distance (132–135 pm) is consistent with its formulation as NO\(^-\). Another novel complex is \([\text{Os(CO)}_4\text{Cl}_2(\text{HNO})(\text{PPh}_3)_2]\) (Fig. 11.14b) which is formed by direct reaction of HCl with \([\text{Os(CO)}(\text{NO})(\text{PPh}_3)_2]\).\(^{123}\) The complex is the first to contain the HNO ligand which is itself thermally unstable as a free molecule. The ligand is \(N\)-coordinated and coplanar with the \([\text{Os(CO)}_4\text{Cl}_2]\) moiety and has H–N 94 pm, N–O 119 pm and angle HNO 99°.

Figure 11.14 (a) Quadruply bridging NO in the anion \([\text{Re}_3(\mu-H)_3(CO)_{10}]_2(\mu_4-\eta^7-\text{NO})\]\(^-\). (b) The neutral complex \([\text{Os(CO)}_4\text{Cl}_2(\text{HNO})(\text{PPh}_3)_2]\).

In contrast to the numerous complexes of NO which have been prepared and characterized, complexes of the thionitrosyl ligand (NS) are virtually unknown, as is the free ligand itself. The first such complex \([\text{Mo(NS)}(\text{S}_2\text{CNMe}_2)_3]\) was obtained as orange-red air-stable crystals by treating \([\text{MoN(S}_2\text{CNMe}_2)_3]\) with sulfur in

---

refluxing MeCN, and was shown later to have an M–N–S angle of 172.1°.\(^{(124)}\) More recently \([\text{Cr}(\eta^5-\text{C}_5\text{H}_5)(\text{CO})_2(\text{NS})]\) was made by reacting \(\text{Na}[\text{Cr}(\eta^5-\text{C}_5\text{H}_5)(\text{CO})_3]\) with \(\text{S}_2\text{N}_2\text{Cl}_3\) and again the NS group was found to adopt an essentially linear coordination with Cr–N–S 176.8°.\(^{(125)}\) See also pp. 721–46 for other sulphur–nitrogen species.

**Dinitrogen trioxide, \(\text{N}_2\text{O}_3\)**

Pure \(\text{N}_2\text{O}_3\) can only be obtained at low temperatures because, above its \(\text{mp} (-100.1°C)\), it dissociates increasingly according to the equilibria:

\[
\text{N}_2\text{O}_3 \rightleftharpoons \text{NO} + \text{NO}_2;
\]

Blue \text{Colourless Brown}

\[
2\text{NO}_2 \rightleftharpoons \text{N}_2\text{O}_4
\]

Brown \text{Colourless}

The solid is pale blue; the liquid is an intense blue at low temperatures but the colour fades and becomes greenish due to the presence of \(\text{NO}_2\) at higher temperatures. The dissociation also limits the precision with which physical properties of the compound can be determined. At 25°C the dissociative equilibrium in the gas phase is characterized by the following thermodynamic quantities:

\[
\text{N}_2\text{O}_3(\text{g}) \rightleftharpoons \text{NO(}g\text{)} + \text{NO}_2(\text{g}); \quad \Delta H = 40.5 \text{kJ mol}^{-1};
\]

\[
\Delta G = -1.59 \text{kJ mol}^{-1}
\]

Hence \(\Delta S = 139 \text{JK}^{-1} \text{mol}^{-1}\) and the equilibrium constant \(K(25°C) = 1.91 \text{ atm.}\) Molecules of \(\text{N}_2\text{O}_3\) are planar with \(\text{C}_3\) symmetry.

Structural data are in the diagram; these data were obtained from the microwave spectrum of the gas at low temperatures. The long (weak) N–N bond is notable (cf. 145 pm in hydrazine, p. 428). In this \(\text{N}_2\text{O}_3\) resembles \(\text{N}_2\text{O}_4\) (p. 455).

\(\text{N}_2\text{O}_3\) is best prepared simply by condensing equimolar amounts of \(\text{NO}\) and \(\text{NO}_2\) at \(-20°C\) or by adding the appropriate amount of \(\text{O}_2\) to \(\text{NO}\) in order to generate the \(\text{NO}_2\) *in situ*:

\[
2\text{NO} + \text{N}_2\text{O}_4 \xrightarrow{\text{cool}} 2\text{N}_2\text{O}_3
\]

\[
4\text{NO} + \text{O}_2 \longrightarrow 2\text{N}_2\text{O}_3
\]

Alternative preparations involve the reduction of 1:1 nitric acid by \(\text{As}_2\text{O}_3\) at 70°, or the reduction of fuming \(\text{HNO}_3\) with \(\text{SO}_2\) followed by hydrolysis:

\[
2\text{HNO}_3 + 2\text{H}_2\text{O} + \text{As}_2\text{O}_3 \longrightarrow \text{N}_2\text{O}_3 + 2\text{H}_3\text{AsO}_4
\]

\[
2\text{HNO}_3 + 2\text{SO}_2 \longrightarrow 2\text{NOHSO}_4 \xrightarrow{\text{2H}_2\text{O}} \text{N}_2\text{O}_3 + \text{H}_2\text{SO}_4
\]

However, these methods do not yield a completely anhydrous product and dehydration can prove difficult.

Studies of the chemical reactivity of \(\text{N}_2\text{O}_3\) are complicated by its extensive dissociation into \(\text{NO}\) and \(\text{NO}_2\) which are themselves reactive species. With water \(\text{N}_2\text{O}_3\) acts as the formal anhydride of nitrous acid and in alkaline solution it is converted essentially quantitatively to nitrite:

\[
\text{N}_2\text{O}_3 + \text{H}_2\text{O} \xrightarrow{\text{aq}} 2\text{HNO}_2
\]

\[
\text{N}_2\text{O}_3 + 2\text{OH}^- \longrightarrow 2\text{NO}_2^- + \text{H}_2\text{O}
\]

Reaction with concentrated acids provides a preparative route to nitrosyl salts such as \(\text{NO}[\text{HSO}_4]\), \(\text{NO}[\text{HSeO}_4]\), \(\text{NO}[\text{ClO}_4]\), and \(\text{NO}[\text{BF}_4]\), e.g.:

\[
\text{N}_2\text{O}_3 + 3\text{H}_2\text{SO}_4 \longrightarrow 2\text{NO}^+ + \text{H}_3\text{O}^+ + 3\text{HSO}_4^-
\]

Nitrogen dioxides, NO₂, and dinitrogen tetroxide, N₂O₄

The facile equilibrium \( \text{N}_2\text{O}_4 \leftrightarrow 2\text{NO}_2 \) makes it impossible to study the pure individual compounds in the temperature range \(-10^\circ\text{C}\) to \(+140^\circ\text{C}\) though the molecular properties of each species in the equilibrium mixture can often be determined. At all temperatures below the freezing point \((-11.2^\circ\text{C})\) the solid consists entirely of \( \text{N}_2\text{O}_4 \) molecules but the liquid at this temperature has 0.01% NO₂. At the bp (21.5°C) the liquid contains 0.1% NO₂ but the gas is more extensively dissociated and contains 15.9% NO₂ at this temperature and 99% NO₂ at 135°C. The increasing dissociation can readily be followed by a deepening of the brown colour due to NO₂ and an increase in the paramagnetism; the thermodynamic data for the dissociation of \( \text{N}_2\text{O}_4(\text{g}) \) at 25°C are:

\[
\Delta H^\circ = 57.20 \text{kJ mol}^{-1}; \quad \Delta G^\circ = 4.77 \text{kJ mol}^{-1}; \\
\Delta S^\circ = 175.7 \text{JK}^{-1}\text{mol}^{-1}
\]

The unpaired electron in NO₂ appears to be more localized on the N atom than it is in NO and this may explain the ready dimerization. NO₂ is also readily ionized either by loss of an electron (9.91 eV) to give the nitryl cation NO₂⁺ (isoelectronic with CO₂) or by gain of an electron to give the nitrite ion NO₂⁻ (isoelectronic with \( \text{O}_3 \)). These changes are accompanied by a dramatic diminution in bond angle and an increase in N–O distance as the number of valence electrons increases from 16 to 18 (top diagram).

The structure of \( \text{N}_2\text{O}_4 \) in the gas phase is planar \((D_{2h})\) with a remarkably long N–N bond, and these features persist in both the monoclinic crystalline form near the mp and the more stable low-temperature cubic form. Data for the monoclinic form are in the lower diagram† together with those for the isoelectronic species \( \text{B}_2\text{F}_4 \) and the oxalate ion \( \text{C}_2\text{O}_4^{2-} \). The trends in bond angles and terminal bond distances are clear but the long central bond in \( \text{N}_2\text{O}_4 \) is not paralleled in the other 2 molecules where the B–B distance (p. 148) and C–C distance (p. 292) are normal. However, the B–B bond in \( \text{B}_2\text{Cl}_4 \) is also long (175 pm).

In addition to the normal homolytic dissociation of \( \text{N}_2\text{O}_4 \) into 2NO₂, the molecule sometimes reacts as if by heterolytic fission: thus in media of high dielectric constant the compound often reacts as though dissociated according to the equilibrium \( \text{N}_2\text{O}_4 \leftrightarrow \text{NO}^+ + \text{NO}_3^- \) (see p. 457). This has sometimes been taken to imply

† Values for the gas phase are similar but there is a noticeable contraction in the cubic crystalline form (in parentheses). N–N 175 pm (164 pm), N–O 118 pm (117 pm), angle O–N–O 133.7° (126°). In addition, infrared studies on \( \text{N}_2\text{O}_4 \) isolated in a low-temperature matrix at liquid nitrogen temperature \((-196^\circ\text{C})\) have been interpreted in terms of a twisted (non-planar) molecule \( \text{O}_2\text{N}-\text{NO}_2 \), and similar experiments at liquid helium temperature \((-269^\circ\text{C})\) have been interpreted in terms of the unstable oxygen-bridged species ONONO₂.
the presence in liquid N$_2$O$_4$ of oxygen-bridged species such as ONONO$_2$ or even ONO
but there is no evidence for such species in solution and it seems unnecessary to invoke them since similar reactions also occur with the oxalate ion:

Thus

\[
\begin{align*}
\text{N}_2\text{O}_4 & \rightarrow \text{NO}^+ + \text{NO}_3^- + 2\text{H}^+ \\
\text{H}_2\text{NO}_3^+ & \rightarrow \text{NO}^+ + \text{NO}_2^+ + \text{H}_3\text{O}^+
\end{align*}
\]

Compare

\[
\begin{align*}
\text{C}_2\text{O}_4^{2-} & \rightarrow \text{CO} + \text{CO}_3^{2-} + 2\text{H}^+ \\
\text{H}_2\text{CO}_3 & \rightarrow \text{CO} + \text{CO}_2 + \text{H}_3\text{O}^+
\end{align*}
\]

There is no noticeable tendency for pure N$_2$O$_4$ to dissociate into ions and the electrical conductivity of the liquid is extremely low ($1.3 \times 10^{-13}$ ohm$^{-1}$ cm$^{-1}$ at 0°C). The physical properties of N$_2$O$_4$ are summarized in Table 11.1.

N$_2$O$_4$ is best prepared by thermal decomposition of rigorously dried Pb(NO$_3$)$_2$ in a steel reaction vessel, followed by condensation of the effluent gases and fractional distillation:

\[
2\text{Pb(NO}_3)_2 \rightarrow 400^\circ \rightarrow 4\text{NO}_2 + 2\text{PbO} + \text{O}_2
\]

Other methods (which are either more tedious or more expensive) include the reaction of nitric acid with SO$_2$ or P$_2$O$_{10}$ and the reaction of nitrosyl chloride with AgNO$_3$:

\[
\begin{align*}
2\text{HNO}_3 + \text{SO}_2 & \rightarrow \text{N}_2\text{O}_4 + \text{H}_2\text{SO}_4 \\
4\text{HNO}_3 + \text{P}_4\text{O}_{10} & \rightarrow 2\text{N}_2\text{O}_4 + \text{O}_2 + 4\text{HPO}_3 \\
\text{NOCl} + \text{AgNO}_3 & \rightarrow \text{N}_2\text{O}_4 + \text{AgCl}
\end{align*}
\]

The compound is also formed when NO reacts with oxygen:

\[
2\text{NO} + \text{O}_2 \rightleftharpoons 2\text{NO}_2 \rightleftharpoons \text{N}_2\text{O}_4
\]

These equilibria limit the temperature range in which reactions of N$_2$O$_4$ and NO$_2$ can be studied since dissociation of N$_2$O$_4$ into NO$_2$ is extensive above room temperature and is virtually complete by 140°C whereas decomposition of NO$_2$ into NO and O$_2$ becomes significant above 150°C and is complete at about 600°C.

N$_2$O$_4$/NO$_2$ react with water to form nitric acid (p. 466) and the moist gases are therefore highly corrosive:

\[
\begin{align*}
\text{N}_2\text{O}_4 + \text{H}_2\text{O} & \rightarrow \text{HNO}_3 + \text{HNO}_2; \\
3\text{HNO}_2 & \rightarrow \text{HNO}_3 + 2\text{NO} + \text{H}_2\text{O}
\end{align*}
\]

The oxidizing action of NO$_2$ is illustrated by the following:

\[
\begin{align*}
\text{NO}_2 + 2\text{HCl} & \rightarrow \text{NOCl} + \text{H}_2\text{O} + \frac{1}{2}\text{Cl}_2 \\
\text{NO}_2 + 2\text{HX} & \rightarrow \text{NO} + \text{H}_2\text{O} + \text{X}_2 (\text{X} = \text{Cl, Br}) \\
2\text{NO}_2 + \text{F}_2 & \rightarrow 2\text{FNO}_2 \\
\text{NO}_2 + \text{CO} & \rightarrow \text{NO} + \text{CO}_2
\end{align*}
\]

N$_2$O$_4$ has been extensively studied as a nonaqueous solvent system$^{126}$ and it is uniquely useful for preparing anhydrous metal nitrates and nitrato complexes (p. 468). Much of the chemistry can be rationalized in terms of a self-ionization equilibrium similar to that observed for

\[\text{NOCl} + \text{AgNO}_3 \rightarrow \text{N}_2\text{O}_4 + \text{AgCl}\]

---

formation of nitrosyl compounds, e.g.:

\[ \text{TiI}_4 + 4\text{N}_2\text{O}_4 \rightleftharpoons \text{Ti(NO}_3)_4 + 4\text{NO} + 2\text{I}_2 \]

Many carboxyls react similarly, e.g.:

\[
\begin{align*}
[\text{Mn}_2(\text{CO})_{10}^+] + \text{N}_2\text{O}_4 & \rightarrow [\text{Mn(}\text{CO})_5(\text{NO}_3)]^+ + [\text{Mn(}\text{CO})_6(\text{NO})_y] \\
\text{[Fe(}\text{CO})_5] + 4\text{N}_2\text{O}_4 & \rightarrow \text{[Fe(}\text{NO}_3)_3.\text{N}_2\text{O}_4] + 5\text{CO} + 3\text{NO}
\end{align*}
\]

Solvates are frequently formed in these various reactions, e.g.:

\[
\text{Cu} + 3\text{N}_2\text{O}_4 \rightarrow \text{[Cu(}\text{NO}_3)_2.\text{N}_2\text{O}_4] + 2\text{NO}
\]

Some of these may contain undissociated solvent molecules \(\text{N}_2\text{O}_4\) but structural studies have revealed that often such “solvates” are actually nitrosonium nitrato-complexes. For example it has been shown\(^{127}\) that \([\text{Sc(NO}_3)_3.2\text{N}_2\text{O}_4]\) is, in fact, \([\text{NO}]_2^+\text{[Sc(NO}_3)_3]^2^-\). Similarly, X-ray crystallography revealed\(^{128}\) that \([\text{Fe(NO}_3)_3.1\frac{1}{2}\text{N}_2\text{O}_4]\) is \([\text{NO}]_+^+\text{[Fe(NO}_3)_4]^2^-\text{[NO}_3]^-,\) in which there is a fairly close approach of 3 \(\text{NO}^+\) groups to the “uncoordinated” nitrate ion to give a structural unit of stoichiometry \([\text{N}_4\text{O}_6]^2^+\) (see also p. 472).

In contrast to the wealth of reactions in which \(\text{N}_2\text{O}_4\) tends to behave as \(\text{NO}^+\text{NO}_3^-\), there is no evidence for reactions based on the alternative heterolytic dissociation \(\text{NO}_2^+\text{NO}_2^-\).\(^{129}\) Earlier claims\(^{129a}\) to have identified \(\text{BF}_3\) adducts such as \([\text{NO}_2]^+\text{[ONOBF}_3]^-\) have been shown to be incorrect and the predominant products of the reaction of \(\text{BF}_3\) with \(\text{N}_2\text{O}_4\) (and also with \(\text{N}_2\text{O}_3\) and with \(\text{N}_2\text{O}_5\)) are, in fact, \(\text{NO}^+\text{BF}_4^-\) and \(\text{NO}_2^+\text{BF}_4^-\).\(^{129b}\) This latter compound had

earlier (1956) been introduced by G. A. Olah as a powerful, stable nitrating agent in organic chemistry and it has been widely used since then.\(^{130}\)

\(\text{N}_2\text{O}_4\) has also been used extensively as a hypogolic oxidizer for hydrazine-based fuels in spacecraft. For example, the Apollo manned lunar landing modules (1969–72) used 5.0 tonnes of liquid \(\text{N}_2\text{O}_4\) during descent to the lunar surface and 1.5 tonnes during the return ascent, the fuel being a 1:1 mixture of \(\text{MeNHNH}_2\) and \(\text{Me}_2\text{NNH}_2\).

**Dinitrogen pentoxide, \(\text{N}_2\text{O}_5\), and nitrogen trioxide, \(\text{NO}_3\)**

\(\text{N}_2\text{O}_5\) is the anhydride of nitric acid and is obtained as a highly reactive deliquescent, light-sensitive, colourless, crystalline solid by carefully dehydrating the concentrated acid with \(\text{P}_4\text{O}_{10}\) at low temperatures:

\[
4\text{HNO}_3 + \text{P}_4\text{O}_{10} \xrightarrow{-10^\circ} 2\text{N}_2\text{O}_5 + 4\text{HPO}_3
\]

The solid has a vapour pressure of 100 mmHg at 7.5°C and sublimes (1 atm) at 32.4°C, but is thermally unstable both as a solid and as a gas above room temperature. Thermodynamic data at 25°C are:

X-ray diffraction studies show that solid \(\text{N}_2\text{O}_5\) consists of an ionic array of linear \(\text{NO}_2^+\) (N–O 115.4 pm) and planar \(\text{NO}_3^-\) (N–O 124 pm). In the gas phase and in solution (\(\text{CCl}_4\), \(\text{CHCl}_3\), \(\text{OPCl}_3\)) the compound is molecular; the structure is not well established but may be \(\text{O}_2\text{N}–\text{O}–\text{NO}_2\) with a central N–O–N angle close to 180°. The molecular form can also be obtained in the solid phase by rapidly quenching the gas to \(-180^\circ\), but it rapidly reverts to the more stable ionic form on being warmed to \(-70^\circ\). [cf. ionic and covalent forms of \(\text{BF}_3\cdot2\text{H}_2\text{O}\) (p. 198), \(\text{AlCl}_3\) (p. 234), \(\text{PCl}_3\) (p. 498), etc.]

\(\text{N}_2\text{O}_5\) is readily hydrated to nitric acid and reacts with \(\text{H}_2\text{O}_2\) to give pernitric acid as a coproduct:

\[
\begin{align*}
\text{N}_2\text{O}_5 + \text{H}_2\text{O} & \longrightarrow 2\text{HONO}_2 \\
\text{N}_2\text{O}_5 + \text{H}_2\text{O}_2 & \longrightarrow \text{HONO}_2 + \text{HOONO}_2
\end{align*}
\]

It reacts violently as an oxidizing agent towards many metals, non-metals and organic substances, e.g.:

\[
\begin{align*}
\text{N}_2\text{O}_5 + \text{Na} & \longrightarrow \text{NaNO}_3 + \text{NO}_2 \\
\text{N}_2\text{O}_5 + \text{NaF} & \longrightarrow \text{NaNO}_3 + \text{FNO}_2 \\
\text{N}_2\text{O}_5 + \text{I}_2 & \longrightarrow \text{I}_2\text{O}_5 + \text{N}_2
\end{align*}
\]

Like \(\text{N}_2\text{O}_4\) (p. 457) it dissociates ionically in strong anhydrous acids such as \(\text{HNO}_3\), \(\text{H}_3\text{PO}_4\), \(\text{H}_2\text{SO}_4\), \(\text{HSO}_3\text{F}\) and \(\text{HClO}_4\), and this affords a convenient source of nitronium ions and hence a route to nitronium salts, e.g.:

\[
\begin{align*}
\text{N}_2\text{O}_5 + 3\text{H}_2\text{SO}_4 & \longrightarrow 2\text{NO}_2^+ + \text{H}_3\text{O}^+ + 3\text{HSO}_4^- \\
\text{N}_2\text{O}_5 + \text{HSO}_3\text{F} & \longrightarrow [\text{NO}_2]^+\{\text{FSO}_3\}^- + \text{HNO}_3 \\
\text{N}_2\text{O}_5 + 2\text{SO}_3 & \longrightarrow [\text{NO}_2]^+\{\text{2SO}_3\}^2^-
\end{align*}
\]

In the gas phase, \(\text{N}_2\text{O}_5\) decomposes according to a first-order rate law which can be explained by a dissociative equilibrium followed by rapid reaction according to the scheme

\[
\text{N}_2\text{O}_5 \rightleftharpoons \text{NO}_2 + \{\text{NO}_3\} \longrightarrow \text{NO}_2 + \text{O}_2 + \text{NO}
\]

\[
\text{N}_2\text{O}_5 + \text{NO} \rightleftharpoons 3\text{NO}_2
\]

The fugitive, paramagnetic species \(\{\text{NO}_3\}\) is also implicated in several other gas-phase reactions involving the oxides of nitrogen and, in the \(\text{N}_2\text{O}_5\)-catalysed decomposition of ozone, its concentration is sufficiently high for its absorption spectrum to be recorded, thereby establishing its integrity as an independent chemical species. Such reactions are the subject of considerable current interest for environmental reasons. \(\text{NO}_3\) probably has a symmetrical planar structure (like \(\text{NO}_3^-\)) but it has not been isolated as a pure compound.

Nitrogen forms numerous o xoacids, though several are unstable in the free state and are known only in aqueous solution or as their salts. The principal species are summarized in Table 11.12; of these by far the most stable is nitric acid and this compound, together with its salts the nitrates, are major products of the chemical industry (p. 466).

**Hyponitrous acid and hyponitrites**

Hyponitrous acid crystallizes from ether solutions as colourless crystals which readily decompose.

</table>

---

(a) The structure of nitramide is as shown, the dihedral angle between NH₂ and NNO₂ is 52°. Nitramide is a weak acid pK₁ 6.6 (K₁ 2.6 × 10⁻⁷) and it decomposes into N₂O and H₂O by a base-catalysed mechanism:

\[
\text{H}_2\text{NNO}_2 + \text{B} \xrightarrow{\text{slow}} \text{BH}^+ + [\text{HNNO}_2]^- \xrightarrow{\text{fast}} \text{N}_2\text{O} + \text{OH}^-
\]

(b) Sodium nitroxylate can be prepared as a yellow solid by reduction of sodium nitrite with Na/NH₃(liq.):

\[
2\text{NaNO}_2 + 2\text{Na} \xrightarrow{\text{NH}_3} \text{Na}_4\left[\begin{array}{c}
\text{O} \\
\text{N} \\
\text{N} \\
\text{O}
\end{array}\right]
\]

(c) Peroxonitrous acid is formed as an unstable intermediate during the oxidation of acidified aqueous solutions of nitrites to nitrates using H₂O₂; such solutions are orange-red and are more highly oxidizing than either H₂O₂ or HNO₃ alone (e.g. they liberate Br₂ from Br⁻). Alkaline solutions are more stable but the yellow peroxonitrites M[OONO] have not been isolated pure. The chemistry of peroxonitrites has recently been reviewed J. O. EDWARDS and R. C. PLUMB, in K. D. KARLIN (ed). *Progr. Inorg. Chem.* 41, 599–635 (1994).
(explosively when heated). Its structure has not been determined but the molecular weight indicates a double formula $\text{H}_2\text{N}_2\text{O}_2$, i.e. $\text{HON}=\text{NOH}$, consistent with this the compound yields $\text{N}_2\text{O}$ when decomposed by $\text{H}_2\text{SO}_4$, and hydrazine when reduced. The free acid is obtained by treating $\text{Ag}_2\text{N}_2\text{O}_2$ with anhydrous $\text{HCl}$ in ethereal solution. It is a weak dibasic acid: $\text{pK}_1$ 6.9, $\text{pK}_2$ 11.6. Aqueous solutions are unstable between pH 4-14 due to base catalysed decomposition via the hydrogen-hyponitrite ion:

\[
\text{HONNOH} \xrightarrow{\text{base}} [\text{HONNO}^-] \xrightarrow{\text{fast \ (minutes)}} \text{N}_2\text{O} + \text{OH}^-
\]

At higher acidities (lower pH) decomposition is slower ($t_{1/2}$ days or weeks) and the pathways are more complex. The stoichiometry, kinetics and mechanisms of several other reactions of $\text{H}_2\text{N}_2\text{O}_2$ with, for example, NO and with $\text{HNO}_2$ have also been studied.\(^{132}\)

Hyponitrites can be prepared in variable (low) yields by several routes of which the commonest are reduction of aqueous nitrite solutions using sodium (or magnesium) amalgam, and condensation of organic nitrites with hydroxylamine in $\text{NaOEt/EtOH}$:

\[
\begin{align*}
2\text{NaNO}_3 + 8\text{Na/Hg} + 4\text{H}_2\text{O} & \longrightarrow \\
\text{Na}_2\text{N}_2\text{O}_2 + 8\text{NaOH} + 8\text{Hg}
\end{align*}
\]

\[
\begin{align*}
2\text{AgNO}_3 + 2\text{NaNO}_2 + 4\text{Na/Hg} + 2\text{H}_2\text{O} & \longrightarrow \\
\text{Ag}_2\text{N}_2\text{O}_2 + 2\text{NaNO}_3 + 4\text{NaOH} + 4\text{Hg}
\end{align*}
\]

\[
\begin{align*}
\text{Ca(NO}_3)_2 + 4\text{Mg/Hg} + 4\text{H}_2\text{O} & \longrightarrow \\
\text{CaN}_2\text{O}_2 + 4\text{Mg(OH)}_2 + 4\text{Hg}
\end{align*}
\]

\[
\begin{align*}
\text{NH}_2\text{OH} + \text{RONO} + 2\text{NaOEt} & \xrightarrow{\text{EthOH}} \\
\text{Na}_2\text{N}_2\text{O}_2 + \text{ROH} + 2\text{EtOH}
\end{align*}
\]

Vibrational spectroscopy indicates that the hyponitrite ion has the trans- ($C_{2h}$) configuration (1) in the above salts.

As implied by the preparative methods employed, hyponitrites are usually stable towards reducing agents though under some conditions they can be reduced (p. 434). More frequently they themselves act as reducing agents and are thereby oxidized, e.g. the analytically useful reaction with iodine:

\[
[\text{ONNOO}]^{2-} + 3\text{I}_2 + 3\text{H}_2\text{O} \longrightarrow [\text{NO}_3^-] + [\text{NO}_2^-] + 6\text{HI}
\]

There is also considerable current environmental interest in hyponitrite oxidation because it is implicated in the oxidation of ammonia to nitrite, an important step in the nitrogen cycle (p. 410). Specifically, it seems likely that the oxidation proceeds from ammonia through hydroxylamine and hyponitrous acid to nitrite ($\text{N}_2\text{O}$).

With liquid $\text{N}_2\text{O}_4$ stepwise oxidation of hyponitrites occurs to give $\text{Na}_2\text{N}_2\text{O}_x$ ($x = 3-6$):

\[
\begin{align*}
\text{Na}_2\text{N}_2\text{O}_2 & \xrightarrow{\text{fast}} \text{Na}_2\text{N}_2\text{O}_3 \\
\text{Na}_2\text{N}_2\text{O}_5 & \xrightarrow{\text{slow \ 100^\circ}} \text{Na}_2\text{N}_2\text{O}_6
\end{align*}
\]

Angeli's salt $\text{Na}_2\text{N}_2\text{O}_3$ has been shown by vibration spectroscopy to contain the trioxodinitrate(II) anion structure (2). Its decomposition and reactions in aqueous solutions have been extensively studied by $^{15}\text{N}$ nmr spectroscopy and other techniques.\(^{133}\)

In contrast to the stepwise oxidation of sodium hyponitrite in liquid $\text{N}_2\text{O}_4$, the oxidation goes rapidly to the nitrate ion in an inert solvent of high dielectric constant such as nitromethane:

\[
[\text{ON}==\text{NO}]^{2-} + 2\text{N}_2\text{O}_4 \xrightarrow{\text{MeNO}_2} 2[\text{NO}_3^-] + [\text{ONON}==\text{NONO}] \longrightarrow \text{N}_2 + 2\text{NO}_2
\]

More recently it has been found that the hyponitrite ion can act as a bidentate ligand in either a bridging or a chelating mode. Thus, the controversy about the nature of the black and red isomers of nitrosyl pentammine cobalt(III) complexes has been resolved by X-ray crystallographic studies which show that the black chloride \([\text{Co(NH}_3)_5\text{NO}]\text{Cl}_2\) contains a mononuclear octahedral \(\text{Co}^{III}\) cation with a linear \(\text{Co}–\text{N}–\text{O}\) group whereas the red isomer, in the form of a mixed nitrate-bromide, is dinuclear with a bridging cis-hyponitrite-\((\text{N},\text{O})\) group as shown in Fig. 11.15\(^{134}\). The cis-configuration is probably adopted for steric reasons since this is the only configuration that allows the bridging of two \([\text{Co(NH}_3)_5\text{]}\) groups by an ONNO group without steric interference between them. The cis-chelating mode \((\text{O},\text{O})\) was found in the air-sensitive yellow crystalline complex \([\text{Pt(O}_2\text{N})_2(\text{PPh}_3)_2]\) which has already been mentioned on p. 446. The presence of the cis-configuration in this complex invites speculation as to whether cis-[ON-N0I]\(^2\)– can also exist in simple hyponitrites. Likely candidates appear to be the “alkali metal nitrosyls” MNO prepared by the action of NO on Na/NH\(_3\); infrared data suggest they are not M[NO]– and might indeed contain the cis-hyponitrite ion. They would therefore not be salts of nitroxy HNO which has often been postulated as an intermediate in reactions which give \(\text{N}_2\text{O}\) and which is well known in the gas phase. Nitroxy can be prepared by the action of atomic H or HI on NO and decomposes to \(\text{N}_2\text{O}\) and \(\text{H}_2\text{O}\). As expected, the molecule is bent (angle \(\text{H}–\text{N}–\text{O}\) 109°). See also Fig. 11.14(b), p. 453.

### Nitrous acid and nitrites

Nitrous acid, HNO\(_2\), has not been isolated as a pure compound but it is a well known and important reagent in aqueous solutions and has also been studied as a component in gas-phase equilibria. Solutions of the free acid can readily be obtained by acidification of cooled aqueous nitrite solutions but even at room temperature disproportionation is noticeable:

\[
3\text{HNO}_2(\text{aq}) \rightleftharpoons \text{H}_3\text{O}^+ + \text{NO}_3^- + 2\text{NO}
\]

It is a fairly weak acid with \(pK_a\) 3.35 at 18°C, i.e. intermediate in strength between acetic (4.75) and chloroacetic (2.85) acids at 25°C, and very similar to formic (3.75) and sulfanilic (3.23) acids. Salt-free aqueous solutions can be made by choosing combinations of reagents which give insoluble salts, e.g.:

\[
\text{Ba(NO}_2)_2 + \text{H}_2\text{SO}_4 \overset{\text{aq}}{\longrightarrow} 2\text{HNO}_2 + \text{BaSO}_4
\]

\[
\text{AgNO}_2 + \text{HCl} \overset{\text{aq}}{\longrightarrow} \text{HNO}_2 + \text{AgCl}
\]

---

When the presence of salts in solution is unimportant, the more usual procedure is simply to acidify NaNO₂ with hydrochloric acid below 0°C.

In the gas phase, an equilibrium reaction producing HNO₂ can be established by mixing equimolar amounts of H₂O, NO and NO₂:

\[
2\text{HNO}_2(g) \rightleftharpoons \text{H}_2\text{O}(g) + \text{NO}(g) + \text{NO}_2(g);
\]
\[
\Delta H°(298 \text{ K}) = 38 \text{ kJ/mol HNO}_2;
\]
\[
K_p(298 \text{ K}) = 8.0 \times 10^5 \text{ N m}^{-2} (7.9 \text{ atm})
\]

Microwave spectroscopy shows that the gaseous compound is predominantly in the **trans**-planar (C₂) configuration with the dimensions shown. The differences between the two N–O distances is notable. Despite the formal single-bond character of the central bond the barrier to rotation is 45.2 kJ mol⁻¹. Infrared data suggest that the **trans**-form is ~2.3 kJ mol⁻¹ more stable (ΔG°) than the **cis**- form at room temperature.

Nitrites are usually obtained by the mild reduction of nitrates, using C, Fe or Pb at moderately elevated temperatures, e.g.:

\[
\text{NaNO}_3 + \text{Pb} \xrightarrow{\text{melt}} \text{NaNO}_2 + \text{PbO}
\]

On the industrial scale, impure NaNO₂ is made by absorbing “nitrous fumes” in aqueous alkali or carbonate solutions and then recrystallizing the product:

\[
\text{NO} + \text{NO}_2 + 2\text{NaOH} (\text{or Na}_2\text{CO}_3) \xrightarrow{\text{aq}} 2\text{NaNO}_2 + \text{H}_2\text{O} (\text{or CO}_2)
\]

The sparingly soluble AgNO₂ can be obtained by metathesis, and simple variants yield the other stable nitrites, e.g.:

\[
\text{NaNO}_2 + \text{AgNO}_3 \xrightarrow{\text{aq}} \text{AgNO}_2 + \text{NaNO}_3
\]

\[
\text{NaNO}_2 + \text{KCl} \xrightarrow{\text{aq}} \text{KNO}_2 + \text{NaCl}
\]

\[
2\text{NH}_3 + \text{H}_2\text{O} + \text{N}_2\text{O}_3 \rightleftharpoons 2\text{NH}_4\text{NO}_2
\]

\[
\text{Ba(OH)}_2 + \text{NO} + \text{NO}_2 \xrightarrow{\text{aq}} \text{Ba(NO}_2)_2 + \text{H}_2\text{O}
\]

Many stable metal nitrites (Li, Na, K, Cs, Ag, Tl¹, NH₄, Ba) contain the bent [O–N–O]⁻ anion (p. 413) with N–O in the range 113–123 pm and the angle 116–132°. Nitrites of less basic metals such as Co(II), Ni(II) and Hg(II) are often highly coloured and are probably essentially covalent assemblages. Solubility (g per 100 g H₂O at 25°C) varies considerably, e.g. AgNO₂ 0.41, NaNO₂ (hygroscopic) 85.5, KNO₂ (deliquescent) 314. Thermal stability also varies widely; e.g. the alkali metal nitrites can be fused without decomposition (mp NaNO₂ 284°C, KNO₂ 441°C), whereas Ba(NO₂)₂ decomposes when heated above 220°C, AgNO₂ above 140°C and Hg(NO₂)₂ above 75°C. Such trends are a general feature of oxoacid salts (pp. 469, 863, 868). NH₄NO₂ can decompose explosively.

The aqueous solution chemistry of nitrous acid and nitrites has been extensively studied. Some reduction potentials involving these species are given in Table 11.4 (p. 434) and these form a useful summary of their redox reactions. Nitrites are quantitatively oxidized to nitrate by permanganate and this reaction is used in titrimetric analysis. Nitrites (and HNO₂) are readily reduced to NO and N₂O with SO₂, to H₂N₂O₂ with Sn(II), and to NH₃ with H₂S. Hydrazinium salts yield azides (p. 432) which can then react with further HNO₂:

\[
\text{HNO}_2 + 2\text{H}_2\text{S}^+ \longrightarrow \text{HN}_3 + \text{H}_2\text{O} + \text{H}_3\text{O}^+
\]

\[
\text{HNO}_2 + \text{HN}_3 \longrightarrow \text{N}_2\text{O} + \text{N}_2 + \text{H}_2\text{O}
\]

This latter reaction is most unusual in that it simultaneously involves an element (N) in four different oxidation states. Use of ¹⁵N-enriched reagents shows that all the N from HNO₂ goes quantitatively to the internal N of N₂O₅.(¹³⁵)

\[
\text{HN}_3 + \text{HO}^{15}\text{NO} \xrightarrow{\text{H}_2\text{O}} \{\text{NNN}^{15}\text{NO}\}
\]

\[
\longrightarrow \text{NN} + \text{N}^{15}\text{NO}
\]

NaNO₂ is mildly toxic (tolerance limit \( \sim 100 \text{mg/kg body weight per day, i.e.} \ 4-8 \text{ g/day for humans})\). NaNO₂ (or a precursor such as NaN₂O₃, which is itself harmless) has been much used for curing meat and for treating preserved foods stuffs to prevent bacterial spoilage and consequent poisoning by the (often deadly) toxins produced by *Clostridium botulinum* etc., (normal dietary intake of NO₂⁻ 10-15 \( \mu \text{g per day} \)). NaNO₂ is used industrially on a large scale for the synthesis of hydroxylamine (p. 431), and in acid solution for the diazotization of primary aromatic amines:

\[
\text{HCl}_\text{aq} \quad \text{ArNH}_2 + \text{HNO}_2 \rightarrow [\text{ArNN}]\text{Cl} + 2\text{H}_2\text{O}
\]

The resulting diazo reagents undergo a wide variety of reactions including those of interest in the manufacture of azo dyes and pharmaceuticals. With primary *aliphatic* amines the course of the reaction is different: N₂ is quantitatively evolved and alcohols usually result:

\[
\text{RNH}_2 + \text{HNO}_2 \rightarrow \text{RNHNO}^{-} \rightarrow \text{RN} = \text{NOH}
\]

The reaction is generally thought to involve carbonium-ion intermediates but several puzzling features remain. Secondary aliphatic amines give nitrosamines without evolution of N₂:

\[
\text{RNH}_2 + \text{HONO} \rightarrow \text{RNNO} + \text{H}_2\text{O}
\]

Tertiary aliphatic amines react in the cold to give nitrite salts and these decompose on warming to give nitrosamines and alcohols:

\[
\text{RN} + \text{HNO}_2 \rightarrow [\text{RN}]\text{NO}_2
\]

In addition to their general use in synthetic organic chemistry, these various reactions afford the major route for introducing \(^{15}\text{N}\) into organic compounds by use of Na\(^{15}\text{NO}_2\).

The nitrite ion, NO₂⁻, is a versatile ligand and can coordinate in at least five different ways (i) - (v):

\[
\begin{align*}
(i) \text{Nitro} \quad (ii) \text{Nitrito} \quad (iii) \text{Chelating} \\
(iv) \text{Unsymmetrical bridging (NO)} \quad (v) \eta^1-O \text{ bridging}
\end{align*}
\]

Nitro-nitrito isomerism (i), (ii), was discovered by S. M. Jørgensen in 1894-9 and was extensively studied during the classic experiments of A. Werner (p. 912); the isomers usually have quite different colours, e.g. [Co(NH₃)₅(NO₂)]²⁺, yellow, and [Co(NH₃)₅(NO)]²⁺, red. The nitrito form is usually less stable and tends to isomerize to the nitro form. The change can also be effected by increase in pressure since the nitro form has the higher density. For example application of 20 kbar pressure converts the violet nitrito complex [Ni(en)₂(NO₂)₂] to the red nitro complex [Ni(en)₂(NO₂)₂] at 126°C, thereby reversing the change from nitro to nitrito which occurs on heating the complex from room temperature at atmospheric pressure. An X-ray study of the thermally induced nitrito \( \rightarrow \) nitro isomerization and the photochemically induced nitro \( \rightarrow \) nitrito isomerization of Co(III) complexes has shown that both occur intra-molecularly by rotation of the NO₂ group in its own plane, probably via a 7-coordinated cobalt intermediate. Similarly, the base-catalysed nitrito \( \rightarrow \) nitro isomerization of [M(III)(NH₃)₅(ONO)]²⁺ (M = Co, Ni) has also been studied in detail. \(^{136}\) The coordination chemistry of this isomerization has been reviewed. \(^{137,138}\)

Rh, Ir) is intramolecular and occurs without \(^{18}\text{O}\) exchange of the coordinated ONO\(^{-}\) with H\(_2\)\(^{18}\text{O}\), \(^{18}\text{OH}^{-}\) or “free” N\(^{18}\text{O}_2\)^{-}.\(^{139}\)

However, an elegant \(^{17}\text{O}\) nmr study using specifically labelled [Co(NH\(_3\))\(_2\)(\(^{17}\text{ONO}\))]\(^{2+}\) and [Co(NH\(_3\))\(_2\)(ON\(^{17}\text{O}\))]\(^{2+}\) established that spontaneous intramolecular O-to-O exchange in the nitrite ligand occurs at a rate comparable to that of the spontaneous O-to-N isomerization.\(^{140}\)

A typical value for the N-O distance in nitro complexes is 124 pm whereas in nitrito complexes the terminal N-O (121 pm) is shorter than the internal N-O(M) ~129 pm.

In the bidentate chelating mode (iii) the 2 M-O distances may be fairly similar as in [Cu(bipy)\(_2\)O\(_2\)N]NO\(_3\) or quite different as in [Cu(bipy)(O\(_2\)N)\(_2\)]:

It is possible that a sixth (symmetrical bridging) mode M-O-N-O-M occurs in some complexes such as Rb\(_3\)Ni(NO\(_2\))\(_3\) but this has not definitely been established; an unsymmetrical bridging mode with a trans-configuration of metal atoms is also possible, i.e.

\[
\begin{array}{c}
\text{N--O} \\
\text{M} \\
\text{O--M}
\end{array}
\]

[compare with (iv)].

The familiar problem of misleading stoichiometries, and the frequent impossibility of deducing the correct structural formula from the empirical composition is well illustrated by the
§11.3.7 Oxoacids, oxoanions and oxoacid salts of nitrogen

recent synthesis of the novel alkali metal oxide nitrites Na₄N₂O₅ (yellow) and K₄N₂O₅ (red). These compounds are made by heating powdered mixtures of M₂O and MN₂O₅ at 340° for 8 days in a silver crucible and have an anti-K₂NiF₄ type structure, [(NO₂)₂OM₄], i.e. M₄O(NO₂)₂, with N-O 122.1 pm, angle O-N-O 114.5° and octahedrally coordinated O²⁻ (i.e. OM₆ with K-O 260 pm).

Nitric acid and nitrates

Nitric acid is one of the three major acids of the modern chemical industry and has been known as a corrosive solvent for metals since alchemical times in the thirteenth century. It is now invariably made by the catalytic oxidation of ammonia under conditions which promote the formation of NO rather than the thermodynamically more favoured products N₂ or N₂O (p. 423). The NO is then further oxidized to NO₂ and the gases absorbed in water to yield a concentrated aqueous solution of the acid. The vast scale of production requires the optimization of all the reaction conditions and present-day operations are based on the intricate interaction of fundamental thermodynamics, modern catalyst technology, advanced reactor design, and chemical engineering aspects of process control (see Panel). Production in the USA alone now exceeds 7 million tonnes annually, of which the greater part is used to produce nitrates for fertilizers, explosives and other purposes (see Panel).

Anhydrous HNO₃ can be obtained by low-pressure distillation of concentrated aqueous nitric acid in the presence of P₄O₁₀ or anhydrous H₂SO₄ in an all-glass, grease-free apparatus in the dark. The molecule is planar in the gas phase with the dimensions shown (microwave). The difference in N-O distances, the slight but real tilt of the NO₂ group away from the H atom by 2°, and the absence of free rotation are notable features. The same general structure obtains in the solid state but detailed data are less reliable. Physical properties are shown in Table 11.13. Despite its great thermodynamic stability (with respect to the elements) pure HNO₃ can only be obtained in the solid state; in the gas and liquid phases the compound decomposes spontaneously to NO₂ and this occurs more rapidly in daylight (thereby accounting for the brownish colour which develops in the acid on standing):

\[ 2\text{HNO}_3 \rightleftharpoons 2\text{NO}_2 + \text{H}_2\text{O} + \frac{1}{2}\text{O}_2 \]

In addition, the liquid undergoes self-ionic dissociation to a greater extent than any other nominally covalent pure liquid (cf. BF₃.2H₂O, p. 198); initial autoprotolysis is followed by rapid loss of water which can then react with a further molecule of HNO₃:

\[ 2\text{HNO}_3 \rightleftharpoons \text{H}_2\text{NO}_3^+ + \text{NO}_3^- \rightleftharpoons \text{H}_2\text{O} + [\text{NO}_2]^+ + [\text{NO}_3^-]^- \]

\[ \text{HNO}_3 + \text{H}_2\text{O} \rightleftharpoons [\text{H}_3\text{O}]^+ + [\text{NO}_3^-]^- \]

---

Production and Uses of Nitric Acid

Before 1900 the large-scale production of nitric acid was based entirely on the reaction of concentrated sulfuric acid with NaNO₃ and KNO₃ (p. 407). The first successful process for making nitric acid directly from N₂ and O₂ was devised in 1903 by E. Birkeland and S. Eyde in Norway and represented the first industrial fixation of nitrogen:

\[ \frac{1}{2} \text{N}_2 + \frac{1}{4} \text{O}_2 + \frac{1}{2} \text{H}_2\text{O}(l) \rightarrow \text{HNO}_3(l); \quad \Delta H^\circ(298 K) = -30.3 \text{kJmol}^{-1} \]

The overall reaction is exothermic but required the use of an electric arc furnace which, even with relatively cheap hydroelectricity, made the process very expensive. The severe activation energy barrier, though economically regrettable, is in fact essential to life since, in its absence, all the oxygen in the air would be rapidly consumed and the oceans would be a dilute solution of nitric acid and its salts. [Dilution of HNO₃(l) to HNO₃(aq) evolves a further 33.3kJmol⁻¹ at 25°C.]

The modern process for manufacturing nitric acid depends on the catalytic oxidation of NH₃ over heated Pt to give NO in preference to other thermodynamically more favoured products (p. 423). The reaction was first systematically studied in 1901 by W. Ostwald (Nobel Prize 1909) and by 1908 a commercial plant near Bochum, Germany, was producing 3 tonnes/day. However, significant expansion in production depended on the economical availability of synthetic ammonia by the Haber–Bosch process (p. 421). The reactions occurring, and the enthalpy changes per mole of N atoms at 25°C are:

\[
\begin{align*}
\text{NH}_3 + \frac{1}{2} \text{O}_2 & \rightarrow \text{NO} + \frac{1}{2} \text{H}_2\text{O}(l); \quad \Delta H^\circ = -292.5 \text{kJmol}^{-1} \\
\text{NO} + \frac{1}{2} \text{O}_2 & \rightarrow \text{NO}_2; \quad \Delta H^\circ = -56.8 \text{kJmol}^{-1} \\
\text{NO}_2 + \frac{1}{2} \text{H}_2\text{O}(l) & \rightarrow \frac{1}{2} \text{HNO}_3(l) + \frac{1}{2} \text{NO}; \quad \Delta H^\circ = -23.3 \text{kJmol}^{-1}
\end{align*}
\]

Whence, multiplying the second and third reactions by \(\frac{1}{2}\) and adding:

\[
\text{NH}_3(g) + 2\text{O}_2(g) \rightarrow \text{HNO}_3(l) + \text{H}_2\text{O}(l); \quad \Delta H^\circ = -412.6 \text{kJmol}^{-1}
\]

In a typical industrial unit a mixture of air with 10% by volume of NH₃ is passed very rapidly over a series of gauzes (Pt, 5–10% Rh) at ~850°C and 5 atm pressure; contact time with the catalyst is restricted to ≤1 ms in order to minimize unwanted side reactions. Conversion efficiency is ~96% (one of the most efficient industrial catalytic reactions known) and the effluent gases are passed through an absorption column to yield 60% aqueous nitric acid at about 40°C. Loss of platinum metal from the catalyst under operating conditions is reduced by alloying with Rh but tends to increase with pressure from about 50–100mg/tonne of HNO₃ produced at atmospheric pressure to about 250mg/tonne at 10 atm; though this is not a major part of the cost, the scale of operations means that about 0.5 tonne of Pt metals is lost annually in the UK from this cause and more than twice this amount in the USA.

Concentration by distillation of the 60% aqueous nitric acid produced in most modern ammonia-burning plants is limited by the formation of a maximum-boiling azeotrope (122°C) at 68.5% by weight; further concentration to 98–99% can be effected by countercurrent dehydration using concentrated H₂SO₄ or by distillation from concentrated Mg(NO₃)₂ solutions. Alternatively 99% pure HNO₃ can be obtained directly from ammonia oxidation by incorporating a final oxidation of N₂O₄ with the theoretical amounts of air and water at 70°C and 50 atm over a period of 4 h:

\[
\text{N}_2\text{O}_4 + \frac{1}{2} \text{O}_2 + \text{H}_2\text{O} \rightarrow 2\text{HNO}_3
\]

The largest use of nitric acid (~75%) is in the manufacture of NH₄NO₃ and of this, about 75% is used for fertilizer production. Many plants have a capacity of 2000 tonnes/day or more and great care must be taken to produce the NH₄NO₃ in a readily handleable form (e.g. prills of about 3 mm diameter); about 1% of a “conditioner” is usually added to improve storage and handling properties. NH₄NO₃ is thermally unstable (p. 469) and decomposition can become explosive. For this reason a temperature limit of 140°C is imposed on the neutralization step and pH is strictly controlled. The decomposition is catalysed by many inorganic materials including chloride, chromates, hypophosphites, thiosulfates and powdered metals (e.g. Cu, Zn, Hg). Organic materials (oil, paper, string, sawdust, etc.) must also be rigorously excluded during neutralization since their oxidation releases additional heat. Indeed, since the mid-1950s NH₄NO₃ prills mixed with fuel oil have been extensively used as a direct explosive in mining and quarrying operations (p. 469) and this use now accounts for up to 15% of the NH₄NO₃ produced.

Panel continues

Some 8–9% of HNO_3 goes to make cyclohexanone, the raw material for adipic acid and ε-caprolactam, which are the monomers for nylon-6,6 and nylon-6 respectively. A further 7–10% is used in other organic nitration reactions to give nitroglycerine, nitrocellulose, trinitrotoluene and numerous other organic intermediates. Minor uses (which still consume large quantities of the acid) include the pickling of stainless steel, the etching of metals, and its use as the oxidizer in rocket fuels. In Europe nitric acid is sometimes used to replace sulfuric acid in the treatment of phosphate rock to give nitrophosphate fertilizers according to the idealized equation:

\[
\text{Ca}_{10}(\text{PO}_4)_6\text{F}_2 + 14\text{HNO}_3 \rightarrow 3\text{Ca(H}_2\text{PO}_4)_2 + 7\text{Ca(NO}_3)_2 + 2\text{HF}
\]

Another minority use is in the manufacture of nitrates (other than NH_4NO_3) for use in explosives, propellants, and pyrotechnics generally; typical examples are:

- explosives: gun powder, KNO_3/S/powdered C (often reinforced with powdered Si)
- white smokes: ZnO/CaSi_2/KNO_3/C_2Cl_6
- incendiary agents: Al/NaNO_3/methylmethacrylate/benzene
- local heat sources: Al/Fe_3O_4/Ba(NO_3)_2: Mg/Sr(NO_3)_2/SrC_2O_4/thiokol polysulfide
- photoflashes: Mg/NaNO_3
- flares (up to 10 min): Mg/NaNO_3/CaC_2O_4/polyvinyl chloride/varnish: Ti/NaNO_3/boiled linseed oil
- coloured flares: Mg/Sr(NO_3)_2/chlorinated rubber (red): Mg/Ba(NO_3)_2/chlorinated rubber (green).

These equilibria effect a rapid exchange of N atoms between the various species and only a single ^15N nmr signal is seen at the weighted average position of HNO_3, [NO_2]^+ and [NO_3]^- . They also account for the high electrical conductivity of the “pure” (stoichiometric) liquid (Table 11.13), and are an important factor in the chemical reactions of nitric acid and its non-aqueous solutions see below.

The phase diagram HNO_3–H_2O shows the presence of two hydrates, HNO_3.H_2O mp −37.68°, and HNO_3.3H_2O mp −18.47°. A further hemihydrate, 2HNO_3.H_2O, can be extracted into benzene or toluene from 6 to 16 M aqueous solutions of nitric acid, and a dimer hydrate, 2HNO_3.3H_2O, is also known, though neither can be crystallized. The structure of the two crystalline hydrates is dominated by hydrogen bonding as expected; e.g. the monohydrate is [H_3O]^+.[NO_3]^- in which there are puckered layers comprising pyramidal [H_3O]^+ hydrogen bonded to planar [NO_3]^- so that there are 3 H bonds per ion. The trihydrate forms a more complex three-dimensional H-bonded framework. (See also p. 468 for the structure of hydrogen-nitrates.)

The solution chemistry of nitric acid is extremely varied. Redox data are summarized in Table 11.4 and Fig. 11.9 (pp. 434–8). In dilute aqueous solutions (<2 M) nitric acid is extensively dissociated into ions and behaves as a typical strong acid in its reactions with metals, oxides, carbonates, etc. More concentrated aqueous solutions are strongly oxidizing and attack most metals except Au, Pt, Rh and Ir, though some metals which react at lower concentrations are rendered passive, probably because of the formation of an oxide film (e.g. Al, Cr, Fe, Cu). Aqua regia (a mixture of concentrated hydrochloric and nitric acids in the ratio of ~3:1 by volume) is even more aggressive, due to the formation of free Cl_2 and CINO and the superior complexing ability of the chloride ion; it has long been known to “dissolve” both gold and the platinum metals, hence its name. In concentrated H_2SO_4 the chemistry of nitric acid is dominated by the presence of the nitronium ion (pp. 458, 465):

\[
\text{HNO}_3 + 2\text{H}_2\text{SO}_4 \rightleftharpoons \text{NO}_2^+ + \text{H}_3\text{O}^+ + 2\text{HSO}_4^-
\]

Such solutions are extensively used in aromatic nitration reactions in the heavy organic chemicals industry. See also pp. 457–8.

Anhydrous nitric acid has been studied as a nonaqueous ionizing solvent, though salts tend to be rather insoluble unless they produce NO_2^+ or
Nitrogen

Addition of water to nitric acid at first diminishes its electrical conductivity by repressing the autoprotolysis reactions mentioned above. For example, at \(-10^\circ\) the conductivity decreases from \(3.67 \times 10^{-2} \text{ ohm}^{-1} \text{ cm}^{-1}\) to a minimum of \(1.08 \times 10^{-2} \text{ ohm}^{-1} \text{ cm}^{-1}\) at 1.75 molal \(\text{H}_2\text{O} (82.8\% \text{ N}_2\text{O}_5)\) before rising again due to the increasing formation of the hydroxonium ion according to the acid-base equilibrium

\[
\text{HNO}_3 + \text{H}_2\text{O} \leftrightarrow \text{H}_3\text{O}^+ + \text{NO}_3^-
\]

By contrast, Raman spectroscopy and conductivity measurements show that \(\text{N}_2\text{O}_4\) ionizes almost completely in anhydrous \(\text{HNO}_3\) to give \(\text{NO}^+\) and \(\text{NO}_3^-\) and such solutions show no evidence for the species \(\text{N}_2\text{O}_4^-, \text{NO}_2^+,\) or \(\text{NO}_2^-\).\(^{(126)}\) \(\text{N}_2\text{O}_5\) is also extremely soluble in anhydrous nitric acid in which it is completely ionized as \(\text{NO}_3^+\text{NO}_3^-\).

Nitrates, the salts of nitric acid, can readily be made by appropriate neutralization of the acid, though sometimes it is the hydrate which crystallizes from aqueous solution. Anhydrous nitrates and nitrato complexes are often best prepared by use of donor solvents containing \(\text{N}_2\text{O}_4\) (p. 456). The reaction of liquid \(\text{N}_2\text{O}_5\) with metal oxides and chlorides affords an alternative route, e.g.

\[
\text{TiCl}_4 + 4\text{N}_2\text{O}_5 \rightarrow \text{Ti(NO}_3)_4 + 2\text{N}_2\text{O}_4 + 2\text{Cl}_2
\]

Many nitrates are major items of commerce and are dealt with under the appropriate metal (e.g. \(\text{NaNO}_3, \text{KNO}_3, \text{NH}_4\text{NO}_3\), etc.). In addition, various hydrogen dinitrates and dihydrogen trinitrates are known of formula \(\text{M}[(\text{HNO}_3)_2]\) and \(\text{M}[(\text{H}_2\text{NO}_3)_3]\) where \(\text{M}\) is a large cation such as \(\text{K}, \text{Rb}, \text{Cs}, \text{NH}_4\) or \(\text{AsPh}_4\). In \(\text{[AsPh}_4][(\text{HNO}_3)_2]\) 2 coplanar \(\text{NO}_3^-\) ions are linked by a short \(\text{H}\) bond as shown in (a) whereas \(\text{[trans-RhBr}_2(\text{py})_4][(\text{HNO}_3)_2]\) features a slightly distorted tetrahedral group of 4 oxygen atoms in which the position of the \(\text{H}\) atom is not obvious [structure (b)]. In \(\text{[NH}_4][(\text{H}_2\text{NO}_3)_3]\) there is a more extended system of \(\text{H}\) bonds in which 2 coplanar molecules of \(\text{HNO}_3\) are symmetrically bridged by an \(\text{NO}_3^-\) ion at right angles as shown in (c).

§11.3.7 Oxoacids, oxoanions and oxoacid salts of nitrogen

As with the salts of other oxoacids, the thermal stability of nitrates varies markedly with the basicity of the metal, and the products of decomposition are equally varied. Thus the nitrates of Group 1 and 2 metals find use as molten salt baths because of their thermal stability and low mp (especially as mixtures). Representative values of mp and the temperature (Td) at which the decomposition pressure of O2 reaches 1 atm are:

\[
\begin{array}{cccccccc}
M & Li & Na & K & Rb & Cs & Ag & Tl \\
\hline
\text{MP of } \text{MN}_3 & 255 & 307 & 333 & 310 & 414 & 212 & 206 \\
\text{Td/°C} & 474 & 525 & 533 & 548 & 584 & - & - \\
\end{array}
\]

The product of thermolysis is the nitrite or, if this is unstable at the temperature employed, the oxide (or even the metal if the oxide is also unstable):  

\[
\begin{align*}
2\text{NaN}_3 & \rightarrow 2\text{NaN}_2 + \text{O}_2 \quad \text{(see p. 462)} \\
2\text{KNO}_3 & \rightarrow \text{K}_2\text{O} + \text{N}_2 + \frac{5}{2}\text{O}_2 \\
\text{Pb(NO}_3)_2 & \rightarrow \text{PbO} + 2\text{NO}_2 + \frac{1}{2}\text{O}_2 \quad \text{(see p. 456)} \\
2\text{AgNO}_3 & \rightarrow \text{Ag} + 2\text{NO}_2 + \text{O}_2
\end{align*}
\]

As indicated in earlier sections, \(\text{NH}_4\text{N}_3\) can be exploded violently at high temperatures or by use of detonators (p. 466), but slow controlled thermolysis yields \(\text{N}_2\text{O}\) (p. 443):

\[
\begin{align*}
2\text{NH}_4\text{N}_3 & \underset{>300°}{\rightarrow} 2\text{N}_2 + \text{O}_2 + 4\text{H}_2\text{O} \\
\text{NH}_4\text{N}_3 & \underset{200-260°}{\rightarrow} \text{N}_2\text{O} + 2\text{H}_2\text{O}
\end{align*}
\]

The presence of organic matter or other reducible material also markedly affects the thermal stability of nitrates and the use of KNO3 in gunpowder has been known for centuries (p. 645).

The nitrate group, like the nitrite group, is a versatile ligand and numerous modes of coordination have been found in nitrate complexes. The "uncoordinated" \(\text{NO}_3^-\) ion (isoelectronic with BF3, BO3^3-, CO3^2-, etc.) is planar with N-O near 122 pm; this value increases to 126 pm in AgNO3 and 127 pm in \(\text{Pb(NO}_3)_2\). The most common mode of coordination is the symmetric bidentate mode Fig. 11.16a, though unsymmetrical bidentate coordination (b) also occurs and, in the limit, unidentate coordination (c). Bridging modes include the syn-syn conformation (d) (and the anti-anti analogue), and also geometries in which a single O atom bridges 2 or even 3 metal atoms (e), (f). Sometimes more than one mode occurs in the same compound.

Symmetrical bidentate coordination (a) has been observed in complexes with 1-6 nitrates coordinated to the central metal, e.g. \([\text{Cu(NO}_3]_2(\text{PPh}_3)_2\); \([\text{Cu(NO}_3)_2]\), \([\text{Co(NO}_3)_2(\text{OPMe}_3)_2]\); \([\text{Co(NO}_3)_2]\) in which the 6 coordinating O atoms define an almost regular octahedron (Fig. 11.17a), \([\text{La(NO}_3]_2(\text{bipy})_2\); \([\text{Ti(NO}_3]_4]\), \([\text{Mn(NO}_3]_4]_2^2-\), \([\text{Fe(NO}_3]_4]_2^2-\) and \([\text{Sn(NO}_3]_4]\), which feature dodecahedral coordination about the metal; \([\text{Ce(NO}_3]_6]_2^2-\) in which the 5 bidentate nitrate groups define a trigonal bipyramid leading to tenfold coordination of cerium (Fig. 11.17b); \([\text{Ce(NO}_3]_6]_2^2-\) and \([\text{Th(NO}_3]_6]_2^2-\), which feature nearly regular icosahedral (p. 141) coordination of the metal by 12 O atoms; and many lanthanide and uranyl \([\text{UO}_2]^{2+}\) complexes. It seems, therefore, that the size of the metal centre is not necessarily a dominant factor.

Unsymmetrical bidentate coordination (Fig. 11.16b) is observed in the high-spin d7 complex \([\text{Co(NO}_3]_4]_2^2-\) (Fig. 11.17c), in \([\text{SnMe}_2(\text{NO}_3]_2]\) and also in several CuII complexes of formula \([\text{CuL}_2(\text{NO}_3]_2]\), where \(\text{L}\) is MeCN, \(\text{H}_2\text{O}\), py or 2-Me_2C_5H_4N (α-picoline). An example of unidentate coordination is furnished by \(\text{K[Ag(NO}_3]_4}\) as shown in Fig. 11.18(a), and further examples are in cis-[\(\text{Pd(NO}_3]_2(\text{OSMe}_2)_2]\), \([\text{Re(CO}_2(\text{NO}_3]\), \([\text{Ni(NO}_3]_2(\text{H}_2\text{O}]_4]\), \([\text{Zn(NO}_3]_2(\text{H}_2\text{O}]_4]\) and several CuII complexes such as \([\text{CuL}_2(\text{NO}_3]_2]\) where \(\text{L}\) is pyridine N-oxide or 1,4-diazacycloheptane. It appears that a combination of steric effects and the limited availability of coordination sites in these already highly coordinated late-transition-metal complexes restricts each nitrate group to one coordination site. When more

---

Fig. 11.16 Coordination geometries of the nitrate group showing typical values for the interatomic distances and angles. Further structural details are in ref. 150.

Fig. 11.17 Structures of (a) Co(NO$_3$)$_3$, (b) [Co(NO$_3$)$_5$]$_2^-$ and (c) [Co(NO$_3$)$_4$]$_2^-$.
Oxoacids, oxoanions and oxoacid salts of nitrogen

Figure 11.18 (a) Structure of $[\text{Au(NO}_3\text{)}_4]$ . (b) $\alpha$-$[\text{Cu(NO}_3\text{)}_2]$.

Figure 11.19 Schematic diagram of the centrosymmetric dimer in $[\text{Cu}_2(\text{NO}_3)_2(\text{py})_2]_2\text{py}$ showing the two bridging nitrato groups each coordinated to the 2 Cu atoms by a single O atom; the dimer also has an unsymmetrical bidentate nitrate group on each Cu.

shown in Fig. 11.18(b). The single oxygen atom bridging mode (e) occurs in $[\text{Cu(NO}_3)_2(\text{py})_2]_2\text{py}$ (Fig. 11.19) and the triple-bridge (f) may occur in $[\text{Cu}_4(\text{NO}_3)_2(\text{OH})_6]$ though there is some uncertainty about this structure and further refinement would be desirable. Finally, the structure of the unique yellow solvate of formula $[\text{Fe(NO}_3)_3.1\text{N}_2\text{O}_4]$ (p. 457) has been shown$^{128}$ to be $[\text{N}_4\text{O}_6]^{2+}[\text{Fe(NO}_3)_3]^-$. Each anion has 4 symmetrically bidentate NO$_3$ groups in which the coordinating O atoms lie at the corners of a trigonal dodecahedron, as is commonly found in tetranitrato species (N - O, 120 pm, N - O(Fe) 127 pm, angles O - N - O 113.4° and O - Fe - O 60.0°). The $[\text{N}_4\text{O}_6]^{2+}$ cation comprises a central planar nitrate group (N - O 123 pm) surrounded by 3 NO groups at distances which vary from 241 to 278 pm (Fig. 11.20); the interatomic distance in the NO groups is very short (90 - 99 pm) implying NO$^+$ and the distances of these to the central NO$_3$ group are slightly less than the sum of the van der Waals radii for N and O.

Orthonitrates, $M_3\text{NO}_4$

There is no free acid $H_3\text{NO}_4$ analogous to orthophosphoric acid $H_3\text{PO}_4$ (p. 516), but the alkali metal orthonitrates $Na_3\text{NO}_4$ and $K_3\text{NO}_4$...
Nitrogen

The compound forms white crystals that are very sensitive to atmospheric moisture and CO₂:

\[
\text{Na}_3\text{NO}_4 + \text{H}_2\text{O} + \text{CO}_2 \rightarrow \text{NaNO}_3 + \text{NaOH} + \text{NaHCO}_3
\]

X-ray structural analyses have shown that the \(\text{NO}_4^{3-}\) ion has regular \(T_d\) symmetry with the unexpectedly small N - O distance of 139 pm. This suggests that substantial polar interactions are superimposed on the N - O single bonds since the \(d_\pi\) orbitals on N are too high in energy to contribute significantly to multiple covalent bonding. It further implies that \(d_\pi - p_\sigma\) interactions need not necessarily be invoked to explain the observed short interatomic distance in the isoelectronic oxoanions \(\text{PO}_4^{3-}\), \(\text{SO}_4^{2-}\) and \(\text{ClO}_4^-\).

12
Phosphorus

12.1 Introduction

Phosphorus has an extensive and varied chemistry which transcends the traditional boundaries of inorganic chemistry not only because of its propensity to form innumerable covalent "organophosphorus" compounds, but also because of the numerous and crucial roles it plays in the biochemistry of all living things. It was first isolated by the alchemist Hennig Brandt in 1669 by the unsavoury process of allowing urine to putrify for several days before boiling it down to a paste which was then reductively distilled at high temperatures; the vapours were condensed under water to give the element as a white waxy substance that glowed in the dark when exposed to air. Robert Boyle improved the process (1680) and in subsequent years made the oxide and phosphoric acid; he referred to the element as "aerial noctiluca", but the name phosphorus soon became generally accepted (Greek φως, light; Greek φορός, bringing).

As shown in the Panel on the next page, phosphorus is probably unique among the elements in being isolated first from animal (human) excreta, then from plants, and only a century later being recognized in a mineral.

In much of its chemistry phosphorus stands in relation to nitrogen as sulfur does to oxygen. For example, whereas \( N_2 \) and \( O_2 \) are diatomic gases, \( P \) and \( S \) have many allotropic modifications which reflect the various modes of catenation adopted. Again, the ability of \( P \) and \( S \) to form multiple bonds to \( C, N \) and \( O \), though it exists, is less highly developed than for \( N \) (p. 416), whereas the ability to form extended networks of \( -P-O-P-O- \) and \( -S-O-S-O- \) bonds is greater; this is well illustrated by comparing the oxides and oxoanions of \( N \).

---

Time Chart for Phosphorus Chemistry

- 1669: Phosphorus isolated from urine by H. Brandt.
- 1680: R. Boyle improved the process and showed air was necessary for the phosphorescence of P.
- 1688: Phosphorus first detected in the vegetable kingdom (by B. Albino).
- 1694: $\text{P}_4\text{O}_{10}$ and $\text{H}_3\text{PO}_4$ first made by R. Boyle.
- 1769: Phosphorus shown by J. G. Gahn and C. W. Scheele to be an essential constituent in the bones of man and animals, thereby revealing a plentiful source of fertilizers.
- 1779: Phosphorus first discovered in a mineral by J. G. Gahn (pyromorphite, a lead phosphate); subsequently found in the much more abundantapatite by T. Bergman and J. L. Proust.
- 1783: $\text{PH}_3$ first prepared by P. Gengenibre (and independently in 1786 by R. Kirwan).
- 1808: $\text{PCl}_3$ and $\text{PCl}_5$ made by J. L. Gay Lussac and L. J. Thenard (and by H. Davy).
- 1811: N. L. Vauquelin isolated the first organic P compound (lethicin) from brain fat; it was characterized as a phospholipid by Gobbley in 1850.
- 1816: P. L. Dulong first clearly demonstrated the existence of two oxides of P.
- 1820: First synthesis of an organo-P compound by J. L. Laigne who made alkyl phosphites from $\text{H}_3\text{PO}_4 + \text{ROH}$.
- 1833: T. Graham (who later became the first President of the Chemical Society) classified phosphates as ortho, pyro or meta, following J. J. Berzelius’s preparation of pyrophosphoric acid by heat.
- 1834: $\{\text{PNCl}_3\}_2$ made by F. Wohler and J. von Liebig (originally formulated as $\text{P}_2\text{N}_2\text{Cl}_4$).
- 1843: J. Murray patented his production of “superphosphate” fertilizer (a name coined by him for the product of $\text{H}_2\text{SO}_4$ on phosphate rock).
- 1844: A. Albright started the manufacture of elemental P in England (for matches); 0.75 tonne in 1844, 26.5 tonnes in 1851.
- 1845: Polyphosphoric acids made by T. Fleitmann and W. Hennepberg.
- 1848: Red (amorphous) P discovered by A. Schrotter.
- 1850: First commercial production of “wet process” phosphoric acid.
- 1868: E. F. Hoppe-Seyler and F. Miescher isolated “nuclein”, the first nucleic acid, from pus.
- 1880: Modern cyclic formulation of tetrametaphosphate anion suggested by A. Glatzel. (Ring structure of metaphosphate definitely established by L. Pauling and J. Sherman 1937.)
- 1888: “Strike-anywhere” matches devised by H. Sèvène and E. D. Cahen in France; previously the brothers Lundström had exhibited “safety matches” in 1855, and the first P-containing striking match had been invented by F. Désnoes in 1812.
- 1892: C. H. Fiske and Y. Subbarow discovered adenosine triphosphate (ATP) in muscle fibre; it was synthesized some 20 y later by A. Todd et al. (Nobel Prize 1957).
- 1929: Elucidation of the glycolysis process (by G. Embden and by O. Meyerhof) followed by the glucose oxidation process (H. A. Krebs, 1937) established the intimate involvement of P compounds in many biochemical reactions.
- 1935: Radioactive $^{32}$P made by $(n,\gamma)$ reaction on $^{31}$P.
- 1940: Highly polymeric phosphate esters (nucleic acids) present in all cells and recognized as essential constituents of chromosomes.
- 1951: First $^{31}$P nmr chemical shifts measured by W. C. Dickinson (for $\text{POC}_3$, $\text{PCl}_3$, etc. relative to aq. $\text{H}_3\text{PO}_4$).
- 1952: Detergents (using polyphosphates) overtake soap as main washing agent in the USA. (Heavy duty liquid detergents with polyphosphates introduced in 1955.)
- 1960: Concept of “pseudorotation” introduced by R. S. Berry to interpret the stereochemical non-rigidity of trigonal bipyramidal $\text{PF}_3$ (and $\text{SF}_3$, $\text{ClF}_3$); the 5 F atoms are equivalent (1953) due to interconversion via a square pyramidal intermediate.
- 1961: First 2-coordinate compound of P prepared by A. B. Burg (Me$_3$P$\equiv$PCF$_3$). First 1-coordinate P compound (HC$\equiv$P) made by T. E. Geer.
- 1966: First heterocyclic aromatic analogue of pyridine ($\text{Ph}_3\text{C}_6\text{H}_2\text{P}$) prepared by G. Märkl, followed by the parent compound $\text{C}_6\text{H}_5\text{P}$ in 1971 (A. J. Ashe).
- 1977+: $\text{P}_4$ as an $\eta^1$, $\eta^2$, etc. ligand (see Fig. 12.9, p. 488).
- 1979: G. Wittig shared the Chemistry Nobel Prize for his development of the Wittig reaction (first published with G. Geissler in 1953).
- 1983+: Characterization of extended conjuncto-polypophosphate clusters (p. 491) and polyphosphazenes (p. 492).
and P. "Valency expansion" is another point of difference between the elements of the first and second periods of the periodic table for, although compounds in which N has a formal oxidation state of +5 are known, no simple "single-bonded" species such as NF5 or NCl6− have been prepared, analogous to PF5 or PCl6−. This finds interpretation in the availability of 3d orbitals for bonding in P (and S) but not for N (or O). The extremely important Wittig reaction for olefin synthesis (p. 545) is another manifestation of this property. Discussion of more extensive group trends in which N and P are compared with the other Group 15 elements As, Sb and Bi, is deferred until the next chapter (pp. 550–4).

Because of the great importance of phosphorus and its compounds in the chemical industry, several books and reviews on their preparation and uses are available. Some of these applications reflect the fact that P is a vital element for the growth and development of all plants and animals and is therefore an important constituent in many fertilizers. Phosphorus compounds are involved in energy transfer processes (such as photosynthesis (p. 126), metabolism, nerve function and muscle action), in heredity (via DNA), and in the production of bones and teeth. Topics in phosphorus chemistry are regularly reviewed.

12.2 The Element
12.2.1 Abundance and distribution

Phosphorus is the eleventh element in order of abundance in crustal rocks of the earth and it occurs there to the extent of ~1120 ppm (cf. H ~1520 ppm, Mn ~1060 ppm). All its known terrestrial minerals are orthophosphates though the reduced phosphate mineral schreibersite (Fe,Ni)3P occurs in most iron meteorites. Some 200 crystalline phosphate minerals have been described, but by far the major amount of P occurs in a single mineral family, the apatites, and these are the only ones of industrial importance, the others being rare curiosities. Apatites (p. 523) have the idealized general formula 3Ca3(PO4)2.CaX2, that is Ca10(PO4)6X2, and common members are fluorapatite Ca5(PO4)3F, chloroapatite Ca5(PO4)3Cl, and hydroxyapatite Ca5(PO4)3(OH). In addition, there are vast deposits of amorphous phosphate rock, phosphorite, which approximates in composition to fluorapatite. These deposits are widely

---

spread throughout the world as indicated in Table 12.1 and reserves (1982 estimates) are adequate for several centuries with present technology. The phosphate content of commercial phosphate rock generally falls in the range \((72 \pm 10\%)\) BPL [i.e. "bone phosphate of lime", \(\text{Ca}_3(\text{PO}_4)_2\)] corresponding to \((33 \pm 5\%)\ \text{P}_2\text{O}_5\) or \(12–17\%\) P. The USA is the principal producer, having produced one-third of the total world output in 1985, and Morocco is the largest exporter, mainly to the UK and continental Europe. World production is a staggering 151 million tonnes of phosphate rock per annum (1985), equivalent to some 20 million tonnes of contained phosphorus (p. 480).

Phosphorus also occurs in all living things and the phosphate cycle, including the massive use of phosphatic fertilizers, is of great current interest. Phosphates are slowly leached from the igneous or sedimentary rocks by weathering, and transported by rivers to the lakes and seas where they are precipitated as insoluble metal phosphates or incorporated into the aquatic food chain. The solubility of metal phosphates clearly depends on pH, salinity, temperature, etc., but in neutral solution \(\text{Ca}_3(\text{PO}_4)_2\) (solubility product \(\sim 10^{-29}\) mol\(^5\) l\(^{-5}\)) may first precipitate and then gradually transform into the less soluble hydroxyapatite \([\text{Ca}_5(\text{PO}_4)_3(\text{OH})]\), and, finally, into the least-soluble member, fluorapatite (solubility product \(\sim 10^{-60}\) mol\(^9\) l\(^{-9}\)). Sedimentation follows and eventually, on a geological time scale, uplift to form a new land mass. Some idea of actual concentrations of ions involved may be obtained from the fact that in sea water there is one phosphate group per million water molecules; at a salinity of 3.3%, pH 8 and 20°C 87% of the inorganic phosphate exist as \([\text{HPO}_4]^{2-}\), 12% as \([\text{PO}_4]^{3-}\) and 1% as \([\text{H}_2\text{PO}_4]^-\). Of the \([\text{PO}_4]^{3-}\) species, 99.6% is complexed with cations other than \(\text{Na}^+\).

The secondary biological cycles stem from the crucial roles that phosphates and particularly organophosphates play in all life processes. Thus organophosphates are incorporated into the backbone structures of DNA and RNA which regulate the reproductive processes of cells, and they

---

are also involved in many metabolic and energy-transfer processes either as adenosine triphosphate (ATP) (p. 528) or other such compounds. Another role, restricted to higher forms of life, is the structural use of calcium phosphates as bones and teeth. Tooth enamel is nearly pure hydroxyapatite and its resistance to dental caries is enhanced by replacement of OH\(^-\) by F\(^-\) (fluoridation) to give the tougher, less soluble \([\text{Ca}_5(\text{PO}_4)_3\text{F}]\). It is also commonly believed that the main inorganic phases in bone are hydroxyapatite and an amorphous phosphate, though many crystallographers favour an isomorphous solution of hydroxyapatite and the carbonate-apatite mineral dahlite, \([(\text{Na,Ca})_5(\text{PO}_4,\text{CO}_3)_3(\text{OH})]\), as the main crystalline phase with little or no amorphous material. Young bones also contain brushite, \([\text{CaHPO}_4.2\text{H}_2\text{O}]\), and the hydrated octacalcium phosphate \([\text{Ca}_8\text{H}_2(\text{PO}_4)_6.5\text{H}_2\text{O}]\) which is composed, essentially, of alternate layers of apatite and water oriented parallel to (001).\(^{[21]}\)

The land-based phosphate cycle is shown in Fig. 12.1.\(^{[22]}\) The amount of phosphate in untrilled soil is normally quite small and remains fairly stable because it is present as the insoluble salts of Ca\(^{II}\), Fe\(^{III}\) and Al\(^{III}\). To be used by plants, the phosphate must be released as the soluble \([\text{H}_2\text{PO}_4]^-\) anion, in which form it can be taken up by plant roots. Although acidic soil conditions will facilitate phosphate absorption, phosphorus is the nutrient which is often in shortest supply for the growing plant. Most mined phosphate is thus destined for use in fertilizers and this accounts for up to 75% of phosphate rock in technologically advanced countries and over 90% in less advanced (more

---

agriculturally based) countries. Moderation in all things, however: excessive fertilization of natural waters due to detergents and untreated sewage in run-off water can lead to heavy overgrowth of algae and higher plants, thus starving the water of dissolved oxygen, killing fish and other aquatic life, and preventing the use of lakes for recreation, etc. This unintended over-fertilization and its consequences has been termed eutrophication (Greek ἐὖ, eu, well; τρέφειν, trephein, to nourish) and is the subject of active environmental legislation in several countries. Reclamation of eutrophied lakes can best be effected by addition of soluble Al\(^{III}\) salts to precipitate the phosphates.

As just implied, the land-based phosphorus cycle is connected to the water-based cycle via the rivers and sewers. It has been estimated that, on a global scale, about 2 million tonnes of phosphate are washed into the seas annually from natural processes and rather more than this amount is dumped from human activities. For example in the UK some 200 000 tonnes of phosphate enters the sewers each year: 100 000 tonnes from detergents (now decreasing), 75 000 from human excreta, and 25 000 tonnes from industrial processes. Details of the subsequent water-based phosphate cycle are shown schematically in Fig. 12.2. The water-based cycle is the most rapid of the three phosphate cycles and can be completed within weeks (or even days). The first members of the food chain are the algae and experiments with radioactive \(^{32}\text{P}\) (p. 482) have shown that, within minutes of entering an aquatic environment, inorganic phosphate is absorbed by algae and bacteria (50% uptake in 1 min, 80% in 3 min). In the seas and oceans the various phosphate anions

---

*Figure 12.2 The water-based phosphate cycle.*

\((\text{fig:water-based-phosphate-cycle})\)
Allotropes of phosphorus

form insoluble inorganic phosphates which gradually sink to the sea bed. The concentration of phosphate therefore increases with depth (down to about 1000 m, below which it remains fairly constant); by contrast the sunlight, which is necessary for the primary photosynthesis in the food chain, is greatest at the surface and rapidly diminishes with depth. It is significant that those regions of the sea where the deeper phosphate-rich waters come welling up to the surface support by far the greatest concentration of the world’s fish population; such regions, which occur in the mid-Pacific, the Pacific coast of the Americas, Arabia and Antarctica, account for only 0.1% of the sea’s surface but support 50% of the world’s fish population.

12.2.2 Production and uses of elemental phosphorus

For a century after its discovery the only source of phosphorus was urine. The present process of heating phosphate rock with sand and coke was proposed by E. Aubertin and L. Boblige in 1867 and improved by J. B. Readman who introduced the use of an electric furnace. The reactions occurring are still not fully understood, but the overall process can be represented by the idealized equation:

\[
2\text{Ca}_3(\text{PO}_4)_2 + 6\text{SiO}_2 + 10\text{C} \xrightarrow{1400-1500\degree C} 6\text{CaSiO}_3 + 10\text{CO} + \text{P}_4; \quad \Delta H = -3060 \text{ kJ/mol P}_4
\]

The presence of silica to form slag which is vital to large-scale production was perceptively introduced by Robert Boyle in his very early experiments. Two apparently acceptable mechanisms have been proposed and it is possible that both may be occurring. In the first, the rock is thought to react with molten silica to form slag and P4O10, which is then reduced by the carbon:

\[
2\text{Ca}_3(\text{PO}_4)_2 + 6\text{SiO}_2 \rightarrow 6\text{CaSiO}_3 + \text{P}_4\text{O}_{10} + 10\text{C} \rightarrow 10\text{CO} + \text{P}_4
\]

In the second possible mechanism, the rock is considered to be directly reduced by CO and the CaO so formed then reacts with the silica to form slag:

\[
2\text{Ca}_3(\text{PO}_4)_2 + 10\text{CO} \rightarrow 6\text{CaO} + 10\text{CO}_2 + \text{P}_4
\]

\[
6\text{CaO} + 6\text{SiO}_2 \rightarrow 6\text{CaSiO}_3
\]

\[
10\text{CO}_2 + 10\text{C} \rightarrow 20\text{CO}
\]

Whatever the details, the process is clearly energy intensive and, even at 90% efficiency, requires \(~15\text{ MWh per tonne of phosphorus}\) (see Panel).

12.2.3 Allotropes of phosphorus\textsuperscript{23}

Phosphorus (like C and S) exists in many allotropic modifications which reflect the variety of ways of achieving catenation. At least five crystalline polymorphs are known and there are also several “amorphous” or vitreous forms (see Fig. 12.3). All forms, however, melt to give the same liquid which consists of symmetrical \(\text{P}_4\) tetrahedral molecules, P–P 225 pm. The same molecular form exists in the gas phase (P–P 221 pm), but at high temperatures (above ~800°C) and low pressures \(\text{P}_4\) is in equilibrium with the diatomic form P⇌P (189.5 pm). At atmospheric pressure, dissociation of \(\text{P}_4\) into 2P\_2 reaches 50% at ~1800°C and dissociation of P\_2 into 2P reaches 50% at ~2800°C.

The commonest form of phosphorus, and the one which is usually formed by condensation from the gaseous or liquid states, is the waxy, cubic, white form \(\alpha-\text{P}_4\) (d 1.8232 g cm\(^{-3}\) at 20°C). This, paradoxically, is also the most volatile and reactive solid form and thermodynamically the least stable. It is the slow phosphorescent oxidation of the vapour above these crystals that gives white phosphorus its most characteristic property. Indeed, the emission of yellow-green light from the oxidation of \(\text{P}_4\) is one of the earliest recorded examples of chemiluminescence, though the details of the reaction

Production of White Phosphorus\(^{(3,11,17)}\)

A typical modern phosphorus furnace (12 m diameter) can produce some 4 tonnes per hour and is rated at 60–70 MW (i.e. 140000 A at 500 V). Three electrodes, each weighing 60 tonnes, lead in the current. The amounts of raw material required to make 1 tonne of white phosphorus depend on their purity but are typically 8 tonnes of phosphoric rock, 2 tonnes of silica, 1.5 tonnes of coke, and 0.4 tonnes of electrode carbon. The phosphorus vapour is driven off from the top of the furnace together with the CO and some H\(_2\); it is passed through a hot electrostatic precipitator to remove dust and then condensed by water sprays at about 70°C (P\(_4\) melts at 44.1°C). The byproduct CO is used for supplementary heating.

As most phosphate rock approximates in composition to fluoroapatite, \([\text{Ca}_5(\text{PO}_4)_3]\text{F}\), it contains 3–4 wt% F. This reacts to give the toxic and corrosive gas SiF\(_4\) which must be removed from the effluent. The stoichiometry of phosphoric rock might suggest that about 1 mole of SiF\(_4\) is formed for each 3 moles of P\(_4\), but only about 20% of the fluorine reacts in this way, the rest being retained in the slag. Nevertheless, since a typical furnace can produce over 30000 tonnes of phosphorus per year this represents a substantial waste of a potentially useful byproduct (~5000 tonnes SiF\(_4\) yearly per furnace). In some plants the SiF\(_4\) is recovered by treatment with water and soda ash (Na\(_2\)CO\(_3\)) to give Na\(_2\)SiF\(_6\) which can be used in the fluoridation of drinking water.

Another troublesome impurity in phosphate rock (1–5%) is Fe\(_2\)O\(_3\) which is reduced in the furnace to “ferrophosphorus”, an impure form of Fe\(_2\)P. This is a dense liquid at the reaction temperature; it sinks beneath the slag and can be drained away at intervals. As every tonne of ferrophosphorus contains ~0.25 tonne of P, this is a major loss, but is unavoidable since the Fe\(_2\)O\(_3\) cannot economically be removed beforehand. The few uses of ferrophosphorus depend on its high density (~6.6 g cm\(^{-3}\)). It can be mixed with dynamite for blasting or used as a filler in high-density concrete and in radiation shields for nuclear reactors. It is also used in the manufacture of special steels and cast-irons, especially for non-sparking railway brake-shoes. The other substantial byproduct, CaSiO\(_3\) slag, has little economic use and is sold as hard core for road-fill or concrete aggregate; about 7–9 tonnes are formed per tonne of P produced.

World capacity for the production of elemental P is ~1.5 million tonnes per year. Some figures for 1984 are as follows:

<table>
<thead>
<tr>
<th>Country</th>
<th>USSR</th>
<th>USA</th>
<th>Germany</th>
<th>Netherlands</th>
<th>Canada</th>
<th>France</th>
</tr>
</thead>
<tbody>

</tr>
</tbody>
</table>

About 80–90% of the elemental P produced is reoxidized to (pure) phosphoric acid (p. 521). The rest is used to make phosphorus oxides (p. 503), sulfides (p. 506), phosphorus chlorides and oxochloride (p. 496), and organic P compounds. A small amount is converted to red phosphorus (see below) for use in the striking surface of matches for pyrotechnics and as a flame retarding agent (in polyamides). Bulk price for P\(_4\) is ~$2.00/kg.

Mechanism are still not fully understood: the primary emitting species in the visible region of the spectrum are probably (PO\(_2\)) and HPO\(_2\); ultraviolet emission from excited states of PO also occurs.\(^{(24)}\) At -76.9°C and atmospheric pressure the \(\alpha\)-form of P\(_4\) converts to the very similar white hexagonal \(\beta\)-form (\(d\ 1.88\text{ g cm}^{-3}\)), possibly by loss of rotational disorder; \(\Delta H(\alpha \rightarrow \beta) = -15.9\text{ kJ (mol P}_4\text{)}^{-1}\). White phosphorus is insoluble in water but exceedingly soluble (as P\(_4\)) in CS\(_2\) (~880 g per 100 g CS\(_2\) at 10°C). It is also very soluble in PC\(_13\), POC\(_13\), liquid SO\(_2\), liquid NH\(_3\) and benzene, and somewhat less soluble in numerous other organic solvents. The \(\beta\)-form can be maintained as a solid up to 64.4°C under a pressure of 11600 atm, whereas the \(\alpha\)-form melts at 44.1°C. White phosphorus is highly toxic and ingestion, inhalation or even contact with skin must be avoided; the fatal dose when taken internally is about 50 mg.

Amorphous red phosphorus was first obtained in 1848 by heating white P\(_4\) out of contact with air for several days, and is now made on a commercial scale by a similar process at 270°–300°C. It is denser than white P\(_4\) (~2.16 g cm\(^{-3}\)), has a much higher m.p.

Hittorf's violet

brown

scarlet

vitreous grey

This is well illustrated by the crystal structure of Hittorf's violet monoclinic allotrope \( (d = 2.35 \text{ g cm}^{-3}) \) which was first made in 1865 by crystallizing phosphorus in molten lead. The structure is exceedingly complex\(^{25}\) and consists of \( P_8 \) and \( P_9 \) groups linked alternately by pairs of \( P \) atoms to form tubes of pentagonal cross-section and with a repeat unit of \( 21P \) (Fig. 12.4). These tubes, or complex chains, are stacked (without direct covalent bonding) to form sheets and are linked by \( P-P \) bonds to similar chains which lie at right angles to the first set in an adjacent parallel layer. These pairs of composite parallel sheets are then stacked to form the crystal. The average \( P-P \) distance is 222 pm (essentially the

same as in P₄) but the average P-P-P angle is 101° (instead of 60°).

Black phosphorus, the thermodynamically most stable form of the element, has been prepared in three crystalline forms and one amorphous form. It is even more highly polymeric than the red form and has a correspondingly higher density (orthorhombic 2.69, rhombohedral 3.56, cubic 3.88 g cm⁻³). Black phosphorus (orthorhombic) was originally made by heating white P₄ to 200° under a pressure of 12 000 atm (P. W. Bridgman, 1916). Higher pressures convert it successively to the rhombohedral and cubic forms (Fig. 12.3). Orthorhombic black P (mp ~610°) has a layer structure which is based on a puckered hexagonal net of 3-coordinate P atoms with 2 interatomic angles of 102° and 1 of 96.5° (P–P 223 pm). The relation of this form to the rhombohedral and cubic forms is shown in Fig. 12.5. Comparison with the rhombohedral forms of As, Sb and Bi is also instructive in showing the increasing tendency towards octahedral coordination and metallic properties (p. 551). Black P is semiconducting but its electrical properties are probably significantly affected by impurities introduced during its preparation.

12.2.4 Atomic and physical properties

Phosphorus has only one stable isotope, ³¹P, and accordingly (p. 17) its atomic weight is known with extreme accuracy, 30.973 762(4). Sixteen radioactive isotopes are known, of which ³²P is by far the most important; it is made on the multikilogram scale by the neutron irradiation of ³²S(n,p) or ³¹P(n,y) in a nuclear reactor, and is a pure β-emitter of half life 14.26 days, E₁₇₉ 1.709 MeV, E₁₆₆ 0.69 MeV. It finds extensive use in tracer and mechanistic studies. The stable isotope ³¹P has a nuclear spin quantum number of ⁵⁄₂ and this is much used in nmr spectroscopy. Chemical shifts and coupling constants can both be used diagnostically to determine structural information.

In the ground state, P has the electronic configuration [Ne]3s²3p¹3p¹3p¹ with 3 unpaired

---

same as in \( \text{P}_4 \) but the average P-P-P angle is 101° (instead of 60°).

Black phosphorus, the thermodynamically most stable form of the element, has been prepared in three crystalline forms and one amorphous form. It is even more highly polymeric than the red form and has a correspondingly higher density (orthorhombic 2.69, rhombohedral 3.56, cubic 3.88 g cm\(^{-3}\)). Black phosphorus (orthorhombic) was originally made by heating white \( \text{P}_4 \) to 200° under a pressure of 12 000 atm (P. W. Bridgman, 1916). Higher pressures convert it successively to the rhombohedral and cubic forms (Fig. 12.3). Orthorhombic black P (mp ~610°) has a layer structure which is based on a puckered hexagonal net of 3-coordinate P atoms with 2 interatomic angles of 102° and 1 of 96.5° (P-P 223 pm). The relation of this form to the rhombohedral and cubic forms is shown in Fig. 12.5. Comparison with the rhombohedral forms of As, Sb and Bi is also instructive in showing the increasing tendency towards octahedral coordination and metallic properties (p. 551). Black P is semiconducting but its electrical properties are probably significantly affected by impurities introduced during its preparation.

12.2.4 Atomic and physical properties\(^{(26)}\)

Phosphorus has only one stable isotope, \(^{31}\text{P}\), and accordingly (p. 17) its atomic weight is known with extreme accuracy, 30.973762(4). Sixteen radioactive isotopes are known, of which \(^{32}\text{P}\) is by far the most important; it is made on the multikilogram scale by the neutron irradiation of \(^{32}\text{S}(n,p)\) or \(^{31}\text{P}(n,\gamma)\) in a nuclear reactor, and is a pure \( \beta \)-emitter of half life 14.26 days, \( E_{\text{max}} \) 1.709 MeV, \( E_{\text{mean}} \) 0.69 MeV. It finds extensive use in tracer and mechanistic studies. The stable isotope \(^{31}\text{P}\) has a nuclear spin quantum number of \( \frac{1}{2} \) and this is much used in nmr spectroscopy.\(^{(27)}\) Chemical shifts and coupling constants can both be used diagnostically to determine structural information.

In the ground state, P has the electronic configuration \([\text{Ne}]3s^23p^3\) with 3 unpaired electrons.
electrons; this, together with the availability of low-lying vacant 3d orbitals, accounts for the predominant oxidation states III and V in phosphorus chemistry. Ionization energies, electronegativity, and atomic radii are compared with those of N, As, Sb and Bi on p. 550. White phosphorus (α-P₄) has mp 44.1°C (or 44.25°C when ultrapure), bp 280.5°C and a vapour pressure of 0.122 mmHg at 40°C. It is an insulator with an electrical resistivity of ~10¹¹ Ω cm at 11°C, a dielectric constant of 4.1 (at 20°C) and a refractive index n_D (29.2°) 1.8244. The heat of combustion of P₄ to P₄O₁₀ is −2971 kJ mol⁻¹ and the heat of transition to amorphous red phosphorus is −29 kJ (mol P₄)⁻¹.

### 12.2.5 Chemical reactivity and stereochemistry

The spontaneous chemiluminescent reaction of white phosphorus with moist air was the first property of the element to be observed and was the origin of its name (p. 473); its spontaneous ignition temperature in air is ~35°C. We have already seen (p. 481) that the reactivity of phosphorus depends markedly upon which allotrope is being studied and that increasing catenation of the polymeric red and black forms notably diminishes both reactivity and solubility. The preference of phosphorus for these forms rather than for the gaseous form P₂, which is its most obvious distinction from nitrogen, can be rationalized in terms of the relative strengths of the triple and single bonds for the 2 elements. Reliable values are hard to obtain but generally accepted values are as follows:

<table>
<thead>
<tr>
<th>E(N≡N)/kJ per mol of N</th>
<th>E(P≡P)/kJ per mol of P</th>
</tr>
</thead>
<tbody>
<tr>
<td>946</td>
<td>490</td>
</tr>
<tr>
<td>E(&gt;N=N&lt;)/kJ per mol of N (or 296)</td>
<td>E(&gt;P=P&lt;)/kJ per mol of P</td>
</tr>
<tr>
<td>159</td>
<td>200</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Ratio</th>
<th>Ratio</th>
</tr>
</thead>
<tbody>
<tr>
<td>5.95</td>
<td>2.45</td>
</tr>
</tbody>
</table>

It is clear that, for nitrogen, the triple bond is preferred since it has more than 3 times the energy of a single bond, whereas for phosphorus the triple-bond energy is less than 3 times the single-bond energy and so allotropes having 3 single bonds per P atom are more stable than that with a triple bond.

---

Phosphorus forms binary compounds with all elements except Sb, Bi and the noble gases. It reacts spontaneously with O\(_2\) and the halogens at room temperature, the mixtures rapidly reaching incandescence. Sulfur and the alkali metals also react vigorously with phosphorus on warming, and the element combines directly with all metals (except Bi, Hg, Pb) frequently with incandescence (e.g. Fe, Ni, Cu, Pt). White phosphorus (but not red) also reacts readily with heated aqueous solutions to give a variety of products (pp. 493 and 513ff), and with many other aqueous and nonaqueous reagents.

The stereochemistry and bonding of P are very varied as will become apparent in later sections: the element is known in at least 14 coordination geometries with CN up to 9, though the most frequently met have CN 3, 4, 5 and 6. Some typical coordination geometries are summarized in Table 12.2 and illustrated in Fig. 12.6. Many of these compounds will be more fully discussed in later sections.

The great propensity of P atoms to catenate into chains, rings and clusters, P\(_n\), has already been noted during the discussion on allotropy (pp. 479–83). These groupings and other similar ones also feature in the structures of metal phosphides (p. 489), polyphosphines (p. 492) and organopolyporphanes (p. 542). Moreover, neutral or charged groupings, P\(_n\), (n = 2–6, 10) can also serve as ligands\(^{(42-44)}\), as can isolated P atoms in anions such as \([\text{Co(CO)}_3]_2(\mu_5\eta^2-P_2)\) and other structures shown at the foot of Fig. 12.6. Two decades ago virtually nothing was known about this aspect of phosphorus chemistry, but it is now a burgeoning field, and the substantial progress which has been made in recent years now permits a general overview to be given.

Figure 12.6  Schematic representation of some of the coordination geometries of phosphorus.
§12.2.5 Chemical reactivity and stereochemistry

The cyclo-P₃ ligand can act in either the η¹,η² or η³ mode as shown schematically in Fig. 12.8(a)-(c).⁴²,⁵⁰ Each of the three P atoms in 8(b) can also have a further pendant MLₙ group attached thereby making the cyclo-P₃ ligand η₂, η₃ or η₄. In addition, the more open structure 8(d) is known in the binuclear cation [[(triphos)Ni(P₃Pt(PPh₃)₂)]⁺, where triphos is 1,1,1-tris(diphenylphosphinomethyl)ethane, {CH₃C(CH₂PPh₂)₃}.⁵² The η¹ and η² modes in Fig. 12.8(a) have only recently been established (in [(η³-C₅Mes)(CO)₂FeP₃]⁺, Cr(CO)₄)⁵⁰ but the η³ mode in Fig. 12.8(b) has been known since 1976 when it was found that one of the main products of the reaction between P₄ and [Co₂(CO)₈] was the reactive pale-yellow solid [Co(CO)₅(η³-P₃)].⁵¹ Numerous other examples featuring Co, Rh and Ir, and the isoelectronic cationic metal centres with Ni, Pd and Pt are now known. Metals in earlier groups require more electron donation from pendant ligands to achieve the 15-electron vertex configuration isolobal with the subrogated P atom in P₄, e.g. (Mo(q⁵-C₅Mes)(CO)₂). The binuclear η³,η³ mode of cyclo-P₃ (Fig. 12.8c) and its As₃ homologues were extensively studied by L. Sacconi and others in the early 1980s.⁴²,⁴³ As a ligand, P₄ can adopt various geometries,⁴²,⁴³ including the P₄ tetrahedron, planar cyclo-P₄ (both square and trapezoidal), and a planar zig-zag chain. In principle, the tetrahedral cluster P₄ could ligate in η¹,η² and η³ modes.

---

though only the first two have so far been established (Fig. 12.9 (a), (b)). [Note, however, the face-coordinated \( \eta^3 \) configuration in the Bi\(_4\) complex \([\text{Fe(CO)}_4\text{Fe}(\mu_4,\eta^3\text{-Bi}_4)]\text{[Fe(CO)}_3\text{]}_2^{2-}\).\(^{52}\)]

The first example of what turned out to be a complex involving the \( \eta^1 \) mode was the unstable red-brown compound \([\text{Fe(CO)}_4\text{P}_4]\) which was made in 1977 by reacting \( \text{P}_4 \) with \( \text{Fe}_2(\text{CO})_9 \) in benzene at room temperature.\(^{53}\) One vertex of the \( \text{P}_4 \) tetrahedron was coordinated \( \eta' \) to one of the \( \text{[Fe(CO)}_4\text{]} \) groups while opposite edges of the \( \text{P}_4 \) cluster were bonded \( \eta^2 \) to the other two \( \text{[Fe(CO)}_4\text{]} \) groups. The first \( \eta^1 \)-\( \text{P}_4 \) complex to be characterized by X-ray structural analysis was \([\text{Ni}(\eta^3\text{-np}_3)\text{Ni}(\eta^1\text{-P}_4)]\).\(^{54}\) Formed by direct reaction of white \( \text{P}_4 \) with the \( \text{Ni}^{10} \) complex \([\text{Ni}(\eta^4\text{-np}_3)]\) in thf at 0°C where \( \text{np}_3 \) is \( \text{N(CH}_2\text{CH}_2\text{PPh}_2)_3 \). Coordination results in a slight elongation of the tetrahedron with \( \text{P}_\text{basal} - \text{P}_\text{apical} = 220 \text{ pm} \) and \( \text{P}_\text{basal} - \text{P}_\text{basal} = 209 \text{ pm} \) (cf. 221 pm in \( \alpha\text{-P}_4 \)). The \( \eta^2 \)-\( \text{P}_4 \) mode of coordination is featured in many complexes with \( \text{Rh} \), \( \text{Ir} \), etc., for example \([\text{RhCl}(\eta^2\text{-P}_4)\text{(PPh}_3)_2]\).\(^{55}\) Formed by direct reaction of \( \text{P}_4 \) with \([\text{RhCl(PPh}_3)_3]\) in \( \text{CH}_2\text{Cl}_2 \) at \(-78^\circ\text{C} \). The coordinated edge is almost perpendicular to the \( \{\text{RhClL}_2\} \) plane and is lengthened by about 25 pm to 246.2 pm, whereas the other \( \text{P} - \text{P} \) distances are essentially unchanged from those in uncoordinated \( \text{P}_4 \).\(^{56}\)

Square planar \( \text{cyclo-P}_4 \) features as a ligand in \([\text{Nb}(\eta^3\text{-C}_3\text{H}_3\text{Bu'}_2\text{-1,3})(\text{CO)}_3(\eta^4\text{-P}_4)]\)\(^{57}\) and the corresponding \( \text{Ta} \) analogue.\(^{58}\) The compounds are formed by uv photolysis of \( \text{P}_4 \) with \([\text{M(cp)}^*(\text{CO)}_4]\) and the square-pyramidal \( \text{nido} \) structure of the \( \text{MP}_4 \) cluster (Fig. 12.9c) is consistent with its 14e \((2n^1 + 4)\) cluster-electron count (p. 161). The \( \text{P} - \text{P} \) distances in the coplanar \( \text{P}_4 \) ligand are in the range 214–218 pm for the \( \text{Nb} \) complex, with \( \text{Nb} - \text{P}_4(\text{centre}) \) being 142 pm and the basal \( \text{PPP} \) angles being 92.6° and 88.4°. In the \( \text{Ta} \) complex, the \( \text{P} - \text{P} \) distances are 215–217 pm. A co-product of the photolysis reaction is the related bis-(\( \text{P}_2 \)) complex \([\text{Ta}(\text{C}_3\text{H}_3\text{Bu'}_2)(\text{CO})_3(\mu,\eta^2\text{-P}_2)]\).\(^{59}\) Fig. 12.9d, in which the \( \text{P} - \text{P} \) distance is 212 pm within each \( \text{P}_2 \) ligand and 357 pm between the coplanar \( \text{P}_2 \) ligands. Several similar binuclear bis-(\( \text{P}_2 \)) complexes are known, including \( \text{Rh/Rh} \) and mixed metal species involving \( \text{Nb/Ta} \) and \( \text{Ta/Co} \).\(^{58}\)

A still more open configuration occurs in the zig-zag \( \text{P}_4 \) chain shown in Fig. 12.10(a).\(^{59}\) This was found in the dianion of the deep

red crystalline compound $[\text{Li(dme)}_3]^{+}2[(\text{SiMe}_3)_{2}\{\text{Cr}(\text{CO})_5\}P-P\equiv P-P\equiv P[\text{Cr}(\text{CO})_5]_2(\text{SiMe}_3)]^{2-}$, which was obtained by reacting $\text{Li}[P(\text{SiMe}_3)_2\{\text{Cr}(\text{CO})_5\}]$ with $\text{BrCH}_2\text{CH}_2\text{Br}$ in 1,2-dimethoxy-ethane (dme). The interatomic distances $P-P$ 221.9 pm and $P=P$ 202.5 pm reflect the bond orders indicated.

Because cyclo-P$_5$ and cyclo-P$_6$ can be considered as isoelectronic with C$_5$H$_5$ and C$_6$H$_6$ their appearance as ligands is not entirely unexpected, but the recent synthesis and characterization of such complexes was nevertheless a noteworthy achievement.$^{(43)}$ Typical examples are $[(\text{Mn}(\text{CO})_3(\eta^5-P_5))]$,$^{(60)}$ (formed by the direct action of $\text{KP}_5$ on $[\text{Mn}(\text{CO})_5\text{Br}]$ in dmf at 155°C) and $[\text{Fe}(\eta^5-C_5\text{H}_5)(\mu-\eta^2,\eta^5-P_5)\text{Fe}(\eta^5-C_5\text{Me}_4\text{R})]$$^{(43)}$ (Fig. 12.10(b)) for cyclo-P$_5$; and $[(\text{Mo}(\eta^5-C_5\text{Me}_5)]_2(\mu-\eta^1,\eta^5-P_6)]$$^{(43)}$ (Fig. 12.10(c)) for planar cyclo-P$_6$. Several cyclo-As$_5$ and -As$_6$ analogues are also known. The complex $[[\text{Ti}(\eta^5-C_5\text{Me}_5)]_2(\mu-\eta^3,\eta^3-P_6)]$ features a puckered P$_6$ ring in the chain conformation, so that the overall cluster core has a distorted cubane geometry.$^{(61)}$

The most complex P$_n$ ligand so far characterized is the astonishing $\mu_5$ hexadentate P$_{10}$ unit in $[(\text{Cr}(\eta^5-C_5\text{H}_5)(\text{CO})_2)_3\text{P}_{10}]$ (see ref. 62 for details).

12.3 Compounds

12.3.1 Phosphides$^{(63-65)}$

Phosphorus forms stable binary compounds with almost every element in the periodic table and those with metals are called phosphides. Like borides (p. 145) they are known in a bewilderingly large number of stoichiometries, and typical formulae are M$_4$P, M$_3$P, M$_{12}$P$_5$, M$_7$P$_3$, M$_{12}$P$_5$, M$_2$P, M$_7$P$_4$, M$_5$P$_3$, M$_3$P$_2$, M$_4$P$_3$, M$_5$P$_4$, M$_6$P$_5$, MP, M$_3$P$_4$, M$_2$P$_3$, MP$_3$, M$_5$P$_3$, M$_3$P$_{11}$, M$_3$P$_{14}$, MP$_5$, M$_5$P$_{16}$, MP$_{26}$, MP$_7$, M$_2$P$_{16}$ and M$_5$P$_{15}$. Many metals (e.g. Ti, Ta, W, Rh) form as many as 5 or 6 phosphides and Ni has at least 8 (Ni$_3$P, Ni$_5$P$_2$, Ni$_{12}$P$_5$, NiP$_2$, Ni$_5$P$_4$, NiP, Ni$_2$P and Ni$_3$P)$_2$. Ternary and more complex metal phosphides are also known.

The most general preparative route to phosphides (Faraday's method) is to heat the metal with the appropriate amount of red P at high temperature in an inert atmosphere or an evacuated sealed tube:

$$n\text{M} + m\text{P} \xrightarrow{\text{heat}} \text{M}_n\text{P}_m$$

An alternative route (Andrieux's method) is the electrolysis of fused salts such as molten

---

$^{63}$ A. WILSON, *The metal phosphides*, Chap. 3 (pp. 289–363) in ref. 23, see also p. 256.

alkali-metal phosphates to which appropriate metal oxides or halides have been added:

\[ \text{[(NaPO}_3\text{)]}_n/\text{NaCl/WO}_3 \text{] fused } \xrightarrow{\text{electrol}} \text{ W}_3\text{P} \]

Variation in current, voltage and electrolyte composition frequently results in the formation of phosphides of different stoichiometries. Less-general routes (which are nevertheless extremely valuable in specific instances) include:

(a) Reaction of \( \text{PH}_3 \) with a metal, metal halide or sulfide, e.g.:

\[
\begin{align*}
\text{PH}_3 + 2\text{Ti} &\xrightarrow{800^\circ} \text{Ti}_2\text{P} \\
2\text{PH}_3 + 3\text{Ni(O}_2\text{CMe)}_2 &\xrightarrow{\text{H}_2\text{O}} \text{Ni}_3\text{P}_2 \\
&\quad + 6\text{HOAc} \xrightarrow{\text{further reaction}} \text{Ni}_5\text{P}_2
\end{align*}
\]

(b) Reduction of a phosphate such as apatite with \( \text{C} \) at high temperature, e.g.:

\[
\text{Ca}_3(\text{PO}_4)_2 + 8\text{C} \xrightarrow{1200^\circ} \text{Ca}_3\text{P}_2 + 8\text{CO}
\]

(c) Reaction of a metal phosphide with further metal or phosphorus to give a product of different stoichiometry, e.g.:

\[
\begin{align*}
\text{Th}_3\text{P}_4 + \text{Th} &\xrightarrow{900^\circ} 4\text{ThP} \\
4\text{RuP} + \text{P}_4(g) &\xrightarrow{650^\circ} 4\text{RuP}_2 \\
4\text{IrP}_2 &\xrightarrow{1150^\circ \text{ (low press)}} 2\text{Ir}_2\text{P} + 1\frac{1}{2}\text{P}_4(g)
\end{align*}
\]

Phosphides resemble in many ways the metal borides (p. 145), carbides (p. 297), and nitrides (p. 417), and there are the same difficulties in classification and description of bonding. Perhaps the least-contentious procedure is to classify according to stoichiometry, i.e. (a) metal-rich phosphides \((\text{M/P} > 1)\), (b) monophosphides \((\text{M/P} = 1)\), and (c) phosphorus-rich phosphides \((\text{M/P} < 1)\):

(a) **Metal-rich phosphides** are usually hard, brittle, refractory materials with metallic lustre, high thermal and electrical conductivity, great thermal stability and general chemical inertness. Phosphorus is often in trigonal prismatic coordination being surrounded by 6 \( \text{M} \), or by 7, 8 or 9 \( \text{M} \) (see Fig. 6.7 on p. 148 and Fig. 12.6). The antifluorite structure of many \( \text{M}_2\text{P} \) also features eightfold (cubic) coordination of \( \text{P} \) by \( \text{M} \). The details of the particular structure adopted in each case are influenced predominantly by size effects.

(b) **Monophosphides** adopt a variety of structures which appear to be influenced by both size and electronic effects. Thus the Group 3 phosphides \( \text{MP} \) adopt the zinc-blende structure (p. 1210) with tetrahedral coordination of \( \text{P} \), whereas \( \text{SnP} \) has the \( \text{NaCl}\)-type structure (p. 242) with octahedral coordination of \( \text{P} \). \( \text{VP} \) has the hexagonal \( \text{NiAs}\)-type structure (p. 556) with trigonal prismatic coordination of isolated \( \text{P} \) atoms by \( \text{V} \), and \( \text{MoP} \) has the hexagonal \( \text{WC}\)-type structure (p. 299) in which both \( \text{Mo} \) and \( \text{P} \) have a trigonal prismatic coordination by atoms of the other kind. More complicated arrangements are also encountered, e.g.:

\[
\begin{align*}
\text{TiP}, \text{ZrP}, \text{HfP}: & \text{ half the P trigonal prismatic and half octahedral;} \\
\text{MP (M = Cr, Mn, Fe, Co, Ru, W)}: & \text{ distorted trigonal prismatic coordination of P by M plus two rather short contacts to P atoms in adjacent trigonal prisms, thus building up a continuous chain of P atoms; NiP is a distortion of this in which the P atoms are grouped in pairs rather than in chains (or isolated as in VP).}
\end{align*}
\]

(c) **Phosphorus-rich phosphides** are typified by lower mps and much lower thermal stabilities when compared with monophosphides or metal-rich phosphides. They are often semiconductors rather than metallic conductors and feature increasing catenation of the P atoms (cf. boron rich borides, p. 148). \( \text{P}_2 \) units occur in \( \text{FeP}_2, \text{RuP}_2 \) and \( \text{OsP}_2 \) (marcasite-type, p. 680) and in \( \text{PtP}_2 \) (pyrites type, p. 680) with \( \text{P–P} \) 217 pm. Planar \( \text{P}_4 \) rings (square or rectangular) occur in several \( \text{MP}_3 \) (\( \text{M} = \text{Co, Ni, Rh, Pd, Ir} \)) with \( \text{P–P} \) typically 223 pm in the square ring of \( \text{RhP}_3 \). Structures are also known in which the P atoms form chains (\( \text{PdP}_2, \text{NiP}_2, \text{CdP}_2, \text{BaP}_3 \)),

TiP, ZrP, HfP: half the P trigonal prismatic and half octahedral;

MP (M = Cr, Mn, Fe, Co, Ru, W): distorted trigonal prismatic coordination of P by M plus two rather short contacts to P atoms in adjacent trigonal prisms, thus building up a continuous chain of P atoms; NiP is a distortion of this in which the P atoms are grouped in pairs rather than in chains (or isolated as in VP).

(c) **Phosphorus-rich phosphides** are typified by lower mps and much lower thermal stabilities when compared with monophosphides or metal-rich phosphides. They are often semiconductors rather than metallic conductors and feature increasing catenation of the P atoms (cf. boron rich borides, p. 148). \( \text{P}_2 \) units occur in \( \text{FeP}_2, \text{RuP}_2 \) and \( \text{OsP}_2 \) (marcasite-type, p. 680) and in \( \text{PtP}_2 \) (pyrites type, p. 680) with \( \text{P–P} \) 217 pm. Planar \( \text{P}_4 \) rings (square or rectangular) occur in several \( \text{MP}_3 \) (\( \text{M} = \text{Co, Ni, Rh, Pd, Ir} \)) with \( \text{P–P} \) typically 223 pm in the square ring of \( \text{RhP}_3 \). Structures are also known in which the P atoms form chains (\( \text{PdP}_2, \text{NiP}_2, \text{CdP}_2, \text{BaP}_3 \)),
double chains (ZnPbP₁₄, CdPbP₁₄, HgPbP₁₄), or layers (CuP₃, AgP₂, CdP₄); in the last 3 phosphides the layers are made up by a regular fusion of puckered 10-membered rings of P atoms with the metal atoms in the interstices. The double-chained structure of MPbP₁₄ is closely related to that of violet phosphorus (p. 482).

In addition, phosphides of the electropositive elements in Groups 1, 2 and the lanthanoids form phosphides with some degree of ionic bonding. The compounds Na₃P₁₁ and Sr₃P₁₄ have already been mentioned (p. 484) and other somewhat ionic phosphides are M₃P (M = Li, Na), M₃P₂ (M = Be, Mg, Zn, Cd), MP (M = La, Ce) and Th₃P₄. However, it would be misleading to consider these as fully ionized compounds of P³⁻ and there is extensive metallic or covalent interaction in the solids. Such compounds are characterized by their ready hydrolysis by water or dilute acid to give PH₃.

Recent extensive structural studies by X-ray crystallography and by ³¹P nmr spectroscopy have revealed an astonishing variety of conjuncto-polyphosphides with quasi-ionic cluster structures. Thus, the yellow compound Li₃P₇ (which has been known since 1912) and its Na–Cs analogues have been found to contain the P₇³⁻ cluster shown schematically in Fig. 12.11(a). The cluster can be regarded as being related to the P₄ tetrahedron (p. 479) by the notional insertion of three 2-connected P⁻ atoms (cf. the structure of P₄S₃, p. 507, with which it is precisely isoelectronic). Substitution of P by As leads to a series of closely related anions [P₇₋ₓAsₓ]³⁻; x = 1–5, (68) and As₇³⁻ is also known for Na, Rb, Cs). Catenation of the P₇³⁻ unit, as shown in Fig. 12.11(b), leads to the stoichiometry M⁺P₇⁻. The repeating unit =P₈=, which is clearly related to a segment in the structure of Hittorf’s allotrope (p. 482), is shown in Fig. 12.11(c). A more complex

---

cluster occurs in the yellow/orange compounds \( M_3^+P_{11}^{3-} \) (Fig. 12.11d): \( P_{11}^{3-} \) can be thought of as comprising two axial \( PP_3 \) tetrahedra joined by a central belt of three 2-connected \( P^- \) atoms, so that the sequence of cluster planes contains \( 1,3,(3),3,1 \) \( P \) atoms, respectively.

Even more complex \textit{conjuncto}-polyphosphate anions can be constructed, such as those of stoichiometry \( P_{16}^{2-}, P_{21}^{3-} \) and \( P_{26}^{4-} \), Fig. 12.12(a)(b)(c).\(^{66,67}\) These bear an obvious structural relationship to \( =P_8= \) (Fig. 12.11c) and to Hittorr's phosphorus (Fig. 12.4) and can be viewed as ladders of \( P \) atoms with alternate \( P-P \) and \( P(P^-)P \) rungs, terminated at each end by a ring-closing \( P(P^-) \) unit. The \( P-P \) distances and \( PPP \) angles in these various species are much as expected. These cluster anions, and those mentioned in the preceding paragraphs, can be partially or completely protonated (see next subsection) and they also occur in neutral organopolyphosphanes (p. 495).

A completely different structural motif has very recently been found in the red-brown phosphide \( \text{Ca}_3P_8 \), formed by direct fusion of Ca metal and red \( P \) in the correct atom ratio in a corundum crucible at 1000°C.\(^ {69}\) The structure comprises \( \text{Ca}^{2+} \) cations and \( P_8^{10-} \) anions, the latter adopting a staggered ethane conformation. (Note that \( P^+ \) is isolobal with \( C \) and \( P^{2-} \) with \( H \) so that \( C_2P_6 = [(P^+)_2(P^{2-})_6] = P_8^{10-} \). The internal \( P-P \) distance is 230.1 pm and the terminal \( P-P \) distances 214.9–216.9 pm, while the internal \( PPP \) angles are 104.2–106.4° and the outer angles are 103.4–103.7°.

Few industrial uses have so far been found for phosphides. “Ferrophosphorus” is produced on a large scale as a byproduct of \( P_4 \) manufacture, and its uses have been noted (p. 480). Phosphorus is also much used as an alloying element in iron and steel, and for improving the workability of \( Cu \). Group 3 monophosphides are valuable semiconductors (p. 255) and \( \text{Ca}_3P_2 \) is an important ingredient in some navy sea-flares since its reaction with water releases spontaneously flammable phosphines. By contrast the phosphides of \( Nb, Ta \) and \( W \) are valued for their chemical inertness, particularly their resistance to oxidation at very high temperatures, though they are susceptible to attack by oxidizing acids or peroxides.

### 12.3.2 Phosphine and related compounds

The most stable hydride of \( P \) is phosphine (phos- phane), \( \text{PH}_3 \). It is the first of a homologous open-chain series \( \text{P}_n\text{H}_{n+2} \ (n = 1–9) \) the members of which rapidly diminish in thermal stability, though \( \text{P}_2\text{H}_4 \) and \( \text{P}_3\text{H}_5 \) have been isolated pure. There are ten other (unstable) homologous series: \( \text{P}_n\text{H}_{n-2} \ (n = 4–12) \), and \( \text{P}_n\text{H}_{n-4} \ (n = 5–13) \) and so on up to \( \text{P}_n\text{H}_{n-18} \ (n = 19–22) \text{;} \) in all of these there is a tendency to form cyclic and condensed polyphosphanes at the expense of open-chain structures. Some 85 phosphines have so far been identified and structurally characterized by nmr spectroscopy and other techniques, although few have been obtained pure because of problems involving thermal instability, ready disproportionation, light-sensitivity and great chemical reactivity.\(^ {67,70,71}\) Phosphorane, \( \text{PH}_5 \), has not been prepared or even detected, despite numerous attempts, although \( \text{HPF}_4, \text{H}_2\text{PF}_3 \) and \( \text{H}_3\text{PF}_2 \) have recently been well characterized.\(^ {72,73}\)

\( \text{PH}_3 \) is an extremely poisonous, highly reactive, colourless gas which has a faint garlic odour at concentrations above about 2 ppm by volume. It is intermediate in thermal stability between \( \text{NH}_3 \) (p. 421) and \( \text{AsH}_3 \) (p. 557). Several convenient routes are available for its preparation:

1. Hydrolysis of a metal phosphide such as \( \text{AlP} \) or \( \text{Ca}_3P_2 \); the method is useful even

---

§12.3.2 Phosphine and related compounds

Phosphine is rather insoluble in water at atmospheric pressure but is more soluble in organic liquids, and particularly so in CS$_2$ and CCl$_3$CO$_2$H. Some typical values are:

| Solvent | H$_2$O | CH$_3$CO$_2$H | C$_6$H$_6$
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Solubility/ml PH$_3$ (g) per 100 ml solvent</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Solvent ($T$°C)</td>
<td>CS$_2$(21°)</td>
<td>CCl$_3$CO$_2$H</td>
<td></td>
</tr>
<tr>
<td>Solubility/ml PH$_3$ (g) per 100 ml solvent</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

[Note: 1 ml PH$_3$(g) ≈ 1.5 mg]

Aqueous solutions are neutral and there is little tendency for PH$_3$ to protonate or deprotonate:

PH$_3$ + H$_2$O ⇌ PH$_2^-$ + H$_3$O$^+$;

\[ K_A = 1.6 \times 10^{-29} \]

PH$_3$ + H$_2$O ⇌ PH$_4^+$ + OH$^-$;

\[ K_B = 4 \times 10^{-28} \]

In liquid ammonia, however, phosphine dissolves to give NH$_4^+$PH$_2^-$ and with potassium gives KPH$_2$ in the same solvent. Again, phosphine reacts with liquid HCl to give the sparingly soluble PH$_4^+$Cl$^-$ and this reacts further with BCl$_3$ to give PH$_4$BCl$_4$. The corresponding bromides and PH$_4$I are also known.

More generally, phosphine readily acts as a ligand to numerous Lewis acids and typical coordination complexes are [BH$_3$(PH$_3$)$_2$], [BF$_3$(PH$_3$)$_2$], [AlCl$_3$(PH$_3$)$_2$], [Cr(CO)$_2$(PH$_3$)$_4$], [Cr(CO)$_3$-(PH$_3$)$_2$], [Co(CO)$_2$(NO)(PH$_3$)$_2$], [Ni(PF$_3$)$_2$(PH$_3$)$_2$] and [CuCl(PH$_3$)]. Further details are in the Panel and other aspects of the chemistry of PH$_3$ have been extensively reviewed.\(^{(74)}\)

Phosphine is also a strong reducing agent: many metal salts are reduced to the metal and PCl$_3$ yields PCl$_3$. The pure gas ignites in air at about 150° but when contaminated with traces of P$_2$H$_4$ it is spontaneously flammable:

\[ \text{PH}_3 + 2\text{O}_2 \rightarrow \text{H}_3\text{PO}_4 \]

When heated with sulfur, PH$_3$ yields H$_2$S and a mixture of phosphorus sulfides. Probably the most important reaction industrially is:

up to the 10-mole scale and can be made almost quantitative

\[ \text{Ca}_3\text{P}_2 + 6\text{H}_2\text{O} \rightarrow 2\text{PH}_3 + 3\text{Ca(OH)}_2 \]

2. Pyrolysis of phosphorous acid at 205–210°; under these conditions the yield of PH$_3$ is 97% though at higher temperatures the reaction can be more complex (p. 512)

\[ 4\text{H}_3\text{PO}_3 \rightarrow 200° \rightarrow \text{PH}_3 + 3\text{H}_3\text{PO}_4 \]

3. Alkaline hydrolysis of PH$_4$I (for very pure phosphine):

\[ \text{P}_4 + 2\text{I}_2 + 8\text{H}_2\text{O} \rightarrow 2\text{PH}_4\text{I} + 2\text{HI} + 2\text{H}_3\text{PO}_4 \]

\[ \text{PH}_4\text{I} + \text{KOH(aq)} \rightarrow \text{PH}_3 + \text{KI} + \text{H}_2\text{O} \]

4. Reduction of PCl$_3$ with LiAlH$_4$ or LiH:

\[ \text{PCl}_3 + \text{LiAlH}_4 \rightarrow \text{Et}_2\text{O}/ < 0° \rightarrow \text{PH}_3 + \ldots \]

\[ \text{PCl}_3 + 3\text{LiH} \rightarrow \text{warm} \rightarrow \text{PH}_3 + 3\text{LiCl} \]

5. Alkaline hydrolysis of white P$_4$ (industrial process):

\[ \text{P}_4 + 3\text{KOH} + 3\text{H}_2\text{O} \rightarrow \text{PH}_3 + 3\text{K}_2\text{H}_2\text{PO}_3 \]

Phosphine has a pyramidal structure, as expected, with P–H 142 pm and the H–P–H angle 93.6° (see p. 557). Other physical properties are mp −133.5°, bp −87.7°, dipole moment 0.58 D, heat of formation $\Delta H_f^{\circ}$ −9.6 kJ mol$^{-1}$ (uncertain) and mean P–H bond energy 320 kJ mol$^{-1}$. The free energy change (at 25°C) for the reaction $\frac{1}{2}\text{P}_4(\alpha\text{-white}) + \frac{3}{2}\text{H}_2(\text{g}) = \text{PH}_3(\text{g})$ is −13.1 kJ mol$^{-1}$, implying a tendency for the elements to combine, though there is negligible reaction unless H$_2$ is energized photolytically or by a high-current arc. The inversion frequency of PH$_3$ is about 4000 times less than for NH$_3$ (p. 423); this reflects the substantially higher energy barrier to inversion for PH$_3$ which is calculated to be −155 kJ mol$^{-1}$ rather than 24.7 kJ mol$^{-1}$ for NH$_3$.

More generally, phosphine readily acts as a ligand to numerous Lewis acids and typical coordination complexes are [BH$_3$(PH$_3$)$_2$], [BF$_3$(PH$_3$)$_2$], [AlCl$_3$(PH$_3$)$_2$], [Cr(CO)$_2$(PH$_3$)$_4$], [Cr(CO)$_3$-(PH$_3$)$_2$], [Co(CO)$_2$(NO)(PH$_3$)$_2$], [Ni(PF$_3$)$_2$(PH$_3$)$_2$] and [CuCl(PH$_3$)]. Further details are in the Panel and other aspects of the chemistry of PH$_3$ have been extensively reviewed.\(^{(74)}\)

Phosphine is also a strong reducing agent: many metal salts are reduced to the metal and PCl$_3$ yields PCl$_3$. The pure gas ignites in air at about 150° but when contaminated with traces of P$_2$H$_4$ it is spontaneously flammable:

\[ \text{PH}_3 + 2\text{O}_2 \rightarrow \text{H}_3\text{PO}_4 \]

When heated with sulfur, PH$_3$ yields H$_2$S and a mixture of phosphorus sulfides. Probably the most important reaction industrially is:

\[ \text{PH}_3 + 2\text{O}_2 \rightarrow \text{H}_3\text{PO}_4 \]

\[ 4\text{H}_3\text{PO}_3 \rightarrow 200° \rightarrow \text{PH}_3 + 3\text{H}_3\text{PO}_4 \]

Phosphine and its Derivatives as Ligands

A wide variety of 3-coordinate phosphorus(III) compounds are known and these have been extensively studied as ligands because of their significance in improving our understanding of the stability and reactivity of many coordination complexes. Among the most studied of these ligands are PH₃, PF₃ (p. 493, PCl₃ (p. 496), PR₃ (R = alkyl), PPh₃ and P(OR)₃, together with a large number of “mixed” ligands such as Me₂NF₃, PMePh₂, etc., and many multidentate (chelating) ligands such as Ph₃PCH₂CH₂PPh₂, etc.

In many of their complexes PF₃ and PPh₃ (for example) resemble CO (p. 926) and this at one time encouraged the belief that their bonding capabilities were influenced not only by the factors (p. 198) which affect the stability of the σ P→M interaction which uses the lone-pair of electrons on P³⁺ and a vacant orbital on M, but also by the possibility of synergic π back-donation from a “nonbonding” dₓ² pair of electrons on the metal into a “vacant” 3dₓ orbital on P. It is, however, not clear to what extent, if any, the σ and π bonds reinforce each other, and more recent descriptions are based on an MO approach which uses all (σ and π) orbitals of appropriate symmetry on both the phosphine and the metal-containing moiety. To the extent that CT and π bonding effects on the stability of metal-phosphorus bonds can be isolated from each other and from steric factors (see below) the accepted sequence of effects is as follows:

<table>

</tr>
</tbody>
</table>

Bulky tertiary phosphine ligands exert both steric and electronic influences when they form complexes (since an increase in bulkiness of a substituent on P increases the inter-bond angles and this in turn can be thought of as an increase in “p-character” of the lone-pair of electrons on P). For example, the sterically demanding di-t-butylphospliines, PBu₃ (R = alkyl or aryl), promote spatially less-demanding features such as hydride formation, coordinative unsaturation at the metal centre, and even the stabilization of unusual oxidation states, such as Irᴵᴵ. They also favour internal C- or O- metallation reactions for the same reasons. Indeed, the metallation of C-H and C-P bonds of coordinated tertiary phosphines can be considered as examples of intramolecular oxidative addition, and these have important mechanistic implications for homogeneous and heterogeneous catalysis.

Other notable examples are the orthometallation (orthophenylation) reactions of many complexes of aryl phosphines (PAr₃) and aryl phosphites P(OAr)₃ with platinum metals in particular, e.g.:

\[
\text{[RuCH(P(OH)₃)₄]} \xrightarrow{\text{heat}(-\text{H₂})} \text{H₂} \quad \xrightarrow{\text{PhO₂PO-ÇH₄-RuCl(P(OH)₃)₃}} \text{[RuCH(P(OH)₃)₄]}\]

75 Chapter 5 in ref. 2, Phosphorus(III) ligands in transition-metal complexes, pp. 177–207.

77 O. STELZER, Topics in Phosphorus Chemistry 9, 1–229 (1977). An extensive review with over 1700 references arranged by element and by technique but with no assessment or generalizations.

its hydrophosphorylation of formaldehyde in aqueous hydrochloric acid solution:

$$\text{PH}_3 + 4\text{HCHO} + \text{HCl} \rightarrow [\text{P}((\text{CH}_2\text{OH})_4]\text{Cl}$$

The tetrakis(hydroxymethyl)phosphonium chloride so formed is the major ingredient with urea-formaldehyde or melamine-formaldehyde resins for the permanent flame-proofing of cotton cloth.

Of the many other hydrides of phosphorus, diphosphane (diphosphine), $\text{P}_2\text{H}_4$, is the most studied. It is best made\(^{(71)}\) by treating CaP with cold oxygen-free water. Passage of PH$_3$ through an electric discharge at $5\cdots10$ kV is an alternative method for small amounts. P$_2$H$_4$ is a colourless, volatile liquid (mp $-99^\circ$) which is thermally unstable even below room temperature and is decomposed slowly by water. Its vapour pressure at 0°C is 70.2 mmHg but partial decomposition precludes precise determination of the bp (63.5°C extrap); \(d \simeq 1.014 \text{g cm}^{-3}\) at 20°C. Electron-diffraction measurements on the gas establish the gauche-$\text{C}_2$ configuration (p. 428) with P–P 222 pm, P–H 145 pm, and the angle H–P–H 91.3°, though vibration spectroscopy suggests a trans-$\text{C}_2\text{h}$ configuration in the solid phase. These results can be compared with those for the halides $\text{P}_2\text{X}_4$ on p. 498.

The next member of the open-chain series $\text{P}_n\text{H}_{n+2}$ is $\text{P}_3\text{H}_5$, i.e. $\text{PH}_2\text{PHPH}_2$, a colourless liquid that can be stored in the dark at $-80^\circ$ for several days.\(^{(67,71)}\) It can be made by disproportionation ($2\text{P}_2\text{H}_4 \rightarrow \text{P}_3\text{H}_5 + \text{PH}_3$) but it is difficult to purify because of its own fairly ready disproportionation and reactivity, e.g. $2\text{P}_3\text{H}_5 \rightarrow \text{P}_2\text{H}_6 + \text{P}_2\text{H}_4$; and $\text{P}_3\text{H}_5 + \text{P}_2\text{H}_4 \rightarrow \text{P}_4\text{H}_6 + \text{PH}_3$. Tetraphosphane(6), $\text{P}_4\text{H}_6$, exists as an equilibrium mixture of the two structural isomers $\text{H}_2\text{PPPHPH}_2$ (n) and $\text{P}((\text{PH}_2)_3(i)$, and itself reacts with $\text{P}_3\text{H}_5$ at $-20^\circ$ according to the idealized stoichiometry $\text{P}_2\text{H}_6 + \text{P}_3\text{H}_5 \rightarrow 2\text{PH}_3 + \text{P}_3\text{H}_5$, i.e. cyclo-$(\text{PH})_5$. All members of the series cyclo-$\text{P}_n\text{H}_n$ ($n = 3\cdots10$) have been detected mass spectrometrically in the thermolysis products from $\text{P}_3\text{H}_4$.\(^{(70)}\)

Polycyclic polyphosphanes are often best prepared by direct protonation of the corresponding polyphosphide anions (Figs. 12.11 and 12.12) with HX, though other routes are also available. Thus, treatment of $\text{P}_2\text{H}_3^-$ yields $\text{P}_7\text{H}^2-$, $\text{P}_7\text{H}_2^-$ and $\text{P}_7\text{H}_3$ by successive protonation of the three 2-connected P$^-$ sites. The alkyl derivatives are more stable than the parent polycyclic phosphanes and provide many examples of the elegant solution of complex conformational problems by the use of nmr spectroscopy.\(^{(67,70)}\)

12.3.3 Phosphorus halides

Phosphorus forms three series of halides $\text{P}_2\text{X}_4$, $\text{PX}_3$ and $\text{PX}_5$. All 12 compounds may exist, although there is considerable doubt about $\text{P}_7\text{X}_5$.\(^{(80)}\) Numerous mixed halides $\text{PX}_2\text{Y}$ and $\text{PX}_3\text{Y}_3$ are also known as well as various pseudohalides such as $\text{P(CN)}_3$, $\text{P(CNO)}_3$, $\text{P(CNS)}_3$ and their mixed halogeno-counterparts. The compounds form an extremely useful extended series with which to follow the effect of progressive substitution on various properties, and the pentahalides are particularly significant in spanning the “ionic-covalent” border, so that they exist in various structural forms depending on the nature of the halogen, the phase of aggregation, or the polarity of the solvent. Some subhalides such as $\text{P}_4\text{X}_2$ and $\text{P}_7\text{X}_3$, and some curious polyhalides such as $\text{PB}_{17}$ and $\text{PB}_{11}$ have also been characterized. Physical properties of the binary halides are summarized in Table 12.3 (on the next page). Ternary (mixed) halides tend to have properties intermediate between those of the parent binary halides.

Phosphorus trihalides

All 4 trihalides are volatile reactive compounds which feature pyramidal molecules. The fluoride is best made by the action of CaF$_2$, ZnF$_2$ or AsF$_3$ on PCl$_3$, but the others are formed by direct halogenation of the element. PF$_3$ is colourless, odourless and does not fume in air, but is very hazardous due to the formation of a complex with blood haemoglobin (cf.

CO, p. 1101). It is about as toxic as COCl₂. The similarity of PF₃ and CO as ligands was first noted by J. Chatt(81) and many complexes with transition elements are now known,(82) e.g. [Ni(CO)ₙ(PF₃)₄₋ₙ] (n = 0–4), [Pd(PF₃)₄], [Pt(PF₃)₄], [CoH(PF₃)₄], [Co₂(μ-PF₂)₂(PF₃)₆], etc. Such complexes can be prepared by ligand replacement reactions, by fluorination of PCl₃ complexes, by direct reaction of PF₃ with metal salts or even by direct reaction of PF₃ with metals at elevated temperatures and pressures.

PF₃, unlike the other trihalides of phosphorus, hydrolyses only slowly with water, the products being phosphorous acid and HF: PF₃ + 3H₂O → H₃PO₃ + 3HF.

The reaction is much more rapid in alkaline solutions, and in dilute aqueous KHCO₃ solutions the intermediate monofluorophosphorous acid is formed:

\[
\text{PF₃} + 2\text{H₂O} \xrightarrow{2\% \text{aq KHCO₃}} \text{O=PH(OH)F} + 2\text{HF}
\]

PCl₃ is the most important compound of the group and is made industrially on a large scale† by direct chlorination of phosphorus suspended in a precharge of PCl₃ — the reaction is carried out under reflux with continuous take-off of the PCl₃ formed. PCl₃ undergoes many substitution reactions, as shown in the diagram, and is the main source of organophosphorus compounds. Particularly notable are PR₃, PRₙCl₃₋ₙ, PRₙ(OR)₃₋ₙ, (PhO)₃PO, and (RO)₃PS. Many of these compounds are made on the 1000-tonne scale pa, and the major uses are as oil additives, plasticizers, flame retardants, fuel additives and intermediates in the manufacture of insecticides.(83) PCl₃ is also readily oxidized to the important phosphorus(V) derivatives PCl₅, POCl₃ and PSCl₃. It is oxidized by As₂O₃ to P₂O₅ though this is not the commercial route to this compound (p. 505). It fumes in moist air and is more readily hydrolysed (and oxidized) by water than is PF₃. With cold N₂O₄ (~10°) it undergoes a curious oxidative coupling reaction to give Cl₃P=N–POCl₂,

---

83 D. H. CHADWICK and R. S. WATT, Chap. 19 in ref. 11, pp. 1221–79.

† World production exceeds one third of a million tonnes pa; of this USA produces ~155 000 tonnes, Western Europe ~115 000 and Japan ~35 000 tonnes pa.
mp 35.5°; (note the presence of two different 4-coordinate P^V atoms). Other notable reactions of PCl₃ are its extensive use to convert alcohols to RCl and carboxylic acids to RCOCl, its reduction to P₂I₄ by iodine, and its ability to form coordination complexes with Lewis acids such as BX₃ and Ni⁰.

P₂I₃ is emerging as a powerful and versatile deoxygenating agent. For example solutions of P₂I₃ in CH₂Cl₂ at or below room temperature convert sulfoxides (RR'SO) into diorganosulfides, selenoxides (RR'SeO) into selenides, aldehyde oximes (RCH=NOH) into nitriles, and primary nitroalkanes (RCH₂NÖ₂) into nitriles, all in high yield (75–95%). The formation of nitriles, R-CN, in the last two reactions requires the presence of triethylamine in addition to the P₂I₃.

Diphosphorus tetrahalides and other lower halides of phosphorus

The physical properties of P₂X₄, in so far as they are known, are summarized in Table 12.3. P₂F₄ was first made in other than trace amounts in

---

1966, using the very effective method of coupling two PF₂ groups at room temperature under reduced pressure:

$$2\text{PF}_2\text{I} + 2\text{Hg} \xrightarrow{86\% \text{ yield}} \text{P}_2\text{F}_4 + \text{Hg}_2\text{I}_2$$

The compound hydrolyses to F₂POPF₂ which can also be prepared directly in good yield by the reaction of O₂ on P₂F₄.

P₂Cl₄ can be made (in low yield) by passing an electric discharge through a mixture of PCl₃ and H₂ under reduced pressure or by microwave discharge through PCl₃ at 1–5 mmHg pressure. The compound decomposes slowly at room temperature to PCl₃ and an involatile solid, and can be hydrolysed in basic solution to give an equimolar mixture of P₂H₄ and P₂(OH)₄.

Little is known of P₂Br₄, said to be produced by an obscure reaction in the system C₂H₄–PBr₃–Al₂Br₆.\(^{(86)}\) By contrast, P₂I₄ is the most stable and also the most readily made of the 4 tetrahalides; it is formed by direct reaction of I₂ and red P at 180° or by I₂ and white P₄ in CS₂ solution, and can also be made by reducing PF₅ with red P, or PCl₃ with iodine. Its X-ray crystal structure shows that the molecules of P₂I₄ adopt the trans-, centrosymmetric (C₂h) form (see N₂H₄, p. 428, N₂F₄, p. 439). Reaction of P₂I₄ with sulfur in CS₂ yields P₂I₄S₂, which probably has the symmetrical structure

\[
\begin{array}{c|c|c}
| & S & S \\
\hline
I & & I \\
\hline
P & P & \\
\end{array}
\]

but most reactions of P₂I₄ result in cleavage of the P–P bond, e.g. Br₂ gives PBrI₂ in 90% yield. Hydrolysis yields various phosphines and oxoacids of P, together with a small amount of hypophosphoric acid, (HO)₂(O)PP(O)(OH)₂.

Several ternary diphosphorus tetrahalides, P₂X₄Y₄–ₙ, (X, Y = Cl, Br, I) have recently been detected in CS₂ solutions by \(^{31}\)P nmr spectroscopy.\(^{(87)}\) It has also been found that reactions CS₂ solution between P₄ and half a mole-equivalent of Br₂ yielded not only P₂Br₄ but also small amounts of the new “butterfly” molecules exo,exo-P₄Br₂ and exo,endo-P₄Br₂. The structure of these can be viewed as being formed by the scission of one P–P bond in the P₄ tetrahedron by Br₂ (cf. the structure of B₄H₁₀, p. 154) which is also a 22 valence-electron species. The molecules P₄BrCl and P₄Cl₂ were also identified, following chlorination of the bromide solution using MesSnCl. Other products of the initial reactions included P₇Br₃ and P₇I₃ which are structurally related to P₇H₃ (p. 495). None of these novel subhalides has been isolated pure.\(^{(87)}\)

Phosphorus pentahalides

Considerable theoretical and stereochemical interest attaches to these compounds because of the variety of structures they adopt; PCl₅ is also an important chemical intermediate. Thus, PF₅ is molecular and stereochemically non-rigid (see below), PCl₅ is molecular in the gas phase, ionic in the crystalline phase, [PCl₄]⁺[PCl₆]⁻, and either molecular or ionically dissociated in solution, depending on the nature of the solvent. PBr₅ is also ionic in the solid state but exists as [PBr₄]⁺[Br]⁻ rather than [PBr₄]⁺[PBr₅]⁻. The pentafluoride does not exist\(^{(88)}\) (except perhaps as P₁₅I₂, but certainly not as P₄I⁺I⁻ as originally claimed\(^{(88)}\)).

PF₅ is a thermally stable, chemically reactive gas which can be made either by fluorinating PCl₅ with AsF₃ (or CaF₂), or by thermal decomposition of NaPF₆, Ba(PF₆)₂ or the corresponding diazonium salts. Single-crystal X-ray analysis (at −164°C) indicates a trigonal bipyramidal structure with P–F₅ (158.0 pm) being

\(^{87}\) B. W. Tattershall and N. L. Kendall, Polyhedron 13, 1517–21 (1994).

significantly longer than $P-F_{eq}$ (152.2 pm). This confirms the deductions from a gas phase electron-diffraction study ($D_{3h}$: $P-F_{ax}$ 158 pm, $P-F_{eq}$ 153 pm). However, the $^{19}F$ nmr spectrum, as recorded down to $-100^\circ C$, shows only a single fluorine resonance peak (split into a doublet by $^{31}P-^{19}F$ coupling) implying that on this longer time scale (milliseconds, as distinct from “instantaneous” for electron diffraction) all 5 F atoms are equivalent. This can be explained if the axial and equatorial F atoms interchange their positions more rapidly than this, a process termed “pseudorotation” by R. S. Berry (1960); indeed, PF$_5$ was the first compound to show this effect. The proposed mechanism is illustrated in Fig. 12.13 and is discussed more fully in ref. 91; the barrier to notation has been calculated as 16 ± 2 kJ mol$^{-1}$.\(^{(92)}\)

The mixed chlorofluorides PCl$_4$F (mp $-59^\circ$, bp $+67^\circ$) and PCl$_4$F$_2$ (mp $-63^\circ$) are also trigonal bipyramidal with axial F atoms; likewise PCl$_5$F$_3$ (mp $-125^\circ$, bp $+7.1^\circ$) has 2 axial and 1 equatorial F atoms and PCIF$_4$ (mp $-132^\circ$, bp $-43.4^\circ$) has both axial positions occupied by F atoms.\(^{(93)}\) These compounds are obtained by addition of halogen to the appropriate phosphorus(III) chlorofluoride, but if PCl$_5$ is fluorinated in a polar solvent, ionic isomers are formed, e.g. [PCl$_4$]$^+$[PCl$_4$F$_2$]$^-$(colourless crystals, subl $175^\circ$) and [PCl$_4$]$^+$[PF$_6$]$^-$(white crystals, subl $135^\circ$ with decomposition). The crystalline hemifluoride [PCl$_4$]$^+$[PCl$_5$F]$^-$ has also been identified. The analogous parallel series of covalent and ionic bromofluorides is less well characterized but PBr$_2$F$_3$ is known both as an unstable molecular liquid (decomp $15^\circ$) and as a white crystalline powder [PBr$_4$]$^+$[PF$_6$]$^-$ (subl $135^\circ$ decomp). It can be noted that PF$_5$(NH$_2$)$_2$ is a trigonal bipyramidal molecule with C$_{2v}$ symmetry (i.e. equatorial NH$_2$ groups),\(^{(94)}\) whereas the most stable form of tetra-arylfluorophosphoranes is ionic, [PR$_4$]$^+$F$^-$, although molecular monomers R$_4$PF and an ionic dimer [PR$_4$]$^+$[PR$_4$F$_2$]$^-$ also exist.\(^{(95)}\)

PCl$_5$ is even closer to the ionic-covalent borderline than is PF$_5$, the ionic solid [PCl$_4$]$^+$[PCl$_6$]$^-$ melting (or subliming) to give a covalent molecular

---

liquid (or gas). Again, when dissolved in non-polar solvents such as CCl₄ or benzene, PCl₅ is monomeric and molecular, whereas in ionizing solvents such as MeCN, MeNO₂ and PhNO₂ there are two competing ionizing equilibria:

\[
2\text{PCl}_5 \rightleftharpoons \text{[PCl₄]}^+ + \text{[PCl₆]}^-
\]

\[
\text{PCl}_5 \rightleftharpoons \text{[PCl₄]}^+ + \text{Cl}^-
\]

As might be expected, the former equilibrium predominates at higher concentrations of PCl₅ (above about 0.03 mol l⁻¹) whilst the latter predominates below this concentration. The P–Cl distances (pm) in these various species are: PCl₅ 214 (axial), 202 (equatorial); [PCl₄]⁺ 197; [PCl₆]⁻ 208 pm. Ionic isomerism is also known and, in addition to [PCl₄]⁺[PCl₆]⁻, another (metastable) crystalline phase of constitution [PCl₄]⁺[PCl₆]⁻Cl⁻ can be formed either by application of high pressure or by crystallizing PCl₅ from solutions of dichloromethane containing Br₂ or SCl₂. When gaseous PCl₅ (in equilibrium with PCl₃ + Cl₂) is quenched to 15 K the trigonal-bipyramidal molecular structure is retained; this forms an ordered molecular crystal lattice on warming to ~130 K, but further warming towards room temperature results in chloride-ion transfer to give [PCl₄]⁺[PCl₆]⁻. The first alkali metal salt of [PCl₆]⁻, CsPCl₆, has only recently been made.

The delicate balance between ionic and covalent forms is influenced not only by the state of aggregation (solid, liquid, gas) or the nature of the solvent, but also by the effect of substituents. Thus PhPCl₄ is molecular with Ph equatorial whereas the corresponding methyl derivative is ionic, [MePCl₃]+Cl⁻. Despite this the [PhPCl₃]⁺ cation is known and can readily be formed by reacting PhPCl₄ with a chlorine ion acceptor such as BCl₃, SbCl₅, or even PCl₅ itself:

\[
\text{PhPCl}_4 + \text{PCl}_5 \rightarrow \text{[PhPCl₃]}^+ + \text{[PCl₆]}^-
\]

Likewise crystalline Ph₂PCl₃ is molecular whereas the corresponding Me and Et derivatives are ionic [R₂PCl₂]⁺Cl⁻. However, all 3 triorganophosphorus dihalides are ionic [R₃PCl]⁺Cl⁻ (R = Ph, Me, Et). The pale-yellow, crystalline mixed halide P₂BrCl₅ appears to be [PCl₄]⁺[PCl₃Br]⁺[P₂Cl₆]⁻[Br]⁻ (i.e. P₁₂Br₆-Cl₅₄).

Phosphorus pentabromide is rather different. The crystalline solid is [PBr₄]⁺Br⁻ but this appears to dissociate completely to PBr₃ and Br₂ in the vapour phase; rapid cooling of this vapour to 15 K results in the formation of a disordered lattice of PBr₃ and PBr₇ (i.e. [PBr₄]⁺[Br₃]⁻) and this mixture reverts to [PBr₄]⁺Br⁻ on being warmed to 180 K. The corresponding trichloride, [PBr₄]⁺[Cl₃]⁻ is also known. [PI₄]⁺ has been identified only as its salt [PI₄]⁺[AsF₆]⁻.

PCl₅ is made on an industrial scale by the reaction of Cl₂ on PCl₃ dissolved in an equal volume of CCl₄. World production probably exceeds 20000 tonnes pa. On the laboratory scale Cl₂ gas (or liquid) can be passed directly into PCl₃. PCl₅ reacts violently with water to give HCl and H₃PO₄ but in equimolar amounts the reaction can be moderated to give POCl₃:

\[
\text{PCl}_5 + \text{H}_2\text{O} \rightarrow \text{POCl}_3 + 2\text{HCl}
\]

PCl₅ chlorinates alcohols to alkyl halides and carboxylic acids to the corresponding ROCOCI. When heated with NH₄Cl the phosphonitrilic chlorides are obtained (p. 536). These and other reactions are summarized in the diagram.
The chlorination of phosphonic and phosphinic acids and esters are of considerable importance. \( \text{PCl}_5 \) can also act as a Lewis acid to give 6-coordinate P complexes, e.g. pyPCl_5, and pyz-PCl_5, where py = C_5H_5N (pyridine) and pyz = cyclo-1,4-C_4H_4N_2 (pyrazine).\(^{103}\)

### Pseudohalides of phosphorus(III)

Paralleling the various phosphorus trihalides are numerous pseudohalides and mixed pseudohalide-halides of which the various isocyanates and isothiocyanates are perhaps the best known. Most are volatile liquids, e.g.

The corresponding phosphoryl and thiophosphoryl pseudohalides are also known, i.e. PO(\( \text{NCO}_3 \), PS(\( \text{NCO}_3 \), etc. Preparations are by standard procedures such as those on the diagram for \( \text{PCl}_3 \) (p. 497). As indicated there, \( \text{PCl}_3 \) has also been made: it is a highly reactive white crystalline solid mp 203° which reacts violently with water to give mainly phosphorous acid and HCN.

### 12.3.4 Oxohalides and thiohalides of phosphorus

The propensity of phosphorus(III) compounds to oxidize to phosphorus(V) by formation of an additional P=O bond is well illustrated by the

§12.3.4  Oxohalides and thiohalides of phosphorus

The corresponding phosphoryl and thiophosphoryl pseudohalides are also known, i.e. PO(NCO)₃, PS(NCO)₃, etc. Preparations are by standard procedures such as those on the diagram for PCl₅ (p. 497). As indicated there, P(CN)₃ has also been made: it is a highly reactive white crystalline solid mp 203° which reacts violently with water to give mainly phosphorous acid and HCN.

12.3.4 Oxohalides and thiohalides of phosphorus

The propensity of phosphorus(III) compounds to oxidize to phosphorus(V) by formation of an additional P=O bond is well illustrated by the

---

ease with which the trihalides are converted to their phosphoryl analogues POX₃. Thus, PCl₃ reacts rapidly with pure O₂ (less rapidly with air) at room temperature or slightly above and this reaction is used on an industrial scale. Alternatively, a slurry of P₄O₁₀ in PCl₃ can be chlorinated, the PCl₅ so formed reacting instantaneously with the P₄O₁₀:

\[ \text{P}_4\text{O}_{10} + 6\text{PCl}_5 \rightarrow 10\text{POCl}_3 \]

POBr₃ can be made by similar methods, but POF₃ is usually made by fluorination of POCI₃ using a metal fluoride (e.g. M = Na, Mg, Zn, Pb, Ag, etc.). POI₃ was first made in 1973 by iodinating POCI₃ with LiI, or by reacting ROPI₂ with iodine (ROPI₂ + I₂ → RI + POI₃). Mixed (phosphoryl) halides, POX₃Y⁻n, and pseudohalides (e.g. X = NCO, NCS) are known, as also are the thiophosphoryl halides PSX₃, e.g.:

\[ \text{P}_2\text{S}_5 + 3\text{PCl}_5 \rightarrow 5\text{PSCl}_3 \]

Most of the phosphoryl and thiophosphoryl compounds are colourless gases or volatile liquids though PSBr₃ forms yellow crystals, mp 37.8°, POI₃ is dark violet, mp 53°, and PSI₃ is red-brown, mp 48°. All are monomeric tetrahedral (C₃ᵥ) or pseudotetrahedral. Some physical properties are in Table 12.4. The P–O interatomic distance in these compounds generally falls in the range 154–158 pm, the small value being consistent with considerable “double-bond character”. Likewise the P–S distance is relatively short (185–194 pm).

The phosphoryl and thiophosphoryl halides are reactive compounds that hydrolyse readily on contact with water. They form adducts with Lewis acids and undergo a variety of substitution reactions to form numerous organophosphorus derivatives and phosphate esters. Thus, alcohols give successively (RO)POCl₂, (RO)₂POCl and (RO)₃PO; phenols react similarly but more slowly. Likewise, amines yield (RNH)POCl₂, (RNH)₂POCl and (RNH)₃PO whereas Grignard reagents yield RₙPOCl₃₋ₙ (n = 1–3). Many of these compounds find extensive use as oil additives, insecticides, plasticizers, surfactants or flame retardants, and are manufactured on the multikilotonne scale.

In addition to the monophosphorus phosphoryl and thiophosphoryl compounds discussed above, several poly-phosphoryl and -thiophosphoryl halides have been characterized. Pyrophosphoryl fluoride, \( O=\text{PF}_2—O—P(=O)\text{F}_2 \) (mp −0.1°, bp 72° extrap) and the white crystalline cyclic tetramer \( [O=P(F)=O]_4 \) were obtained by subjecting equimolar mixtures of PF₃ and O₂ to a silent electric discharge at −70°. Pyrophosphoryl chloride, \( O=\text{PCl}_2—O—P(=O)\text{Cl}_2 \) is conveniently prepared by passing Cl₂ into a boiling suspension.

---

of $\text{P}_4\text{O}_{10}$ in $\text{PCl}_3$ diluted with $\text{CCl}_4$:

$$\text{P}_4\text{O}_{10} + 4\text{PCl}_3 + 4\text{Cl}_2 \rightarrow 2\text{P}_2\text{O}_3\text{Cl}_4 + 4\text{POCl}_3$$

It is a colourless, odourless, non-fuming, oily liquid, mp $-16.5^\circ$, bp $215^\circ$ (decomp), with reactions similar to those of $\text{POCl}_3$. Sealed-tube reactions between $\text{P}_4\text{O}_{10}$ and $\text{POCl}_3$ at 200–230° give more highly condensed cyclic and open-chain polyphosphoryl chlorides. A rather different structural motif occurs in $\text{P}_2\text{S}_4\text{F}_4$; this compound is obtained by fluorinating $\text{P}_4\text{S}_{10}$ with an alkali-metal fluoride to give the anion $[\text{S}_2\text{PF}_2]^-$ which is then oxidized by bromine to $\text{P}_2\text{S}_4\text{Br}_4$ (bp 60° at 10 mmHg). Vibrational and nmr spectra are consistent with the structure $\text{F}_2(\text{S})\text{PSSP( S)}\text{F}_2$.

Bromination of $\text{P}_4\text{S}_7$ in cold $\text{CS}_2$ yields, in addition to $\text{PBBr}_3$ and $\text{PSBr}_3$, two further thiobromides $\text{P}_2\text{S}_6\text{Br}_2$ (mp 118° decomp) and $\text{P}_2\text{S}_5\text{Br}_4$ (mp 90° decomp). The first of these has the cyclic structure shown in which the ring adopts a skew-boat configuration. An even more complex, bicyclic arrangement is found in the orange-yellow compound $\text{P}_4\text{S}_3\text{I}_2$ (mp 120° decomp) which is formed (together with several other products) when equiatomic amounts of P, S and I are allowed to react. The P and S atoms are arranged in two 5-membered rings having a common P–S–P group as shown; in each there is a P–P group and the I atoms are bonded in cis-configuration to the P atoms not common to the two rings. The orange compound $\text{P}_2\text{S}_2\text{I}_4$ (mp 94°) was mentioned on p. 498.

By contrast to the plethora of simple oxo-halides and thiohalides of $\text{P}^\text{V}$, the corresponding derivatives of $\text{P}^\text{III}$ are fugitive species that require matrix isolation techniques for preparation and characterization.$^{105}$ $\text{CIPO}$, $\text{BrPO}$, $\text{FPS}$ and $\text{BrPS}$ all form non-linear triatomic molecules, as expected. The corresponding oxosulfide, $\text{BrP(O)S}_2$,$^{106}$ and its thio-analogue, $\text{FP(S)S}_2$,$^{107}$ have also recently been isolated.

### 12.3.5 Phosphorus oxides, sulfides, selenides and related compounds

The oxides and sulfides of phosphorus are amongst the most important compounds of the element. At least 6 binary oxides and 9 well-defined sulfides are known, together with a similar number of selenides and several oxosulfides. It will be convenient to discuss first the preparation and structure of each group of compounds and then to mention the chemical reactions of the more important members in so far as they are known. It is notable that, in contrast to the ubiquitous NO and its many complexes (pp. 445 ff), little is known about its analogue, PO (see p. 506), although it is probably the most abundant P-containing molecule in interstellar clouds.$^{108}$ The first complex with a PO ligand was first synthesized as recently as 1991, when dark green crystals of the square-based pyramidal hetero-atom cluster $[\text{W(CO)}_4(\eta^5-\text{C}_5\text{H}_5\text{P}_3))]_2(\mu^2,\eta^2-\text{P}_2)$ was oxidized with bis(trimethylsilyl) peroxide, (Me$_3$Si)$_2$O$_2$, to yield black crystals of the corresponding $[\text{W(CO)}_4(\eta^5-\text{C}_5\text{H}_5\text{P}_3))]_2(\mu^2,\eta^2,\eta^2-\text{PO})_2$.$^{108}$

#### Oxides

$\text{P}_4\text{O}_6$ is obtained by controlled oxidation of $\text{P}_4$ in an atmosphere of 75% $\text{O}_2$ and 25% $\text{N}_2$ at 90 mmHg and ~50° followed by distillation of the product from the mixture. Careful

---

Molecular structures, symmetries and dimensions of the 5 oxides \( P_{4}O_{6+n} \) \((n = 0 - 4)\) compared with \( \alpha-P_{4} \). The \( P \cdots P \) distances in the oxides are \( \sim 280 - 290 \text{ pm} \), i.e. essentially nonbonding.

some precautions are necessary if good yields are to be obtained.\(^{109}\) It forms soft white crystals, mp 23.8\(^{\circ}\), bp 175.4\(^{\circ}\), and is soluble in many organic solvents. The molecular structure has tetrahedral symmetry and comprises 4 fused 6-membered \( P_{3}O_{3} \) heterocycles each with the chair conformation as shown in Fig. 12.14.\(^{110}\) When \( P_{4}O_{6} \) is heated to 200 - 400\(^{\circ}\) in a sealed, evacuated tube it disproportionate into red phosphorus and a solid-solution series of composition \( P_{4}O_{n} \) depending on conditions. The \( \alpha \)-phase has a composition in the range \( P_{4}O_{8.1} - P_{4}O_{9.2} \) and comprises a solid solution of oxides in which one or two of the “external” \( O \) atoms in \( P_{4}O_{10} \) have been removed. The \( \beta \)-phase has a composition range \( P_{4}O_{8.0} - P_{4}O_{7.7} \) and appears to be a solid solution of \( P_{4}O_{8} \) and \( P_{4}O_{7} \), the latter compound having only one \( O \) atom external to the \( P_{4}O_{6} \) cluster (\( C_{3v} \) symmetry). \( P_{4}O_{7} \) is now best prepared from \( P_{4}O_{6} \) dissolved in thf, using \( Ph_{3}PO \) as a catalyst (not an oxidant) at room temperature. The molecular structure and dimensions of \( P_{4}O_{7} \) are given in Fig. 12.14 from which it is apparent that there is a gradual lengthening of \( P \cdots O \) distances in the sequence \( P^{V}O_{4} < P^{V}O_{4} < P^{III}O_{4} \). Similar trends are apparent in the dimensions of the other members of the series \( P_{4}O_{6+n} \) shown in Fig. 12.14.\(^{110}\) In addition, ring angles at \( P \) (96 - 103\(^{\circ}\)) are always less than those at \( O \) (122 - 132\(^{\circ}\)), as expected.

\( P_{4}O_{6} \) hydrolyses in cold water to give \( H_{3}PO_{3} \) i.e. \( HP(O)(OH)_{2} \); this is interesting in view of the structure of \( P_{4}O_{6} \) and implies an oxidative rearrangement of \( [P-OH] \) to \( [H-\!-P=\!-O] \) (p. 514). The oxide itself ignites and burns when heated in air; the progress of the reaction depends very much on the

Purity of the oxide and the conditions employed, and, when traces of elemental phosphorus are present in the oxide, the reaction is spontaneous even at room temperature. $P_4O_6$ reacts readily (often violently) with many simple inorganic and organic compounds but well-characterized products have rarely been isolated until recently.$^{159}$ It behaves as a ligand and successively displaces CO from $[Ni(CO)_4]$ to give compounds such as $[P_4O_6Ni(CO)_3]_4$, $[Ni(CO)_2(P_2O_5)_2]$ and $[Ni(CO)(P_2O_6)]$. With diborane adducts of formula $[P_4O_6(BH_3)_n]$ ($n = 1–3$) are obtained.

“Phosphorus pentoxide”, $P_4O_{10}$, is the commonest and most important oxide of phosphorus. It is formed as a fine white smoke or powder when phosphorus burns in air and, when condensed rapidly from the vapour phase in this way, is obtained in the H (hexagonal) form comprising tetrahedral molecules as shown in Fig. 12.14. This compound and the other phosphorus oxides are the first we have considered that feature the $\{PO_4\}$ group as a structural unit; this group dominates most of phosphate chemistry and will recur repeatedly during the rest of this chapter. The common hexagonal form of $P_4O_{10}$ is, in fact, metastable and can be transformed into several other modifications by suitable thermal or high-pressure treatment. A metastable orthorhombic (O) form is obtained by heating H for 2 h at 400° and the stable orthorhombic (O') form is obtained after 24 h at 450°. Both consist of extensive sheet polymers of interlocking heterocyclic rings composed of fused $\{PO_4\}$ groups. There is also a high-pressure form and a glass, which probably consists of an irregular three-dimensional network of linked $\{PO_4\}$ tetrahedra. These polymeric forms are hard and brittle because of the P–O–P bonds throughout the lattice and, as expected, they are much less volatile and reactive than the less-dense molecular H form. For example, whilst the common H form hydrolyses violently, almost explosively, with evolution of much heat, the polymeric forms react only slowly with water to give, finally, $H_3PO_4$. Some properties of the various polymorphs are compared in Table 12.5. The limpid liquid obtained by rapidly heating the H form contains $P_4O_{10}$ molecules but these rapidly polymerize and rearrange to layer or three-dimensional polymeric forms with a concomitant drop in the vapour pressure and an increase in the viscosity and mp.

Because of its avidity for water, $P_4O_{10}$ is widely used as a dehydrating agent, but its efficacy as a desiccant is greatly impaired by the formation of a crusty surface film of hydrolysis products unless it is finely dispersed on glass wool. Its largest use is in the industrial production of ortho- and poly-phosphoric acids (p. 520) but it is also an intermediate in the production of phosphate esters. Thus, triethylphosphate is made by reacting $P_4O_{10}$ with diethyl ether to form ethylpolyphosphates which, on subsequent pyrolysis and distillation, yield the required product:

$$P_4O_{10} + 6Et_2O \overset{\text{heat}}{\longrightarrow} 4PO(OEt)_3$$

Direct reaction with alcohols gives mixed mono- and di-alkyl phosphoric acids by cleavage of the P–O–P bonds:

$$P_4O_{10} + 6ROH \overset{65^\circ}{\longrightarrow} 2(RO)PO(OH)_2 + 2(RO)_2PO(OH)$$

Under less-controlled conditions $P_4O_{10}$ dehydrates ethanol to ethene and methyarylcarbinols to the corresponding styrenes. $H_2SO_4$ is dehydrated to $SO_3$, $HNO_3$ gives $N_2O_5$ and amides...
(RCONH₂) yield nitriles (RCN). In each of these reactions metaphosphoric acid HPO₃ is the main P-containing product. P₄O₁₀ reacts vigorously with both wet and dry NH₃ to form a range of amorphous polymeric powdery materials which are used industrially for water softening because of their ability to sequester Ca ions; composition depends markedly on the preparative conditions employed but most of the commercial products appear to be condensed linear or cyclic amido-polyphosphates which can be represented by formulae such as:

![Diagram]

The annual production/consumption of P₄O₁₀ in USA and Western Europe totals about 15,000 tonnes.

Other oxides of phosphorus are less well characterized though the suboxide PO and the peroxide P₂O₆ seem to be definite compounds. PO was obtained as a brown cathodic deposit when a saturated solution of Et₃NHCl in anhydrous POCl₃ was electrolysed between Pt electrodes at 0°. Alternatively it can be made by the slow reaction of POBr₃ with Mg in Et₂O under reflux:

$$2\text{POBr}_3 + 3\text{Mg} \rightarrow 2\text{PO} + 3\text{MgBr}_2$$

Its structure is unknown but is presumably based on a polymeric network of P–O–P links. It reacts with water to give PH₃ and is quantitatively oxidized to P₂O₅ by oxygen at 300°. The peroxide P₂O₆ is thought to be the active ingredient in the violet solid obtained when P₄O₁₀ and O₂ are passed through a heated discharge tube at low pressure. The compound has not been obtained pure but liberates I₂ from aqueous KI, hydrolyses to a peroxophosphoric acid, and liberates O₂ when heated to 130° under reduced pressure. Its structure may be (O=)₂P–O–O–P(=O)₂ or, in view of the variable composition of the product, it may be a mixture of P₄O₁₁ and P₄O₁₂ obtained by replacing P–O–P links by P–O–O–P in P₄O₁₀.

Sulfides

The sulfides of phosphorus form an intriguing series of compounds which continue to present puzzling structural features. The compounds P₄S₁₀, P₄S₉, P₄S₇, α-P₄S₅, β-P₄S₅, α-P₄S₄, β-P₄S₄, P₄S₃ and P₄S₂ are all based on the P₄ tetrahedron but only P₄S₁₀ (and possibly P₄S₁₀) is structurally analogous to the oxide. P₄S₆ is conspicuous by its absence. Structural data are summarized in Fig. 12.15 and some physical properties are in Table 12.6.

P₄S₃ is the most stable compound in the series and can be prepared by heating the required amounts of red P and sulfur above 180° in an inert atmosphere and then purifying the product by distillation at 420° or by recrystallization from toluene. The retention of a P₃ ring in the structure is notable. Its reactions and commercial application in match manufacture are discussed on p. 509.

The curious phase relations between phosphorus, sulfur and their binary compounds are worth noting. Because both P₄ and S₈ are stable molecules the phase diagram, if studied below 100°, shows only solid solutions with a simple eutectic at 10° (75 atom % P). By contrast, when the mixtures are heated above 200° the elements react and an entirely different phase diagram is obtained; however, as only the most stable compounds P₄S₃, P₄S₇ and P₄S₁₀

</table>
melt congruently, only these three appear as compounds in equilibrium with the melt. Careful work at lower temperatures is needed to detect peritectic equilibria involving \( \text{P}_4\text{S}_9 \), \( \text{P}_4\text{S}_5 \) (and possibly even \( \text{P}_4\text{S}_2 \)),\(^{112}\) and it is notable that these compounds are normally prepared by low-temperature reactions involving addition of \( \text{S} \) to \( \text{P}_4\text{S}_7 \) and \( \text{P}_4\text{S}_3 \) respectively. Likewise there is no sign of \( \text{P}_4\text{S}_4 \) on the phase diagram, and claims to have detected it in this way have been shown to be erroneous.\(^{113}\)

\( \text{P}_4\text{S}_4 \) is one of the most recent binary sulfides to be isolated and characterized and it exists in two structurally distinct forms.\(^{113,114}\) Each can be made in quantitative yield by reacting the appropriate isomer of \( \text{P}_4\text{S}_3\text{I}_2 \) (p. 503) with \( [(\text{Me}_3\text{Sn})_2\text{S}] \) in CS\(_2\) solution:

As seen from Fig. 12.15 the structure of \( \alpha\text{-P}_4\text{S}_4 \) resembles that of \( \text{As}_4\text{S}_4 \) (p. 579) rather than \( \text{N}_4\text{S}_4 \) (p. 723). The 4 P atoms are in tetrahedral array and the 4 S atoms form a slightly distorted square. The 2 P–P bonds are long (as also in \( \text{P}_4\text{S}_5 \), and \( \text{P}_4\text{S}_7 \)) when compared with corresponding distances in \( \text{P}_4\text{S}_5 \) (225 pm) and \( \text{P}_4 \) itself (221 pm). The structure of \( \beta\text{-P}_4\text{S}_4 \) has not been determined by X-ray crystallography but spectroscopic data indicate the absence of \( \text{P}==\text{S} \) groups and the \( C_5 \) structure shown in Fig. 12.15 is the only other possible arrangement of 3 coordinate P for this composition.

\( \text{P}_4\text{S}_5 \) disproportionates below its mp \( (2\text{P}_4\text{S}_5 \rightleftharpoons \text{P}_4\text{S}_3 + \text{P}_4\text{S}_7) \) and so cannot be obtained directly from the melt. It is best prepared by irradiating a solution of \( \text{P}_4\text{S}_3 \) and \( \text{S} \) in CS\(_2\) solution using a trace of iodine as catalyst. Its structure is quite unexpected and features a single exocyclic \( \text{P}==\text{S} \) group and 3 fused heterocycles containing, respectively, 4, 5 and 6 atoms; there are 2 short P–P bonds and the 4-membered \( \text{P}_3\text{S} \) ring is almost square planar.

\( \text{P}_4\text{S}_7 \) is the second most stable sulfide (after \( \text{P}_4\text{S}_3 \)) and can be obtained by direct reaction of the elements. Perhaps surprisingly the structure retains a P–P bond and has two exocyclic \( \text{P}==\text{S} \) groups. \( \text{P}_4\text{S}_9 \) is formed reversibly by heating \( \text{P}_4\text{S}_7 + 2\text{P}_4\text{S}_{10} \) and has the structure shown in Fig. 12.15.

\( \text{P}_4\text{S}_{10} \) is commercially the most important sulfide of P and is formed by direct reaction of liquid white \( \text{P}_4 \) with a slight excess of sulfur above 300°. It can also be made from byproduct ferrophosphorus (p. 480).

\[
\text{4Fe}_2\text{P} + 18\text{FeS}_2 \xrightarrow{\text{heat}} \text{P}_4\text{S}_{10} + 26\text{FeS}
\]

\[
\text{4Fe}_2\text{P} + 18\text{S} \rightarrow \text{P}_4\text{S}_{10} + 8\text{FeS}
\]

It has essentially the same structure as the H form of \( \text{P}_4\text{O}_{10} \) and hydrolyses mainly according to the overall equation

\[
\text{P}_4\text{S}_{10} + 16\text{H}_2\text{O} \rightarrow 4\text{H}_3\text{PO}_4 + 10\text{H}_2\text{S}
\]

Presumably intermediate thiophosphoric acids are first formed and, indeed, when the hydrolysis is carried out in aqueous NaOH solution at 100°, substantial amounts of the mono- and di-thiophosphates are obtained. P–S bonds are also retained during reaction of \( \text{P}_4\text{S}_{10} \) with alcohols or phenols and the products formed are used extensively in industry for a wide variety of

Phosphorus Sulfides in Industry

The two compounds of importance are \( P_4S_3 \) and \( P_4S_{10} \). The former is made on a large scale for use in "strike anywhere" matches according to a formula evolved by Sèvène and Cahen in France in 1898. The ignition results from the violent reaction between \( P_4S_3 \) and \( KClO_3 \) which is initiated by friction of the match against glass paper (on the side of the box) or other abrasive material. A typical formulation for the match head is:

<table>
<thead>
<tr>
<th>Reactants</th>
<th>Fillers (moderators)</th>
<th>Adhesives</th>
</tr>
</thead>
<tbody>
<tr>
<td>( KClO_3 )</td>
<td>( P_4S_3 )</td>
<td>Ground glass</td>
</tr>
<tr>
<td>20%</td>
<td>9%</td>
<td>14%</td>
</tr>
</tbody>
</table>

Formulations of this type have completely replaced earlier "strike anywhere" matches based on (poisonous) white \( P_4S_{10} \), sulfur, and \( KClO_3 \), though "safety matches" still use a match head which is predominantly \( KClO_3 \) struck against the side of the match-box which has been covered with a paste of (non-toxic) red \( P(49.5\%) \), antimony sulfide (27.6%), \( Fe_2O_3 \) (1.2%) and gun arabic (21.7%). About \( 10^{11} \) matches are used annually in the UK alone.

\( P_4S_{10} \) is made on an even larger scale than \( P_4S_3 \) and is the primary source of a very wide range of organic \( P-S \) compounds. World production of \( P_4S_{10} \) exceeds 250,000 tonnes annually of which about half is made in the USA, one-third in the UK/Europe, and the remaining 30,000 tonnes elsewhere (Japan, Romania, the former Soviet Union, Mexico, etc.). The most important reaction of \( P_4S_{10} \) is with alcohols or phenols to give dialkyl or diaryl dithiophosphoric acids:

\[
P_4S_{10} + 8ROH \rightarrow 4(RO)P(S)SH + 2H_2S
\]

The zinc salts of these acids are extensively used as additives to lubricating oils to improve their extreme-pressure properties. The compounds also act as antioxidants, corrosion inhibitors and detergents. Short-chain dialkyl dithiophosphates and their sodium and ammonium salts are used as flotation agents for zinc and lead sulfide ores. The methyl and ethyl derivatives \((RO)P(S)SH\) and \((RO)P(S)Cl\) are of particular interest in the large-scale manufacture of pesticides such as parathion, malathion, dimethylparathion, etc. For example parathion, which first went into production as an insecticide in Germany in 1947, is made by the following reaction sequence:

\[
(\text{EtO})_2P(\text{S})SH + \text{Cl}_2 \rightarrow \text{HCl} + S + (\text{EtO})_2P(\text{S})\text{Cl}
\]

\[
(\text{EtO})_2P(\text{S})\text{Cl} + \text{NaOC}_6\text{H}_4-p-\text{NO}_2 \rightarrow (\text{EtO})_2P(\text{S})\text{OC}_6\text{H}_4-p-\text{NO}_2 \quad \text{(parathion)}
\]

Methylparathion is the corresponding dimethyl derivative. Later (1952) malathion found favour because of its decreased toxicity to mammals; it is readily made in 90% yield by the addition of dimethylithiophosphate to diethylmaleate in the presence of \( NEt_3 \) as a catalyst and hydroquinone as a polymerization inhibitor:

\[
(\text{MeO})_2P(\text{S})\text{SH} + \xrightarrow{\text{NEt}_3/\text{HQ} \ 60\%} (\text{MeO})_2P(\text{S})\text{CHCO_2Et}
\]

\[
\text{CHCO_2Et}
\]

The scale of manufacture of these organophosphorus pesticides can be gauged from data referring to the USA production in 1975 (tonnes): methylparathion 46,000, parathion 36,000 and malathion 16,000. In addition, some 15 other thioorganophosphorus insecticides are manufactured in the USA on a scale exceeding 2000 tonnes pa each.\(^4\) They act by inhibiting cholinesterase, thus preventing the natural hydrolysis of the neurotransmitter acetylcholine in the insect.\(^2\)

---

M\[cyclo-P_5S_{10}\] and M\[cyclo-P_6S_{12}\] were obtained using red phosphorus, whereas white P\(_4\) yielded [NH\(_4\)]\(_4\)[cyclo-P\(_4\)S\(_8\)].\(_2\)H\(_2\)O as shiny platelets. This unique P\(_4\)S\(_{10}\)\(^{4-}\) anion is the first known homocycle of 4 tetracoordinated P atoms and X-ray studies reveal that the P atoms form a square with rather long P–P distances (228 pm).\(^{117}\)

The new planar anion PS\(_3\)\(^-\) (cf. the nitrate ion, NO\(_3\)\(^-\)) has been isolated as its tetraphenylarsonium salt, mp 183\(^\circ\), following a surprising reaction of P\(_4\)S\(_{10}\) with KCN/H\(_2\)S in MeCN, in which the coproduct was the known dianion \([\text{(NC)P(S)\(_2\)-S-P(S)\(_2\)-(CN)}]_2\)\(^-\)(\(^{118}\)) The first sulfido hexaphosphane cluster anions, \[P_7(S)\(_3\)-\] and \[HP_7(S)\(_2\)-\] (cf. PT\(_3\)-, p. 491), have also recently been characterized.\(^{119}\)

**Oxosulfides**

When P\(_4\)O\(_{10}\) and P\(_4\)S\(_{10}\) are heated in appropriate proportions above 400\(^\circ\), P\(_4\)O\(_6\)S\(_4\) is obtained as colourless hygroscopic crystals, mp 102\(^\circ\).

\[
3\text{P}_4\text{O}_{10} + 2\text{P}_4\text{S}_{10} \rightarrow 5\text{P}_4\text{O}_6\text{S}_4
\]

The structure is shown in Fig. 12.15. The related compound P\(_4\)O\(_4\)S\(_6\) is said to be formed by the reaction of H\(_2\)S with POCl\(_3\) at 0\(^\circ\) (A. Besson, 1897) but has not been recently investigated. An amorphous yellow material of composition P\(_4\)O\(_4\)S\(_3\) is obtained when a solution of P\(_4\)S\(_3\) in CS\(_2\) or organic solvents is oxidized by dry air or oxygen. Other oxosulfides of uncertain authenticity such as P\(_5\)O\(_{10}\)S\(_5\) have been reported but their structural integrity has not been established and they may be mixtures. However, the following series can be prepared by appropriate redistribution reactions: P\(_4\)O\(_6\)S\(_n\) \((n = 1–3)\), P\(_4\)O\(_6\)Se\(_n\) \((n = 1–3)\), P\(_4\)O\(_6\)S\(_2\)Se, P\(_4\)O\(_7\)Se\(_n\) \((n = 1–3)\), P\(_4\)O\(_7\)Se, P\(_4\)O\(_8\)S\(_n\) \((n = 1, 2)\).\(^{120}\) The crystal and molecular structures of P\(_4\)O\(_6\)S\(_2\) and P\(_4\)O\(_8\)S\(_3\) have recently been determined.\(^{121}\)

Two isomers each of \(\beta\)-P\(_4\)S\(_2\)SeI\(_2\) and \(\beta\)-P\(_4\)SSe\(_2\)I\(_2\), prepared by reaction of P\(_4\)S\(_3\)-Se\(_n\) with I\(_2\) in CS\(_2\) have been structurally identified by \(^{31}\)P nmr spectroscopy.\(^{122}\)

### 12.3.6 Oxoacids of phosphorus and their salts

The oxoacids of P are more numerous than those of any other element, and the number of oxoanions and oxo-salts is probably exceeded only by those of Si. Many are of great importance technologically and their derivatives are vitally involved in many biological processes (p. 528). Fortunately, the structural principles covering this extensive array of compounds are very simple and can be stated as follows:\(^\dagger\)

1. All P atoms in the oxoacids and oxoanions are 4-coordinate and contain at least one P–O unit (1).

   ![Diagram](image)

2. All P atoms in the oxoacids have at least one P–OH group (2a) and this often occurs in the anions also; all such groups are ionizable as proton donors (2b).

\(^\dagger\) Heteropolyacids containing P fall outside this classification and are treated, together with the isopolyacids and their salts, on pp. 1010–16. Organic esters such as P(OR)\(_3\) are also excluded.
M\[cyclo-P_5S_{10}\] and M\[cyclo-P_6S_{12}\] were obtained using red phosphorus, whereas white P\(_4\) yielded [NH\(_4\)]\(_4\)[cyclo-P\(_4S_8\)].2H\(_2\)O as shiny platelets. This unique P\(_4S_{8}\)\(^{4-}\) anion is the first known homocycle of 4 tetracoordinated P atoms and X-ray studies reveal that the P atoms form a square with rather long P–P distances (228 pm).\(^{117}\)

The new planar anion PS\(_3\)\(^{-}\) (cf. the nitrate ion, NO\(_3\)\(^{-}\)) has been isolated as its tetraphenylarsonium salt, mp 183\(^\circ\), following a surprising reaction of P\(_4S_{10}\) with KCN/H\(_2\)S in MeCN, in which the coproduct was the known dianion [(NC)P(S)\(_2\)-S-P(S)\(_2\)(CN)]\(^{2-}\).\(^{118}\) The first sulfido heptaphosphane cluster anions, [P\(_7(S)_{3}\)]\(^{3-}\) and [HP\(_7(S)_{2}\)]\(^{2-}\) (cf. PT\(^{-}\), p. 491), have also recently been characterized.\(^{119}\)

**Oxosulfides**

When P\(_4O_{10}\) and P\(_4S_{10}\) are heated in appropriate proportions above 400\(^\circ\), P\(_4O_6S_4\) is obtained as colourless hygroscopic crystals, mp 102\(^\circ\).

\[
3P_4O_{10} + 2P_4S_{10} \rightarrow 5P_4O_6S_4
\]

The structure is shown in Fig. 12.15. The related compound P\(_4O_4S_4\) is said to be formed by the reaction of H\(_2\)S with POC\(_13\) at 0\(^\circ\) (A. Besson, 1897) but has not been recently investigated. An amorphous yellow material of composition P\(_4O_4S_3\) is obtained when a solution of P\(_4S_3\) in CS\(_2\) or organic solvents is oxidized by dry air or oxygen. Other oxosulfides of uncertain authenticity such as P\(_6O_{10}Se\) have been reported but their structural integrity has not been established and they may be mixtures. However, the following series can be prepared by appropriate redistribution reactions: P\(_4O_6S_n\) (n = 1–4), P\(_4O_6Se_n\) (n = 1–3), P\(_4O_6SSe\), P\(_4O_7S_n\) (n = 1–3), P\(_4O_7Se\), P\(_4O_8S_n\) (n = 1, 2),\(^{120}\) the crystal and molecular structures of P\(_4O_6S_2\) and P\(_4O_6S_3\) have recently been determined.\(^{121}\) Two isomers each of \(\beta\)-P\(_4S_{2}S\)I\(_2\) and \(\beta\)-P\(_4SSe\)I\(_2\), prepared by reaction of P\(_4S_{3-n}Se_n\) with I\(_2\) in CS\(_2\) have been structurally identified by \(^{31}\)P nmr spectroscopy.\(^{122}\)

### 12.3.6 Oxoacids of phosphorus and their salts

The oxoacids of P are more numerous than those of any other element, and the number of oxoanions and oxo-salts is probably exceeded only by those of Si. Many are of great importance technologically and their derivatives are vitally involved in many biological processes (p. 528). Fortunately, the structural principles covering this extensive array of compounds are very simple and can be stated as follows:;

(i) All P atoms in the oxoacids and oxoanions are 4-coordinate and contain at least one P–O unit (1).

(ii) All P atoms in the oxoacids have at least one P–OH group (2a) and this often occurs in the anions also; all such groups are ionizable as proton donors (2b).

---

† Heteropolyacids containing P fall outside this classification and are treated, together with the isopolyacids and their salts, on pp. 1010–16. Organic esters such as P(OR)$_3$ are also excluded.
(iii) Some species also have one (or more) P–H group (3); such directly bonded H atoms are not ionizable.

(iv) Catenation is by P–O–P links (4a) or via direct P–P bonds (4b); with the former both open chain ("linear") and cyclic species are known but only corner sharing of tetrahedra occurs, never edge- or face-sharing.

(v) Peroxo compounds feature either \( \text{P—OOH} \) groups or \( \text{POOP} \) links.

It follows from these structural principles that each P atom is 5-covalent. However, the oxidation state of P is 5 only when it is directly bound to 4 O atoms; the oxidation state is reduced by 1 each time a P–OH is replaced by a P–P bond and by 2 each time a P–OH is replaced by a P–H. Some examples of phosphorus oxoacids are listed in Table 12.7 together with their recommended and common names. It will be seen that the numerous structural types and the variability of oxidation state pose several problems of nomenclature which offer a rich source of confusion in the literature.

The oxoacids of P are clearly very different structurally from those of N (p. 459) and this difference is accentuated when the standard reduction potentials (p. 434) and oxidation-state diagrams (p. 437) for the two sets of compounds are compared. Some reduction potentials \( (E^{\circ}/V) \) in acid solution are in Table 12.8\(^{123} \) and these are shown schematically below, together with the corresponding data for alkaline solutions.

The alternative presentation as an oxidation state diagram is in Fig. 12.16 which shows the dramatic difference to N (p. 438).

The fact that the element readily dissolves in aqueous media with disproportionation into \( \text{PH}_3 \) and an oxoacid is immediately clear from the fact that P lies above the line joining \( \text{PH}_3 \) and either \( \text{H}_3\text{P}O_2 \) (hypophosphorous acid), \( \text{H}_3\text{P}O_3 \) (phosphorous acid) or \( \text{H}_3\text{P}O_4 \) (orthophosphoric acid). The reaction is even

(a) Some acids are known only as their salts in which one or more $-\text{OH}$ group has been replaced by $\text{O}^{-}$

(b) The number in parentheses after the formula indicates the maximum basicity, where this differs from the total number of H atoms in the formula.

more effective in alkaline solution. Similarly, H$_4$P$_2$O$_6$ disproportionates into H$_3$PO$_3$ and H$_3$PO$_4$. Figure 12.16 also illustrates that H$_3$PO$_2$ and H$_3$PO$_3$ are both effective reducing agents, being readily oxidized to H$_3$PO$_4$, but this latter compound (unlike HNO$_3$) is not an oxidizing agent.

A comprehensive treatment of the oxoacids and oxoanions of P is inappropriate but selected examples have been chosen to illustrate
interesting points of stereochemistry, reaction chemistry or technological applications. The treatment begins with the lower oxoacids and their salts (in which P has an oxidation state less than +5) and then considers phosphoric acid, phosphates and polyphosphates. The peroxoacids H₃PO₅ and H₄P₂O₇ and their salts will not be treated further (except peripherally) nor will the peroxohydrates of orthophosphates, which are obtained from aqueous H₂O₂ solutions.  

Hypophosphorous acid and hypophosphites [H₂PO(OH)₂ and H₂PO₂⁻]

The recommended names for these compounds (phosphinic acid and phosphinates) have not yet gained wide acceptance for inorganic compounds but are generally used for organophosphorus derivatives. Hypophosphites can be made by heating white phosphorus in aqueous alkali:

$$\text{P}_4 + 4\text{OH}^- + 4\text{H}_2\text{O} \xrightarrow{\text{warn}} 4\text{H}_2\text{PO}_2^- + 2\text{H}_2$$

Phosphite and phosphine are obtained as byproducts (p. 493) and the former can be removed via its insoluble calcium salt:

$$\text{P}_4 + 4\text{OH}^- + 2\text{H}_2\text{O} \xrightarrow{2\text{Ca}^{2+}} \text{Ca(HPO}_3)_2 + 2\text{PH}_3$$

²P refers to white phosphorus, $\frac{1}{2}\text{P}_4(s)$.

Free hypophosphorous acid is obtained by acidifying aqueous solutions of hypophosphites but the pure acid cannot be isolated simply by evaporating such solutions because of its ready oxidation to phosphorous and phosphoric acids and disproportionation to phosphine and phosphorous acid (Fig. 12.16). Pure H₃PO₂ is obtained by continuous extraction from aqueous solutions into Et₂O; it forms white crystals mp
26.5° and is a monobasic acid $pK_a$ 1.244 at 25°.¹²⁵

During the past few decades hydrated sodium hypophosphite, NaH$_2$PO$_2$·H$_2$O, has been increasingly used as an industrial reducing agent, particularly for the electroless plating of Ni onto both metals and non-metals.¹²⁶ This developed from an accidental discovery by A. Brenner and Grace E. Riddel at the National Bureau of Standards, Washington, in 1944. Acid solutions ($E \approx -0.40$ V at pH 4–6 and $T > 90°$) are used to plate thick Ni layers on to other metals, but more highly reducing alkaline solutions (pH 7–10; $T \approx 25–50°$) are used to plate plastics and other non-conducting materials:

$$\text{HPO}_2^{2-} + 2\text{H}_2\text{O} + 2e^- \rightleftharpoons \text{H}_2\text{PO}_3^+ + 3\text{OH}^-; \quad E \approx -1.57 \text{ V}$$

Typical plating solutions contain 10–30 g/l of nickel chloride or sulfate and 10–50 g/l NaH$_2$PO$_2$; with suitable pump capacities it is possible to plate up to 10 kg Ni per hour from such a bath (i.e. 45 m$^2$ surface to a thickness of 25 μm). Chemical plating is more expensive than normal electrolytic plating but is competitive when intricate shapes are being plated and is essential for non-conducting substrates. (See also the use of BH$_4^-$ in this connection, p. 167.)

**Phosphorous acid and phosphites**

[HPO(OH)$_2$ and HP0$_3^{2-}$]

Again, the recommended names (phosphonic acid and phosphonates) have found more general acceptance for organic derivatives such as RPO$_2^{2-}$, and purely inorganic salts are still usually called phosphites. The free acid is readily made by direct hydrolysis of PCl$_3$ in cold CC1$_4$ solution:

$$\text{PCl}_3 + 3\text{H}_2\text{O} \rightarrow \text{HPO(OH)}_2 + 3\text{HCl}$$

On an industrial scale PCl$_3$ is sprayed into steam at 190° and the product sparged of residual water and HCl using nitrogen at 165°. Phosphorous acid forms colourless, deliquescent crystals, mp 70.1°, in which the structural units shown form four essentially linear H bonds (O···H 155–160 pm) which stabilize a complex 3D network. The molecular dimensions were determined by low-temperature single-crystal neutron diffraction at 15 K.¹²⁷

In aqueous solutions phosphorous acid is dibasic ($pK_1$ 1.257, $pK_2$ 6.7)¹²⁵ and forms two series of salts: phosphites and hydrogen phosphites (acid phosphites), e.g.

"normal": [NH$_4$]$_2$[HPO$_3$], H$_2$O, Li$_2$[HPO$_4$], Na$_2$[HPO$_3$], 5H$_2$O, K$_2$[HPO$_3$]

"acid": [NH$_4$][HPO$_3$(OH)], Li[HPO$_2$(OH)], Na[HPO$_2$(OH)]$_2$, 2$\frac{1}{2}$H$_2$O, K[HPO$_2$(OH)] and M[HPO$_2$(OH)]$_2$ (M = Mg, Ca, Sr).

Dehydration of these acid phosphites by warming under reduced pressure leads to the corresponding pyrophosphites M$_2$[HP(O)$_2$–O–P(O)$_2$H] and M$^{II}$[HP$(O)$$_2$–O–P(O)$_2$H].

Organic derivatives fall into 4 classes RPO(OH)$_2$, HPO(OR)$_2$, R'PO(OR)$_2$ and the phosphate esters P(OR)$_3$; this latter class has no purely inorganic analogues, though it is, of course, closely related to PCl$_3$. Some preparative routes have already been indicated. Reactions with alcohols depend on conditions:

$$\text{PCl}_3 + 3\text{ROH} \rightarrow \text{HPO(OR)}_2 + \text{RCl} + 2\text{HCl}$$

Phenols give triaryl phosphites \( P(OAr)_3 \) directly at \(-160^\circ\) and these react with phosphorous acid to give diaryl phosphonates:

\[
2P(OAr)_3 + HPO(OH)_2 \rightarrow 3HPO(OAr)_2
\]

Trimethyl phosphite \( P(OMe)_3 \) spontaneously isomerizes to methyl dimethylphosphonate \( MePO(OMe)Me \), whereas other trialkyl phosphites undergo the Michaelis-Arbusov reaction with alkyl halides via a phosphonium intermediate:

\[
P(OR)_3 + R'X \rightarrow \{[R'P(OR)_3]X\} \rightarrow R'PO(OR)_2 + RX
\]

Further discussion of these fascinating series of reactions falls outside our present scope.\(^{(2)}\)

**Hypophosphoric acid (\( H_4P_2O_6 \)) and hypophosphates**

There has been much confusion over the structure of these compounds but their diamagnetism has long ruled out a monomeric formulation, \( H_3PO_3 \). In fact, as shown in Table 12.7, isomeric forms are known: (a) hypophosphoric acid and hypophosphates in which both P atoms are identical and there is a direct P–P bond; (b) isohypophosphoric acid and isohypophosphates in which 1 P has a direct P–H bond and the 2 different P atoms are joined by a \( P^{III} - O - P^{V} \) link.\(^{(23)}\)

Hypophosphoric acid, \( (HO)_2P(O) - P(O)(OH)_2 \), is usually prepared by the controlled oxidation of red P with sodium chlorite solution at room temperature: the tetrasodium salt, \( Na_4P_2O_6.10H_2O \), crystallizes at pH 10 and the disodium salt at pH 5.2:

\[
2P + 2NaClO_2 + 8H_2O \rightarrow NaH_2P_2O_6.6H_2O + 2HCl
\]

Ion exchange on an acid column yields the crystalline “dihydrate” \( H_4P_2O_6.2H_2O \) which is actually the hydroxonium salt of the dihydrogen hypophosphate anion \([H_3O]^+ [HO]P(O) - P(O)(OH)]^2−\); it is isostructural with the corresponding ammonium salt for which X-ray diffraction studies establish the staggered structure shown.

The anhydrous acid is obtained either by the vacuum dehydration of the dihydrate over \( P_4O_{10} \)
or by the action of H₂S on the insoluble lead salt Pb₂P₂O₆. As implied above, the first proton on each -PO(OH)₂ unit is more readily removed than the second and the successive dissociation constants at 25° are pK₁ 2.2, pK₂ 2.8, pK₃ 7.3, pK₄ 10.0. Both H₄P₂O₈ and its dihydrate are stable at 0° in the absence of moisture. The acid begins to melt (with decomposition) at 73° but even at room temperature it undergoes rearrangement and disproportionation to give a mixture of isohypophosphoric, pyrophosphoric, and pyrophosphorous acids as represented schematically on the previous page.

Hypophosphoric acid is very stable towards alkali and does not decompose even when heated with 80% NaOH at 200°. However, in acid solution it is less stable and even at 25° hydrolyses at a rate dependent on pH (e.g. t½ 180 days in 1 M HCl, t½ < 1 h in 4 M HCl):

\[
\text{(HO)₃P(O)·P(O)(OH)₂ + H₂O \quad \text{pH} < 0} \quad \rightarrow \quad \text{HP(O)(OH)₂ + P(O)(OH)₃}
\]

The presence of P–H groups amongst the products of these reactions was one of the earlier sources of confusion in the structures of hypophosphoric and isohypophosphoric acids.

The structure of isohypophosphoric acid and its salts can be deduced from ³¹P nmr which shows the presence of 2 different 4-coordinate P atoms, the absence of a P–P bond and the presence of a P–H group (also confirmed by Raman spectroscopy). It is made by the careful hydrolysis of PCl₃ with the stoichiometric amounts of phosphoric acid and water at 50°:

\[
\text{PCl₃ + H₃PO₄ + 2H₂O \quad 50°} \quad \rightarrow \quad \text{iso-[H₃(HP₂O₆)]} + 3\text{HCl}
\]

The trisodium salt is best made by careful dehydration of an equimolar mixture of hydrated disodium hydrogen phosphate and sodium hydrogen phosphate at 180°:

\[
\text{Na₂HPO₄·12H₂O + NaH₂PO₃·2½H₂O \quad 180°} \quad \rightarrow \quad \text{Na₃[HP₂O₆] + 15½H₂O}
\]

The structural relation between the reacting anions and the product is shown schematically below:

![Structural relation between the reacting anions and the product](image)

**Other lower oxoacids of phosphorus**

The possibility of P–H and P–P bonds in phosphorus oxoacids, coupled with the ease of polymerization via P–O–P linkages enables innumerable acids and their salts to be synthesized. Frequently mixtures are obtained and these can be separated by paper chromatography, paper electrophoresis, thin-layer chromatography, ion exchange or gel chromatography. Much ingenuity has been expended in designing appropriate syntheses but no new principles emerge. A few examples are listed in Table 12.9 to illustrate both the range of compounds available and also the abbreviated notation, which proves to be more convenient than formal systematic nomenclature in this area. In this notation the sequence of P–P and P–O–P links is indicated and the oxidation state of each P is shown as a superscript numeral which enables the full formula (including P–H groups) to be deduced.

**The phosphoric acids**

This section deals with orthophosphoric acid (H₃PO₄), pyrophosphoric acid (H₄P₂O₇) and the polyphosphoric acids (H₄₊₂PₙO₃ₙ₊₁). Several of these compounds can be isolated pure but their facile interconversion renders this area of phosphorus chemistry far more complex.

---

than might otherwise appear. The corresponding phosphate salts are discussed in subsequent sections as also are the cyclic metaphosphoric acids (\(\text{HPO}_3\)), the polymetaphosphoric acids (\(\text{HPO}_3\)), and their salts.

Orthophosphoric acid is a remarkable substance: it can only be obtained pure in the crystalline state (mp 42.35°C) and when fused it slowly undergoes partial self-dehydration to diphosphoric acid:

\[
2\text{H}_3\text{PO}_4 \rightleftharpoons \text{H}_2\text{O} + \text{H}_4\text{P}_2\text{O}_7
\]

The sluggish equilibrium is obtained only after several weeks near the mp but is more rapid at higher temperatures. This process is accompanied by extremely rapid autoprotolysis (see below) which gives rise to several further (ionic) species in the melt. As the concentration of these various species builds up the mp slowly drops until at equilibrium it is 34.6°C, corresponding to about 6.5 mole% of diphosphate.\(^\text{129}\) Slow crystallization of stoichiometric molecular \(\text{H}_3\text{PO}_4\) from this isocompositional melt gradually reverses the equilibria and the mp eventually rises again to the initial value. Crystalline \(\text{H}_3\text{PO}_4\) has a hydrogen-bonded layer structure in which each \(\text{PO(OH)}_3\) molecule is linked to 6 others by H bonds which are of two lengths, 253 and 284 pm. The shorter bonds link OH and O=\(\equiv\)P groups whereas the longer H bonds are between 2 OH groups on adjacent molecules.

Extensive H bonding persists on fusion and phosphoric acid is a viscous syrupy liquid that readily supercools. At 45°C (just above the mp) the viscosity is 76.5 centipoise (cP) and this increases to 177.7 cP at 25°C. These values can be compared with 1.00 cP for \(\text{H}_2\text{O}\) at 20°C and 24.5 cP for anhydrous \(\text{H}_2\text{SO}_4\) at 25°C. As shown in the Table\(^\text{129}\) trideuterophosphoric acid has an even higher viscosity and deuteration also raises the mp and density.

</table>

Despite this enormous viscosity, fused \(\text{H}_3\text{PO}_4\) (and \(\text{D}_3\text{PO}_4\)) conduct electricity extremely well and this has been shown to arise from extensive self-ionization (autoprotolysis) coupled with a proton-switch conduction mechanism for the \(\text{H}_2\text{PO}_4^-\) ion:\(^\text{129,130}\)

\[
2\text{H}_3\text{PO}_4 \rightleftharpoons \text{H}_4\text{PO}_4^+ + \text{H}_2\text{PO}_4^- \quad (1)
\]

In addition, the diphosphate group is also deprotonated:

\[
2\text{H}_3\text{PO}_4 \rightleftharpoons \text{H}_2\text{O} + \text{H}_4\text{P}_2\text{O}_7
\
\rightleftharpoons \text{H}_3\text{O}^+ + \text{H}_3\text{P}_2\text{O}_7^-
\
\text{H}_3\text{P}_2\text{O}_7^- + \text{H}_3\text{PO}_4 \rightleftharpoons \text{H}_4\text{PO}_4^+ + \text{H}_2\text{P}_2\text{O}_7^{2-}
\]

i.e. \(3\text{H}_3\text{PO}_4 \rightleftharpoons \text{H}_3\text{O}^+ + \text{H}_4\text{PO}_4^+ + \text{H}_2\text{P}_2\text{O}_7^{2-}\) \((2)\)

At equilibrium, the concentration of \(\text{H}_3\text{O}^+\) and \(\text{H}_2\text{P}_2\text{O}_7^{2-}\) are each \(~0.28\) molal and \(\text{H}_3\text{PO}_4^-\) is \(~0.26\) molal, thereby implying a

---

concentration of 0.54 molal for \( \text{H}_2\text{PO}_4^+ \). These values are about 20–30 times greater than the concentrations of ions in molten \( \text{H}_2\text{SO}_4 \), namely \([\text{HSO}_4^-] 0.0178\) molal, \([\text{H}_2\text{SO}_4] \) 0.0135 molal and \([\text{HS}_2\text{O}_7^-] 0.0088\) molal (see p. 711). Because of the very high viscosity of molten \( \text{H}_3\text{PO}_4 \) electrical conduction by normal ionic migration is negligible and the high conductivity is due almost entirely to a rapid proton-switch followed by a relatively slow reorientation involving the \( \text{H}_2\text{PO}_4^- \) ion, H-bonded to the solvent structure (Fig. 12.17). Note that the tetrahedral \( \text{H}_2\text{PO}_4^+ \) ion, i.e. \([\text{P(OH)}_4]^+ \), like the \( \text{NH}_4^+ \) ion in liquid \( \text{NH}_3 \), does not contribute to the proton-switch conduction mechanism in \( \text{H}_3\text{PO}_4 \) because, having no dipole moment, it does not orient preferentially in the applied electric field; accordingly any proton switching will occur randomly in all directions independently of the applied field and therefore will not contribute to the electrical conduction.

Addition of the appropriate amount of water to anhydrous \( \text{H}_3\text{PO}_4 \), or crystallization from a concentrated aqueous solution of syrupy phosphoric acid, yields the hemihydrate \( 2\text{H}_3\text{PO}_4\cdot\text{H}_2\text{O} \) as a congruently melting compound (mp 29.3°C). The crystal structure\(^{131}\) shows the presence of 2 similar \( \text{H}_3\text{PO}_4 \) molecules which, together with the \( \text{H}_2\text{O} \) molecule, are linked into a three-dimensional H-bonded network: each of the nine O atoms participates in at least 1 relatively strong O·H···O bond (255–272 pm) and the interatomic distances P=O (149 pm) and P–OH (155 pm) are both slightly shorter than the corresponding distances in \( \text{H}_3\text{PO}_4 \). Hydrogen bonding persists in the molten compound, and the proton-switch conductivity is even higher than in the anhydrous acid (See Table on p. 518).

In dilute aqueous solutions \( \text{H}_3\text{PO}_4 \) behaves as a strong acid but only one of the hydrogens is readily ionizable, the second and third ionization constants decreasing successively by factors of \(~10^5\) (see p. 50). Thus, at 25°C:

\[
\text{H}_3\text{PO}_4 + \text{H}_2\text{O} \rightleftharpoons \text{H}_3\text{O}^+ + \text{H}_2\text{PO}_4^-;
\]
\[
K_1 = 7.11 \times 10^{-3}; \quad pK_1 = 2.15
\]
\[
\text{H}_2\text{PO}_4^- + \text{H}_2\text{O} \rightleftharpoons \text{H}_3\text{O}^+ + \text{HPO}_4^{2-};
\]
\[
K_2 = 6.31 \times 10^{-8}; \quad pK_2 = 7.20
\]
\[
\text{HPO}_4^{2-} + \text{H}_2\text{O} \rightleftharpoons \text{H}_3\text{O}^+ + \text{PO}_4^{3-};
\]
\[
K_3 = 4.22 \times 10^{-13}; \quad pK_3 = 12.37
\]

Accordingly, the acid gives three series of salts, e.g. \( \text{NaH}_2\text{PO}_4 \), \( \text{Na}_2\text{HPO}_4 \), and \( \text{Na}_3\text{PO}_4 \) (p. 523). A typical titration curve in this system is shown in Fig. 12.18: there are three steps with two inflexions at pH 4.5 and 9.5. The first inflexion, corresponding to the formation of \( \text{NaH}_2\text{PO}_4 \), can be detected by an indicator such as methyl

Industrial production and uses of $\text{H}_3\text{PO}_4^{3-}$

Phosphoric acid\(^{132}\) is manufactured on a vast scale and is produced in a wide variety of concentrations and purities. It is therefore convenient to express production figures in terms of the amount of contained $\text{P}_4\text{O}_{10}$ (the figures based on the equivalent amount of contained anhydrous $\text{H}_3\text{PO}_4$ can be obtained by multiplying by the factor 1.380, though these may be misleading if they are taken to imply that it is the anhydrous acid that is being produced). World production capacity in 1986 exceeded 43 million tonnes of contained $\text{P}_4\text{O}_{10}$ and was distributed as follows:

<table>
<thead>
<tr>

Production is still increasing steadily in many countries “Thermal” acid (made by oxidation of phosphorus in the presence of water vapour) is about 3 times as expensive as “wet” acid (made by treating rock phosphate with sulfuric acid). The present approximate pattern of production and uses is shown in the following scheme:

```
Phosphate rock 90% → Phosphoric acid (impure) 95% → Fertilizers
              10%          5%               

Elemental phosphorus 80% → Phosphoric acid (pure) 80% → 
                        20%          20% 
Phosphorus sulfides Metal treatment (e.g. pickling, cleaning, 
Phosphorus chlorides or rust-proofing, polishing) 
Organic P compounds 
```

Many of these uses have already been discussed, or will be in later sections (pp. 524, 527).

Applications of phosphoric acid in metal treatment date from 1869 when a British patent was granted for the prevention of rusting of corset stays by damp air or perspiration. Improvements followed the incorporation of certain metal ions in the phosphating solution (notably Mn, Fe and Zn), and today corrosion resistance is imparted in this way to innumerable metal objects such as nuts, bolts, screws, tools, car-engine parts, gears, etc. In addition, car-bodies, refrigerators, washing machines and other electrical appliances with painted or enameled surfaces all use phosphatized undercoatings to prevent the paint from blistering or peeling. The simple immersion process may take up to 2 h at 90°C but can be accelerated 25-fold by adding small amounts of oxidizing agent such as $\text{NaNO}_3$ and $\text{Cu(NO}_3)_2$. A zinc phosphatized coating is usually about 0.6 μm thick (i.e. 2.2 g m\(^{-2}\)). Another important process is “bright dip” or chemical polishing of Al metal which has replaced chrome plating for car trims and other uses: the metal is immersed at 91—99°C in a solution containing 95 parts by weight of 85% $\text{H}_3\text{PO}_4$, 4 parts of 68% $\text{HNO}_3$, and 0.01% $\text{Cu(NO}_3)_2$, followed by electrolytic anodization to give the mirror-like surface a protective coating of transparent $\text{Al}_2\text{O}_3$.

Polyphosphoric acid supported on diatomaceous earth (p. 342) is a petrochemicals catalyst for the polymerization, alkylation, dehydrogenation, and low-temperature isomerization of hydrocarbons. Phosphoric acid is also used in the production of activated carbon (p. 274). In addition to its massive use in the fertilizer industry (p. 524) free phosphoric acid can be used as a stabilizer for clay soils: small additions of $\text{H}_3\text{PO}_4$ under moist conditions gradually leach out Al and Fe from the clay and these form polymeric phosphates which bind the clay particles together. An allied, though more refined use is in the setting of dental cements.

By far the greatest consumption of pure aqueous phosphoric acid is in the preparation of various salts for use in the food, detergent and tooth-paste industries (p. 524). When highly diluted the free acid is non-toxic and devoid of odour, and is extensively used to impart the sour or tart taste to many soft drinks (“carbonated beverages”) such as the various colas (~0.05% $\text{H}_3\text{PO}_4$, pH 2.3), root beers (~0.01% $\text{H}_3\text{PO}_4$, pH 5.0), and sarsaparilla (~0.01% $\text{H}_3\text{PO}_4$, pH ~4.5).

orange (pKₐ 3.5) and the second, corresponding to Na₂HPO₄, is indicated by the phenolphthalein end point (pKₐ 9.5). The third equivalence point cannot be detected directly by means of a coloured indicator. Between the two inflexions the pH changes relatively slowly with addition of NaOH and this is an example of buffer action. Indeed, one of the standard buffer solutions used in analytical chemistry comprises an equimolar mixture of Na₂HPO₄ and KH₂PO₄. Another important buffer, which has been designed to have a pH close to that of blood, consists of 0.03043 M Na₂HPO₄ and 0.008695 M KH₂PO₄, i.e. a mole ratio of 3.5:1 (pH 7.413 at 25°C).

Concentrated H₃PO₄ is one of the major acids of the chemical industry and is manufactured on the multimillion-tonne scale for the production of phosphate fertilizers and for many other purposes (see Panel). Two main processes (the so-called “thermal” and “wet” processes) are used depending on the purity required. The “thermal” (or “furnace”) process yields concentrated acid essentially free from impurities and is used in applications involving products destined for human consumption (see also p. 524); in this process a spray of molten phosphorus is burned in a mixture of air and steam in a stainless steel combustion chamber:

$$\text{P}_4 + 5\text{SO}_2 \rightarrow \text{P}_4\text{O}_{10} + 6\text{H}_2\text{O} \rightarrow 4\text{H}_3\text{PO}_4$$

Acid of any concentration up to 84 wt% P₄O₁₀ can be prepared by this method (72.42% P₄O₁₀ corresponds to anhydrous H₃PO₄) but the usual commercial grades are 75–85% (expressed as anhydrous H₃PO₄). The hemihydrate (p. 518) corresponds to 91.58% H₃PO₄ (66.33% P₄O₁₀). The somewhat older “wet” (or “gypsum”) process involves the treatment of rock phosphate (p. 476) with sulfuric acid, the idealized stoichiometry being:

$$\text{Ca}_5(\text{PO}_4)_3\text{F} + 5\text{H}_2\text{SO}_4 + 10\text{H}_2\text{O} \rightarrow 3\text{H}_3\text{PO}_4 + 5\text{CaSO}_4 \cdot 2\text{H}_2\text{O} + \text{HF}$$
Figure 12.19 The composition of the strong phosphoric acids shown as the weight per cent of P₂O₅ present in the form of each acid plotted against the overall stoichiometric composition of the mixture. The overall stoichiometries corresponding to the three congruently melting species H₃P⁰₄, ½H₂O, H₅P₂O₇ and H₁₂P₃O₁₀ are indicated. Compositions above 82 wt P₂O₅ are shown on an expanded scale in the inset using the mole ratio [P₂O₅]/[H₂O] as the measure of stoichiometry. (For comparison, H₅P₂O₇ corresponds to a mole ratio of 0.500, H₁₂P₃O₁₀ to a ratio 0.600, H₆P₄O₁₃ to 0.667, etc.). In both diagrams the curves labelled 1, 2, 3, ..., refer to ortho-, di-, tri-, ... phosphoric acids, and “highpoly” refers to highly polymeric material hydrolysed from the column.

The gypsum is filtered off together with other insoluble matter such as silica, and the fluorine is removed as insoluble Na₂SiF₆. The dilute phosphoric acid so obtained (containing 35–70% H₃PO₄ depending on the plant used) is then concentrated by evaporation. It is usually dark green or brown in colour and contains many metal impurities (e.g. Na, Mg, Ca, Al, Fe, etc.) as well as residual sulfate and fluoride, but is suitable for the manufacture of phosphatic fertilizers, metallurgical applications, etc. (see Panel on p. 520).

Diphosphoric acid H₄P₂O₇ becomes an increasingly prevalent species as the system P₂O₁₀/H₂O becomes increasingly concentrated: indeed, the phase diagram shows that, in addition to the hemihydrate (mp 29.30°) and orthophosphoric acid (mp 42.35°) the only other congruently melting phase in the system is H₄P₂O₇. The compound is dimorphic with a metastable modification mp 54.3° and a stable form mp 71.5°, but in the molten state it comprises an iso-compositional mixture of various polyphosphoric acids and their autoprotolysis products. Equilibrium is reached only sluggishly and the actual constitution of the melt depends sensitively both on the precise stoichiometry and the temperature (Fig. 12.19). For the nominal stoichiometry corresponding to H₄P₂O₇ typical concentrations of the species Hₙ₊₂PₙO₃ₙ₊₁ from \( n = 1 \) (i.e. H₃P₀₄) to \( n = 8 \) are as follows:

Thus, although H₄P₂O₇ is marginally the most abundant species present, there are substantial amounts of H₃P₀₄, H₅P₁O₁₀, H₆P₂O₁₃ and higher polyphosphoric acids. Note that the table indicates mole% of each molecular species present whereas the graphs in Fig. 12.19 plot weight percentage of P₂O₅ present as each acid shown.

In dilute aqueous solution H₄P₂O₇ is a somewhat stronger acid than H₃P₀₄; the 4 dissociation constants at 25° are: \( K₁ \sim 10^{-1}, \)_

$K_2 \sim 1.5 \times 10^{-2}$, $K_3 2.7 \times 10^{-7}$ and $K_4 2.4 \times 10^{-10}$, and the corresponding negative logarithms are: $pK_1 \sim 1.0$, $pK_2 \sim 1.8$, $pK_3 6.57$ and $pK_4 9.62$. The $P-O-P$ linkage is kinetically stable towards hydrolysis in dilute neutral solutions at room temperature and the reaction half-life can be of the order of years. Such hydrolytic breakdown of polyphosphate is of considerable importance in certain biological systems and has been much studied. Some factors which affect the rate of degradation of polyphosphates are shown in Table 12.10.

Orthophosphates\(^{(23,64)}\)

Phosphoric acid forms several series of salts in which the acidic H atoms are successively replaced by various cations; there is considerable commercial application for many of these compounds.

Lithium orthophosphates are unimportant and differ from the other alkali metal phosphates in being insoluble. At least 10 crystalline hydrated or anhydrous sodium orthophosphates are known and these can be grouped into three series:

- $Na_3PO_4.nH_2O \ (n = 0, \frac{1}{2}, 6, 8, 12)$
- $Na_2HPO_4.nH_2O \ (n = 0, 2, 7, 8, 12)$
- $NaH_2PO_4.nH_2O \ (n = 0, 1, 2)$

$NaH_2PO_4.H_3PO_4 [i.e. NaH_5(PO_4)_2]$

$NaH_2PO_4.Na_2HPO_4 [i.e. Na_3H_3(PO_4)_2]$

and $2NaH_2PO_4.Na_3HPO_4.2H_2O$

Likewise, there are at least 10 well-characterized potassium orthophosphates and several ammonium analogues. The presence of extensive H bonding in many of these compounds leads to considerable structural complexity and frequently confers important properties (see later). The mono- and di-sodium phosphates are prepared industrially by neutralization of aqueous $H_3PO_4$ with soda ash (anhydrous $Na_2CO_3$, p. 89). However, preparation of the trisodium salts requires the use of the more expensive $NaOH$ to replace the third H atom. Careful control of concentration and temperature are needed to avoid the simultaneous formation of pyrophosphates (diphosphates). Some indication of the structural complexity can be gained from the compound $Na_3PO_4.12H_2O$ which actually crystallizes with variable amounts of $NaOH$ up to the limiting composition $4(Na_3PO_4.12H_2O).NaOH$. The structure is built from octahedral $[Na(H_2O)_6]$ units which join to form “hexagonal” rings of 6 octahedra which in turn form a continuous two-dimensional network of overall composition $[Na(H_2O)_4]$; between the sheets lie $[PO_4]$ connected to them by H bonds.\(^{(134)}\) Some industrial, domestic, and scientific applications of $Na$, $K$ and $NH_4$ orthophosphates are given in the Panel.

Calcium orthophosphates are particularly important in fertilizer technology, in the chemistry of bones and teeth, and in innumerable industrial and domestic applications (see Panel). They are also the main source of phosphorus and phosphorus chemicals and occur in vast deposits as apatites and rock phosphate (p. 475). The main compounds occurring in the $CaO-H_2O-P_4O_{10}$ phase diagram are: $Ca(H_2PO_4)_2$, $Ca(H_2PO_4)_2.H_2O$, $Ca(HPO_4)_2.nH_2O \ (n = 0, \frac{1}{2}, 2)$, $Ca_3(PO_4)_2$, $Ca_2PO_4(OH).2H_2O$, $Ca_3(PO_4)_3OH$ (i.e. apatite), $Ca_4P_2O_9$ [probably $Ca_3(PO_4)_2.CaO]$ and $CaH_2(PO_4)_3.5H_2O$.

In all of these alkali-metal and alkaline earth-metal orthophosphates there are discrete, approximately regular tetrahedral $PO_4$ units in

Uses of Orthophosphates

Phosphates are used in an astonishing variety of domestic and industrial applications but their ubiquitous presence and their substantial impact on everyday life is frequently overlooked. It will be convenient first to indicate the specific uses of individual compounds and the properties on which they are based, then to conclude with a brief summary of many different types of application and their interrelation. The most widely used compounds are the various phosphate salts of Na, K, NH₄ and Ca. The uses of di-, tri- and poly-phosphates are mentioned on pp. 527–29.

Na₃PO₄ is strongly alkaline in aqueous solution and is thus a valuable constituent of scouring powders, paint strippers and greasing compounds. Its complex with NaOCl [(Na₃PO₄)_1.1H₂O₄NaOCl], is also strongly alkaline (a 1% solution has pH 11.8) and, in addition, it releases active chlorine when wetted; this combination of scouring, bleaching and bacteriocidal action makes the adduct valuable in formulations of automatic dishwashing powders.

Na₂HPO₄ is widely used as a buffer system (p. 521). The use of the dihydrate (~2% concentration) as an emulsifier in the manufacture of pasteurized processed cheese was patented by J. L. Kraft in 1916 and is still used, together with insoluble sodium metaphosphate or the mixed phosphate Na₁₅Al₃(PO₄)₉, to process cheese on the multikilotonne scale daily. Despite much study, the reason why phosphate salts act as emulsifiers is still not well understood in detail. Na₂HPO₄ is also added (~0.1%) to evaporated milk to maintain the correct Ca/P-O₄ balance and to prevent gelation of the milk powder to a mush. Its addition at the 5% level to brine (15–20% NaCl solution) for the pickling of ham makes the product more tender and juicy by preventing the exudation of juices during subsequent cooking. Another major use in the food industry is as a starch modifier: small additions enhance the ability to form stable cold-water gels (e.g. instant pudding mixes), and the addition of 1% to farinaceous products raises the pH to slightly above 7 and provides “quick-cooking” breakfast cereals.

NaH₂PO₄ is a solid water-soluble acid, and this property finds use (with NaHCO₃) in effervescent laxative tablets and in the pH adjustment of boiler waters. It is also used as a mild phosphatizing agent for steel surfaces and as a constituent in the undercoat for metal paints.

K₃PO₄ (like Na₃PO₄) is strongly alkaline in aqueous solution and is used to absorb H₂S from gas streams; the solution can be regenerated simply by heating. K₅PO₄ is also used as a regulating electrolyte to control the stability of synthetic latex during the polymerization of styrenebutadiene rubbers. The buffering action of K₃HPO₄ has already been mentioned (p. 521) and is for its addition as a corrosion inhibitor to car-radiator coolants which otherwise tend to become acidic due to the glycol antifreeze. K₂HPO₄ is a piezoelectric (p. 57) and finds use in submarine sonar systems. For many applications, however, the cheaper sodium salts are preferred unless there is a specific advantage for the potassium salt; one example is the specialist balanced commercial fertilizer formulation [KH₂PO₄.(NH₄)₂HPO₄] which contains 10.5%, N, 53% P₂O₅ and 17.2% K₂O (i.e. N-P-K 10–53–17).

(NH₄)₂HPO₄ and (NH₄)H₂PO₄ can be used interchangeably as specialist fertilizers and nutrients in fermentation broths; though expensive, their high concentration of active ingredients ameliorate this, particularly in localities where transportation costs are high. Indeed, (NH₄)₂HPO₄ in granulated or liquid form consumes more phosphate rock than any other single end-product (over 8 million tonnes pa in the USA alone in 1974). Ammonium phosphates are also much used as flame retardants for cellulose materials, about 3–5% gain in dry weight being the optimum treatment. Their action probably depends on their ready dissociation into NH₃ and H₃PO₄ on heating; the H₃PO₄ then catalyses the decomposition of cellulose to a slow-burning char (carbon) and this, together with the suppression of flammable volatiles, smothers the flame. As the ammonium phosphates are soluble, they are used mainly for curtains, theatre scenery and disposable paper dresses and costumes. The related compound urea phosphate (NH₄CONH₂.H₃PO₄) has also been used to flameproof cotton fabrics: the material is soaked in a concentrated aqueous solution, dried (~5% weight gain) and cured at 160° to bond the retardant to the cellulose fibre. The advantage is that the retardant does not wash out, but the strength of the fabric is somewhat reduced by the process.

Calcium phosphates have a broad range of applications both in the food industry and as bulk fertilizers. The vast scale of the phosphate rock industry has already been indicated (p. 476) and this is further elaborated for the particular case of the USA in the Scheme on the page opposite (kilotonnes pa and %, 1974).

The crucial importance of Ca and Po₄ as nutrient supplements for the healthy growth of bones, teeth, muscle and nerve cells has long been recognized. The non-cellular bone structure of an average adult human consists of ~60% of some form of “tricalcium phosphate” [Ca₃(PO₄)₂OH]; teeth likewise comprise ~70% and average persons carry 3.5 kg of this material in their bodies. Phosphates in the body are replenished by a continuous cycle, and used P is carried by blood to the kidneys and then excreted in urine, mainly as Na(NH₄)H₂PO₄. An average adult eliminates 3–4 g of Po₄ equivalent daily (cf. the discovery of P in urine by Brandt, p. 473).

Calcium phosphates are used in baking acids, toothpastes, mineral supplements and stock feeds. Ca(H₂PO₄)₂ was introduced as a leavening acid in the late nineteenth century (to replace "cream of tartar" KHC₄H₄O₆) but the monohydrate (introduced in the 1930s) finds more use today. "Straight baking powder", a mixture of Ca(H₂PO₄)₂.H₂O and NaHCO₃ with some 40% starch coating, tends to produce CO₂ too quickly during dough mixing and so "combination baking

* Note that ammoniation of H3PO4 to give granulated or liquid ammonium phosphates consumes more phosphate rock in the USA than any other single end product.

powder", which also incorporates a slow-acting acid such as NaAl(SO4)2, is preferred. Nearly 90% of all US household baking powders now use such combinations, e.g.:

\[
Ca(H2PO4)2\cdot H2O + 2NaHCO3 \rightarrow 2CO2 + 3H2O + 'Na2Ca(HPO4)2' \\
NaAl(SO4)2 + 3NaHCO3 \rightarrow H2O + 3CO2 + Al(OH)3 + 2Na2SO4
\]

A typical powder contains 28% NaHCO3, 10.7% Ca(H2PO4)2.H2O, 21.4% NaAl(SO4)2 and 39.9% starch and the scale of manufacture approaches 10^5 tonnes pa.

In toothpastes, CaHPO4·2H2O was first used to replace chalk as a mild abrasive and polishing agent in the early 1930s. It is still widely used provided the toothpaste does not also contain fluoride, since this would precipitate as CaF2 and effectively eliminate the desired anion. Some 25 000 tonnes of CaHPO4·2H2O are used in this way annually in the USA and the compound typically comprises 50% by weight of the paste. The first important fluoride toothpaste contained 39% of the diphosphate Ca2P2O7 which is the most insoluble and inert of all calcium phosphates. It is made by careful dehydration of CaHPO4·2H2O at 150° and then above 400°. It was first used in Procter and Gamble’s “Crest” which also contained 0.4% SnF2 and 1% SnF2·O7.

Synthetic Ca5(P2O7)OH is added to table salt (1–2%) to impart free-flowing properties and it is likewise added to granulated sugar, baking powders and even fertilizers. It is prepared by adding H3PO4 to a slurry of hydrated lime — this is the reverse order of addition to that used for making Ca(H2PO4)2 and CaHPO4 since the aim is to deprotonate all three OH groups. The compound is extremely insoluble and precipitates as very fine particles (~0.5–3 μm diameter).

The idea of converting insoluble “tricalcium phosphate” or phosphate rock into soluble “monocalcium phosphate” Ca(H2PO4)2 dates back to the 1830s when J. von Liebig observed that acidulated bones made good fertilizer. The limited supply of bones (including those from old battlefields!) was soon replaced by Suffolk coprolites and apatites, though the vast North African deposits were still unknown. The phosphate fertilizer industry originated in England (Lawes, 1843); it grew rapidly as shown by the dramatic increase in world production of phosphate rock, which leapt from 500 tonnes in 1847 to 500 kilotonnes in 1880, 3.1 million tonnes in 1900, and now exceeds 150 Mt (p. 476). This unprecedented demand for phosphatic fertilizers is, of course, closely related to the demand for food from an exploding world population of humans which reached 1 billion (10^9) in 1830, 2 billion in 1930, 3 billion in 1960, 4 billion in 1974 and will be over 8 billion by the end of the century.

“Superphosphate” is now made by the (highly exothermic) addition of H2SO4 to fine-ground phosphate rock:

\[
2Ca5(PO4)3F + 7H2SO4 + H2O \rightarrow 7CaSO4 + 3Ca(H2PO4)2\cdot H2O + 2HF
\]
Phosphorus Ch. 12

The CaSO₄ or its hydrate (gypsum) acts only as an unwanted diluent. Its presence can be avoided by using H₃PO₄ instead of H₂SO₄ for the acidulation, thus giving rise to "triple superphosphate"

\[
Ca₃(PO₄)₂ + 7H₃PO₄ + H₂O \rightarrow 5Ca(H₂PO₄)₂ ⋅ H₂O + HF
\]

Commercial triple superphosphate contains almost 3 times the amount of available (soluble) P₂O₅ as ordinary superphosphate, hence its name (45–50 wt% vs. 18–20 wt%).

which P–O is usually in the range 153 ± 3 pm and the angle O–P–O is usually in the range 109 ± 5°. Extensive H-bonding and M–O interactions frequently induce substantial deviations from a purely ionic formulation (p. 81). This trend continues with the orthophosphates of tervalent elements M₃[PO₄] (M = B, Al, Ga, Cr, Mn, Fe) which all adopt structures closely related to the polymorphs of silica (p. 342). NaBePO₄ is similar, and YPO₄ adopts the zircon (ZrSiO₄) structure. The most elaborate analogy so far revealed is for AlPO₄ which can adopt each of the 6 main polymorphs of silica as indicated in the scheme below. The analogy covers not only the structural relations between the phases but also the sequence of transformation temperatures (°C) and the fact that the α–β-transitions occur readily whilst the others are sluggish (p. 343). Similarly, the orthophosphates of B, Ga and Mn are known in the β-quartz and the α- and β-cristobalite forms whereas FePO₄ adopts either the α- or β-quartz structure. Numerous hydrated forms are also known. The Al–PO₄–H₂O system is used industrially as the basis for many adhesives, binders and cements.¹³⁵ Novel chain and sheet aluminium phosphate anions of composition [H₂AlP₂O₈] and [Al₅P₄O₁₈]³⁻, respectively, have also recently been structurally characterized.¹³⁶

**Chain polyphosphates**²³,⁶⁴

A rather different structure-motif is observed in the chain polyphosphates: these feature corner-shared [PO₄] tetrahedra as in the polyphosphoric acids (p. 522). The general formula for such anions is [PₙOₙ+2]ⁿ⁻, of which the diphosphates, P₂O₇⁻, and triplyphosphates, P₃O₁₀⁻, constitute the first two members. Chain polyphosphates have been isolated with n up to 10 and with n “infinite”, but those of intermediate chain length (10 < n < 50) can only be obtained as glassy or amorphous mixtures. As the chain length increases, the ratio (3n + 1)/n approaches 3.00 and the formula approaches that of the polymetaphosphates [PO₃⁻]ₙ.

Diphosphates (pyrophosphates) are usually prepared by thermal condensation of dihydrogen

---

phosphates or hydrogen phosphates:

\[ 2\text{MH}_2\text{PO}_4 \xrightarrow{\Delta} \text{M}_2\text{H}_2\text{P}_2\text{O}_7 + \text{H}_2\text{O} \]

\[ 2\text{M}_2\text{HPO}_4 \xrightarrow{\Delta} \text{M}_4\text{P}_2\text{O}_7 + \text{H}_2\text{O} \]

They can also be prepared in specialized cases by (a) metathesis, (b) the action of \( \text{H}_3\text{PO}_4 \) on an oxide, (c) thermolysis of a metaphosphate, (d) thermolysis of an orthophosphate, or (e) reductive thermolysis, e.g.:

(a) \( \text{Na}_4\text{P}_2\text{O}_7 + 4\text{AgNO}_3 \xrightarrow{\Delta} \text{Ag}_4\text{P}_2\text{O}_7\downarrow + 4\text{NaNO}_3 \)

(b) \( 2\text{H}_3\text{PO}_4 + \text{PbO}_2 \rightarrow \text{PbP}_2\text{O}_7\downarrow + 3\text{H}_2\text{O} \)

(c) \( 4\text{Cr(PO}_3)_3 \xrightarrow{\Delta} \text{Cr}_4(\text{P}_2\text{O}_7)_3 + 3\text{P}_2\text{O}_5 \)

(d) \( 2\text{Hg}_3(\text{PO}_4)_2 \xrightarrow{\Delta} 2\text{Hg}_2\text{P}_2\text{O}_7 + 2\text{Hg} + \text{O}_2 \)

(e) \( 2\text{FePO}_4 + \text{H}_2 \rightarrow \text{Fe}_2\text{P}_2\text{O}_7 + \text{H}_2\text{O} \)

Many diphosphates of formula \( \text{M}^{\text{IV}}\text{P}_2\text{O}_7 \), \( \text{M}^{\text{III}}\text{P}_2\text{O}_7 \) and hydrated \( \text{M}_2\text{P}_2\text{O}_7 \) are known and there has been considerable interest in the relative orientation of the two linked \{PO_4\} groups and in the P−O−P angle between them. For small cations the 2 \{PO_4\} are approximately staggered whereas for larger cations they tend to be nearly eclipsed. The P−O−P angle is large and variable, ranging from 130° in \( \text{Na}_4\text{P}_2\text{O}_7.10\text{H}_2\text{O} \) to 156° in \( \alpha-\text{Mg}_2\text{P}_2\text{O}_7 \). The apparent collinearity in the higher-temperature (β) form of many diphosphates, which was previously ascribed to a P−O−P angle of 180°, is now generally attributed to positional disorder. Bridging P−O distances are invariably longer than terminal P−O distances, typical values (for \( \text{Na}_4\text{P}_2\text{O}_7.10\text{H}_2\text{O} \)) being P−O_µ 161 pm, P−O_β 152 pm. Note that bridging can also be via a peroxo group as in ammonium peroxodiphosphate \(^{138} \) which features the zig-zag anion \( [\text{O}_3\text{P}−\text{O}−\text{O}−\text{PO}_3]^− \) with P−O_µ 165.8 pm, P−O_β 150.8 pm and O−O 150.1 pm (cf. 145.3 pm in \( \text{H}_2\text{O}_2 \) and 148−150 pm in \( \text{S}_2\text{O}_5^{2−} \)).

As diphosphoric acid is tetrabasic, four series of salts are possible though not all are always known, even for simple cations. The most studied are those of Na, K, NH_4 and Ca, e.g.:

\[ \text{Na}_4\text{P}_2\text{O}_7.10\text{H}_2\text{O} (\text{mp 79.5°}), \text{Na}_4\text{P}_2\text{O}_7 (\text{mp 985°}) \]

\[ \text{Na}_3\text{HP}_2\text{O}_7.9\text{H}_2\text{O} \xrightarrow{30−35°} \text{Na}_3\text{HP}_2\text{O}_7.\text{H}_2\text{O} \xrightarrow{150°} \text{Na}_3\text{HP}_2\text{O}_7 \]

\[ \text{Na}_2\text{H}_2\text{P}_2\text{O}_7.6\text{H}_2\text{O} \xrightarrow{27°} \text{Na}_2\text{H}_2\text{P}_2\text{O}_7 \]

\[ \text{NaH}_3\text{P}_2\text{O}_7 (\text{mp 185°}) \]

Before the advent of synthetic detergents, \( \text{Na}_4\text{P}_2\text{O}_7 \) was much used as a dispersant for lime soap scum which formed in hard water, but it has since been replaced by the tripolyphosphate (see below). However, the ability of diphosphate ions to form a gel with soluble calcium salts has made \( \text{Na}_4\text{P}_2\text{O}_7 \) a useful ingredient for starch-type instant pudding which requires no cooking. The main application of \( \text{Na}_2\text{H}_2\text{P}_2\text{O}_7 \) is as a leavening acid in baking: it does not react with NaHCO_3 until heated, and so large batches of dough or batter can be made up and stored. \( \text{Ca}_2\text{P}_2\text{O}_7 \), because of its insolubility, inertness, and abrasive properties, is used as a toothpaste additive compatible with Sn^{II} and fluoride ions (see Panel on p. 525).

Of the tripolyphosphates only the sodium salt need be mentioned. It was introduced in the mid-1940s as a “builder” for synthetic detergents, and its production for this purpose is now measured in megatonnes per annum (see Panel on the next page). On the industrial scale \( \text{Na}_5\text{P}_3\text{O}_{10} \) is usually made by heating an intimate mixture of powdered \( \text{Na}_2\text{HPO}_3 \) and \( \text{NaH}_2\text{PO}_4 \) of the required stoichiometry under carefully controlled conditions:

\[ 2\text{Na}_2\text{HPO}_3 + \text{NaH}_2\text{PO}_4 \rightarrow \text{Na}_5\text{P}_3\text{O}_{10} + 2\text{H}_2\text{O} \]

The low-temperature form (I) converts to the high-temperature form (II) above 417°C and both forms react with water to give the crystalline hexahydrate. All three materials contain the

---

Uses of Sodium Tripolyphosphate

Many synthetic detergents contain 25–45% Na$_3$P$_3$O$_10$ though the amount is lower in the USA than in Europe because of the problems of eutrophication in some areas (p. 478). It acts mainly as a water softener, by chelating and sequestering the Mg$^{2+}$ and Ca$^{2+}$ in hard water. Indeed, the formation constants of its complexes with these ions are nearly one million-fold greater than with Na$^+$: (Na$_3$P$_3$O$_10$$^{6-}$ $\text{pK} \approx 2.8$; MgP$_3$O$_10$$^{3-}$ $\text{pK} \approx 8.6$; CaP$_3$O$_10$$^{3-}$ $\text{pK} \approx 8.1$). In addition, Na$_3$P$_3$O$_10$ increases the efficiency of the surfactant by lowering the critical micelle concentration, and by its ability to suspend and peptize dirt particles by building up a large negative charge on the particles by adsorption; it also furnishes a suitable alkalinity for cleansing action without irritating eyes or skin and it provides effective buffering action at these pHs. The dramatic growth of synthetic detergent powders during the 1950s was accompanied by an equally dramatic drop in the use of soap powders.\(^{(11)}\)

Na$_3$P$_3$O$_10$ is also used as a dispersing agent in clay suspensions used in oil-well drilling. Again, addition of $<1\%$ Na$_3$P$_3$O$_10$ to the slurries used in manufacturing cement and bricks enables much less water to be used to attain workability, and thus less to be removed during the setting or calcining processes.

The complicated solubility relations, rates of hydrolysis, self-disproportionation and interconversion with other phosphates depends sensitively on pH, concentration, temperature and the presence of impurities.\(^{(139)}\) Though of great interest academically and of paramount importance industrially these aspects will not be further considered here.\(^{(11,23,64,140)}\) Triphosphates such as adenosine triphosphate (ATP) are also of vital importance in living organisms (see text books on biochemistry, and also ref. 141).

The stoichiometric formula of a chain-polypophosphate can sometimes be an unreliable guide to its structure. For example, the crystalline compound “CaNb$_2$P$_6$O$_{21}$” has been shown by X-ray crystal structure analysis to contain equal numbers of oxide(2$-$), diphosphate(4$-$) and tetraphosphate(6$-$) anions, i.e. CaNb$_2$O[P$_2$O$_7$][P$_4$O$_13$].\(^{(142)}\) By contrast, CsM$_2$P$_5$O$_{16}$ (M = V, Fe) does contain the anticipated homologous catena-pentaphosphate [P$_n$O$_{3n+1}$]$^{n+2-}$ anion (p. 512) with $n = 5$.\(^{(143)}\)

Long-chain polyphosphates, M$_n$$^+$$^2$P$_n$O$_{3n+1}$, approach the limiting composition M$^4$PO$_3$ as $n \to \infty$ and are sometimes called linear metaphosphates to distinguish them from the cyclic metaphosphates of the same composition (p. 529). Their history extends back over 150 y to the time when Thomas Graham described the formation of a glassy sodium polyphosphate mixture now known as Graham’s salt. Various heat treatments converted this to crystalline compounds known as Kurrol’s salt, Maddrell’s salt, etc., and it is now appreciated, as a result of X-ray crystallographic studies, that these and many related substances all feature unbranched chains of corner-shared [PO$_4$] units which differ only in the mutual orientations and

Figure 12.20 Types of polyphosphate chain configuration. The diagrams indicate the relative orientations of adjacent PO₄ tetrahedra, extended along the chain axes. (a) (RbPO₄)ₙ and (CsPO₄)ₙ, (b) (LiPO₄)ₙ, low temp, and (KPO₄)ₙ, (c) (NaPO₄)ₙ, high-temperature Maddrell salt and [Na₂H(PO₃)₄]ₙ, (d) [Ca(PO₃)₂]ₙ and [Pb(PO₃)₂]ₙ, (e) (NaPO₃)ₙ, Kurrol A and (AgPO₃)ₙ, (f) (NaPO₃)ₙ, Kurrol B, (g) [CuNH₄(PO₃)₃]ₙ and isomorphous salts, (h) [CuK₂(PO₃)₃]ₙ and isomorphous salts. Each crystalline form of Kurrol salt contains equal numbers of right-handed and left-handed spiralling chains.

repeat units of the constituent tetrahedra.⁴⁴ These, in turn, are dictated by the size and coordination requirements of the counter cations present (including H). Some examples are shown schematically in Fig. 12.20 and the geometric resemblance between these and many of the chain metasilicates (p. 350) should be noted. In most of these polyphosphates P–Oᵣ is 161 ± 5 pm, P–O₁ 150 ± 2 pm, P–O₂–P 125–135° and O₁–P–O₂ 115–120° (i.e. very similar to the dimensions and angles in the tripolyphosphate ion, p. 528).

The complex preparative interrelationships occurring in the sodium polyphosphate system are summarized in Fig. 12.21 (p. 531). Thus anhydrous NaH₂PO₄, when heated to 170° under conditions which allow the escape of water vapour, forms the diphosphate Na₂H₂P₂O₇, and further dehydration at 250° yields either Maddrell’s salt (closed system) or the cyclic trimetaphosphate (water vapour pressure kept low). Maddrell’s salt converts from the low-temperature to the high-temperature form above 300°, and above 400° reverts to the cyclic trimetaphosphate. The high-temperature form can also be obtained (via Graham’s and Kurrol’s salts) by fusing the cyclic trimetaphosphate (mp 526°C) and then quenching it from 625° (or from 580° to give Kurrol’s salt directly). All these linear polyphosphates of sodium revert to the cyclic trimetaphosphate on prolonged annealing at ~400°C.

Fuller treatments of the phase relations and structures of polyphosphates, and their uses as glasses, ceramics, refractories, cements, plasters and abrasives, are available.⁴⁴–⁴⁶

Cyclo-polyphosphoric acids and cyclo-polyphosphates⁴⁶

These compounds were formerly called metaphosphoric acids and metaphosphates but the IUPAC cyclo- nomenclature is preferred as being structurally more informative. The only

---

two important acids in the series are \textit{cyclo}-triphosphoric acid $\text{H}_3\text{P}_3\text{O}_9$ and \textit{cyclo}-tetraphosphoric acid $\text{H}_4\text{P}_4\text{O}_{12}$, but well-characterized salts are known with heterocyclic anions $[\text{cyclo-}(\text{PO}_3)_n]^{-n}$ $(n = 3-8, 10)$\textsuperscript{(147)} and larger rings are undoubtedly present in some mixtures.

The structural relationship between the \textit{cyclo}-phosphates and $\text{P}_2\text{O}_{10}$ (p. 504) is shown schematically below. In $\text{P}_2\text{O}_{10}$ all 10 $\text{P}-\text{O(-P)}$ bridges are equivalent and hydrolytic cleavage of any one leads to "$\text{H}_2\text{P}_2\text{O}_{11}$" in which $\text{P}\cdot\text{O(-P)}$ bridges are now of two types. Cleavage of "type a" leads to \textit{cyclo}-tetraphosphoric acid or its salts (as shown in the upper line of the scheme), whereas cleavage of any of the other bridges leads to a \textit{cyclo}-triphosphate ring with a pendant $-\text{OP(O)OH}$ group which can subsequently be hydrolysed off to leave $(\text{HPO}_3)_3$ or its salts (lower line of scheme). \textit{Cyclo-$(\text{HPO}_3)_4$} can, indeed, be made by careful hydrolysis of hexagonal $\text{P}_2\text{O}_{10}$ with ice-water, and similar treatment with iced NaOH or NaHCO$_3$ gives a 75\% yield of the corresponding salt $\text{cyclo-}(\text{NaPO}_3)_4$. The preparation of \textit{cyclo-$(\text{NaPO}_3)_2$} by controlled thermolytic dehydration of NaH$_2$PO$_4$ was mentioned in the preceding section and acidification yields \textit{cyclo}-triphosphoric acid.

The \textit{cyclo-$(\text{PO}_3)_4$} anion adopts the chair configuration with dimensions as shown; \textit{cyclo-$(\text{PO}_3)_9$} is also known in this configuration though this can be modified by changing the cation.

The crystal structure of the \textit{cyclo}-hexaphosphate anion in $\text{Na}_6\text{P}_6\text{O}_{18}.6\text{H}_2\text{O}$ shows that all 6 $\text{P}$ atoms are coplanar and that bond lengths are similar to those in the $\text{P}_3\text{O}_9^{3-}$ and $\text{P}_4\text{O}_{12}^{5-}$ anions. See ref. 147 for the structure of the hydrated \textit{cyclo}-decaphosphate $\text{K}_{10}\text{P}_{10}\text{O}_{30}.4\text{H}_2\text{O}$. Higher \textit{cyclo}-metaphosphates can be isolated by

still elude a detailed and satisfactory description. It occurs in innumerable compounds, frequently of great stability, and in many of these the strength of the bond and the shortness of the interatomic distance have been interpreted in terms of “partial double-bond character”. In fact, the conventional symbols \( P-N \) and \( P=N \) are more an aid to electron counting than a description of the bond in any given compound (see p. 538).

Many compounds containing the \( P-N \) link can be considered formally as derivatives of the oxoacids of phosphorus and their salts (pp. 510-31) in which there has been isoelectronic replacement of \( \text{PH} \) [or \( P(OH) \)] by \( P(NH_2) \) or \( P(NR_2) \);
\[
P=O \quad \text{[or } P=S \text{]} \quad \text{by} \quad P=NH \quad \text{or} \quad P=NR;\]

---

**12.3.7 Phosphorus–nitrogen compounds**

The \( P-N \) bond is one of the most intriguing in chemistry and many of its more subtle aspects...
P–O–P by P–NH–P or P–NR–P.

Examples are phosphoramidic acid, H2NP(O)-(OH)2; phosphordiamidic acid, (H2N)2P(O)(OH); phosphoric triamide, (H2N)3PO; and their derivatives. There are an enormous number of compounds featuring the 4-coordinate group shown in structure (1) including the versatile nonaqueous solvent hexamethylphosphoramide (Me2N)3PO; this is readily made by reacting POCl3 with 6Me2NH, and dissolves metallic Na to give paramagnetic blue solutions similar to those in liquid NH3 (p. 77).

Another series includes the cyclo-metaphosphimic acids, which are tautomers of the cyclo-polyphosphazene hydroxides (p. 541). Similarly, halogen atoms in PX3 or other P–X compounds can be successively replaced by the isoelectronic groups –NH2, –NHR, –NR2, etc., and sometimes a pair of halogens can be replaced by =NH or =NR. These, in turn, can be used to prepare a large number of other derivatives as indicated schematically opposite for P(NMe2)3(2).

Although such compounds all formally contain P–N single bonds, they frequently display properties consistent with more extensive bonding. A particularly clear example is PF2(NMe2)

which features a short interatomic P–N distance and a planar N atom as indicated in the diagram below. (In the absence of this additional \(\pi\) bonding the PII–I N single-bond distance is close to 177 pm.) Again, the proton nmr of such compounds sometimes reveals restricted rotation about P–N at low temperatures and typical energy barriers to rotation (and coalescence temperatures of the non-equivalent methyl proton signals) are PCI2(NMe2) 35 kJ mol\(^{-1}\) (–120°), P(CF3)2(NMe2) 38 kJ mol\(^{-1}\) (–120°), PCIPh(NMe2) 50 kJ mol\(^{-1}\) (–50°).

Other unusual P/N systems which have recently been investigated include the crystalline compound HPN2, i.e. PN(NH), which is formed by ammonolysis of P3N5 at 580°C and which has a \(\beta\)-cristobalite (SiO2) type structure,(150) PNO (cf. N2O), which can be studied as a matrix-isolated species,(151) various phosphine azides, RR'PN3, and their reactions,(152) and numerous substituted phosphonyl triphenylphosphazenes, Ph3P=N–PX2, (X=Cl, F, OPh, SEt, NEt2, etc.)(153) The iminophosphenium ion, [ArN=PCI]\(^{+}\) (Ar = 2,4,6-Bu3C6H2) has been obtained as its pale yellow AlCl4\(^{-}\) salt by reaction of the corresponding covalently bonded chloride, ArN=PCI, with AlCl3; the ion is notable.

148 D. A. PALGRAVE, Section 28, pp. 760–815, in ref. 26
as the first stable species having a P≡N triple
bond (P–N 148 pm, angle C–N–P 177°).\textsuperscript{(154)}
The coordination chemistry of phosphorane imi-
nato complexes (containing the R₃PN⁻ ligand) of
transition metals has been reviewed.\textsuperscript{(155)}

\textbf{Cyclophosphazanes}

Many heterocyclic compounds contain for-
mally single-bonded P–N groups, the simplest
being the cyclo-diphosphazanes (X₃PNR)₂ and
[X(O,S)PNR]₂. These contain P⁵⁺ and have the
structures shown in Fig. 12.22. A few
phosph(III)azane dimers are also known, e.g.
(RPNR')₂. A more complex example, contain-
ing fused heterocycles of alternating P⁵⁺ and
N atoms, is the interesting hexamethyl deriva-
tive P₄(NMe)₆ mp 122°. This stable compound
(Fig. 12.23a) is readily obtained by reacting
PCI₃ with 6MeNH₂; it is isoelectronic with and
isostructural with P₄O₆ (p. 504) and undergoes
many similar reactions. The stoichiometrically
similar compound P₄(NPr')₆ can be prepared
in the non-adamantane-type structure shown in
Fig. 12.23b, though it converts to structure-type
a on being heated at 157° for 12 days.\textsuperscript{(158)} A
different sequence of atoms occurs in P₂(NMe)₆

\textsuperscript{156} O. J. Scherer, K. Andres, C. Kruger, Y.-H. Tsay and
Figure 12.22 Structures of (a) \((\text{Cl}_2\text{PNMe})_2\) and (b) \(\{\text{Cl(S)PNMe}\}_2\). Note the difference in length of the axial P–N and equatorial P–N bonds (and of the axial and equatorial P–Cl bonds) about the trigonal bipyramidal P atoms in (a).

Figure 12.23 Structures of (a) \(\text{P}_4(\text{NMe})_6\), (b) \(\text{P}_3(\text{NPri})_5\), and (c) \(\text{P}_2(\text{NMe})_6\) (see text).

(Fig. 12.23c) and many other "saturated" heterocycles featuring either P\(^{\text{III}}\) or P\(^{\text{V}}\) have been made. A typical example, made by slow addition of \(\text{PCl}_3\) to \(\text{PhNH}_2\) in toluene at 0\(^°\), is \([	ext{PhNHP}_2(\text{NPh})_2]\text{NPh}\); the crystal structure of the 1:1 solvate of this compound with \(\text{CH}_2\text{Cl}_2\) (mp 250\(^°\)) reveals that all N atoms are essentially planar with distances to P as indicated in the following diagram.\(^{157}\)

**Phosphazenes**

Formally "unsaturated" PN compounds are called phosphazenes and contain P\(^{\text{V}}\) in the
grouping \( \overset{\cdot}{P}=\overset{\cdot}{N}^{-} \). A few phosph(III)azenes are also known. Phosphazenes can be classified into monophosphazenes (e.g. \( X_3P=NR \)), diphosphazenes (e.g. \( X_3P=\overset{\cdot}{N}P(O)X_2 \)), polyphosphazenes containing 2,3,4,\ldots \infty \cdot X_3P=\overset{\cdot}{N}^{-} \) units, and the cyclo-polyphosphazenes \( [-X_2P=\overset{\cdot}{N}^{-} ]_n \), \( n = 3,4,5 \ldots 17 \).

Monophosphazenes, particularly those with organic substituents, \( R_3P=NR' \), derive great interest from being the N analogues of phosphorus ylides \( R_3P=CR_2 \) (p. 545). They were first made by H. Staudinger in 1919 by reacting an organic azide such as \( PhN_3 \) with \( PR_3 \) (\( R=Cl, OR, NR_2, Ar, \) etc.), e.g.:

\[
\begin{align*}
PPh_3 + PhN_3 & \rightarrow N_2 + Ph_3P=NPPh; \text{ mp } 132^\circ
\end{align*}
\]

More recently they have been made via a reaction associated with the name of A. V. Kirsanov (1962), e.g.:

\[
\begin{align*}
Ph_3PCl_2 + PhNH_2 & \rightarrow Ph_3P=NPPh + 2HCl
\end{align*}
\]

As expected, the \( P=N \) distance is short and the angle at \( N \) is \( \sim 120^\circ \), e.g. (a) and (b) above. Over 600 such compounds are now known, especially those with the \( Cl_3P=N^- \) group.\(^{158}\)

Diphosphazenes can be made by reacting \( PCl_3 \) with \( NH_4Cl \) in a chlorohydrocarbon solvent under mild conditions:

\[
3PCl_5 + NH_4Cl \rightarrow 4HCl
\]

\[
+ [Cl_3P=N=PCl_3]^+PCl_6^-; \text{ mp } 310^\circ
\]

\[
4HCl + [Cl_3P=N\cdotPCl_2=N\cdotPCl_3]^+Cl^-;
\]

The inverse of these compounds are the phosphadiazene cations, prepared by halide ion abstraction from diaminohalophosphoranes in \( CH_2Cl_2 \) or \( SO_2 \) solution, e.g.:

\[
(R_2N)_2PCl + AlCl_3 \rightarrow [(R_2N)_2P]^+[AlCl_4^-]
\]

An X-ray crystal structure of the \( Pr_3N \)-derivative shows the presence of a bent, 2-coordinate \( P \) atom, equal \( P-N \) distances, and accurately planar 3-coordinate \( N \) atoms as in (c) above.\(^{159}\) In liquid ammonia ammonolysis also occurs:

\[
2PCl_5 + 16NH_3(\text{liq.}) \rightarrow
\]

\[
[(H_2N)_3P=N-P(NH_2)_3]^+Cl^- + 9NH_4Cl
\]

The \( P=N \) and \( P-N \) bonds are equivalent in these compounds and they could perhaps better be written as \( [X_3P:=-N:=-PX_3]^+ \), etc. Like the parent phosphorus pentahalides (p. 498), these diphosphazenes can often exist in ionic and covalent forms and they are part of a more extended group of compounds which can be classified into several general series \( Cl(Cl_2PN)_nPCl_4, [Cl(Cl_2PN)_nPCl_3]^+Cl^- \),

\(^{158}\) M. BERMANN, \textit{Topics in Phosphorus Chemistry} 7, 311 - 78, 1972.

Some of these can exist in the ionic form represented by the second series (d):

\[ [\text{Cl}(-\text{P} \equiv \text{N})_{n}\text{Cl}]^{+}\text{Cl}^{-} \quad [\text{Cl}(-\text{P} \equiv \text{N})_{n}\text{Cl}]^{+}\text{Cl}^{-} \]

(b) (e)

Likewise, the third series runs from \( n = 0 \) (i.e. \( \text{PCL}_{4}^{+}\text{PCL}_{6}^{-} \) through \( \text{P}_{3}\text{NCl}_{12}, \text{P}_{4}\text{N}_{2}\text{Cl}_{14} \), and \( \text{P}_{5}\text{N}_{3}\text{Cl}_{16} \) to \( \text{P}_{6}\text{N}_{4}\text{Cl}_{18} \) (e). In the limit, polymeric phosphazene dichlorides are formed \((-\text{NPCl}_{2}^{-})_{n}\), where \( n \) can exceed \( 10^{4} \) and these polyphosphazenes and their cyclo-analogues form by far the most extensive range PN compounds.

**Preparation and structure.** Polyphosphazenes have a venerable history. \( \text{NPCl}_{2} \) oligomers were first made in 1834 by J. von Liebig and F. Wöhler who reacted \( \text{PCl}_{5} \) with \( \text{NH}_{3} \), but their stoichiometry and structure were not elucidated until much later. The fluoro analogues \( \text{NPBr}_{2} \) were first made in 1956 and the bromo compounds \( \text{NPBr}_{2} \) in 1960. The synthesis of \( \text{NPCl}_{2} \) was much improved by R. Schenk and G. Römer in 1924 and their method remains the basis for present-day production on both the laboratory and industrial scales:

\[
n\text{PCl}_{5} + n\text{NH}_{3} \overset{\text{solvent}}{\underset{120-150^\circ}{\longrightarrow}} \text{NPCl}_{2} + 4n\text{HCl}
\]

Appropriate solvents are 1,1,2,2-tetrachloroethane (bp 146°), \( \text{PhCl} \) (bp 132°) and 1,2-dichlorobenzene (bp 179°). By varying the conditions, yields of the cyclic trimer or tetramer and other oligomers can be optimized and the compounds then separated by fractionation. Highly polymeric \( \text{NPCl}_{2} \infty \) can be made by heating cyclo-(\text{NPCl}_{2})_{3} to 150–300°, though heating to 350° induces depolymerization. Polycyclic compounds are rarely obtained in

---

these preparations, one exception being N7P6Cl9, mp 237.5°, which can be obtained in modest yields from the direct thermolytic reaction of PCl5 and NH4Cl. The tricyclic structure is strongly distorted from planarity though the central NP3 group features an accurately planar 3-coordinate N atom with much longer N-P bonds than those in the peripheral macrocycle. The 2 sorts of P-Cl bonds are also noticeably different in length and the 3 central Cl atoms are all on one side of the NP3 plane with \( \angle \text{NPCl}_1 \) 104°.

Many details of the preparative reaction mechanism remain unclear but it is thought that NH4Cl partly dissociates into NH3 and HCl, and that PCl5 reacts in its ionic form \( \text{PCl}_4^+ \text{PCl}_6^- \) (p. 499). Nucleophilic attack by NH3 on \( \text{PCl}_4^+ \) then occurs with elimination of HCl and the \([\text{HN} = \text{PCl}_3]^+ \) attacks a second \( \text{PCl}_4^+ \) to give \([\text{Cl}_3\text{P} = \text{N} - \text{PCl}_3]^+ \) and HCl. After 1 h the major (insoluble) intermediate product is \([\text{Cl}_3\text{P} = \text{N} - \text{PCl}_3]^+ \text{PCl}_6^- \) (i.e. P3NCI12, p. 536) and this then slowly reacts with more NH3 to give HCl and \([\text{Cl}_3\text{P} = \text{N} - \text{PCl}_2 = \text{NH}] \), etc. It is probable that NH4Br and PBr4+Br- react similarly to give \((\text{NPBr}_2)_n \), but NH4F fluorinates PCl5 to NH4PF4 and the fluoroanalogues \((\text{NPF}_2)_n \) are best prepared by fluorinating \((\text{NPCl}_2)_n \) with KSO3F/9SO2 (i.e. KF in liquid SO2). Similarly, standard substitution reactions lead to many derivatives in which all (or some) of the Cl atoms are replaced by OMe, OEt, OCH2CF3, OH, NHPh, NMe2, NR2, R, Ar, etc. Partial replacement leads to geminal derivatives (in which both Cl atoms on 1 P atom are replaced) and to non-geminal derivatives which, in turn, can exist as cis- or trans- isomers.

The cyclic trimer \((\text{NPF}_2)_3 \), mp 28°, has an accurately planar 6-membered ring \((D_{3h} \text{ symmetry}) \) in which all 6 P-N distances are equal (156 pm) and the angles NPN and PNP are all 120 ±1°. Most other trimers are also more-or-less planar with equal P-N distances: for example, \((\text{NPCl}_2)_3 \) is almost planar (pseudo-chair with P-N 158 pm, P-Cl 197 pm, \( \angle \text{NPN} \) 118.4°, \( \angle \text{PNP} \) 121.4°, \( \angle \text{ClPCl} \) 102°. Perhaps surprisingly, the cyclic tetramer \((\text{NPF}_2)_4 \), mp 30.4°, is also a planar heterocycle \((D_{4h} \text{ symmetry}) \) with even shorter P-N bonds (151 pm) and with ring angles of 122.7° and 147.4° at P and N respectively. However, other conformations are found in other derivatives, e.g. chair (C2h), saddle \((D_2d) \), boat \((S_4) \), crown tetrmeric \((C_4v) \) and hybrid. Thus \((\text{NPCl}_2)_4 \) exists in the metastable K form (in which it has the boat conformation) and the stable T form (chair configuration) as shown in Fig. 12.24. The remarkable diversity of molecular conformations observed for the 8-membered heterocycle \{(P4N4)\} suggests that the particular structure adopted in each case results from a delicate balance of intra- and intermolecular forces including the details of skeletal bonding, the orientation of substituents and their polar and steric nature, crystal-packing effects, etc. The mps for various series of cyclo-\((\text{NPX}_2)_n \) frequently show an alternation, with values for \( n \) even being greater than those for adjacent \( n \) odd. Some examples are in Fig. 12.25. The crystal structures of the four compounds \((\text{NPMe}_2)_9 \)–12 have recently been determined.\(^{162}\)

**Bonding.** All phosphazeneces, whether cyclic or chain, contain the formally unsaturated

\[
\begin{array}{c}
\text{X} \\
\text{X}
\end{array}
\]

with 2-coordinate N and

---

4-coordinate P. The experimental facts that have to be interpreted by any acceptable theory of bonding are:

(i) the rings and chains are very stable;
(ii) the skeletal interatomic distances are equal around the ring (or along the chain) unless there is differing substitution at the various P atoms;
(iii) the P–N distances are shorter than expected for a covalent single bond (~177 pm) and are usually in the range 158 ± 2 pm (though bonds as short as 147 pm occur in some compounds);
(iv) the N–P–N angles are usually in the range 120 ± 2° but the P–N–P angles in various compounds span the range from 120-148.6°;
(v) skeletal N atoms are weakly basic and can be protonated or form coordination complexes, especially when there are electron-releasing groups on P;
(vi) unlike many aromatic systems the phosphazene skeleton is hard to reduce electrochemically;
(vii) spectral effects associated with organic π-systems (such as the bathochromic ultraviolet shift that accompanies increased electron delocalization) are not found.

*Figure 12.24* Molecular structure and dimensions of the two forms of (NPCl₂)₄ and of (NPCl₂)₅.

*Figure 12.25* Melting points of various series of cyclo-polyphosphazenes (NPX₂)ₙ showing the higher values for n even.

In short, the bonding in phosphazenes is not adequately represented by a sequence of alternating double and single bonds –N=P–N=P– yet it
differs from aromatic $\sigma-\pi$ system in which there is extensive electron delocalization via $p_\pi-p_\pi$ bonding. The possibility of $p_\pi-d_\pi$ bonding in N–P systems has been considered by many authors since the mid-1950s but there is still no consensus, and for nearly every argument that can be mounted in favour of $P(3d)$-orbital contributions another can be raised against it. It seems generally agreed that 2 electrons on N occupy an $sp^2$ lone-pair in the plane of the ring (or the plane of the local PNP triangle) as in Fig. 12.26a. The situation at P is less clear mainly because of uncertainties concerning the d-orbital energies and the radial extent (size) of these orbitals in the bonding situation (as distinct from the free atom). In so far as symmetry is concerned, the $sp^2$ lone-pair on each N can be involved in coordinate bonding in the $xy$ plane.
and HClO₄; compounds with alkyl or NR₂ substituents on P are more basic than the halides, as expected, and their adducts with HCl have been well characterized. There is usually a substantial lengthening of the two N--P bonds adjacent to the site of protonation and a noticeable contraction of the next-nearest N--P bonds. For example, the relevant distances in [HN₃P₃Cl₂(NHP₃)₄]Cl and the parent compound are:

![Image](https://via.placeholder.com/150)

**Figure 12.27** (a) Schematic representation of possible 3-centre islands of π bonding above and below the ring plane for (NPX₂). (b) Experimental electron bonding density study on benzene clathrate of hexa(1-aziridinyl)cyclotriphosphazene, 2(CH₂CH₂N)₆-P₃N₃C₆H₆. The possibility of exocyclic π bonding between P(dₓ²) and appropriate orbitals on the substituents X has also been envisaged.

### Reactions

The N atom in cyclo-polyporphazenes can act as a weak Brønsted base (proton acceptor) towards such strong acids as HF and HClO₄; compounds with alkyl or NR₂ substituents on P are more basic than the halides, as expected, and their adducts with HCl have been well characterized. There is usually a substantial lengthening of the two N--P bonds adjacent to the site of protonation and a noticeable contraction of the next-nearest N--P bonds. For example, the relevant distances in [HN₃P₃Cl₂(NHP₃)₄]Cl and the parent compound are:

**Cyclo-polyporphazenes** can also act as Lewis bases (N donor-ligands) to form complexes such as [TiCl₄(N₃P₃Me₆)]⁻, [SnCl₄(N₃P₃Me₆)]⁻, [AlBr₃(N₃P₃Br₆)]⁻ and [AlBr₃(N₃P₃Br₄)]⁻. Not all such adducts are necessarily ring-N donors and the 1:1 adduct of (NPCl₂)₃ with AlCl₃ is thought to be a chloride ion donor, [N₃P₃Cl₅]⁺ [AlCl₄]⁻. By contrast, the complex [PtCl₄(MeCN)] [N₃P₃(η²-N₂P₃)]-MeCN features transannular bridging of 2 N atoms by the PtCl₂ moiety. An intriguing example of a cyclo-polyporphazene acting as a multidentate macrocyclic ligand occurs in the bright orange complex formed when N₆P₆(NMe₂)₂ reacts with equal amounts of CuCl₂ and CuCl. The crystal structure of

---

Figure 12.28 Structure of (a) the free ligand \( \text{N}_6\text{P}_6(\text{NMe}_2)_{12} \), and (b) the \( \eta^4 \) complex cation \([\text{CuCl}[\text{N}_6\text{P}_6(\text{NMe}_2)_{12}]]^+\) showing changes in conformation and interatomic distances in the phosphazene macrocycle. The Cl is obscured beneath the Cu and can be regarded as occupying either the apical position of a square pyramid or, since \( \angle\text{N}(1)-\text{Cu}-\text{N}(1') \) is large (160.9°), an equatorial position of a distorted trigonal bipyramid. Note that coordination tightens the ring, already somewhat crowded in the uncomplexed state, the mean angles at P being reduced from 120.0° to 107.5°, and the mean angles at N being reduced from 147.5° to 133.6°. The lengthening of the 8 P–N bonds contiguous to the 4 donor N atoms from 156 to 162 pm is significant, the other P–N distances (mean 156 pm) remaining similar to those in the free ligand.

The resulting \([\text{N}_6\text{P}_6(\text{NMe}_2)_{12}\text{CuCl}][\text{CuCl}_2]^+\) has been determined (Fig. 12.28b) and detailed comparison with the conformation and interatomic distances in the parent heterocycle (Fig. 12.28a) gives important clues as to the relative importance of the various \( \pi \) and \( \pi' \) bonding interactions involving N (and P) atoms.\(^{166}\) Incidentally, the compound also affords the first example of the linear 2-coordinate Cu\(^1\) complex \([\text{CuCl}_2]^-\). The related (and more extensive) organometallic chemistry of the phosphazenes has been reviewed.\(^{167}\)

As P is isoelectronic with N, it has been found possible to prepare 8-membered diazahexaphosphophocins such as \([\text{NPPh}_2\text{PPh}_2\text{NPPh}_2\text{PPh}_2]^+\), analogous to \((\text{NPPh}_2)_4\).\(^{168}\) The two subrogated P atoms can chelate to PdCl\(_2\) to form a square planar complex.\(^{169}\)

Many of the cyclic and chain dichloro derivatives \((\text{NPCl}_2)_n\) can be hydrolysed to \( n \)-basic acids and the lower members form well-defined salts frequently in the tautomeric metaphosphimic-acid form, e.g.:

\[
\begin{align*}
\text{OH} & \quad \text{OH} \\
\text{N} & \quad \text{P} \\
3_4 & \quad 3_4
\end{align*}
\]

The dihydrate of the tetramer is particularly stable and is, in fact, the bishydroxonium salt of tetrametaphosphamic acid $[\text{H}_3\text{O}]_2^+[(\text{NH}_4)_4\text{P}_4\text{O}_6(\text{OH})_2]^{2-}$, the anion of which has a boat configuration and is linked by short H bonds (246 pm) into a two-dimensional sheet (Fig. 12.29). The related salts $\text{M}_n[(\text{NHPO}_2)_4]_2\cdot n\text{H}_2\text{O}$ show considerable variation in conformation of the tetrametaphosphate anion, as do the 8-membered heterocyclic tetraphosphazenes $(\text{NPX}_2)_4$ (p. 537), e.g.

$[\text{NH}_4]_4[\text{N}_4\text{H}_4\text{P}_4\text{O}_8].2\text{H}_2\text{O}$  boat conformation

$\text{K}_4[\text{N}_4\text{H}_4\text{P}_4\text{O}_8].4\text{H}_2\text{O}$  chair conformation

$\text{Cs}_4[\text{N}_4\text{H}_4\text{P}_4\text{O}_8].6\text{H}_2\text{O}$  saddle conformation.

Figure 12.29  Schematic representation of the boat-shaped anion $[(\text{NH})_4\text{P}_4\text{O}_6(\text{OH})_2]^{2-}$ showing important dimensions and the positions of H bonds.

Applications. Many applications have been proposed for polyphosphazenes, particularly the non-cyclic polymers of high molecular weight, but those with the most desirable properties are extremely expensive and costs will have to drop considerably before they gain widespread use (cf. silicones, p. 365). The cheapest compounds are the chloro series $(\text{NPCl}_2)_n$ but these readily hydrolyse in moist air to polymetaphosphimic acids. Greater stability is displayed by amino, alkoxy, phenoxy and especially fluorinated derivatives, and these are attracting increasing interest as rigid plastics, elastomers, plastic films, extruded fibres and expanded foams.$^{160,170}$ Such materials (MW > 500 000) are water-repellent, solvent-resistant, flame-resistant and flexible at low temperatures (Fig. 12.30). Possible applications are as fuel hoses, gaskets and O-ring seals for use in high-flying aircraft or for vehicles in Arctic climates. Their extraordinary dielectric strength makes them good candidates for metal coatings and wire insulation. Other applications of polyphosphazenes include their use to improve the high-temperature properties of phenolic resins and their use as composites with asbestos or glass for non-flammable insulating material. Some of the more reactive derivatives have been proposed as pesticides and even as ultra-high capacity fertilizers.

12.3.8 Organophosphorus compounds

A general treatment of the vast domain of organic compounds of phosphorus$^{171}$ falls outside the scope of this book though several important classes of compound have already been briefly mentioned, e.g. tertiary phosphine ligands (p. 494), alkoxyphosphines and their derivatives (p. 496), organophosphorus halides (p. 500), phosphate esters in life processes (p. 528) and organic derivatives of PN compounds (preceding section). There are also innumerable organic derivatives of the polycyclic polyphosphanes (p. 495),$^{67,70,172}$ and vast numbers of heterocyclic organophosphorus compounds.

---

(b) Fibres of poly[bis(trifluoroethoxy)phosphazene]; these fibres are water-repellent, resistant to hydrolysis or strong sunlight, and do not burn. (c) Cotton cloth treated with a poly(flouroalkoxyphosphazene) showing the water repellancy conferred by the phosphazene. (d) Polyphosphazene elastomers are now being manufactured for use in fuel lines, gaskets, O-rings, shock absorbers, and carburettor components; they are impervious to oils and fuels, do not burn, and remain flexible at very low temperatures. Photographs by courtesy of H. R. Allcock (Pennsylvania State University) and the Firestone Tire and Rubber Company.
compounds.\(^{173,174}\) Within the general realm of organic compounds of phosphorus it is convenient to distinguish organophosphorus compounds as a particular group, i.e. those which contain one or more direct P–C bond. In such compounds the coordination number of P can be 1, 2, 3, 4, 5 or 6 (p. 484). Examples of coordination number 1 were initially restricted to the relatively unstable compounds HCP, FCP and MeCP (cf. HCN, FCN and MeCN). HC\(\equiv\)P was first made in 1961 by subjecting PH\(_3\) gas at 40 mmHg pressure to a low-intensity rotating arc struck between graphite electrodes;\(^{175}\) it is a colourless, reactive gas, stable only below its triple point of \(-124^\circ\) (30 mmHg). Monomeric HCP slowly polymerizes at \(-130^\circ\) (more rapidly at \(-78^\circ\)) to a black solid, and adds 2HCl at \(-110^\circ\) to give MePCl\(_2\) as the sole product. Both monomer and polymer are pyrophoric in air even at room temperature. More recently\(^{176}\) MeCP was made by pyrolysing MeCH\(_2\)PCl\(_2\) at 930° in a low-pressure flow reactor and trapping the products at \(-78^\circ\). Dramatic stabilization of a phospha-alkyne has been achieved by \(\eta^2\)-complexation to a metal centre:\(^{177}\)

\[
\text{Bu'C\(\equiv\)P} + [\text{Pt(C}_2\text{H}_4)(\text{PPh}_3)_2] \xrightarrow{\text{room temp}} \text{C}_2\text{H}_4
\]

\[
+ [\text{Pt(\(\eta^2\)-Bu'C)}\text{P})(\text{PPh}_3)_2].\text{C}_6\text{H}_6
\]

The translucent, cream-coloured benzene solvate was characterized by single-crystal X-ray analysis and by \(\text{^31P} \text{nmr spectroscopy. The first free phospha-alkyne stable to polymerization was Bu'C\(\equiv\)P,}^{178}\) and its chemistry has been extensively investigated.\(^{179,180}\) The similarly bulky ArC\(\equiv\)P (Ar = 2,4,6-\text{Bu'C}_6\text{H}_3)\(_2\) has been studied by X-ray crystallography\(^{182}\) and the C–P distance found to be 152 pm, similar to the short C–P distance of 154 pm deduced from the microwave spectrum of HCP and MeCP. The most studied reactions of phospha-alkynes are cyclo-additions to give organo-P heterocycles,\(^{179–181}\) and reactions with nucleophiles to give phospha-alkenes and 1,3-diphosphabutadienes.\(^{183}\)

As with coordination number 1, the first 2-coordinate P compound also appeared in 1961:\(^{183}\) Me\(_3\)P=PCF\(_3\) was made as a white solid by cleaving cyclo-\(\text{[P(CF}_3\text{)]}_4\) or \(_5\) with PMe\(_3\); it is stable at low temperatures but readily dissociates into the starting materials above room temperature. More stable is the bent 2-coordinate phosphocation occurring in the orange salt\(^{184}\)

The aromatic heterocycle phosphabenzene C\(_5\)H\(_5\)P (analogous to pyridine) was reported in 1971,\(^{185}\) some years after its triphenyl derivative 2,4,6-\text{Ph}_3C\equiv\text{H}_2P. See also HP=CH\(_2\)\(^{29}\) and \([\text{P(CN)}_2]\)\(^{-}\)\(^{30}\) (p. 484). The burgeoning field of heterocyclic phosphorus compounds featuring

\[^{175} T. E. \text{GER, J. Am. Chem. Soc. 83, 1769–70 (1961).}
\[^{181} R. \text{BARTSCH and J. F. NIXON, Polyhedron, 8, 2407 (1989).}
\[^{183} A. \text{BURG and W. MAHLER, J. Am. Chem. Soc. 83, 2388–9 (1961).}
2-coordinate and 3-coordinate P has been fully reviewed,\(^{173,174}\) as has the equally active field of phospha-alkenes \((-\text{P}==\text{C}\langle\rangle)\) and diphosphenes \((-\text{P}==\text{P}-)\).\(^{179,180,186,187}\)

The most common coordination numbers for organophosphorus compounds are 3 and 4 as represented by tertiary phosphines and their complexes, and quaternary cations such as \([\text{PMe}_4]^+\) and \([\text{PPPh}_4]^+\). Also of great significance are the 4-coordinate P ylides\(^\dagger\) \(\text{R}_3\text{P}==\text{CH}_2\); indeed, few papers have created so much activity as the report by G. Wittig and G. Geissler in 1953 that methylene triphenylphosphorane reacts with benzophenone to give \(\text{Ph}_3\text{PO}\) and 1,1-diphenylethylene in excellent yield.\(^{188}\)

\[\text{Ph}_3\text{P}==\text{CH}_2 + \text{Ph}_2\text{CO} \rightarrow \text{Ph}_3\text{PO} + \text{Ph}_2\text{C}==\text{CH}_2\]

The ylide \(\text{Ph}_3\text{P}==\text{CH}_2\) can readily be made by deprotonating a quaternary phosphonium halide with \(n\)-butyllithium and many such ylides are now known:

\[ [\text{Ph}_3\text{PCH}_3]^+\text{Br}^- \xrightarrow{\text{LiBu}^n} \text{Ph}_3\text{P}==\text{CH}_2 \]

\(+ \text{LiBr} + \text{Bu}^n\text{H} \]

\[ [\text{PMe}_4]^+\text{Br}^- + \text{NaNH}_2 \xrightarrow{\text{thf}/0^\circ} \text{Me}_3\text{P}==\text{CH}_2 \]

\(+ \text{NaBr} + \text{NH}_3 \]

The enormous scope of the Wittig reaction and its variants in affording a smooth, high-yield synthesis of \(\text{C}==\text{C}\) double bonds, etc., has been amply delineated by the work of Wittig and others and culminated in the award of the 1979 Nobel Prize for Chemistry (jointly with H. C. Brown for hydroboration, p. 166). The reaction of P ylides with many inorganic compounds has also led to some fascinating new chemistry.\(^{189}\) The curious yellow compound \(\text{Ph}_3\text{P}==\text{C}==\text{PPh}_3\) should also be noted:\(^{190}\) unlike allene, \(\text{H}_2\text{C}==\text{C}==\text{H}_2\), which has a linear central carbon atom, the molecules are bent and the structure is strikingly unusual in having 2 crystallographically independent molecules in the unit cell which have substantially differing bond angles, 130.1° and 143.8°. The short \(\text{P}==\text{C}\) distances (163 pm as compared with 183.5 pm for \(\text{P}==\text{C(Ph)}\) suggest double bonding, but the nonlinear \(\text{P}==\text{C}==\text{P}\) unit and especially the two values of the angle, are hard to rationalize (cf. the isoelectronic cation \([\text{Ph}_3\text{P}==\text{N}==\text{PPh}_3]^+\) which has various angles in different compounds).

Pentaorgano derivatives of P are rare. The first to be made (by G. Wittig and M. Rieber in 1948) was \(\text{PPPh}_5\):

\[ \text{Ph}_3\text{PO} \xrightarrow{(1) \text{LiPh}} [\text{PPh}_4]^+\text{Cl}^- \xrightarrow{(2) \text{HCl}} \]

\[ [\text{PPh}_4]^+\text{I}^- \xrightarrow{\text{LiPh}} \text{PPh}_5 \text{ (d. 124°)} \]

Unlike \(\text{SbPh}_5\) (which has a square-pyramidal structure p. 598), \(\text{PPPh}_5\) adopts a trigonal bipyramidal coordination with the axial \(\text{P}==\text{C}\) distances (199 pm) being appreciably longer than the equatorial \(\text{P}==\text{C}\) distances (185 pm). More recently (1976) \(\text{P(CF}_3)_2\text{Me}_2\) and \(\text{P(CF}_3)_2\text{Me}_3\) were obtained by methylating the corresponding chlorides with \(\text{PbMe}_4\). There are also many examples of 5-coordinate P in which not all the directly bonded atoms are carbon. One such is the dioxaphenylspiro-phosphorane shown in Fig. 12.31; the local symmetry about P is essentially square pyramidal, and the factors which affect the choice between this geometry and trigonal bipyramidal is a topic of active

\(^{187}\) N. C. NORMAN, Polyhedron 12, 2431-6 (1993).

\(^\dagger\) An ylide can be defined as a compound in which a carb-anion is attached directly to a heteroatom carrying a high degree of positive charge:

\[
\begin{align*}
\text{C}^- & \text{X}^+ \\
\text{C}==\text{X} & \\
\end{align*}
\]

Thus \(\text{Ph}_3\text{P}==\text{CH}_2\) is triphenylphosphonium methylide (see pp. 274-304 of reference 2, or textbooks of organic chemistry for a fuller treatment of the Wittig reaction).

\(^{188}\) G. WITTIG and G. GEISSLER, Annalen 580, 44-57 (1953).

Figure 12.31 Schematic representation of the molecular structure of [P(C,HMe,)(O,C,b)Ph] showing the rectangular-based pyramidal disposition of the 5 atoms bonded to P; the P atom is 44 pm above the C2O2 plane.

current interest.(39,191) It should also be noted that the compounds, Ph3PBr2 and Ph3PI2, which might have been thought to involve 5-coordinate P, feature instead 4-coordinate P and an unusual end-on bonding of the dihalogen moiety, i.e. Ph3P–Br–Br,192 and Ph3P–I–I.(193) The corresponding interhalogen adducts Ph3PIX (X = Cl, Br) appear to be 4-coordinate but ionic, i.e. [Ph3PI]+X−.(194)

Many organophosphorus compounds are highly toxic and frequently lethal. They have been actively developed for herbicides, pesticides and more sinister purposes such as nerve gases which disorient, harass, paralyse or kill.(9)

13
Arsenic, Antimony and Bismuth

13.1 Introduction

The three elements arsenic, antimony and bismuth, which complete Group 15 of the periodic table, were amongst the earliest elements to be isolated and all were known before either nitrogen (1772) or phosphorus (1669) had been obtained as the free elements. The properties of arsenic sulfide and related compounds have been known to physicians and professional poisoners since the fifth century BC though their use is no longer recommended by either group of practitioners. Isolation of the element is sometimes credited to Albertus Magnus (AD 1193–1280) who heated orpiment (As₂S₃) with soap, and its name reflects its ancient lineage. [Arsenic, Latin arsenicum from Greek ἄρσενικόν (arsenicon) which was itself derived (with addition of ōn) from Persian az-zarnikh, yellow orpiment (zar = gold).] Antimony compounds were also known to the ancients and the black sulfide, stibnite, was used in early biblical times as a cosmetic to darken and beautify women’s eyebrows; a rare Chaldean vase of cast antimony dates from 4000 BC and antimony-coated copper articles were used in Egypt 2500–2200 BC. Pliny (~AD 50) gave it the name stibium and writings attributed to Jabir (~AD 800) used the form antimonium; indeed, both names were used for both the element and its sulfide until the end of the eighteenth century (Lavoisier). The history of the element, like that of arsenic, is much obscured by the intentionally vague and misleading descriptions of the alchemists, though the elusive Benedictine monk Basil Valentine may have prepared it in 1492 (about the time of Columbus). N. Lémery published his famous Treatise on Antimony in 1707. Bismuth was known as the metal at least by 1480 though its previous history in the Middle Ages is difficult to unravel because the element was sometimes confused with Pb, Sn, Sb or even Ag. The Gutenberg printing presses (1440 onwards) used type that had been cut from brass or cast from Pb, Sn or Cu, but about 1450 a secret method of casting type from Bi alloys came into use and this particular use is still an important application of the element (p. 549). The name derives from the German Wismut (possibly white metal or meadow mines) and this was latinized to bisemutum by the sixteenth-century German scientist G. Bauer (Agricola) about 1530. Despite the difficulty of
assigning precise dates to discoveries made by alchemists, miners and metal workers (or indeed even discerning what those discoveries actually were), it seems clear that As, Sb and Bi became increasingly recognized in their free form during the thirteenth to fifteenth centuries; they are therefore contemporary with Zn and Co, and predate all other elements except the 7 metals and 2 non-metallic elements known from ancient times (Au, Ag, Cu, Fe, Hg, Pb, Sn; C and S).

Arsenic and antimony are classed as metalloids or semi-metals and bismuth is a typical B subgroup (post-transition-element) metal like tin and lead.

### 13.2 The Elements

#### 13.2.1 Abundance, distribution and extraction

None of the three elements is particularly abundant in the earth’s crust though several minerals contain them as major constituents. As can be seen from Table 13.1, arsenic occurs about halfway down the elements in order of abundance, grouped with several others near 2 ppm. Antimony has only one-tenth of this abundance and Bi, down by a further factor of 20 or more, is about as unabundant as several of the commoner platinum metals and gold. In common with all the post-transition-element metals, As, Sb and Bi are chalcophiles, i.e. they occur in association with the chalcogens S, Se and Te rather than as oxides and silicates.

Arsenic minerals are widely distributed throughout the world and small amounts of the free element have also been found. Common minerals include the two sulfides realgar (As₄S₄) and orpiment (As₂S₃) and the oxidized form arsenolite (As₂O₃). The arsenides of Fe, Co and Ni and the mixed sulfides with these metals form another set of minerals, e.g. loellingite (FeAs₂), safforlote (CoAs), niccolite (NiAs), rammelsbergite (NiAs₂), arsenopyrite (FeAsS), cobaltite (CoAsS), enargite (Cu₃AsS₄), gersdorffite (NiAsS) and the quaternary sulfide glaucodot [(Cu,Fe)AsS]. Elemental As is obtained on an industrial scale by smelting FeAs₂ or FeAsS at 650–700°C in the absence of air and condensing the sublimed element: FeAsS → FeS + As(g) → As(s). Residual As trapped in the sulfide residues can be released by roasting them in air and trapping the sublimed As₂O₃ in the flue system. The oxide can then either be used directly for chemical products or reduced with charcoal at 700–800° to give more As. As₂O₃ is also obtained in large quantities as flue dust from the smelting of Cu and Pb concentrates; because of the huge scale of these operations (pp. 1174, 371) this represents the most important industrial source of As. Some production figures and major uses of As and its compounds are listed in the Panel.

Stibnite, Sb₂S₃, is the most important ore of antimony and it occurs in large quantities in China, South Africa, Mexico, Bolivia and Chile. Other sulfide ores include ullmanite (NiSbS), livingstonite (HgSb₄S₈), tetrahedrite (Cu₃SbS₃), wolfsbergite (CuSbS₂) and jamesonite (FePb₄Sb₆S₁₄). Indeed, complex ores containing Pb, Cu, Ag and Hg are an important industrial source of Sb. Small amounts of oxide minerals formed by weathering are also known, e.g. valentinite (Sb₂O₃), cervantite (Sb₂O₄) and stibiconite (Sb₂O₄·H₂O), and minor finds of native Sb have occasionally been reported. Commercial ores have 5–60% Sb, and recovery methods depend on the

Abundance, distribution and extraction

Production and Uses of Arsenic, Antimony and Bismuth\(^{(2)}\)

Until the late 1980s the USA was the principal supplier of “white arsenic” (i.e. As\(_2\)O\(_3\)) but it now relies entirely on imports. World production has been steady for many years at about 52,000 tonnes per annum and the main producers are France (10,000 tpa), Sweden (10,000 tpa), Russia (8,000 tpa) and Chile (7,000 tpa). The price of refined oxide was about $480 per tonne in 1989 and commercial grade As metal (99.9%+) was about $2.20/kg in 1990. High purity As (99.99%+) was $45.00/kg and zone-refined semiconductor grade even more expensive.

The main use of elemental As is in alloys with Pb and to a lesser extent Cu. Addition of small concentrations of As improves the properties of Pb/As for storage batteries (see below), up to 0.75% improves the hardness and castability of type metal, and 0.5–2.0% improves the sphericity of Pb ammunition. Automotive body solder is Pb (92%), Sb (5.0%), Sn (2.5%) and As (0.5%). Intermetallic compounds with Al, Ga and In give the III–V semiconductors (p. 255) of which GaAs and InAs are of particular value for light-emitting diodes (LEDs), tunnel diodes, infrared emitters, laser windows and Hall-effect devices (p. 258).

The use of As compounds as herbicides and pest controls in agriculture is now considerably restricted because of environmental considerations though arsenic acid itself, AsO(OH)\(_3\), is still used in the formulation of wood preservatives. The oxide is widely used to decolorize glass.

World production capacity for antimony and its compounds (as contained Sb) was 116,000 tonnes in 1988, plus a similar amount of secondary (recycled) Sb obtained by smelting. However, actual production was somewhat below this. Typical prices (1988) were $3.50/kg for high-grade Sb\(_2\)O\(_3\) and $2.30/kg for 99.5%+ Sb metal ($1.80/kg in 1990). Lead storage batteries use alloys containing 2.5–3% Sb and a trace of As, to minimize self-discharge, gassing and poisoning of the negative electrode. Other typical uses of Sb alloys in the USA, 1975 (tonnes of contained Sb), are shown in the Table.

As with arsenic, semiconductor grade Sb is prepared by chemical reduction of highly purified compounds. AlSb, GaSb and InSb have applications in infrared devices, diodes and Hall-effect devices. ZnSb has good thermoelectric properties. Applications of various compounds of Sb will be mentioned when the compounds themselves are discussed.

World annual production of bismuth and its compounds has hovered around 4000 tonnes of contained Bi for many years and a similar amount of secondary (refinery) Bi is also produced. Production has been dominated by China, Japan, Peru, Bolivia, Mexico, Canada, USA and Australia which, between them, account for almost all supplies. Prices for the free element have fluctuated wildly since the 1970s, from <$4.00/kg to >$44.00/kg; at the end of 1990 it was $6.30/kg. Consumption of the metal and its compounds has also been unusual, usage in the USA dropping by a factor of 2 from 1973 to 1975, for example. The main uses are in pharmaceuticals, fusible alloys (including type metal, p. 547), and metallurgical additives.

No industrial poisoning by Bi metal has ever been reported but ingestion of compounds and inhalation of dust should be avoided.

\(^{(2)}\) Kirk-Othmer Encyclopedia of Chemical Technology, 4th edn., Vol. 3, Wiley, New York, 1992; Arsenic and arsenic alloys (pp. 624–33); Arsenic compounds (633–59); Antimony and antimony alloys (367–81); Antimony compounds (382–412); Bismuth and bismuth alloys (Vol. 4, 1992 (pp. 237–45); Bismuth compounds (246–70).
Cu; the latter two can be removed by stibnite treatment or heating with charcoal/Na₂SO₄ flux; the As and S can be removed by an oxidizing flux of NaNO₃ and NaOH (or Na₂CO₃); Pb is hard to remove but this is unnecessary if the Sb is to be used in Pb alloys (see below). Electrolysis yields >99.9% purity and remaining impurities can be reduced to the ppm level by zone refining. The scale of production and the various uses of Sb and its compounds are summarized in the Panel.

Bismuth occurs mainly as bismite (α-Bi₂O₃), bismuthinite (Bi₂S₃) and bismutite [(BiO)₂CO₃]; very occasionally it occurs native, in association with Pb, Ag or Co ores. The main commercial source of the element is as a byproduct from Pb/Zn and Cu plants, from which it is obtained by special processes dependent on the nature of the main product. Sulfide ores are roasted to the oxide and then reduced by iron or charcoal. Because of its low mp, very low solubility in Fe, and fairly high oxidative stability in air, Bi can be melted and cast (like Pb) in iron and steel vessels. Like Sb, the metal is too brittle to roll, draw, or extrude at room temperature, but above 225°C Bi can be worked quite well.

13.2.2 Atomic and physical properties

Arsenic and Bi (like P) each have only 1 stable isotope and this occurs with 100% abundance in all natural sources of the elements. Accordingly (p. 17) their atomic weights are known with great precision (Table 13.2). Antimony has 2 stable isotopes (like N); however, unlike N, which has 1 predominantly abundant isotope, the 2 isotopes of Sb are approximately equal in abundance (¹²¹Sb 57.21%, ¹²³Sb 42.79%) and consequently (p. 17) the atomic weight is known with somewhat less accuracy. It is also noteworthy that ²⁰⁹Bi is the heaviest stable isotope of any element; all nuclides beyond ²⁰⁹₈₃Bi are radioactive.

The ground-state electronic configuration of each element in the group is ns²np³ with an unpaired electron in each of the three p orbitals, and much of the chemistry of the group can be interpreted directly on this basis. However, smooth trends are sometimes modified (or even absent altogether), firstly, because of the lack of low-lying empty d orbitals in N, which differentiates it from its heavier congeners, and, secondly, because of the countervailing influence of the underlying filled d and f orbitals in As, Sb and Bi. Such perturbations are apparent when the various ionization energies in Table 13.2 are plotted as a function of atomic number. Table 13.2 also contains approximate data on the conventional covalent single-bond radii for threefold coordination though these values vary by about ±4 pm in various tabulations and should only be used as a rough guide. The 6-coordinate “effective ionic radii” for the +3 and +5

oxidation states are taken from R. D. Shannon's tabulation,\(^3\) but should not be taken to imply the presence of \(M^{2+}\) and \(M^{3+}\) cations in many of the compounds of these elements.

Arsenic, Sb and Bi each exist in several allotropic forms\(^4,5\) though the allotropy is not so extensive as in P (p. 481). There are three crystalline forms of As, of which the ordinary, grey, "metallic", rhombohedral, \(\alpha\)-form is the most stable at room temperature. It consists of puckered sheets of covalently bonded As stacked in layers perpendicular to the hexagonal \(c\)-axis as shown in Fig. 13.1. Within each layer each As has 3 nearest neighbours at 251.7 pm and the angle As–As–As is 96.7°; each As also has a further 3 neighbours at 312 pm in an adjacent layer. The \(\alpha\)-forms of Sb and Bi are isostructural with \(\alpha\)-As and have the dimensions shown in Table 13.3. It can be seen that there is a progressive diminution in the difference between intra-layer and inter-layer distances though the inter-bond angles remain almost constant.

![Figure 13.1](image) Puckered layer structure of As showing pyramidal coordination of each As to 3 neighbours at a distance \(r_1\) (252 pm). The disposition of As atoms in the next layer \(r_2\) (312 pm) is shown by dashed lines.

In the vapour phase As is known to exist as tetrahedral \(\text{As}_4\) molecules with (As–As 243.5 pm) and when the element is sublimed, a yellow, cubic modification is obtained which probably also contains \(\text{As}_4\) units though the structure has not yet been determined because the crystals decompose in the X-ray beam. The mineral arsenolamprite is another polymorph, \(\varepsilon\)-As; it is possibly isostructural with "metallic" orthorhombic P.

Antimony exists in 5 forms in addition to the ordinary \(\alpha\)-form which has been discussed above. The yellow form is unstable above \(-90^\circ\); a black form can be obtained by cooling gaseous Sb, and an explosive (impure?) form can be made electrolytically. The two remaining crystalline forms are made by high-pressure techniques: Form I has a primitive cubic lattice with \(a_0\) 296.6 pm: it is obtained from \(\alpha\)-Sb at 50 kbar (5 GPa, i.e. \(5 \times 10^9\) N m\(^{-2}\)) by increasing the rhombohedral angle from 57.1° to 60.0° together with small shifts in atomic position so that each Sb has 6 equidistant neighbours. Further increase in pressure to 90 kbar yields Form II which is hcp with an interatomic distance of 328 pm for the 12 nearest neighbours.

Several polymorphs of Bi have been described but there is as yet no general agreement on their structures except for \(\alpha\)-Bi (above) and \(\zeta\)-Bi which forms at 90 kbar and has a bcc structure with 8 nearest neighbours at 329.1 pm.

The physical properties of the \(\alpha\)-rhombohedral form of As, Sb and Bi are summarized in Table 13.4. Data for N\(_2\) and P\(_4\) are included for comparison. Crystalline As is rather volatile and the vapour pressure of the solid reaches 1 atm at 615° some 200° below its mp of 816°C (at 38.6 atm, i.e. 3.91 MPa). Antimony and Bi are

(a) yellow as₄ has d₂₅ 1.97 g cm⁻³; cf. difference between the density of rhombohedral black p (3.56 g cm⁻³) and white p₄ (1.823 g cm⁻³) (p. 479).

much less volatile and also have appreciably lower mps than As, so that both have quite long liquid ranges at atmospheric pressure.

arsenic forms brittle steel-grey crystals of metallic appearance. however, its lack of ductility and comparatively high electrical resistivity (33.3 µohm cm), coupled with its amphotericism and intermediate chemical nature between that of metals and non-metals, have led to its being classified as a metalloid rather than a "true" metal. antimony is also very brittle and forms bluish-white, flaky, lustrous crystals of high electrical resistivity (41.7 µohm cm). these values of resistivity can be compared with those for "good" metals such as Ag (1.59), Cu (1.72), and Al (2.82 µohm cm), and with "poor" metals such as Sn (11.5) and Pb (22 µohm cm). bismuth has a still higher resistivity (120 µohm cm) which even exceeds that of commercial resistors such as nichrome alloy (100 µohm cm). bismuth is a brittle, white, crystalline metal with a pinkish tinge. it is the most diamagnetic of all metals (mass susceptibility 17.0 × 10⁻⁹ m³ kg⁻¹ — to convert this SI value to cgs multiply by 10³/4π, i.e. 1.35 ×10⁻⁶ cm³ g⁻¹). it also has the highest Hall effect coefficient of any metal and is unusual in expanding on solidifying from the melt, a property which it holds uniquely with Ga and Ge among the elements.

13.2.3 Chemical reactivity and group trends

arsenic is stable in dry air but the surface oxidizes in moist air to give a superficial golden bronze tarnish which deepens to a black surface coating on further exposure. when heated in air it sublimes and oxidizes to As₄O₆ with a garlic like odour (poisonous). above 250–300° the reaction is accompanied by phosphorescence (cf. p₄, p. 473). when ignited in oxygen, As burns brilliantly to give As₂O₅ and As₂O₃. Metals give arsenides (p. 554), fluorine enflames to give AsF₅ (p. 561), and the other halogens yield AsX₃ (p. 559). Arsenic is not readily attacked by water, alkaline solutions or non-oxidizing acids, but dilute HNO₃ gives arsenious acid (H₃AsO₃). hot conc HNO₃ yields arsenic acid (H₃AsO₄), and hot conc H₂SO₄ gives As₂O₅. Reaction with fused NaOH liberates H₂:

\[ \text{As} + 3\text{NaOH} \rightarrow \text{Na₃AsO₃} + \frac{3}{2}\text{H₂} \]

One important property which As has in common with its neighbouring elements immediately following the 3d transition series (i.e. Ge, As, Se, Br) and which differentiates it from its Group 15 neighbours P and Sb, is its notable reluctance to be oxidized to the group valence of +5. Consequently As₅O₁₀ and H₃AsO₄ are oxidizing agents and arsenates are used for this purpose in titrimetric analysis (p. 577).

the ground-state electronic structure of As, as with all Group 15 elements features 3 unpaired electrons ns²np³; there is a substantial electron affinity for the acquisition of 1 electron but further additions must be effected against considerable coulombic repulsion, and the formation of As³⁻ is highly endothermic. consistent with this there are no "ionic" compounds containing the arsenide ion and
compounds such as Na₂As are intermetallic or alloy-like. However, despite the metalloidal character of the free element, the ionization energies and electronegativity of As are similar to those of P (Table 13.2) and the element readily forms strong covalent bonds to most non-metals. Thus AsX₃ (X = H, hal, R, Ar etc.) are covalent molecules like PX₃ and the tertiary arsines have been widely used as ligands to b-class transition elements (p. 909). Similarly, As₄O₆ and As₄O₁₀ resemble their P analogues in structure; the sulfides are also covalent heterocyclic molecules though their stoichiometry and structure differ from those of P.

Antimony is in many ways similar to As, but it is somewhat less reactive. It is stable to air and moisture at room temperature, oxidizes on being heated under controlled conditions to give Sb₂O₃, Sb₂O₄ or Sb₂O₅, reacts vigorously with Cl₂ and more sedately with Br₂ and I₂ to give SbX₃, and also combines with S on being heated. H₂ is without direct reaction and SbH₃ (p. 557) is both very poisonous and thermally very unstable. Dilute acids have no effect on Sb; concentrated oxidizing acids react readily, e.g. conc HNO₃ gives hydrated Sb₂O₅, aqua regia gives a solution of SbCl₅, and hot conc H₂SO₄ gives the salt Sb₂(SO₄)₃.

Bismuth continues the trend to electropositive behaviour and Bi₂O₃ is definitely basic, compared with the amphoteric oxides of Sb and As and the acidic oxides of P and N. There is also a growing tendency to form salts of oxoacids by reaction of either the metal or its oxide with the acid, e.g. Bi₂(SO₄)₃ and Bi(NO₃)₃. Direct reaction of Bi with O₂, S and X₂ at elevated temperatures yields Bi₂O₃, Bi₂S₃ and BiX₃ respectively, but the increasing size of the metal atom results in a steady decrease in the strength of covalent linkages in the sequence P > As > Sb > Bi. This is most noticeable in the instability of BiH₃ and of many organobismuth compounds (p. 599).

Most of the trends are qualitatively understandable in terms of the general atomic properties in Table 13.2 though they are not readily deducible from them in any quantitative sense. Again, the +5 oxidation state in Bi is less stable than in Sb for the reasons discussed on p. 226; not only is the sum of the 4th and 5th ionization energies for Bi greater than for Sb (9.78 vs. 9.63 MJ mol⁻¹) but the promotion energies of one of the ns² electrons to a vacant nd orbital is also greater for Bi (and As) than for Sb. The discussions on redox properties (p. 577) and the role of d orbitals (p. 222) are also relevant. Finally, Bi shows an interesting resemblance to La in the crystal structures of the chloride oxide, MOCl, and in the isomorphism of the sulfates and double nitrates; this undoubtedly stems from the very similar ionic radii of the 2 cations: Bi³⁺ 103, La³⁺ 103.2 pm.

All coordination numbers from 1–10 (and 12) are known for the sub-group, though 3, 4, 5 and 6 are by far the most frequently met. CN 1 is exemplified by RC≡As(7) (R = 2,4,6-Bu₃C₆H₂; cf RC≡P, p. 544) and by the isolated tetrahedral anions SiAs₄⁻ and GeAs₄⁻ (isoelectronic with SiO₄⁴⁻ and GeO₄⁴⁻) which occur in the lustrous dark metallic Zintl phases Ba₄MAs₄. CN 2 (bent) is quite common in heterocyclic organic compounds (p. 592) and in cluster anions such as As₃⁻, Sb₇⁻ and As₁₃⁻ and their derivates (p. 588). A rare example of linear 2-coordinate As was recently established in the bis(manganese) complex [(η⁵-C₅H₄Me)-(CO)₂Mn≡As≡Mn(CO)₂(η⁵-C₅H₄Me)]⁺, isolated as its dark brown salt with CF₃SO₃⁻: the angle at As was found to be 176.3° and the As–Mn distance was 215 pm. Likewise, examples of pyramidal 3-coordinate As, Sb and Bi are endemic, but planar CN 3 is extremely rare; examples occur in

compounds such as \([\text{PhAs(Cr(CO)}_5]_2\) and \([\text{PhSb(Mn(\eta^5-C_3H_5)CO)}_3]_2\) (p. 597) See later, also, for examples of CN 4 (tetrahedral, flattened tetrahedral and see-saw), CN 5 (trigonal bipyramidal and square pyramidal) and CN 6 (octahedral, 3 + 3, and pentagonal pyramidal).

Higher coordination numbers are less common and are mainly confined to Bi. CN 7 has been found in the tetradentate crown-ether bismuth complex \([\text{BiCl}_3(12\text{-crown-4})]\)\(^{10}\) and in the bismuth complex, \([\text{BiL}]\), of the novel heptadentate anionic ligand of 'saltren', \((\text{H}_3\text{L})\), i.e. \((\text{N(CH}_2\text{CH}_2\text{N-CHC}_6\text{H}_4\text{OH})_3)\).\(^{11}\) The first example of CN 8 was found in the colourless 2:1 adduct \([2\text{BiCl}_3.18\text{-crown-6}]\) which was shown by X-ray analysis to involve an unexpected ionic structure featuring 8-coordinate Bi cations, viz. \([\text{BiCl}_2(18\text{-crown-6})]^{2+}[\text{Bi}_2\text{Cl}_8]^{2-}\)\(^{10}\) CN 9 is represented by the discrete tris(tridentate) complex \([\text{Bi}(\text{O-C(Bu')-C=NC-}(\text{O-C(Bu')-C=}))_3]\) in which Bi has a face-capped, slightly-twisted trigonal-prismatic coordination environment.\(^{12}\) Still higher coordination numbers are exemplified by encapsulated As and Sb atoms in rhodium carbonyl cluster anions: for example As is surrounded by a bicapped square antiprism of 10 Rh atoms in \([\text{Rh}_{10}\text{As(CO)}_{22}]^{3-}\)\(^{13}\) and Sb is surrounded by an icosaehedron of 12 Rh in \([\text{Rh}_{12}\text{Sb(CO)}_{27}]^{3-}\)\(^{(14)}\). In each case the anion is the first example of a complex in which As or Sb acts as a 5-electron donor (cf. P as a 5-electron donor in \([\text{RhP(CO)}_{21}]^{3-}\)) all these clusters then have precisely the appropriate number of valence electrons for closo structures on the basis of Wade’s rules (pp. 161, 174).

13.3 Compounds of Arsenic, Antimony and Bismuth\(^{15}\)

### 13.3.1 Intermetallic compounds and alloys\(^{16,17}\)

Most metals form arsenides, antimonides and bismuthides, and many of these command attention because of their interesting structures or valuable physical properties. Like the borides (p. 145), carbides (p. 297), silicides (p. 335), nitrides (p. 417) and phosphides (p. 489), classification is difficult because of the multitude of stoichiometries, the complexities of the structures and the intermediate nature of the bonding. The compounds are usually prepared by direct reaction of the elements in the required proportions and typical compositions are \(\text{M}_3\text{As}, \text{M}_3\text{As}, \text{M}_4\text{As}, \text{M}_3\text{As}, \text{M}_5\text{As}_2, \text{M}_2\text{As}, \text{M}_5\text{As}_3, \text{M}_4\text{As}_2, \text{M}_4\text{As}_3, \text{M}_5\text{As}_4, \text{MAs}, \text{M}_3\text{As}_4, \text{M}_2\text{As}_3, \text{MAs}_2\) and \(\text{M}_3\text{As}_7\). Antimony and bismuth are similar. Many of these intermetallic compounds exist over a range of composition, and nonstoichiometry is rife.

The (electropositive) alkali metals of Group 1 form compounds \(\text{M}_3\text{E}\) (\(\text{E} = \text{As}, \text{Sb}, \text{Bi}\)) and the metals of Groups 2 and 12 likewise form \(\text{M}_3\text{E}_2\). These can formally be written as \(\text{M}^+\text{E}^{3-}\) and \(\text{M}^+\text{E}^{3-}\)\(^2\) but the compounds are even less ionic than \(\text{Li}_3\text{N}\) (p. 76) and have many metallic properties. Moreover, other stoichiometries are found (e.g. \(\text{LiBi}, \text{KBi}_2, \text{CaBi}_3\)) which are not readily accounted for by the ionic model and, conversely, compounds \(\text{M}_3\text{E}\) are formed by many metals that are not usually thought of as univalent, e.g. \(\text{Ti}, \text{Zr}, \text{Hf}; \text{V}, \text{Nb}, \text{Ta}; \text{Mn}\). There are clearly also strong additional interactions between unlike atoms as indicated by the structures adopted and the high mp of many of the compounds, e.g. \(\text{Na}_3\text{Bi}\) melts...
at 840°, compared with Na 98° and Bi 271°C. Many of the M₃E compounds have the hexagonal Na₃As (anti-LaF₃) structure in which equal numbers of Na and As form hexagonal nets as in boron nitride and the remaining Na atoms are arranged in layers on either side of these nets. Each As has 5 Na neighbours at the corners of a trigonal bipyramid (3 at 294 and 2 at 299) and 6 other Na atoms at 330 pm form a trigonal prism (i.e. 11-coordinate). The Na atoms are of two sorts, both of high mixed CN to As and Na, and all the Na–Na distances (328–330 pm) are less than in Na metal (371.6 pm). The compounds show either metallic conductivity or are semiconductors. An even more compact metal structure (cubic) is adopted by β-Li₃Bi, β-Li₃Sb, and by M₃E, where M = Rb, Cs, and E = Sb, Bi.

Some of the alkali metal–group 15 element systems give compounds of stoichiometry ME. Of these, LiBi and NaBi have typical alloy structures and are superconductors below 2.47 K and 2.22 K respectively. Others, like LiAs, NaSb and KSB, have parallel infinite spirals of As or Sb atoms, and it is tempting to formulate them as M⁺,n(Eₙ⁻) in which the (Eₙ⁻) spirals are iso-electronic with those of covalently catenated Se and Te (p. 752); however, their metallic lustre and electrical conductivity indicate at least some metallic bonding. Within the spiral chains As–As is 246 pm (cf. 252 pm in the element) and Sb–Sb is ~285 pm (cf. 291 pm in the element).

Compounds with Sc, Y, lanthanoids and actinoids are of three types. Those with composition ME have the (6-coordinated) NaCl structure, whereas M₃E₄ (and sometimes M₄E₃) adopt the body-centred thorium phosphide structure (Th₃P₄) with 8-coordinated M, and M₃E₂ are like ThAs₂ in which each Th has 9 As neighbours. Most of these compounds are metallic and those of uranium are magnetically ordered. Full details of the structures and properties of the several hundred other transition metal–Group 15 element compounds fall outside the scope of this treatment, but three particularly important structure types should be mentioned because of their widespread occurrence and relation to other structure types, namely CoAs₃, NiAs and structures related to those adopted by FeS₂ (marcasite, pyrites, loellingite, etc.).

CoAs₃ occurs in the mineral skutterudite; it is a diamagnetic semiconductor and has a cubic structure related to that of ReO₃ (p. 1047) but with a systematic distortion which results in the generation of well-defined planar rings of As₄. The same structure motif is found in MP₃ (M = Co, Ni, Rh, Pd), MAs₃ (M = Co, Rh, Ir) and MSb₃ (M = Co, Rh, Ir). The unit cell (Fig. 13.2) contains 8Co and 24As (i.e. 6As₄), and it follows from the directions in which the various sets of atoms move, that 2 of the 8 original ReO₃ cells do not contain an As₄ group. Each As has a nearly regular tetrahedral arrangement of 2 Co and 2 As neighbours and each Co has a slightly distorted octahedral coordination group of 6 As. The planar As₄ groups are not quite square, the sides of the rectangle being 246 and 257 pm (cf. 244 pm in the tetrahedral As₄ molecule). The distortions from the ReO₃ structure (in which each As would have had 8 equidistant neighbours at about 330 pm) thus permit the closer approach of the As atoms in groups of 4 though this does not proceed so far as to form 6 equidistant As–As links as in the tetrahedral As₄ molecule. The P–P distances in the P₄ rectangles of the isostructural phosphides are 223 and 231 pm (cf. 225 pm in the tetrahedral P₄ molecule).

The NiAs structure is one of the commonest MX structure types, the number of compounds adopting it being exceeded only by those with the NaCl structure. It is peculiar to compounds formed by the transition elements with either As, Sb, Bi, the chalcogens (p. 748) or occasionally Sn. Examples with the Group 15 elements are Ti(As, Sb), V(P, Sb), CrSb, Mn(As, Sb, Bi), FeSb, Co(As, Sb), Ni(As, Sb, Bi), RhBi, Ir(Sb, Bi), PdSb, Pt(Sb, Bi). The structure is illustrated in Fig. 13.3a: each Ni is 8-coordinate, being surrounded by 6 As and by 2 Ni (which are coplanar with 4 of the As); the As atoms form a hcp lattice in which the interstices are occupied by Ni atoms in such a way that each As is surrounded by a trigonal prism of 6 Ni. Another important feature of the NiAs structure is the close approach of Ni atoms...
Figure 13.2 The cubic structure of skutterudite (CoAs$_3$). (a) Relation to the ReO$_3$ structure; (b) unit cell (only sufficient Co–As bonds are drawn to show that there is a square group of As atoms in only 6 of the 8 octants of the cubic unit cell, the complete 6-coordination group of Co is shown only for the atom at the body-centre of the cell); and (c) section of the unit cell showing {CoAs$_6$} octahedra corner-linked to form As$_4$ squares.

Figure 13.3 Structure of nickel arsenide showing (a) 3 unit cells, (b) a single unit cell Ni$_2$As$_2$ and its relation to (c) the unit cell of the layer lattice compound CdI$_2$ (see text).
in chains along the (vertical) c-axis. The unit cell (Fig. 13.3b) contains \(\text{Ni}_2\text{As}_2\), and if the central layer of Ni atoms is omitted the \(\text{CdI}_2\) structure is obtained (Fig. 13.3c). This structural relationship accounts for the extensive ranges of composition frequently observed in compounds with this structure, since partial filling of the intermediate layer gives compositions in the range \(M_{1+x}X_2\) (0 < \(x < 1\)). With the chalcogens the range sometimes extends the whole way from ME to ME\(_2\) but for As, Sb and Bi it never reaches ME\(_2\) and intermetallic compounds of this composition usually have either the marcasite or pyrites structures of Fe\(_2\)S\(_2\) (p. 680) or the compressed marcasite (loellingite) structure of FeAs\(_2\). All three structure types contain the \(E_2\) group. Examples are:

Compounds of As, Sb and Bi with the metals in Group 13 (Al, Ga, In, Tl) comprise the important III–V semiconductors whose structures, properties, and extensive applications have already been discussed (pp. 255–8). Group 14 elements also readily form compounds of which the following serve as examples: GeAs mp 737°C, GeAs\(_2\) mp 732°C, SnAs (NaCl structure, superconductor below 3.5 K), Sn\(_4\)As\(_3\) (defect NaCl structure, superconductor below 1.2 K). The many important industrial applications of dilute alloys of As, Sb and Bi with tin and lead were mentioned on pp. 370 and 371.

### 13.3.2 Hydrides of arsenic, antimony and bismuth

As\(_3\), Sb\(_3\) and Bi\(_3\) are exceedingly poisonous, thermally unstable, colourless gases whose physical properties are compared with those of NH\(_3\) (p. 423) and PH\(_3\) (p. 492) in Table 13.5. The absence of H bonding is apparent; in addition, the proton affinity is very low and there is little tendency to form the onium ions \(M\text{H}^+\) analogous to \(\text{NH}_4^+\). However, very recently the thermally unstable salts \([\text{AsH}_4]^+[\text{SbF}_6]^-\) (decomp. –40°C), \([\text{AsH}_4]^+[\text{AsF}_6]^-\) (d. –75°C) and \([\text{SbH}_4]^+[\text{SbF}_6]^-\) (d. –70°C), have been isolated as colourless air- and moisture-sensitive crystals by protonation of the hydrides \(M\text{H}_3\) with the appropriate superacids. HF/\(\text{MF}_5\) \((M = \text{As}, \text{Sb})\). The gradually increasing densities of the liquids near their bp is expected, as is the increase in \(M-H\) distance. There is a small diminution in the angle H–M–H with increasing molecular weight though the difference for As\(_3\) and Sb\(_3\) is similar to the experimental uncertainty. The rapid diminution in thermal stability is reflected in the standard heats of formation \(\Delta H_f^\circ\); As\(_3\) decomposes to the elements on being warmed to 250–300°C, Sb\(_3\) decomposes steadily.

at room temperature, and BiH₃, cannot be kept above −45°. Arsine, AsH₃, is formed when many As-containing compounds are reduced with nascent hydrogen and its decomposition on a heated glass surface to form a metallic mirror formed the basis of Marsh’s test for the element. The low-temperature reduction of AsCl₃ with LiAlH₄ in diethyl ether solution gives good yields of the gas as does the dilute acid hydrolysis of many arsenides of electropositive elements (Na, Mg, Zn, etc.). Similar reactions yield stibine, e.g.:

\[
\begin{align*}
    \text{ZnSb}_2 + 6\text{H}_3\text{O}^+ & \xrightarrow{\text{aq HCl}} 2\text{SbH}_3 \\
    & + 3\text{Zn}^{2+} + 6\text{H}_2\text{O} \\
    \text{SbO}_3^{3−} + 3\text{Zn} + 9\text{H}_3\text{O}^+ & \longrightarrow \text{SbH}_3 \\
    & + 3\text{Zn}^{2+} + 12\text{H}_2\text{O} \\
    \text{SbCl}_3(\text{in aq NaCl}) + \text{NaBH}_4 & \longrightarrow \text{SbH}_3 \\
    & \text{(high yield)}
\end{align*}
\]

Both AsH₃ and SbH₃ oxidize readily to the trioxide and water, and similar reactions occur with S and Se. AsH₃ and SbH₃ form arsenides and antimonides when heated with metals and this reaction also finds application in semiconductor technology; e.g. highly purified SbH₃ is used as a gaseous n-type dopant for Si (p. 332).

Bismuthine, BiH₃, is extremely unstable and was first detected in minute traces by F. Paneth using a radiochemical technique involving Bi₂Mg₃. These experiments, carried out in 1918, were one of the earliest applications of radiochemical tracer experiments in chemistry. Later work using BH₄⁻ to reduce BiCl₃ was unsuccessful in producing macroscopic amounts of the gas and the best preparation (1961) is the disproportionation of MeBiH₂ at −45° for several hours; Me₂BiH can also be used:

\[
\begin{align*}
    \text{Me}_3−n\text{BiH}_n & \xrightarrow{−45°} \frac{n}{3} \text{BiH}_3 + \frac{3−n}{3} \text{Me}_3\text{Bi} \\
\end{align*}
\]

Lower hydrides such as As₂H₄ have occasionally been reported as fugitive species but little is known of their properties (see p. 583; cf. also N₂H₄, p. 427; P₂H₄, p. 495). Recent fully optimized ab initio calculations (including relativistic core potentials) suggest that the double-bonded species HM═MH (M = P, As, Sb, Bi) should all exist as trans planar (C₂ᵥ) molecules, close agreement with experimental interatomic distances in known organic diphosphenes (p. 544) and diarsenes adds confidence to the computed distances for −Sb═Sb− (260.8 pm) and −Bi═Bi− (271.9 pm) which are both about 9% shorter than the corresponding single-bond distances (cf. also −P═P− 200.5 pm and −As═As− 222.7 pm). The computed bond angles H−M−M in M₂H₂ (M = P, As, Sb, Bi) are 96.2°, 94.4°, 93.0° and 91.8°, respectively.

### 13.3.3 Halides and related complexes

The numerous halides of As, Sb and Bi show highly significant gradations in physical properties, structure, bonding and chemical reactivity. Distinctions between ionic, coordinate and covalent (molecular) structures in the halides and their complexes frequently depend on purely arbitrary demarcations and are often more a hindrance than a help in discerning the underlying structural and bonding principles. Alternations in the stability of the +5 oxidation state are also illuminating. It will be convenient to divide the discussion into five subsections dealing in turn with the trihalides MX₃, the pentahalides MX₅, other halides, halide complexes of M⁺³ and M⁺⁵, and oxohalides.

### Trihalides, MX₃

All 12 compounds are well known and are available commercially; their physical properties are summarized in Table 13.6. Comparisons with the corresponding data for NX₃ (p. 438) and PX₃ (p. 496) are also instructive. Trends in mp, bp and density are far from regular and reflect the differing structures and bond types.

(a) BiF$_3$ is sometimes said to be “infusible” or to have mp at varying temperatures in the range 725–770°, but such materials are probably contaminated with the oxofluoride BiOF (p. 572).

Thus AsF$_3$, AsCl$_3$, AsBr$_3$, SbCl$_3$ and SbBr$_3$ are clearly volatile molecular species, whereas AsI$_3$, SbF$_3$ and BiI$_3$ have more extended interactions in the solid state. Trends in the heats of formation from the elements are more regular being ca. −925 kJ mol$^{-1}$ for MF$_3$, ca. −350 kJ mol$^{-1}$ for MC$_3$, ca. −245 kJ mol$^{-1}$ for MB$_3$ and ca. −100 kJ mol for MI$_3$. Within these average values, however, AsF$_3$ is noticeably more exothermic than SbF$_3$ and BiF$_3$, whereas the reverse is true for the chlorides; there is also a regular trend towards increasing stability in the sequence As $<$ Sb $<$ Bi for the bromides and for the iodides of these elements.

The trifluorides are all readily prepared by the action of HF on the oxide M$_2$O$_3$ (direct fluorination of M or M$_2$O$_3$ with F$_2$ gives MF$_5$, p. 561). Because AsF$_3$ hydrolyses readily, the reaction is best done under anhydrous conditions using H$_2$SO$_4$/CaF$_2$ or HSO$_3$F/CaF$_2$, but aqueous HF can be used for the others. The trichlorides, tribromides and triiodides of As and Sb can all be prepared by direct reaction of X$_2$ with M or M$_2$O$_3$, whereas the less readily hydrolysed BiX$_3$ can be obtained by treating Bi$_2$O$_3$ with the aqueous HX. Many variants of these reactions are possible: e.g., AsCl$_3$ can be made by chlorination of As$_2$O$_3$ with Cl$_2$, S$_2$Cl$_2$, conc HCl or H$_2$SO$_4$/MCl.

The trihalides of As are all pyramidal molecular species in the gas phase with angle X–As–X in the range 96–100°. This structure persists in the solid state, and with AsI$_3$ the packing is such that each As is surrounded by an octahedron of six I with 3 short and 3 long As–I distances (256 and 350 pm; ratio 1.37, mean 303 pm). The I atoms form a regular hcp lattice. A similar layer structure is adopted by SbI$_3$ and BiI$_3$ but with the metal atoms progressively nearer to the centre of the I$_6$ octahedra:

3 Sb–I at 287 pm and 3 at 332 pm; ratio 1.16, mean 310 pm
all 6Bi–I at 310 pm; “ratio” 1.00

This is sometimes described as a trend from covalent, molecular AsI$_3$ through intermediate SbI$_3$ to ionic BiI$_3$, but this exaggerates the difference in bond-type. Arsenic, Sb and Bi have very similar electronegativities (p. 550) and it seems likely that the structural trend reflects more the way in which the octahedral interstices in the hcp iodine lattice are filled by atoms of gradually increasing size. The size of these interstices is about constant (see mean M–X distance) but only Bi is sufficiently large to fill them symmetrically.

Discrete molecules are apparent in the crystal structure of the higher trihalides of Sb, and,
again, these pack to give 3 longer and 3 shorter interatomic distances (Table 13.7).

The structure of BiF₃ is quite different: β-BiF₃ has the “ionic” YF₃ structure with tricapped trigonal prismatic coordination of Bi by 9 F. BiCl₃ has an essentially molecular structure (like SbX₃) but there is a significant distortion within the molecule itself, and the packing gives 5 (not 3) further Cl at 322–345 pm to complete a bicapped trigonal prism. As a consequence of this structure BiCl₃ has smaller unit cell dimensions than SbCl₃ despite the longer Bi–Cl bond (250 pm, as against 236 pm for Sb–Cl). The eightfold coordination has been rationalized by postulating that the ninth position is occupied by the stereochemically active lone-pair of electrons on Bi⁺⁺. On this basis, the 3 long and 3 short M–X distances in octahedrally coordinated structures can also be understood, the lone-pair being directed towards the centre of the more distant triangle of 3X. However, it is hard to quantify this suggestion, particularly as the X–M–X angles are fairly constant at 97 ± 2° (rather than 109.5° for sp³ hybrids), implying little variation in hybridization and a lone-pair with substantial s² character. The effect is less apparent in SbI₃ and absent BiI₃ (see above) and this parallels the diminishing steric influence of the lone-pair in some of the complexes of the heavier halides with Sn⁺⁺ (p. 380) and Te⁺⁴ (p. 757).

Many of the trihalides of As, Sb and Bi hydrolyse readily but can be handled without great difficulty under anhydrous conditions. AsF₃ and SbF₃ are important reagents for converting non-metal chlorides to fluorides. SbF₃ in particular is valuable for preparing organofluorine compounds (the Swarts reaction):

\[
\text{AsF}_3 + 4 \text{SbCl}_3 \rightarrow \text{AsCl}_4 + 4 \text{Sb} + 2 \text{Cl}_2
\]

AsF₃, though a weaker fluorinating agent than SbF₃, is preferred for the preparation of high-boiling fluorides since AsCl₃ (bp 130°) can be distilled off. SbF₃ is preferred for low-boiling fluorides which can be readily fractionated from SbCl₃ (bp 223°). Selective fluorinations are also possible, e.g.:

\[
[\text{PCl}_4]^+ [\text{PCl}_6]^- + 2\text{AsCl}_3 \rightarrow [\text{PCl}_4]^+ [\text{PF}_6]^- + 2\text{AsCl}_3
\]

AsCl₃ and SbCl₃ have been used as non-aqueous solvent systems for a variety of reactions. They are readily available, have convenient liquid ranges (p. 559), are fairly easy to handle, have low viscosities \( \eta \), moderately high dielectric constants \( \varepsilon \) and good solvent properties (Table 13.8).

---

Halides and related complexes

### Table 13.8

</tbody>
</table>

The low conductivities imply almost negligible self-ionization according to the formal scheme:

\[ 2\text{MC}l₃ \rightleftharpoons \text{MCl}_2^+ + \text{MCl}_4^- \]

Despite this, they are good solvents for chloride-ion transfer reactions, and solvo-acid–solvo-base reactions (p. 827) can be followed conductimetrically, voltametrically or by use of coloured indicators. As expected from their constitution, the trihalides of As and Sb are only feeble electron-pair donors (p. 198) but they have marked acceptor properties, particularly towards halide ions (p. 564) and amines.

AsX₃ and SbX₃ react with alcohols (especially in the presence of bases) and with sodium alkoxide to give arsenite and antimonite esters, M(OR)₃ (cf. phosphorus, (p. 515):

\[ \text{AsCl}_3 + 3\text{PhOH} \rightarrow \text{As(OPh)}_3 + 3\text{HCl} \]
\[ \text{SbCl}_3 + 3\text{Bu'OH} + 3\text{NH}_3 \rightarrow \text{Sb(OBu')}_3 + 3\text{NH}_4\text{Cl} \]

Halide esters (RO)₂MX and (RO)MX₂ can be made similarly:

\[ \text{AsCl}_3 + 2\text{NaOEt} \rightarrow (\text{EtO})_2\text{AsCl} + 2\text{NaCl} \]
\[ \text{AsCl}_3 + 3\text{EtOH} \rightarrow (\text{EtO})_3\text{AsCl}_2 + \text{HCl} \]
\[ \text{As(OPr)}_3 + 3\text{MeCOCl} \rightarrow (\text{PrO})_2\text{AsCl} + 3\text{MeCO}_2\text{Pr} \]

Amino derivatives are obtained by standard reactions with secondary amines, lithium amides or by transaminations:

\[ \text{AsCl}_3 + 6\text{Me}_2\text{NH} \rightarrow \text{As(NMe)}_2 + 3[\text{Me}_2\text{NH}_2]\text{Cl} \]
\[ \text{SbCl}_3 + 3\text{LiNMe}_2 \rightarrow \text{Sb(NMe)}_2 + 3\text{LiCl} \]
\[ \text{As(NMe)}_2 + 3\text{Bu}_2\text{NH} \rightarrow \text{As(NBu)}_2 + 3\text{Me}_2\text{NH} \]

As with phosphorus (p. 533) there is an extensive derivative chemistry of these and related compounds.²

### Pentahalides, MX₅

Until fairly recently only the pentafluorides and SbCl₅ were known, but the exceedingly elusive AsCl₅ was finally prepared in 1976 by ultraviolet irradiation of AsCl₃ in liquid Cl₂ at −105°C.²

Some properties of the 5 pentahalides are given in Table 13.9.

The pentfluorides are prepared by direct reaction of F₂ with the elements (As, Bi) or their oxides (As₂O₃, Sb₂O₃). AsCl₅, as noted above, has only a fugitive existence and decomposes to AsCl₃ and Cl₂ at about −50°. SbCl₅ is more stable and is made by reaction of Cl₂ on SbCl₅. No pentabromides or pentaïodides have been characterized, presumably because MV is too highly oxidizing for these heavier halogens (cf. TlI₃, p. 239). The relative instability of AsCl₅ when compared with PCl₅ and SbCl₅ is a further example of the instability of the highest valency state of p-block elements following the completion of the first (3d) transition series (p. 552). This can be understood in terms of incomplete shielding of the nucleus which leads to a "d-block contraction" and a consequent lowering of the energy of the 4s orbital in As and AsCl₃, thereby making it more difficult to promote one of the 4s² electrons

for the formation of AsCl₅. There is no evidence that the As–Cl bond strength itself, in AsCl₅, is unduly weak. The non-existence of BiCl₅ likewise suggests that it is probably less stable than SbCl₅, due the analogous “f-block contraction” following the lanthanide elements (p. 1232).

Evidence from vibration spectroscopy suggests that gaseous AsF₅, solid AsCl₅ and liquid SbCl₅ are trigonal bipyramidal molecules like PF₅ (D₅h), and this is confirmed for AsF₅ by a low-temperature X-ray crystal structure which also indicates that the As–F(axial) distances (171.9 pm) are slightly longer than the As–F(equatorial) distances (166.8 pm). By contrast SbF₅ is an extremely viscous, syrupy liquid with a viscosity approaching 850 centipoise at 20°C; the liquid features polymeric chains of cis-bridged \{SbF₅\} octahedra in which the 3 different types of F atom (a, b, c) can be distinguished by low-temperature ¹⁹F nmr spectroscopy. As shown in Fig. 13.4(a), Fₐ are the bridging atoms and are cis to each other and are, in addition, cis to 1 Fₐ and trans to the other, whereas Fₖ are trans to each other and cis to both Fₐ. In the crystalline state the cis bridging persists but the structure has tetrameric molecular units (Fig. 13.4(b)) rather than high polymers. There are two different Sb–F–Sb bridging angles, 141° and 170°, and the terminal Sb–Fₐ distances (mean 182 ± 5 pm) are noticeably less than the bridging Sb–Fₖ distances (mean 203 ± 5 pm). (See p. 569 for the ionic structures of Sb₈F₃₀, i.e. SbV₅SbIII,F₃₀.) Yet another structure motif is adopted in BiF₅; this crystallizes in long white needles and has the \(α\)-UF₅ structure in which infinite linear chains of trans-bridged \{BiF₅\} octahedra are stacked parallel to each other. The Bi–F–Bi bridging angle between adjacent octahedra in the chain is 180°.

The pentafluorides are extremely powerful fluorinating and oxidizing agents and they also have a strong tendency to form complexes with electron-pair donors. This latter property has already been presaged by the propensity of SbF₅ to polymerize and is discussed more fully on p. 569.

---

---

Figure 13.4 (a) The cis-bridged polymeric structure of liquid SbF₅ (schematic) showing the three sorts of F atom. (b) Structure of the tetrameric molecular unit in crystalline (SbF₅)₄ showing the cis-bridging of 4 \{SbF₅\} octahedra (distances in pm).
Halides and related complexes

See also “superacids” on p. 570. Some typical reactions of SbF₅ and SbCl₅ are as follows:

\[
\text{ClCH}_2\text{PCl}_2 + \text{SbF}_5 \rightarrow \text{ClCH}_2\text{PF}_4
\]

\[
\text{Me}_2\text{As} + \text{SbCl}_5 \rightarrow \text{Me}_2\text{AsCl}_2 + \text{SbCl}_3
\]

\[
\text{R}_3\text{P} + \text{SbCl}_5 \rightarrow [\text{R}_3\text{PCI}]^+[\text{SbCl}_6]^-
\]

\[
(\text{R} = \text{Ph, Et}_2\text{N, Cl})
\]

\[
\text{SbCl}_5 + 5\text{NaOR} \rightarrow \text{Sb(OR)}_5 \rightarrow \text{Na}[\text{Sb(OR)}_5\text{X}]
\]

\[
(\text{X} = \text{OR, Cl})
\]

Perhaps the most reactive compound of the group is BiF₅. It reacts extremely vigorously with H₂O to form O₃, OF₂ and a voluminous brown precipitate which is probably a hydrated bismuth(V) oxide fluoride. At room temperature BiF₅ reacts vigorously with iodine or sulfur; above 50° it converts paraffin oil to fluorocarbons; at 150° it fluorinates UF₄ to UF₆; and at 180° it converts Br₂ to BrF₃ and BrF₅, and Cl₂ to CIF.

Mixed halides and lower halides

Unlike phosphorus, which forms a large number of readily isolable mixed halides of both PIII and P⁵, there is apparently less tendency to form such compounds with As, Sb and Bi, and few mixed halides have so far been characterized. AsF₅ and AsCl₃ are immiscible below 19°C, but at room temperature ¹⁹F nmr indicates some halogen exchange; however equilibrium constants for the formation of AsF₂Cl and AsFCl₂ are rather small. Likewise, Raman spectra show the presence of AsCl₂Br and AsClBr₂ in mixtures of the parent trihalides, though rapid equilibration prevents isolation of the mixed halides. It is said that SbBr₁₂ (mp 88°) can be obtained by eliminating EtBr from EtSbI₂Br₂.

Mixed pentahalides are more readily isolated and are of at least three types: ionic, tetrameric, and less stable molecular trigonal-bipyramidal monomers. Thus, chlorination of a mixture of AsF₃/AsCl₃ with Cl₂, or fluorination of AsCl₃ with CIF₃ (p. 828) gives [AsCl₄]⁺[AsF₆]⁻ (mp 130°(d)) whose X-ray crystal structure has recently been reetermined.²⁶ Similarly, AsCl₃ + SbCl₅ + Cl₂ → [AsCl₄]⁺[SbCl₆]⁻. It also appears that all members of the monomeric molecular series AsCl₅₋ₙFₙ (n = 1 – 4) can be made either by thermolysis of [AsCl₄]⁺[AsF₆]⁻ or, in the case of AsCl₅F₂ (D₃h), by gas-solid reaction of AsCl₂F₃ (g) with CaCl₂ (s); the compounds were characterized as trigonal-bipyramidal molecules by low-temperature matrix ir and Raman spectra.²⁷ The mixed bromofluoride [AsBr₄]⁺[AsF₆]⁻, made by reaction of AsBr₃, Br₂ and SbF₅ at low temperature was also characterized by Raman spectroscopy.²⁸

Antimony chloride fluorides have been known since the turn of the century but the complexity of the system, the tendency to form mixtures of compounds, and their great reactivity have conspired against structural characterization until fairly recently.²⁹ It is now clear that fluorination of SbCl₅ depends crucially on the nature of the fluorinating agent. Thus, with AsF₃ it gives SbCl₄F (mp 83°) which is a cis-F-bridged tetramer as in Fig. 13.4(b) with the terminal F atoms replaced by Cl. Fluorination of SbCl₅ with HF also gives this compound but, in addition, SbCl₂F₂ mp 68° (cis-F-bridged tetramer) and SbCl₂F₃ mp 62°, which turns out to be [SbCl₄]⁺[Sb₂Cl₂F₉]⁻. The anion is F-bridged, i.e. [ClF₄Sb-F-SbF₄Cl]⁻ with angle Sb–F–Sb 163°. Even more extensive fluorination occurs when SbCl₅ is reacted with SbF₅ and the product is [SbCl₄]⁺[Sb₂F₁₁]⁻. By contrast, fluorination of (SbCl₄F)₄ with SbF₅ in liquid SO₂ yields Sb₄Cl₁₃F₇ (mp ~ 50°) which is a cis-F-bridged tetramer of SbCl₃F₂ with two of the Sb atoms having a Cl atom partially replaced by F, i.e. (Sb₂Cl₂F₃)₂ and bridge angles Sb–F–Sb of 166–168°.

The attention which has been paid to the mixed chloride fluorides of SbV is due not only to the intellectual problem of their structures but also to their importance as industrial fluorinating agents (Swarts reaction). Addition of small amounts of SbCl₅ to SbF₅ results in a dramatic decrease in viscosity (due to the breaking of Sb–F–Sb links) and a substantial increase in electrical conductivity (due to the formation of fluoro-complex ions). Such mixed halides are often more effective fluorinating agents than SbF₃, provided that yields are not lowered by oxidation, e.g. SOC₁₂ gives SOF₂; POC₁₃ gives POFC₁₂; and hexachlorobutadiene is partially fluorinated and oxidized to give CF₃CCl═CClCF₃ which can then be further oxidized to CF₃CO₂H:

\[ \text{CCl}_2=\text{CCICCl} = \text{CCl}_2 \xrightarrow{\text{SbF}_5\text{Cl}_2} \text{CF}_3\text{CCl} = \text{CClCF}_3 \]

\[ \xrightarrow{\text{KMnO}_4/\text{KOH}} 2\text{CF}_3\text{CO}_2\text{H} \]

The use of SbF₅ in the preparation of "superacids" such as (HSO₃F + SbF₅ + SO₃) is described in the following subsection (p. 570).

The only well-established lower halide of As is As₂I₄ which is formed as red crystals (mp 137°) when stoichiometric amounts of the 2 elements are heated to 260° in a sealed tube in the presence of octahydrophenanthrene. The compound hydrolyses and oxidizes readily and disproportionates in warm CS₂ solution but is stable up to 150° in an inert atmosphere. Disproportionation is quantitative at 400°:

\[ 3\text{As}_2\text{I}_4 \rightarrow 4\text{AsI}_3 + 2\text{As} \]

Sb₂I₄ is much less stable: it has been detected by emf or vapour pressure measurements on solutions of Sb in SbI₃ at 230° but has not been isolated as a pure compound.

The lower halides of Bi are rather different. The diatomic species BiX (X = Cl, Br, I) occur in the equilibrium vapour above heated Bi–BiX₃ mixtures. A black crystalline lower chloride of composition BiCl₃.167 is obtained by heating Bi–BiCl₃ mixtures to 325° and cooling them during 1–2 weeks to 270° before removing excess BiCl₃ by sublimation or extraction into benzene. The compound is diamagnetic and has an astonishing structure which involves cationic clusters of bismuth and 2 different chloro-complex anions: \[ (\text{Bi}_9^{5+})(\text{BiCl}_5^{2-})_2\text{Bi}_4\text{Cl}_9^{2-}) \], i.e. Bi₂₄Cl₂₈ or Bi₆Cl₁₇. The Bi₉⁺ cluster is a tricapped trigonal prism (p. 591); the anion BiCl₅²⁻ has square pyramidal coordination of the 5 Cl atoms around Bi with the sixth octahedral position presumably occupied by the lone-pair of electrons, and Bi₂Cl₈²⁻ has two such pyramids trans-fused at a basal edge (p. 565). The compound is stable in vacuum below 200° but disproportionates at higher temperatures. It also disproportionates in the presence of ligands which coordinate strongly to BiCl₃ and hydrolyses readily to the oxide chloride.

Bismuth also forms an intriguing family of subiodides, Bi₄I₄, Bi₁₄I₄ and Bi₁₈I₄, which comprise a series of infinite one-dimensional quasi-molecular ribbons of Bi atoms [Bi₉₀I₄]∞ of different width \( (m = 4, 14, 18) \). There are two sorts of Bi atom in these structures: “internal” atoms (Biᵢₙ) surrounded by three other Bi atoms only, at 300–312 pm (cf. 307 pm in Bi metal), and “external” Biₑₓ, connected to differing numbers of Bi and I atoms depending on \( m \). Bi₄Br₄ has a similar structure. The first unambiguous identification of Bi⁺ in the solid state came in 1971 when the structure of the complex halide Bi₁₀Hf₃Cl₁₈ was shown by X-ray diffraction analysis to be (Bi⁺)(Bi₉⁺)(HfCl₆²⁻)₃. The compound was made by the oxidation of Bi with HfCl₄/BiCl₃.

Halide complexes of M⁺ and M⁺

The trihalides of As, Sb and Bi are strong halide-ion acceptors and numerous complexes have been isolated with a wide variety of compositions. They are usually prepared by direct reaction of the trihalide with the appropriate

Halides and related complexes

There is a tendency to dimerize by formation of subsidiary F⋯Sb interactions (Fig. 13.5b) cf. Bi$_2$Cl$_4^{3-}$ in the preceding subsection. With K$_x$B$_F_4$ association proceeds even further to give tetrameric cyclic anions (Fig. 13.5c). In both Na$_x$B$_F_4$ and K$_x$B$_F_4$ the Sb atoms are 5-coordinate but coordination rises to 6 in the polymeric chain anions of the pyridinium and 2-methylpyridinium salts pyH$_x$Sb$_4$Cl$_n$, (2-MeC$_5$H$_4$NH)BiBr$_4$ and (2-MeC$_5$H$_4$NH)BiI$_4$. The structure of (SbCl$_4$)$_n$$^{2-}$ is shown schematically in Fig. 13.5d and the three differing Sb–Cl distances reflect, in part.

---

**Figure 13.5** Structures of some complex halide anions of stoichiometry MX$_4^-$

---

the influence of the lone-pair of electrons on Sb$^{III}$. It will be noted that the shortest bonds are cis to each other, whereas the intermediate bonds are trans to each other; the longest bonds are cis to each other and trans to the short bonds. Corresponding distances in the Bi$^{III}$ analogues are:

$(\text{BiBr}_4)_n^{2-}$: short (2 at 264 pm); intermediate 
(283, 297 pm); long (308, 327 pm)

$(\text{BiI}_4)_n^{-}$: short (2 at 289 pm); intermediate 
(2 at 310 pm); long (311, 345 pm).

Complexes of stoichiometry MX$_5^{2-}$ can feature either discrete 5-coordinate anions as in K$_2$SbF$_5$ and (NH$_4$)$_2$SbCl$_5$ (Fig. 13.6a), or 6-coordinate polymeric anions as in the piperidinium salt (C$_5$H$_{10}$NH$_2$)$_2$BiBr$_5$ (Fig. 13.6b). In the discrete anion SbCl$_5^{2-}$ the Sb–Cl$_{\text{apex}}$ distance (236 pm) is shorter than the Sb–Cl$_{\text{base}}$ distances (2 at 258 and 2 at 269 pm) and the Sb atom is slightly below the basal plane (by 22 pm). The same structure is observed in K$_2$SbCl$_5$.

In addition to the various complex fluorooantimonate(III) salts M$^I$SbF$_4$ and M$^I$SbF$_5$ mentioned above, the alkali metals form complexes of stoichiometry M$^I$Sb$_2$F$_7$. M$^I$Sb$_2$F$_{10}$ and M$^I$Sb$_2$F$_{13}$, i.e. [SbF$_4^-$ (SbF$_3$)$_n$] ($n = 1, 2, 3$) but the mononuclear complexes M$^I$SbF$_6$ have not been found. The structure of M$^I$Sb$_2$F$_7$ depends on the strength of the Sb·F···Sb bridge between the 2 units and this, in turn is influenced by the cation. Thus, in KSb$_2$F$_7$ there are distorted trigonal-bipyramidal SbF$_4^-$ ions (Fig. 13.7a) and discrete pyramidal SbF$_3$ molecules (Sb–F 194 pm) with 2 (rather than 3) contacts between these and neighbouring SbF$_4^-$ units of 241 and 257 pm (cf. SbF$_3$ itself, p. 560). By contrast CsSb$_2$F$_7$ has well-defined Sb$_2$F$_7^-$ anions (Fig. 13.7b) formed from 2 distorted trigonal bipyramidal [SbF$_3$] groups sharing a common axial F atom with long bridge bonds.

Similar structural diversity characterizes the heavier halide complexes of the group. The

![Figure 13.6](image1) Structures of some complex halide anions of stoichiometry MX$_5^{2-}$.

![Figure 13.7](image2) Structures of SbF$_4^-$ and Sb$_2$F$_7^-$ ions in K$_2$SbF$_5$(SbF$_3$) and CsSb$_2$F$_7$, respectively.
[MX₆]³⁻ group occurs in several compounds, and these frequently have a regular octahedral structure like the isoelectronic [TeX₄X₄]²⁻ ions (p. 776), despite the formal 14-electron configuration on the central atom. For example the jet-black compound (NH₄)₂SbBr₆ is actually [(NH₄)₄(SbIIIBr₆)₃-(SbIVBr₆)]⁻ with alternating octahedral SbIII and SbIV ions. The undistorted nature of the SbBr₆³⁻ octahedra suggests that the lone-pair is predominantly 5s² but there is a sense in which this is still stereochemically active since the Sb–Br distance in [SbIIIBr₆]³⁻ (279.5 pm) is substantially longer than in [SbIVBr₆]⁻ (256.4 pm). Similar dimensional changes are found in (pyH)₆Br₂ which is [(pyH⁺)₆(SbIIIBr₆)₃-(SbIVBr₆⁻)₃]. In (Me₂NH)₂BiBr₆ the (BiIIIBr₆)³⁻ octahedron is only slightly distorted. Sixfold coordination also occurs in compounds such as Cs₃Bi₂I₉ and [(pyH⁺)₅(Sb₂Br₉)³⁺(Br⁻)₂] in which M₂X₉³⁻ has the confacial biotahedral structure of Ti₂Cl₉³⁻ (p. 240) (Fig. 13.8). In β-Cs₃Sb₂Cl₉ and Cs₃Bi₂Cl₉, however, there are close-packed Cs⁺ and Cl⁻ with SbIII (or BiIII) in octahedral interstices. In Cs₃As₂Cl₉ the {AsCl₆} groups are highly distorted so that there are discrete AsCl₃ molecules (As–Cl 225 pm) embedded between Cs⁺ and Cl⁻ ions (As–Cl⁻ 275 pm).

Irregular 6- and 7-fold coordination of Sb occurs in the complexes of SbCl₃ with crown thioethers,(34) and 8-fold coordination has been established in its complex with the η⁵-ether ligand 15-crown-5.(35) Crown ethers have also been used to stabilize the first complexed (9-coordinate) trications of SbIII and BiIII, viz. [Sb(12-crown-4)(MeCN)]³⁺[SbCl₆]⁻ and [Bi(12-crown-4)(MeCN)]³⁺[SbCl₆]⁻. (36) The complicated 9- and 10-fold coordination around BiIII in the novel 1:1 and 1:2 arene complexes of BiCl₃ with 1,3,5-Me₃C₆H₃ (i.e. mesitylene) and C₆Me₆, respectively, should also be noted, viz. [(η⁶-mes)₂Bi₂Cl₆] in which each Bi is coordinated by 6C+3Cl (2Cl), and [((μ:η⁶:η⁶-ar)₂Bi₄Cl₁₂] in which each Bi is coordinated by 6C+2Cl+2Cl (2Cl) and each C₆Me₆ ligand bridges two Bi atoms.(37) A planar 6-membered [Bi₃Cl₆] ring occurs in [(Fe(η⁵-C₅H₄Me)(CO)₂]BiCl₃](38) A fascinating variety of discrete (or occasionally polymeric) polynuclear halogeno complexes of AsIII, SbIII and Bi have recently been characterized. A detailed discussion would be inappropriate here, but structural motifs include face-shared and edge-shared distorted {MX₆} octahedral units fused into cubane-like and other related clusters or cluster fragments. Examples (see also preceding paragraph) are:

\[
\text{[As₃Br₁₂]}^{3-}, \quad \text{[As₈Br₈]}^{2-}, \quad \text{[As₈I₈]}^{2-}, \quad \text{[As₈I₂₈]}^{4-}, \quad \text{[Sb₂Cl₈]}^{2-}, \quad \text{[Sb₂I₈]}^{2-}, \quad \text{[Sb₂I₂₄]}^{4-}
\]

Figure 13.8 Structure of M₂X₉³⁻

The detailed coordination geometry about As, Sb or Bi in these clusters varies substantially, and is of considerable significance in describing the nature of the bonding in these species.

No completely general and quantitative theory of the stereochemical activity of the lone-pair of electrons in complex halides of tervalent As, Sb and Bi has been developed but certain trends are discernible. The lone-pair becomes less decisive in modifying the stereochemistry (a) with increase in the coordination number of the central atom from 4 through 5 to 6, (b) with increase in the atomic weight of the central atom (As > Sb > Bi), and (c) with increase in the atomic weight of the halogen (F > Cl > Br > I). The relative energies of the various valence-level orbitals may also be an important factor: the F(σ) orbital of F lies well below both the s and the p valence orbitals of Sb (for example) whereas the σ orbital energies of Cl, Br and I lie between these two levels, at least in the free atoms. It follows that the lone pair is likely to be in a (stereochemically active) metal-based sp^3 hybrid orbital in fluoro complexes of Sb but in a (stereochemically inactive) metal-based σ orbital for the heavier halogens. (49)

In the +5 oxidation state, halide complexes of As, Sb and Bi are also well established and the powerful acceptor properties of SbF_5 in particular have already been noted (p. 562). Such complexes are usually made by direct reaction of the pentahalide with the appropriate ligand. Thus KAsF_6 and NOAsF_6 have octahedral AsF_6^- groups and salts of SbF_6^- and SbCl_6^- (as well as [Sb(OH)_6]^-) are also known. Frequently, however, there is strong residual interaction between the "cation" and the "complex anion" and the structure is better thought of as an extended three-dimensional network. For example the adduct SbCl_5.CCl_3 (i.e. ISbCl_8) comprises distorted octahedra of [SbCl_6] and angular [ICl_2] groups but, as shown in Fig. 13.9, there is additional interaction between the groups which links them into chains and the structure is intermediate between [ICl_2]^+[SbCl_6]^- and [SbCl_6]^+[ICl_4]^- . Complexes are also formed by a variety of oxygen-donors, e.g. [SbCl_5(OPCl_3)] and [SbF_5(OSO)] as

---

shown in Fig. 13.10. Fluoro-complexes in particular are favoured by large non-polarizing cations, and polynuclear complex anions sometimes then result as a consequence of fluorine bridging. For example irradiation of a mixture of SbF₅, F₂ and O₂ yields white crystals of O₂Sb₂F₁₁ which can be formulated as O₂⁺[Sb₂F₁₁]⁻, and this complex, when heated under reduced pressure at 110°, loses SbF₅ to give O₂⁺SbF₆⁻. The dinuclear anion probably has a linear Sb–F–Sb bridge as in [BrF₄]⁺[Sb₂F₁₁]⁻ (p. 834), but in [XeF]⁺[Sb₂F₁₁]⁻ and [XeF₃]⁺[Sb₂F₁₁]⁻ (p. 898) the bridging angle is reduced to 150° and 155° respectively. Even more extended coordination occurs in the 1:3 adduct PF₅SbF₅ which has been formulated as [PF₄]⁺[Sb₁F₁₆]⁻ on the basis of vibrational spectroscopy. The same anion occurs in the scarlet paramagnetic complex [Br₂]⁺[Sb₁F₁₆]⁻ for which X-ray crystallography has established the trans-bridged octahedral structure [F₅SbFₛ(F₄)₅SbF₅]⁺ with a bridging angle SbF₅Sb of 148°; the Sb–F distances (181–184 pm) are significantly less than the asymmetrical Sb–F distances (197 and 210 pm 4 pm). The compound (mp 69°) was prepared by adding a small amount of BrF₅ to a mixture of Br₂ and SbF₅. The structure of the compound AsF₃SbF₅ can be described either as a molecular adduct, F₂AsF→SbF₃, or as an ionic complex, [AsF₄]⁺[SbF₆]⁻; in both descriptions the alternating As and Sb units are joined into an infinite network by further F bonding.

The 1:1 adduct SbF₃SbF₅ has the pseudo-ionic structure [Sb₂F₁₄]⁺[Sb₂F₁₄]⁻; however, the [F₂Sb–F…SbF]⁺ cation features 5 different Sb–F distances (185, 187, 199, 201 and 215 pm) and can be regarded either as an SbF₂⁺ cation coordinated by SbF₅, or as a fluorine-bridged dinuclear cation [F₂Sb–F…SbF]²⁺, or even as part of an infinite three-dimensional polymer [Sb₂F₁₄]⁻ when still longer Sb–F contacts are considered. Several other “adducts” have been prepared leading to the binary fluorides Sb₃F₁₁, Sb₄F₁₄, Sb₅F₂₉, Sb₆F₃₀ and Sb₇F₄₃. The fluoride Sb₆F₃₀ (i.e. 5SbF₃.3SbF₅) is unusual in having more than one structure, depending on its method of preparation. Reduction of SbF₃SbF₅ or of SbF₅ itself with a stoichiometric amount of PF₅ in AsF₃ solutions yields crystals of α-Sb₈F₃₀ comprised of a 3D cross-linked polymeric cation, [Sb₈F₁₃⁺]ₙ, and [SbF₆]⁻ anions. The polymeric cation can be viewed as strongly interacting.

---

{Sb2F5}+, {SbF3} and {Sb2F3}3+ units, and there are also significant cation-anion interactions. Alternatively, the less obvious preparative route of oxidative bromination of MeSCN with Br2 and SbF5 in liquid SO2 yields crystals of β-Sb2F530 which were shown by X-ray structure analysis to be best formulated as [Sb2F3]+[SbF6]−.[56] The compound Sb11F43 (i.e. 6SbF3.5SbF5) was prepared as a white high-melting solid by direct fluorination of Sb; it contains the polymeric chain cation [Sb6F35+]∞ and [SbF6]− anions.[57]

The great electron-pair acceptor capacity (Lewis acidity) of SbF5 has been utilized in the production of extremely strong proton donors (Brønsted acids, p. 48). Thus the acidity of anhydrous HF is substantially increased in the presence of SbF5:

\[
2\text{HF} + \text{SbF}_5 \rightleftharpoons [\text{H}_2\text{F}]^+\text{[SbF}_6]^- \]

Crystalline compounds isolated from such solutions at −20°C to −30°C have been shown by X-ray analysis to be the fluoronium salts [H3F2][Sb2F11]− and [H2F]+[Sb2F11]−.[58]

An even stronger acid ("Magic Acid") results from the interaction of SbF5 with an oxygen atom in fluorosulfuric acid HSO3F (i.e. HF/SO3):

\[
\begin{align*}
\text{SbF}_5 + \text{HOS} &= \text{O} \rightarrow \text{SbF}_5 \\
\text{HSO}_3\text{F} &\rightarrow [\text{HOSOH}]^+ + [\text{O} \equiv \text{S} &= \text{O} \rightarrow \text{SbF}_5]^- \\
&\text{F} &\text{F}
\end{align*}
\]

Such acids, and those based on oleums, H2SO4.mSO3, are extremely strong proton donors with acidities up to 1012 times that of H2SO4 itself, and have been given the generic name ‘superciads’. They have been extensively studied, particularly as they are able to protonate virtually all organic compounds. In addition, they have played a vital rôle in the preparation and study of stable long-lived carboxylations:

\[
\text{RH} + \text{HSO}_3\text{F/\text{SbF}_5} \longrightarrow \text{R}^+ + [\text{FSO}_3\text{.SbF}_5]^- + \text{H}_2
\]

The imaginative exploitation of these and related reactions by G. A. Olah and his group[60–62,64,65] have had an enormous impact on our understanding of organic catalytic processes and on their industrial application, as recognized by the award to Olah of the 1994 Nobel Prize for Chemistry.[66]

**Oxide halides**

The stable molecular nitrosyl halides NOX (p. 442) and phosphoryl halides POX3 (p. 501) find few counterparts in the chemistry of As, Sb and Bi. AsOF has been reported as a product of the reaction of As4O6 with AsF3 in a sealed tube at 320° but has not been fully characterized. AsOF3 is known only as a polymer. Again, just as AsCl5 eluded preparation for over 140 y after Liebig’s first attempt to make it in 1834, so

---

AsOCl₃ defied synthesis until 1976 when it was made by ozonization of AsCl₃ in CFCl₃/CH₂Cl₂ at -78°C: it is a white, monomeric, crystalline solid and is one of the few compounds that can be said to contain a “real” As=O double bond. AsOCl₃ is thermally more stable than AsCl₅ (p. 561) but decomposes slowly at -25°C to give As₂O₃Cl₄:

\[ 3\text{AsOCl}_3 \xrightarrow{0^\circ} \text{AsCl}_3 + \text{Cl}_2 + \text{As}_2\text{O}_3\text{Cl}_4 \]

The compound As₂O₃Cl₄ is polymeric and is thus not isostructural with Cl₂P(O)OP(O)Cl₂.

SbOF and SbOCl can be obtained as polymeric solids by controlled hydrolysis of SbX₃. Several other oxide chlorides can be obtained by varying the conditions, e.g.:

\[ \text{SbCl}_3 \xrightarrow{\text{H}_2\text{O}} \text{SbOCl} \xrightarrow{\text{H}_2\text{O}} \text{Sb}_4\text{O}_5\text{Cl}_2 \]

\[ \text{Sb}_2\text{O}_3 + 2\text{SbCl}_3 \xrightarrow{75^\circ} \text{vac} 3\text{Sb}_4\text{O}_5\text{Cl}_2 (\text{mp} 590^\circ) \]

The compounds Sb₂O₃(OH)₃Cl₂ and Sb₈OCl₂Cl₂ have also been reported. SbOCl itself comprises polymeric sheets of composition [Sb₆O₆Cl₄]²⁺ (formed by linking Sb atoms via O and Cl bridges) interleaved with layers of chloride ions. In addition to polymeric species, finite heterocyclic complexes can also be obtained. For example partial hydrolysis of the polymeric [pyH₃][Sb₃IIICl₉] in ethanol leads to [pyH⁺][Sb₂IIIOCl₆]²⁻ in which the anion contains 2 pseudo-octahedral [:SbOCl₄] units sharing a common face [µ₃-OC₁₂] with the lone-pairs trans to the bridging oxygen atom (Fig. 13.11). Another novel polynuclear antimony oxide halide anion has been established in the dark-blue ferrocenium complex [[Fe(η⁵-C₅H₅)]₂[Sb₄Cl₁₂O]]₂.C₆H₆ which was made by photolysis of benzene solutions of ferrocene (p. 1109) and SbCl₅ in the presence of oxygen; the anion (Fig. 13.12) contains 2 square-pyramidal [Sb₃IIICl₅] units sharing a common edge and joined via a unique quadruply bridging Cl atom to 2 pseudo trigonal bipyramidal [Sb₃IIICl₅O] units which share a common bridging O atom and the unique Cl atom. The structure implies the presence of a lone-pair of electrons beneath the basal plane of the first 2 Sb atoms and in the equatorial plane (with Oₐ and Clₐ) of the second 2 Sb atoms.

Other finite-complex anions occur in the oxyfluorides. For example the hydrated salts K₂[As₂F₁₀O]H₂O and Rb₂[As₂F₁₀O]H₂O

---

Figure 13.12  Schematic representation of the structure of the complex anion \([\text{Sb}_4\text{Cl}_{12}\text{O}]^{2-}\) showing the two different coordination geometries about Sb and the unique quadruply bridging Cl atom.

contain the oxo-bridged binuclear anion \([\text{F}_5\text{AsOAsF}_5]^{2-}\) as shown in Fig. 13.13(7') and the anhydrous salt Rb\(_2\)[Sb\(_2\text{F}_{10}\text{O}\)] contains a similar anion with angle Sb-O-Sb 133°, Sb-F 188 pm, and Sb-O 191 pm.\(^{(72)}\) The compound of empirical formula CsSbF\(_4\)O is, in fact, trimeric with a 6-membered heterocyclic anion in the boat configuration, i.e. Cs\(_3\)[Sb\(_3\)F\(_{12}\)O\(_3\)].\(^{(72)}\) whereas the corresponding arsenic compound\(^{(74)}\) has a dimeric anion \([\text{As}_2\text{F}_8\text{O}_2]^{2-}\) (Fig. 13.14). In both cases the Group 15 element is octahedrally coordinated by 4 F and 2 O atoms in the cis- configuration.

Bismuth oxide halides BiOX are readily formed as insoluble precipitates by the partial hydrolysis of the trihalides (e.g. by dilution of solutions in concentrated aqueous HX). BiOF and BiOI can also be made by heating the corresponding BiX\(_3\) in air. BiOI, which itself decomposes above 300°, is brick-red in colour; the other 3 BiOX are white. All have complex layer-lattice structures.\(^{(33)}\) When BiOCl or BiOBr are heated above 600° oxide halides of composition Bi\(_{24}\text{O}_{31}X_{10}\) are formed, i.e. replacement of 5 O atoms by 10 X in Bi\(_{24}\text{O}_{36}\) (Bi\(_2\text{O}_3\)).

13.3.4 Oxides and oxo compounds

The amphoteric nature of As\(_2\)O\(_3\) and the trends in properties of several of the oxides and oxoacids

Figure 13.13  Schematic representation of the anion structure in M\(_2\)[As\(_2\)F\(_{10}\)O].H\(_2\)O.

Figure 13.14  Schematic representation of the structure of (a) the trimeric anion \([\text{Sb}_3\text{F}_{12}\text{O}_3]^{1-}\), and (b) the dimeric anion \([\text{As}_2\text{F}_8\text{O}_2]^{2-}\).
of As, Sb and Bi have already been mentioned briefly on pp. 552–3. Because of the trend towards greater basicity in the sequence As < Sb < Bi and the trend towards greater acidity in the sequence $M^{\text{III}} < M^{\text{V}}$, coupled with the difficulty of isolating some of the oxides from their “hydrated” forms, it is not convenient to have separate sections on oxides, hydrous oxides, hydroxides, acids, o xoacid salts, polyacid salts and mixed oxides. Accordingly, all these types of compound will be considered in the present section: $M^{\text{III}}$ compounds will be discussed first then intermediate $M^{\text{III}}/M^{\text{V}}$ systems and, finally, $M^{\text{V}}$ oxo-compounds.

**Oxo compounds of $M^{\text{III}}$**

$\text{As}_2\text{O}_3$ (diarsenic trioxide) is the most important compound of As (Panel, p. 549). It is made (a) by burning As in air, (b) by hydrolysis of $\text{AsCl}_3$ or (c) industrially, by roasting sulfide
ores such as arsenopyrite, FeAsS. Sb₂O₃ and Bi₂O₃ are made similarly. All 3 oxides exist in several modifications as shown in the schemes on p. 573. In the vapour phase As₂O₃ exists as As₄O₆ molecules isostructural with P₄O₁₀ (p. 504), and this unit also occurs in the cubic crystalline form. Above 800°C gaseous As₄O₆ partially dissociates to an equilibrium mixture containing both As₄O₆ and As₂O₃ molecules. The less-volatile monoclinic form of As₂O₃ has a sheet-like structure of pyramidal {AsO₃} groups sharing common O atoms. This transformation from molecular As₄O₆ units to polymeric As₂O₃ is accompanied by an 8.7% increase in density from 3.89 to 4.23 g cm⁻³. A similar change from cubic, molecular Sb₄O₆ to polymeric Sb₂O₃ results in an 11.3% density increase from 5.20 to 5.79 g cm⁻³.

The structural relationships in Bi₂O₃ are more complex. At room temperature the stable form is monoclinic α-Bi₂O₃ which has a polymeric layer structure featuring distorted, 5-coordinate Bi in pseudo-octahedral {BiO₅} units. Above 717°C this transforms to the cubic δ-form which has a defect fluorite structure (CaF₂, p. 118) with randomly distributed oxygen vacancies, i.e. [Bi₂O₃□]. The β-form and several oxygen-rich forms (in which some of the vacant sites are filled by O²⁻ with concomitant oxidation of some Bi⁺⁺ to Bi⁺⁺⁺) are related to the δ-Bi₂O₃ structure. There are also numerous double oxides pMOₙ.qBi₂O₃, e.g. Bi₁₂GeO₂₀ (i.e. GeO₂.6Bi₂O₃), and other mixed oxides can be made by fusing Bi₂O₃ with oxides of Ca, Sr, Ba, Cd or Pb; these latter have (BiO)ₓ layers as in the oxide halides, interleaved with M⁺⁺ cations. Bi₁₂Sr₂CaCu₂O₈ is a superconductor with Tc = 85 K (cf. p. 1182).

The oxides M₂O₃ are convenient starting points for the synthesis of many other compounds of As, Sb and Bi. Some reactions of As₂O₃ are shown in the scheme; Sb₂O₃ reacts similarly, but Bi₂O₃ is more basic, being insoluble in aqueous alkali but dissolving in acids to give Bi⁺⁺⁺ salts.

The solubility of As₂O₃ in water, and the species present in solution, depend markedly on pH. In pure water at 25°C the solubility is 2.16 g per 100 g; this diminishes in dilute HCl to a minimum of 1.56 g per 100 g at about 3 M HCl and then increases, presumably due to the formation of chloro-complexes. In neutral or acid solutions the main species is probably pyramidal As(OH)₃, “arsenious acid”, though this compound has never been isolated either from solution or otherwise (cf. carbonic acid, p. 310). The solubility is much greater in basic solutions and spectroscopic evidence points to
the presence of such anions as \([\text{AsO(OH)}_2]^-\), 
\(\text{[AsO}_2\text{(OH)}]\)^{2-}\) and \(\text{[AsO}_3\text{]}^{3-}\), corresponding to successive deprotonation of \(\text{H}_3\text{AsO}_3\). The first 
stage dissociation constant at \(25^\circ\) is \(K_a = \frac{[\text{AsO(OH)}_2]^+ [\text{H}^+]}{[\text{H}_3\text{AsO}_3]} \simeq 6 \times 10^{-10}\), \(pK_a\) 9.2; ortho-arsenic acid is therefore a very 
weak acid (as expected from Pauling’s rules, p. 50) and is comparable in strength to boric 
acid (p. 203). Dissociation as a base is even 
weaker: \(K_b = \frac{[\text{As(OH)}_2^+] [\text{OH}^-]}{[\text{As(OH)}_2]} \simeq 10^{-14}\). There now seems to be less evidence for 
other species that were formerly considered to be 
previously known in solution, e.g. the monomeric meta-acid 
\(\text{HASO}_3\), i.e. \(\text{[AsO(OH)]}\) (by loss of 1 \(\text{H}_2\text{O}\)) and the 
\(\text{hexahydroxoacid H}_3\text{[As(OH)]}_6\) or its hydrate.

Arsenites of the alkali metals are very soluble 
in water, those of the alkaline earth metals less so, and those of the heavy metals are 
virtually insoluble. Many of the salts are obtained 
as meta-arsenites, e.g. \(\text{NaAsO}_2\), which comprises 
polymeric chain anions formed by corner linkage 
of pyramidal \(\{\text{AsO}_3\}\) groups and held together by 
\(\text{Na}\) ions:

\[
\begin{array}{c}
\text{O} \\
\text{As} \\
\text{O} \\
\text{As} \\
\text{O} \\
\text{As} \\
\text{O} \\
\text{O} \\
\text{O} \\
\text{O} \\
\text{O} \\
\end{array}
\]

The sparingly soluble yellow \(\text{Ag}_3\text{AsO}_3\) is 
an example of an orthoarsenite. Copper(II) 
arosenites were formerly used as fine green 
pigments, e.g. Paris green, which is an acetate 
arosenite \(\text{[Cu}_3\text{(MeCO}_3\text{)}(\text{AsO}_3)]\), and Scheele’s 
green, which approximates to the hydrogen 
arosenite \(\text{CuHAsO}_3\) or the dehydrated composition 
\(\text{Cu}_2\text{As}_2\text{O}_5\).

Antimonious acid \(\text{H}_3\text{SbO}_3\) and its salts are less 
well characterized but a few meta-antimonites 
and polyantimonites are known, e.g. \(\text{NaSbO}_2\), 
\(\text{NaSb}_2\text{O}_5\cdot\text{H}_2\text{O}\) and \(\text{Na}_2\text{Sb}_4\text{O}_7\). The oxide itself 
finds extensive use as a flame retardant in 
fibres, paper, paints, plastics, epoxy resins, 
adhesives and rubbers. The scale of industrial 
use can be gauged from the US statistics which 
indicate an annual consumption of \(\text{Sb}_2\text{O}_3\) of some 
10,000 tonnes in that country.

The corresponding Bi compound \(\text{Bi(OH)}_3\) is 
definitely basic rather than acidic. It dissolves 
readily in acid giving solutions of \(\text{Bi}^{3+}\) ions but an 
increase in \(pH\) causes precipitation of oxo-salts. 
Before precipitation, however, polymeric oxo-
compounds can be detected in solution of which the 
best characterized is \(\text{[Bi}_6\text{(OH)}_{12}]^{z/+}\) in perchlorate 
solution. The species (Fig. 13.15) resembles 
\(\text{[Ta}_6\text{Cl}_{12}]^{2+}\) and has 6 Bi at the corners of an 
octahedron with bridging OH groups above each 
of the 12 edges. The shortest Bi–O distance is 
233 pm and the (nonbonding) Bi···Bi distance 
is 370 pm (307 and 353 in Bi metal). This 
contrasts with the bicapped tetrahedral distribution 
of metal atoms in \(\text{[Pb}_6\text{O(OH)}_6]^{2+}\) (p. 395) where there 
is an O atom at the centre of the central 
tetrahedron and OH groups above the faces of the 
capping tetrahedra. A different arrangement of 
oxgen atoms around the \(\text{Bi}_6\) octahedron has been 
found by X-ray and neutron diffraction studies 
on \(\text{[Bi}_6\text{O}_4(\text{OH})_4]^{6+}\text{[ClO}_4]^{-}\cdot\text{H}_2\text{O}\), which can be 
crystallized from solutions prepared by dissolving 
\(\text{Bi}_2\text{O}_3\) in 3 M \(\text{HClO}_4\).\(^{75}\) The eight oxygen 
atoms (4 O and 4 OH) are disposed, respectively, 
on two tetrahedra above the eight triangular faces 
of the octahedron, thus giving the cluster overall

---

---
Td symmetry and with average distances Bi–O 215 pm, Bi–O(H) 240 pm and Bi···Bi 368 pm.

The tendency of Bi
III
 oxo-groups to aggregate is also found in Li₃BiO₃, which is formed as colourless crystals by heating a mixture of Li₂O and Bi₂O₃ (in a 3:1 mole ratio) in Ag capsules (bombs!) at 750°C for 20 days.⁷⁶ The "isolated" pyramidal BiO₃³⁻ ions are arranged in apparently electrostatically unfavourable groups of eight with the 8 Bi atoms at the corners of a cube, all 24 O atoms pointing outwards and the eight lone pairs of electrons pointing inwards; Bi–O 205 pm (av), Bi···Bi 368 pm (av); cf. Bi–Bi 307.2 and 352.9 pm in Bi metal (p. 551). Likewise, colourless crystals of Ag₃BiO₄ and of Ag₅BiO₆, prepared by heating Ag₂O and Bi₂O₃ at 500°–530°C under 100 MPa (1 kbar) of O₂ or hydrothermally at 350°C and 10 MPa of O₂, both feature Bi₂O₄⁸⁻ units. In Ag₅BiO₄ (i.e. Ag₁₀Bi₂O₈) the units are "isolated" and comprise two square-based pyramidal [BiO₃] groups trans-fused at a common basal edge and with Bi–O₈ 231 pm (av), Bi···Bi 214 pm, Bi···Bi 379 pm. In Ag₃BiO₃ these [BiO₃] groups are further linked by the remaining terminal basal O atoms to form a 3D network.⁷⁷ A fascinating mixed valence bismuthate Ag₂₅Bi₃O₁₈ (i.e. Bi²⁺Bi⁵⁺) has been prepared as black crystals by heating Ag₂O and Bi₂O₃ under 10 MPa pressure of O₂.⁷⁸ The Bi
III
 are (3 + 3)-coordinated by O at 221 and 231 pm whereas the Bi
V
 are regularly octahedrally coordinated by 6 O at 213 pm. Intriguingly, application of pressure induces a change in oxidation states (III → V) leading to a delocalization of the 6s² valence electrons.

Mixed-valence oxides

The vapour species produced by heating As₂O₅ (see next paragraph) in vacuo have been isolated in low-temperature matrices and shown by vibration spectroscopy to comprise the complete series of stable molecules As₄O₉ (n = 6–10).⁷⁹ analogous in structures to the phosphorus series (p. 504) The intermediate diamagnetic oxide α-Sb₂O₄ (i.e. Sb
III
Sb
V
O₄) has long been known as the massive, fine-grained, yellow, orthorhombic mineral cervantite and more recently a monoclinic β-form has been recognized. α-Sb₂O₄ can also be obtained by heating Sb₂O₃ in dry air at 460–540°C, and further heating in air or oxygen at 1130°C produces β-Sb₂O₄. Both forms have similar structures with equal numbers of Sb
III
 and Sb
V
. α-Sb₂O₄ is isostructural with SnBiO₄ and SnTaO₄ and consists of corrugated sheets of slightly distorted {SnO₆} octahedra sharing all their vertices (as in the plane layer in K₂NiF₄); the Sb
III
 lie between the layers in positions of irregular pyramidal fourfold coordination, all four O atoms lying on the same side of the Sb
III
. Further oxidation to anhydrous Sb₂O₅ has not been achieved (see below). For oxygen-rich Bi₂O₃+x see pp. 573–4 and also the preceding paragraph.

Oxo compounds of M
V

Arsenic(V) oxide, As₂O₅, is one of the oldest-known oxides, but structural analysis has been thwarted until recently because of poor thermal stability, ease of hydrolysis and the difficulty of growing a single crystal. It is now known to consist of equal numbers of {AsO₆} octahedra and {AsO₄} tetrahedra completely linked by corner sharing to give cross-linked strands which define tubular cavities (cf. the corner sharing in ReO₃ octahedra, p. 1047, and SiO₂ tetrahedra, p. 343).⁸⁰ The structure accounts for the reluctance of the compound to crystallize and also for the observation that only half the As atoms can be replaced by Sb (6-coordinate) and P (4-coordinate) respectively. As₂O₅ can be prepared either by heating As (or As₂O₃) with O₂ under pressure or by dehydrating crystalline

H$_3$AsO$_4$ at about 200°C. It is deliquescent, exceedingly soluble in water (230 g per 100 g H$_2$O at 20°), thermally unstable (loosing O$_2$ near the mp, ca. 300°C) and a strong oxidizing agent (liberating Cl$_2$ from HCl).

Arsenic acid, H$_3$AsO$_4$, can be obtained in aqueous solution by oxidizing As$_2$O$_3$ with concentrated HNO$_3$ or by dissolving As$_2$O$_5$ in water. Crystallization below 30° yields 2H$_3$AsO$_4$.H$_2$O (cf. phosphoric acid hemihydrate, p. 519), whereas crystallization at 100°C or above results in loss of water and the formation of As$_2$O$_5$.5H$_2$O, i.e. ribbon-like polymeric (H$_5$As$_3$O$_{10}$)$_n$. All these materials are strongly H-bonded. Arsenic acid, like H$_3$PO$_4$ (p. 519), is tribasic with pK$_1$ 2.2, pK$_2$ 6.9, pK$_3$ 11.5 at 25°. M'H$_2$AsO$_4$ (M = K, Rb, Cs, NH$_4$) are ferroelectric (p. 57). The corresponding sodium salt readily dehydrates to give meta-arsenate NaAsO$_3$:

NaH$_2$AsO$_4$ $\rightarrow$ NaAsO$_3$ + H$_2$O

NaAsO$_3$ has an infinite polymeric chain anion similar to that in diopside (pp. 349, 529) but with a trimeric repeat unit; LiAsO$_3$ is similar but with a dimeric repeat unit whereas β-KAsO$_3$ appears to have a cyclic trimeric anion As$_3$O$_9^{3-}$ which resembles the cyclo-trimetaphosphates (p. 530). There is thus a certain structural similarity between arsenates and phosphates, though arsenic acid and the arsenates show less tendency to catenation (p. 526). The tetrahedral [AsV$_4$O$_4$] group also resembles [PO$_4$] in forming the central unit in several heteropolyacid anions (p. 1014).

One striking difference between arsenates and phosphates is the appreciable oxidizing tendency of the former. This is clear from the oxidation state diagram for the Group V elements shown in Fig. 13.16, which summarizes a great deal of relevant information (p. 435). Antimony is seen to resemble arsenic quite closely but Bi$_V$–Bi$_{III}$ is a much more strongly oxidizing couple and, indeed (as is clear from Fig. 13.16), it is able to oxidize water to oxygen. It is also clear that the +3 oxidation states of As, Sb and Bi do not disproportionate in solution. Nor do the elements themselves, so there are no reactions comparable to that of P$_4$ with alkali to give phosphine and hypophosphite (p. 513). Redox reactions have proved a useful volumetric method of analysis for both As and Sb. For example As$_{III}$ is quantitatively oxidized in aqueous solution by I$_2$, or by potassium bromate, iodate or permanganate. Such reactions can be formally represented as follows:

$$\text{As}^{III} + I_2 \rightarrow \text{As}^V + 2I^-,$$

Thus, in an acid buffer such as borax-boric acid or Na$_2$HPO$_4$–NaH$_2$PO$_4$ (p. 521):

$$\frac{1}{2}\text{As}_2\text{O}_3(aq) + I_2 + \text{H}_2\text{O} \rightarrow \frac{1}{2}\text{As}_2\text{O}_5(aq) + 2\text{H}^+(aq) + 2I^-$$

Such reactions are not available for Bi$_{III}$ but this can readily be determined by complexometric titration using ethylenediaminetetraacetic acid or similar complexones:

$$\text{Bi}^{III} + \text{H}_4\text{edta} \rightarrow \text{[Bi(edta)]}^- + 4\text{H}^+$$

Antimony(V) oxide has been obtained as a poorly characterized pale-yellow powder of ill-defined stoichiometry by hydrolysing SbCl$_5$ with aqueous ammonia solution and dehydrating the product at 275°. Antimonates generally feature pseudooctahedral {Sb$_6$O$_6$} units but polymerization by corner, edge or face sharing is rife. Some compounds which have been structurally characterized are Na$_2$Sb(OH)$_6$, Li$_2$Sb$_3$O$_9$ (edge-shared), Li$_3$SbO$_4$ (NaCl superstructure with isolated lozenges of [Sb$_4$O$_16$]$^{12-}$), Na$_2$Sb$_3$O$_9$ (ilmenite, p. 963), MgSb$_2$O$_6$ (trirutile, p. 961), Al$_2$SbO$_4$ (rutile, 2M0$_2$ with random occupancy) and Zn$_7$Sb$_2$O$_{12}$ (defect spinel, i.e. 3AB$_2$O$_4$, p. 248).

Bismuth(V) oxide and bismuthates are even less well established though a recent important development has been the synthesis and structural characterization of Li$_3$Bi$_2$O$_5$, prepared by heating an intimate mixture of Li$_2$O and α-Bi$_2$O$_3$ at 650° for 24 h in dry O$_2$. The structure is of the defect rock-salt type with an ordering of...
cations and anion vacancies similar to that found in the ordered low-temperature phase of TiO (p. 962). Note that the nominal ionic radii of Li$^+$ and Bi$^{5+}$ are equal (76 pm). Strong oxidizing agents give brown or black precipitates with alkaline solutions of Bi$^{3+}$, which may be an impure higher oxide, and NaBi$^{5+}$O$_3$ can be made by heating Na$_2$O and Bi$_2$O$_3$ in O$_2$. Such bismuthates of alkali and alkaline earth metals, though often poorly characterized, can be used as strong oxidizing agents in acid solution. Thus Mn in steel can be quantitatively determined by oxidizing it directly to permanganate and estimating the concentration colorometrically.

**13.3.5 Sulfides and related compounds**

Despite the venerable history of the yellow mineral orpiment, As$_2$S$_3$, and the orange-red mineral realgar, As$_4$S$_4$ (p. 547), it is only during the past two or three decades that the structural interrelation of the numerous arsenic sulfides has emerged. As$_2$S$_3$ has a layer-structure analogous to As$_2$O$_3$ (p. 574) with each As bonded pyramidal to 3 S atoms at 224 pm and angle S–As–S 99°. It can be made by heating As$_2$O$_3$ with S or by passing H$_2$S into an acidified solution of the oxide. It sublimes readily, even below its mp of 320°, and the vapour has been shown by electron diffraction studies to comprise As$_4$S$_6$ molecules isostructural with P$_4$O$_6$ (p. 504). The structure can be thought...
Oxidation state diagram for As, Sb and Bi in acid and alkaline solutions, together with selected data on N and P for comparison.

13.3.5 Sulfides and related compounds

Despite the venerable history of the yellow mineral orpiment, As$_2$S$_3$, and the orange-red mineral realgar, As$_4$S$_4$ (p. 547), it is only during the past two or three decades that the structural interrelation of the numerous arsenic sulfides has emerged. As$_2$S$_3$ has a layer-structure analogous to As$_2$O$_3$ (p. 574) with each As bonded pyramidally to 3 S atoms at 224 pm and angle S–As–S 99°. It can be made by heating As$_2$O$_3$ with S or by passing H$_2$S into an acidified solution of the oxide. It sublimes readily, even below its mp of 320°, and the vapour has been shown by electron diffraction studies to comprise As$_4$S$_6$ molecules isostructural with P$_4$O$_6$ (p. 504). The structure can be thought

---

of as being derived from the As$_4$ tetrahedron by placing a bridging S atom above each edge thereby extending the As⋯As distance to a nonbonding value of ~290 pm. If instead of 6 As–S–As bridges there are 3, 4 or 5, then, as illustrated in Fig. 13.17, the compounds As$_4$S$_3$, As$_3$S$_4$ (2 isomers) and As$_4$S$_5$ are obtained. The molecule As$_4$S$_3$ is seen to be isostructural with P$_4$S$_3$ and P$_4$Se$_3$ (p. 507); it occurs in both the α- and the β-form of the orange-yellow mineral dimorphite (literally “two forms”, discovered by A. Scacchi in volcanic fumaroles in Italy in 1849), the two forms differing only in the arrangement of the molecular units.\(^{82}\) The compound can be synthesized by heating As and S in the required proportions and purifying the product by sublimation, the β-form being the stable modification at room temperature and the α-form above 130°. The same molecular form occurs in the recently synthesized isoelectronic cationic clusters As$_3$S$_4^+$ (yellow) and As$_3$Se$_4^+$ (orange)\(^{83}\) and in the isoelectronic clusters P$_7^{3–}$, As$_7^{3–}$ and Sb$_7^{3–}$ (p. 588).

With As$_4$S$_4$ there are two possible geometrical isomers of the molecule depending on whether the 2 As–As bonds are skew or adjacent, as shown in Fig. 13.17. Realgar (mp 307°) adopts the more symmetric $D_{2d}$ form with skew As–As

bonds and, depending on how the molecules pack in the crystal, either α- or β-As₄S₄ results. In addition to the tetrahedral disposition of the 4 As atoms, note that the 4 S atoms are almost coplanar; this is precisely the inverse of the D₂d structure adopted by N₄S₄ (p. 723) in which the 4 S atoms form a tetrahedron and the 4 N atoms a coplanar square. It is also instructive to compare As₄S₄ with S₈ (p. 655): each S atom has 2 unpaired electrons available for bonding whereas each As atom has 3; As₄S₄ thus has 4 extra valency electrons for bonding and these form the 2 transannular As–As bonds. The structure of the second molecular isomer As₄S₄(II) parallels the analogous geometrical isomerism of P₄S₄ (p. 507). It was obtained as yellow-orange platy crystals by heating equi-atomic amounts of the elements to 500–600°C, then rapidly cooling the melt to room temperature and recrystallizing from CS₂.

Orange needle-like crystals of As₄S₅ occasionally form as a minor product when As₄S₄ is made by heating As₄S₃ with a solution of sulfur in CS₂. Its structure (Fig. 13.17) differs from that of P₄S₅ and P₄Se₅ (p. 507) in having only 1 As–As bond and no exocyclic chalcogen As=S; this is a further illustration of the reluctance of As to oxidize beyond As⁴⁺ (p. 552). The compound can also be made by heterolytic cleavage of the As₄S₅²⁻ anion. This anion, which is itself made by base cleavage of one of the As–As bonds in realgar, probably has the structure shown in Fig. 13.17 and this would certainly explain the observed sequence of reactions:

\[
\text{As}_4\text{S}_5 + \text{Na}_2\text{S} \xrightarrow{\text{aq}} 2\text{NaAs}^{\text{III}}\text{S}_2
\]

Reacidification reprecipitates As₄S₅ quantitatively. With alkali metal or ammonium polysulfides thioarsenates are formed which are virtually insoluble even in hot conc HCl:

\[
\text{As}_2\text{S}_3 + (\text{NH}_4)_2\text{S}_n \xrightarrow{\text{aq}} (\text{NH}_4)_3\text{As}^\text{V}\text{S}_4
\]

The structure of As⁵⁺S₅ is unknown. It is said to be formed as a yellow solid by passing a rapid stream of H₂S gas into an ice-cold solution of an arsenate in conc HCl; slower passage of H₂S at room temperature results in reduction of arsenate to arsenite and consequent precipitation of As₂S₃. It decomposes in air above 95°C to give As₂S₃ and sulfur.

Reactions of the various sulfides of arsenic call for little further comment. As₂S₃ burns when heated in air to give As₂O₃ and SO₂. Chlorine converts it to AsCl₃ and S₂Cl₂. It is insoluble in water but dissolves readily in aqueous alkali or alkali-metal sulfide solutions to give thioarsenites:

\[
\text{As}_2\text{S}_3 + \text{Na}_2\text{S} \xrightarrow{\text{aq}} 2\text{NaAs}^{\text{III}}\text{S}_2
\]

When As₂S₃ is treated with boiling sodium carbonate solution it is converted to As₄S₄; this latter compound can also be made by fusing As₂O₃ with sulfur or (industrially) by heating iron pyrites with arsenical pyrites. As₄S₄ is scarcely attacked by water, inflames in Cl₂, and is used in pyrotechny as it violently inflames when heated with KNO₃. Above about 550°C As₄S₄ begins to dissociate reversibly and at 1000°C the molecular weight corresponds to As₂S₂ (of unknown structure).
As₂S₃ and As₄S₄ have also provided a wealth of new ligands for transition-metal complexes, e.g. AsS, As₃S₄, As₂S and, more recently, the geometrically novel bridging \( \eta^2, \eta^2 \)-SAsSAsS ligand. Further diversity is emerging with the synthesis and structural characterization of a range of (halogenated)polythiopolyarsenate(III) ions such as cyclo-[As₂SₓXₙ]⁻, (i.e. cyclo-\([X(AS)₂S₃(μ₃-X)]⁻\); \( X = \text{Cl}, \text{Br, I} \)), cyclo-\([S=\text{AsS₃}]⁻\), bicyclo-[Br₂As(đS₂As₂S₂)(CH₂)]⁻ and \([\text{As₂SBr}₃]^{2⁻}\) [i.e. fac-[Br₂As(μ-S,Br,Br)-AsBr₂]^{2⁻}], all isolated as their [PPh₄]⁺ salts. Three selenides of arsenic are known: As₂Se₃, As₄Se₃ and As₄Se₄; each can be made by direct heating of the elements in appropriate proportions at about 500° followed by annealing at temperatures between 220–280°. As₂Se₃ is a stable, brown, semiconducting glass which crystallizes when annealed at 280°; it melts at 380° and is isomorphous with As₂S₃. α-As₄Se₃ forms fine, dark-red crystals isostructural with α-As₄S₄ (\( C₃ᵥ \)) and the lighter-coloured β-form almost certainly contains the same molecular units. Similarly, As₄Se₄ is isostructural with realgar, α-As₄S₄, and the directly linked As–As distances are very similar in the 2 molecules (257 and 259 pm respectively); other dimensions are As–Se(av) 239 pm, angle Se–As–Se 95°, angle As–Se–As 97° and angle As–As–Se 102° (cf. Fig. 13.17). The cationic cluster As₃Se₄⁺ was mentioned on p. 579, and the heterocyclic anion As₂Se₆⁻ has been isolated as its orange [Na(crypt)]⁺ salt; the anion comprises a 6-membered heterocycle \( \{\text{As₂Se₄}\} \) in the chair conformation and each As carries a further exocyclic Se atom to give overall \( C_{2h} \) symmetry, i.e.

\[
\text{Se}^- \quad \text{As(μ-Se₂)₂As} \quad \text{Se}^- .
\]

Methanolothermal reactions of As₂Se₃ with alkali metal carbonates at 130° yield polymeta-selenoarsenites, MAsSe₂ (\( M = \text{K, Rb, Cs} \)), in which the polymeric anions consist of tetrahedral \{AsSe₃\} units linked by corner sharing into infinite chains. Complexes of the triangular-\( \eta^3 \) ligands As₂Se⁻ and As₂Te⁻, such as \([\text{triphos})\text{Co}(\text{As₂E})]⁺\), can be made by reacting \([\text{Co(H₂O)}₆]^{2⁺}[\text{BF}_₄]⁻\) with the appropriate arsenic chalcogenide in the presence of the tridentate ligand \( \text{CH}_₂\text{C(Ph₃P)}₃ \), (triphos). The binary chalcogenides of Sb and Bi are also readily prepared by direct reaction of the elements at 500–900°. They have rather complex ribbon or layer-lattice structures and have been much studied because of their semiconductor properties. Both n-type and p-type materials can be obtained by appropriate doping (pp. 258, 332) and for the compounds M₂X₃ the intrinsic band gap decreases in the sequence As > Sb > Bi for a given chalcogen, and in the sequence S > Se > Te for a given Group 15 element. Some typical properties of these highly coloured compounds are in Table 13.10, but it should be mentioned that mp, density and even colour are often dependent on crystalline form and purity. The large thermoelectric effect of the selenides and tellurides of Sb and Bi finds use in solid-state refrigerators. Sb₂S₃ occurs as the black or steely grey mineral stibnite and is made industrially on a moderately large scale for use in the manufacture of safety matches, military ammunition, explosives and pyrotechnic products, and in the production of ruby-coloured glass. It reacts vigorously when heated with oxidizing agents but is also useful as a pigment in plastics such as

---

polythene or polyvinylchloride because of its flame-retarding properties. Golden and crimson antimony sulfides (which comprise mixtures of Sb$_2$S$_3$, Sb$_2$S$_4$ and Sb$_2$OS$_3$) are likewise used as flame-retarding pigments in plastics and rubbers. A poorly characterized higher sulfide, sometimes said to be Sb$_2$S$_5$, can be obtained as a red solid by methods similar to those outlined for As$_2$S$_5$ (p. 580). It is used in fireworks, as a pigment, and to vulcanize red rubber.

Of the more complex chalcogenide derivatives of the Group 15 elements two examples must suffice to indicate the great structural versatility of these elements, particularly in the +3 oxidation state where the nonbonding electron pair can play an important stereochemical role. Thus, the compound of unusual stoichiometry Ba$_4$Sb$_4$Sb$_{11}$Se$_{11}$ was found to contain within 1 unit cell: one trans-[Sb$_2$Se$_4$]$^{2-}$ (1), two cis-[Sb$_2$Se$_4$]$^{2-}$ (2), two pyramidal [SbSe$_3$]$^{3-}$ (3), and two Se$_2^{2-}$ ions (Se-Se 236.7 pm) together with the requisite 8 Ba$^{2+}$ cations.$^{(95)}$ Conversely, the apparently simple 6-coordinate tris(dithiophosphinate), [Sb($\eta^2$-S$_2$PPh$_2$)$_3$] (4), features pentagonal pyramidal coordination

geometry, which is most unusual for a main-group element and may result from the comparatively 'small bite' of the ligand, the lone pair of electrons presumably occupying the seventh coordination position below the pentagonal plane. The tris(oxalato) anion, $\text{[Sb}^{III}(\text{C}_2\text{O}_4)_3\text{]}^{3-}$, is perhaps the only other example of this geometry.

### 13.3.6 Metal–metal bonds and clusters

The somewhat limited tendency of N and P to catenate into homonuclear chains has already been noted. The ability to form long chains is even less with As, Sb and Bi, though numerous compounds containing one M–M bond are known and many stable ring and cluster compounds featuring $\text{M}_n$ groups have been emerging in recent years. The Group 15 elements therefore differ only qualitatively from C and the other Group 14 elements (p. 374), and S and the Group 16 elements, on the other (p. 751). The elements As, Sb and Bi (like P, p. 487) form well-defined sets of triangulo-$\text{M}_3$ and tetrahedro-$\text{M}_4$ compounds, whilst Bi in particular has a propensity to form cluster cations $\text{Bi}_m^{n+}$ reminiscent of Sn and Pb clusters (p. 394) and closo-borane anions (p. 153). Before discussing these various classes of compound, however, it is convenient to recall that a particular grouping of atoms may well have strong interatomic bonds yet still be unstable because of disproportionation into even more stable groupings. A pertinent example concerns the bond dissociation energies of the diatomic molecules of the Group 15 elements themselves in the gas phase. Thus, the ground state electronic configuration of the atoms $(ns^2np^3)$ allows the possibility of triple bonding between pairs of atoms $\text{M}_2$(g), and it is notable that the bond dissociation energy of each of the Group 15 diatomic molecules is much greater than for those of neighbouring molecules in the same period (Fig. 13.18). Despite this, only $\text{N}_2$ is stable in the condensed phase because of the even greater stability of $\text{M}_4$ or $\text{M}_{\text{metal}}$ for the heavier congeners (p. 551). A notable advance has, however, been signalled in the isolation and X-ray structural characterization of Sb homologues of $\text{N}_2$ and azobenzene as complex ligands: the red compounds $\{[\text{Sb}^{III}(\text{CO})_3]_3\}$ and $\{[(\eta^1,\eta^1,\mu,\eta^2)-(\text{Sb}^{III})]^{3+}\}^+$ are both stable at room temperature, even on exposure to air.

Diarsane, $\text{As}_2\text{H}_4$, is obtained in small yield as a byproduct of the formation of $\text{AsH}_3$ when an alkaline solution of arsenite is reduced by $\text{BH}_4^-$ upon acidification:

$$2\text{H}_2\text{AsO}_3^- + \text{BH}_4^- + 3\text{H}^+ \longrightarrow \text{As}_2\text{H}_4$$

$$+ \text{B(OH)}_3 + \text{H}_2\text{O} + \text{H}_2$$

Diarsane is a thermally unstable liquid with an extrapolated bp $\sim 100^\circ$; it readily decomposes at room temperature to a mixture of $\text{AsH}_3$ and a polymeric hydride of approximate composition ($\text{As}_2\text{H}_x$). $\text{Sb}_2\text{H}_4$ ($\text{SbCl}_3 + \text{NaBH}_4$/dil HC1) is even less stable. Both compounds can also be prepared by passing a silent electric discharge through $\text{MH}_3$ gas in an ozonizer at low temperature. Mass spectrometric measurements give the thermochemical bond energy $E_{298}^\circ$ ($\text{M}-\text{M}$) as 128 KJ mol$^{-1}$ for $\text{Sb}_2\text{H}_4$ and 167 KJ mol$^{-1}$ for $\text{As}_2\text{H}_4$, compared with 183 KJ mol$^{-1}$ for $\text{P}_2\text{H}_4$. Of the halides, $\text{As}_2\text{I}_4$ is known (p. 564) but no corresponding compounds of Sb or Bi have yet been isolated (cf. $\text{P}_2\text{X}_4$, p. 497).

Organometallic derivatives $\text{M}_2\text{R}_4$ are rather more stable than the hydrides and, indeed, dicacodyl, $\text{Me}_2\text{AsAsMe}_2$, was one of the very first organometallic compounds to be made

---

(L. C. Cadet, 1760; R. Bunsen, 1837): it has mp $-1^\circ$, bp 78°, is extremely poisonous, and has a revolting smell, as indicated by its name (Greek $\kappa\alpha\kappa\omega\delta\iota\alpha$, *cacodia*, stink). It is now readily made by the reaction of Li metal on Me$_2$AsI in thf. Other preparative routes to As$_2$R$_4$ include reaction of R$_2$AsH with either R$_2$AsX or R$_2$AsNH$_2$, and the reaction of R$_2$AsCl with MAsR$_2$ ($M = Li$, Na, K). In addition to alkyl derivatives numerous other compounds are known, e.g. As$_2$Ph$_4$ mp 127°. As$_2$(CF$_3$)$_4$ bp 106° has the *trans* ($C_{2h}$) structure whereas As$_2$Me$_4$ has a temperature-dependent mixture of *trans* and *gauche* isomers (p. 428). Corresponding Sb compounds are of more recent lineage, the first to be made (1931) being the yellow crystalline Sb$_2$Ph$_4$ mp 122°. Other derivatives have R = Me, Bu', CF$_3$, cyclohexyl, $p$-tolyl, cyclopentadienyl, etc. Little is known of organodibismuthanes Bi$_2$R$_4$ despite sporadic attempts to prepare them.

More extensive catenation occurs in the cyclo-polyarsanes (RAs)$_n$ which can readily be prepared from organoarsenic dihalides or from arsionic acids as follows:

$$\text{6PhAsCl}_2 \xrightarrow{\text{Na/Et,O}} \text{(PhAs)}_6 + 12\text{NaCl}$$

$$\text{6PhAsI}_2 \xrightarrow{\text{Hg (fast)}} 3\text{PhIAsAsIPh} \xrightarrow{\text{Hg (slow)}} \text{(PhAs)}_6$$

$$n\text{PhAsO(OH)}_2 \xrightarrow{\text{H_3PO_3}} \text{(PhAs)}_n \quad n = 5, 6$$

In addition to the 6-membered ring in (PhAs)$_6$, 5-membered rings have been obtained with R = Me, Et, Pr, Ph, CF$_3$, SiH$_3$, GeH$_3$ and 4-membered rings occur with R = CF$_3$, Ph. A 3-membered As$_3$ ring has also been made and is the first *all-cis* organocyclotriarsane to be characterized.$^{100}$

The factors influencing ring size and conformation have not yet become clear. Thus, the yellow (MeAs)$_5$ has a puckered As$_5$ ring with As–As 243 pm and angle As–As–As 102°; there is also a more stable red form. (PhAs)$_6$ has a puckered As$_6$ (chair form) with As–As 246 pm and angle As–As–As 91°. Numerous polycyclic compounds As$_n$R$_m$ have also been characterized, for example the bright-yellow crystalline tricyclo-As$_{12}$Bu$_5$.\(^{100a}\)

In view of the excellent donor properties of tertiary arsines, it is of interest to inquire whether these cyclo-polyarsanes can also act as ligands. Indeed, (MeAs)$_5$ can displace CO from metal carbonyls to form complexes in which it behaves as a uni-, bi- or tridentate ligand. For example, direct reaction of (MeAs)$_5$ with M(CO)$_6$ in benzene at 170° (M = Cr, Mo, W) yielded red crystalline compounds [M(CO)$_3$(η$^3$-As$_5$Me$_5$)] for which the structure in Fig. 13.19a has been proposed,\(^{101}\) whereas reaction at room temperature with the ethanol derivative [M(CO)$_5$(EtOH)] gave the yellow dinuclear product [[M(CO)$_3$]$\mu$-η$^1$(η$^3$-As$_5$Me$_5$)] for which a possible structure is given in Fig. 13.19b. Reaction can also lead to ring degradation; e.g., reaction with Fe(CO)$_5$ cleaves the ring to give dark-orange crystals of the catena-tetraarsane [[Fe(CO)$_3$]$\mu$-η$^1$(η$^3$-As$_5$M$_5$)] whose structure (Fig. 13.20a) has been established by X-ray crystallography.\(^{102}\) Even further degradation of the cyclo-polyarsane occurs when (C$_6$F$_5$As)$_4$ reacts with Fe(CO)$_5$ in benzene at 120° to give yellow plates of [Fe(CO)$_4$][((AsC$_6$F$_5$)$_2$)$_2$] mp 150° (Fig. 13.20b).\(^{103}\) In other reactions homoatomic ring expansion or chain extension can occur. For example (AsMe)$_5$ when heated with Cr(CO)$_6$ in benzene at 150° gives crystals of [Cr$_2$(CO)$_6$$\mu$-η$^6$-cyclo(AsMe)$_5$], whereas (AsPr)$_5$ and Mo(CO)$_5$ under similar conditions yield crystals of [Mo$_2$(CO)$_6$$\mu$-η$^4$-catena(AsPr)$_5$]]. The molecular structures were determined by X-ray analysis and are shown in Fig. 13.21.\(^{104}\) In the first, each Cr is 6-coordinate and the As$_9$ ring is hexahapto, donating 3 pairs of electrons to

---

**Figure 13.19** Proposed structures for (a) the tridentate cyclo-polyarsane complex [Cr(CO)$_3$(As$_5$Me$_5$)], and (b) the bismonodentate binuclear complex [[Cr(CO)$_3$]$\mu$-η$^1$(η$^3$-As$_5$Me$_5$)].
Figure 13.20 Crystal structures of (a) \([\text{Fe(CO)}_3]_2([\text{AsMe}_4])\), and (b) \([\text{Fe(CO)}_4((\text{AsC}_6\text{Fs})_2)]\). In (a) the distance between the 2 terminal As atoms is 189 pm, suggesting some "residual interaction" but no direct \(\sigma\) bond.

Figure 13.21 Structures of (a) \([\text{Cr}_2(\text{CO})_6-\mu-\{\eta^5-\text{cyclo(AsMe)}_9\}\]) and (b) \([\text{Mo}_2(\text{CO})_6-\mu-\{\eta^4-\text{catena(AsPr)}_8\}\})\). In both structures the alkyl group attached to each As atom has been omitted for clarity.

Each Cr atom in the second the As atom at each end of the As\(_8\) chain bridges the 2 Mo atoms whereas the 2 central As atoms each bond to 1 Mo atom only and there is an Mo–Mo bond. Complexes of cyclo-As\(_8\) with niobium cyclopentadienyls have also been synthesized,\(^{(105)}\) and it is noteworthy that this ligand is "iso-electronic" with cyclooctatetraene, C\(_8\)H\(_8\). The analogy holds for smaller rings, too, and cyclo-As\(_n\) complexes are known for As\(_3\), As\(_4\), As\(_5^-\), As\(_6\) and As\(_7^-\),\(^{(105)}\)

---

(norbornadiene analogue) as well as for cyclo-
As₈₈⁻ (crown-shaped S₈ analogue).

Some of the compounds mentioned in
the preceding paragraph can be thought of
as heteronuclear cluster compounds and it
is convenient to consider here other such
heteronuclear cluster species before discussing
compounds in which there are homonuclear
clusters of Group 15 atoms. Compounds
structurally related to the As₄ cluster include
the complete series [As₄-n{CO(CO)₃}ₙ] n = 0,
1, 2, 3, 4. It will be noted that the atom As
and the group {CO(CO)₃} are “isoelectronic”
in the sense that each requires 3 additional
electrons to achieve a stable 8- or 18-electron
configuration respectively. Yellow crystals of
[As₃Co(CO)₃] are obtained by heating (MeAs)₅
with Co₂(CO)₈ in hexane at 200° under a
high pressure of CO. The red air-sensitive
liquid [As₃Co(CO)₃] mp -10° is obtained by
the milder reaction of AsCl₃ with Co₂(CO)₈
in thf. Substitution of some carbonyls
by tertiary phosphines is also possible under
ultraviolet irradiation. Typical structural details
are in Fig. 13.22. In the first compound the
η³-triangulo-As₃ group can be thought of as a 3-
electron donor to the cobalt atom; in the second,
the very short As–As bond suggests multiple
bonding and the structure closely resembles
that of the “isoelectronic” acetylene complex
[(Co(CO)₃)₂PhC≡CPh] (p. 933). Phosphorus
analogues are also known, e.g. the sand-coloured
or colourless complexes [M(η³-P₃)L*], where
M = Co, Rh or Ir and L* is the tripod-
like tris(tertiary phosphate) ligand MeC(CH₂-
PPh₂)₃. Likewise the first example of an
η²-P₂ ligand symmetrically bonded to 2 metal
atoms to give a tetrahedral {P₂-Co₂} cluster was
established by the X-ray structure determination
of [(μ-P₂)Co(CO)₃][Co(CO)₃(PPh₃)]. If
the μ-P₂ (or μ-As₂) ligand is replaced by μ-S₂
(μ-Se₂), then isoelectronic and isostructural
clusters can be obtained by replacing Co by Fe,
as in [(μ-S₂)Fe(CO)₃]₂ [107] and [(μ-Se₂)Fe(CO)₃]₂
(p. 758).

Even more intriguing are the “double sandwich”
complexes which feature {η³-P₃} and {η³-As₃}
as symmetrically bridging 3-electron donors.
Thus As₄ reacts smoothly with Co II or Ni II
aquo ions and the triphosphane ligand L* =
MeC(CH₂PPh₂)₃ in thf/ethanol/acetone mixtures
to give the exceptionally air-stable dark-green
paramagnetic cation [L*Co-μ-(η³-As₃)CoL*]²⁺
with the dimensions shown in Fig. 13.23. [109] The
structure of the related P₃ complex [L*μ-(η³-P₃)-
NiL*]²⁺ (prepared in the same way using white

P$_4$ is closely similar$^{111}$ with P–P distances of 216 pm (smaller than for P$_4$ itself, 221 pm). Indeed, a whole series of complexes has now been established with the same structure-motif and differing only in the number of valency electrons in the cluster; some of these are summarized in Table 13.11.$^{111,112}$ The number of valence electrons in all these complexes falls in the range 30–34 as predicted by R. Hoffmann and his colleagues.$^{113}$ Many other cluster types incorporating differing numbers of Group 15 and transition metal atoms are now known and have been fully reviewed.$^{114,115}$

With Sb even larger clusters can be obtained. For example reaction of Co(OAc)$_2$.4H$_2$O and SbCl$_3$ in pentane at 150° under a pressure of H$_2$/CO gave black crystals of [Sb$_4$(Co(CO)$_3$)$_4$] which was found to have a cubane like structure with Sb and Co at alternate vertices of a grossly distorted cube (Fig. 13.24).$^{116}$

In addition to the heteronuclear clusters considered in the preceding paragraphs, As, Sb and Bi also form homonuclear clusters. We have already seen that alkaline earth phosphides M$_2$P$_{14}$ contain the [P$_7$]$^{3-}$ cluster isoelectronic and isostructural with P$_4$S$_3$, and the analogous clusters [As$_7$]$^{3-}$ and [Sb$_7$]$^{3-}$ have also been synthesized. Thus, when As was heated with metallic Ba at 800°C, black lustrous prisms of Ba$_3$As$_{14}$ were obtained, isotypic with Ba$_3$P$_{14}$; these contained the [As$_7$]$^{3-}$ anion with dimensions as shown in Fig. 13.25(a).$^{117}$ Again,

When powdered NaSb or NaSb$_3$ were treated with crypt, $[\text{N(C}_2\text{H}_4\text{OC}_2\text{H}_4\text{OC}_2\text{H}_4)_3\text{N}]$ (p. 98) in dry ethylenediamine, a deep-brown solution was obtained from which brown needles of [Na(crypt)$^+$]$_3$[Sb$_7$]$_3^-$ were isolated with a $C_{3v}$ anion like [As$_7$]$_3^-$ and Sb–Sb distances 286 pm (base), 270 pm (side) and 278 pm (cap). \(^{(118)}\)

The related As$_{22}^4^-$ anion comprises two such [As$_{11}$]$_2^-$ units conjoined by linking two of these equatorial “waist”

atoms as shown in Fig. 13.26(b)\(^{(122)}\) Many other homonuclear and heteronuclear clusters have also been prepared, of which \([\text{As}_5\text{Se}_4]^{3-}\)\(^{(123)}\), \([\text{As}_{10}\text{Te}_3]^{2-}\)\(^{(124)}\) and \([\text{As}_{11}\text{Te}]^{3-}\)\(^{(125)}\) can serve as examples. They were made, respectively, by reduction of As\(_4\)Se\(_4\) with K/C\(_2\)H\(_4\)(NH\(_2\))\(_2\) in the presence of [Ph\(_4\)P]Br, the oxidation of polyarsenides with Te (or reduction of As\(_2\)Te\(_3\) with K), and the reaction of the alloy K\(_{1.6}\)As\(_{1.6}\)Te with a cryptand ligand in ethylenediamine.

In all the cluster compounds discussed above there are sufficient electrons to form 2-centre 2-electron bonds between each pair of adjacent atoms. Such is not the case, however, for the cationic bismuth species now to be discussed and these must be considered as “electron deficient”. The unparalleled ability of Bi/BiCl\(_3\) to form numerous low oxidation-state compounds in the presence of suitable complex anions has already been mentioned (p. 564) and the cationic species shown in Table 13.12 have been unequivocally identified.

The structure of the last 3 cluster cations are shown in Fig. 13.27. In discussing the structure and bonding of these clusters it will be noted that Bi\(^{+}(6s^26p^2)\) can contribute 2\,p electrons to the framework bonding just as \{BH\} contributes 2\,1 electrons to the cluster bonding in boranes (p. 158). Hence, using the theory developed for the boranes, it can be seen that \([\text{Bi}_n\text{H}_n]^{2-}\) is electronically equivalent to \((\text{Bi}^+)\_n^{2-}\) i.e. \([\text{Bi}_n]^{n-}\)\(^{2-}\). This would account for the stoichiometries \(\text{Bi}_3^+\) and \(\text{Bi}_5^3+\) but would also lead one to expect \(\text{Bi}_6^6+\) and \(\text{Bi}_9^7+\) for the larger clusters. However, these charges are very large and it seems likely that the lowest-lying nonbonding orbital would also be occupied in \((\text{Bi}^+)\_n^{2-}\). For \((\text{Bi}^+)\_8^{2-}\) this is an \(e_1\) orbital which can accommodate 4 electrons, thereby reducing the charge from \(\text{Bi}_8^6+\) to \(\text{Bi}_8^{2+}\) as observed. In \((\text{Bi}^+)\_9^{2-}\) the lowest nonbonding orbital is \(a_2^2\) which can accommodate 2\,s electrons, thus reducing the charge from \(\text{Bi}_9^{7+}\) to \(\text{Bi}_9^{5+}\) as observed\(^{(126)}\). It will also be noted that \(\text{Bi}_5^3+\) is isoelectronic with \(\text{Sn}_5^{2-}\) and \(\text{Pb}_5^{2-}\) (p. 394); these penta-atomic species all have 12 valence electrons (not counting the “inert” 2\,s electrons on each atom), i.e. \(n+1\) pairs \((n=5)\) hence a closo-structure would be expected by Wade’s rules (p. 161).

The \(\text{Bi}_5^{3+}\) ion was discovered in 1963 as a result of work by A. Herschaft and J. D. Corbett on the structure of the black subhalide “BiCl” (p. 564) and subsequently was

3.3.7 Other inorganic compounds

The ability to form stable oxoacid salts such as sulfates, nitrates, perchlorates, etc., increases in the order As ≪ Sb < Bi. AsIII is insufficiently basic to enable oxoacid salts to be isolated though species such as [As(OH)(H2SO4)2] and [As(OH)(H2SO4)]+ have been postulated in anhydrous H2SO4 solutions of As2O3. In oleum, species such as [As(H2SO4)2], [(H2SO4)2As]20 and [(H2SO4)2As][SO4] may be present. By contrast, Sb2(SO4)3 can be isolated, as can the hydrates Bi2(SO4)3.nH2O and the double sulfate KBi(SO4)2, though all are readily hydrolysed to basic salts.

The pentahydrate Bi(NO3)3.5H2O can be crystallized from solutions of BiIII oxide or carbonate in conc HNO3. Dilution causes the basic salt BiO(NO3) to precipitate. Attempts at thermal dehydration yield complex oxocations by reactions which have been formulated as follows:

\[
\text{Bi(NO}_3\text{)}_3.5\text{H}_2\text{O} \xrightarrow{50-60^\circ} \text{Bi}_6\text{O}_6\text{O}_6\text{L}_2(\text{NO}_3)_\text{L}_{11-}
\]

\[
\text{(OH)}_6\text{H}_2\text{O} \xrightarrow{77-130^\circ} \text{Bi}_6\text{O}_6\text{L}_6(\text{NO}_3)_6.3\text{H}_2\text{O} \xrightarrow{400-450^\circ} \alpha-\text{Bi}_2\text{O}_3
\]

The \([\text{Bi}_6(\text{OH})_6]^{6+}\) ion is the dehydrated form of \([\text{Bi}_6(\text{OH})_{12}]^{6+}\) (p. 575). Treatment of the
pentahydrate with \( \text{N}_2\text{O}_4 \) yields an adduct which decomposes to oxide nitrates on heating:

\[
\text{Bi(NO}_3\text{)}_3\cdot\text{N}_2\text{O}_4 \xrightarrow{200^\circ} \text{Bi}_2\text{O} (\text{NO}_3)_4
\]

\[
\xrightarrow{415^\circ} \text{Bi}_4\text{O}_5(\text{NO}_3)_2
\]

\( \text{N}_2\text{O}_5 \) also yields a 1:1 adduct and this has been formulated as \([\text{NO}_2]^+\text{[Bi(NO}_3\text{)}_4]^-\). Bi reacts with \( \text{NO}_2 \) in dimethyl sulfoxide to give the solvate \( \text{Bi(NO}_3\text{)}_3 \cdot 3\text{Me}_2\text{SO} \), whereas Sb gives the basic salt \( \text{SbO(NO}_3\text{)}\cdot\text{Me}_2\text{SO} \). \( \text{Bi(ClO}_4\text{)}_3 \cdot 5\text{H}_2\text{O} \) dissolves in water to give complex polymeric oxocations such as \([\text{Bi}_6(\text{OH})_9]^{6+}\) (p. 575).

The first stable arsazene (dark red \( \text{ArN}(\text{H})\text{As}=\text{NAr}, \text{mp 173}^\circ\text{C}, \text{Ar} = \text{C}_6\text{H}_2\text{Bu}^\prime\text{3}-2,4,6\)) and its orange P analogue (mp 203°C) have been prepared by treating \( \text{AsCl}_3 \) (or \( \text{PCl}_3 \)) with Li[\( \text{NHAr} \)]; an X-ray study found \( \text{As} = \text{N} 175\text{pm, As}=\text{N} 171\text{pm} \) and the angle \( \text{NAsN} 98.9^\circ \) (compared with 163pm, 157pm and 103.8° for the N-P=N system).130 The first 2-coordinate iminoarsine (containing an As=N double bond) was prepared by reacting \( \text{AsH}_3 \) with \( (\text{CF}_3)\text{NONO} \) at room temperature, and isolated as a volatile white solid at \(-86^\circ\).131

\[\text{AsH}_3 + (\text{CF}_3)\text{NONO} \rightarrow (\text{CF}_3)\text{NONO} \rightarrow \text{AsH} + \text{H}_2\text{O}\]

Numerous Sb=N and Bi=N containing species are also beginning to appear in the literature, for example:

(a) the Sb-subrogated cyclo-triphosphazene, \( \text{NPX}_2\text{NPX}_2\text{NSb}(\text{OOCMe})_2 \), which was obtained as a white moisture-sensitive solid, the 4-coordinate Sb being pseudo trigonal bipyramidal with the lone pair of electrons in the N\text{Sb}: plane;132

(b) the azastibacubane cluster compound, \( (\text{MeNSbCl}_3)_4 \), which was obtained in good yield as pale yellow crystals by the stoichiometric reaction of \( \text{SbCl}_3 \) with \( \text{MeNR}_2 \) \((\text{R} = \text{SiMe}_3\))133

(c) the homoleptic bismuth amide \( \text{Bi(NPH}_2)_3 \); an X-ray examination of the orange crystals found pyramidal Bi with Bi=N 220 pm (av) and angle NBiN 97° (av).134

### 13.3.8 Organometallic compounds

All 3 elements form a wide range of organometallic compounds in both the +3 and the +5 state, those of As being generally more stable and those of Bi less stable than their Sb analogues. For example, the mean bond dissociation energies \( \bar{D}(\text{M-Me})/\text{kJ mol}^{-1} \) are 238 for \( \text{AsMe}_3 \), 224 for \( \text{SbMe}_3 \) and 140 for \( \text{BiMe}_3 \). For the corresponding \( \text{MPh}_3 \), the values are 280, 267, and 200 kJ mol\(^{-1}\) respectively, showing again that the M=C bond becomes progressively weaker in the sequence As>Sb>Bi. Comparison with organophosphorus compounds (p. 542) is also apposite. In most of the compounds the metals are 3, 4, 5 or 6 coordinate though a few multiply-bonded compounds are known in which they have a coordination number of 2. In view of the vast range of compounds which have been studied, only a representative selection of structure types will be given in this section.

---

Organometallic compounds

Organooarsenic(III) compounds

The first 1-coordinate organooarsenic(III) compound, \( \text{RC}=\text{As} \), \((\text{R} = 2,4,6\text{-tri-}t\text{-butylphenyl})\) was isolated in 1986 as pale yellow crystals, mp. 114°C.\(^{(7)}\)

Some examples of 2-coordinate organoarsenic(III) compounds are:

\[
\begin{align*}
\text{Arsabenzene} & \quad \text{1-Arsanaphtalene} \\
\text{9-Arsananthracene}
\end{align*}
\]

The first such compound to be prepared was the deep-yellow unstable compound 9-arsananthracene\(^{(140)}\) but the thermally stable colourless arsabenzene (arsenin) can now conveniently be made by a general route from 1,4-pentadiyne.\(^{(141)}\)

\[
\begin{align*}
\text{AsC}_5\text{H}_5 & \quad \text{SnBu}_2
\end{align*}
\]

AsC\(_5\)H\(_5\) is somewhat air sensitive but is distillable and stable to hydrolysis by mild acid or base. Using the same route, PBr\(_3\) gave PC\(_5\)H\(_5\) as a colourless volatile liquid (p. 544), SbCl\(_3\) gave SbC\(_5\)H\(_5\) as an isolable though rather labile substance which rapidly polymerized at room temperature, and BiCl\(_3\) gave the even less-stable BiC\(_5\)H\(_5\) which could only be detected spectroscopically by chemical trapping.\(^{(141,142)}\)

Arsanaphtalene is an air-sensitive yellow oil.\(^{(143)}\)

Complexes of some of these heterocycles are also known, e.g. \([\text{Cr}(η^6\text{-C}_5\text{H}_5\text{As})_2]\),\(^{(144)}\) \([\text{Mo}(η^6\text{-C}_5\text{H}_5\text{As})(\text{CO})_3]\),\(^{(145)}\) and \([\text{Fe}(η^5\text{-C}_4\text{H}_4\text{As})_2]\), i.e. diarsaferrrocene.\(^{(146)}\)

Most organooarsenic(III) compounds are readily prepared by standard methods (p. 497) such as the treatment of AsCl\(_3\) with Grignard reagents, organolithium reagents, organoaluminium compounds, or by sodium-alkyl halide (Wurtz) reactions. As\(_2\)O\(_3\) can also be used as starting material as indicated in the scheme on p. 595. AsR\(_3\) and AsAR\(_3\) are widely used as ligands in coordination chemistry.\(^{(6)}\)

Common examples are the 4 compounds AsMe\(_3\), Ph\(_3\)(n = 0, 1, 2, 3). Multidentate ligands have also been extensively studied particularly the chelating ligand “o-phenylenebis(dimethylarsine)” i.e. 1,2-bis(dimethylarseno)benzene which can be prepared from cacodylic acid (dimethylarsinic acid) Me\(_2\)As(OH) (itself prepared as indicated in the general scheme on p. 595):

\[
\begin{align*}
\text{Me}_2\text{AsO(OH)} & \xrightarrow{\text{Zn/HCl}} \text{Me}_2\text{AsH} & \xrightarrow{\text{Na/thf}} \text{NaAsMe}_2 \\
& \xrightarrow{1,2\text{-Cl}_2\text{C}_6\text{H}_4\text{thf}} \text{Me}_2\text{AsMe}_2
\end{align*}
\]

Arsine complexes are especially stable for b-class metals such as Rh, Pd and Pt, and such complexes have found considerable industrial use in hydrogenation or hydroformylation of alkenes,

---

Halogenoarsines $R_2AsX$ and dihalogenoarsines $RAsX_2$ are best prepared by reducing the corresponding arsinic acids $R_2AsO(OH)$ or arsonic acid $RAsO(OH)_2$ with $SO_2$ in the presence of HCl or HBr and a trace of KI. The actual reducing agent is $I^-$ and the resulting $I_2$ is in turn reduced by the $SO_2$. Fluoro compounds are best prepared by metathesis of the chloro derivative with a metal fluoride, e.g. AgF. Interestingly, the compound $Ph_3AsI_2$ has been shown by X-ray analysis to contain 4-coordinate As and an almost linear As–I–I group with As–I 264 pm, I–I 300.5 pm and angle As–I–I 174.8°.\(^{(147)}\)

Hydrolysis of $R_2AsX$ yields arsinous acids $R_2AsOH$ or their anhydrides $(R_2As)_2O$. An alternative route employs a Grignard reagent and $As_2O_3$, e.g. $PhMgBr$ affords $(Ph_2As)_2O$. Hydrolysis of $RAsX_2$ yields either arsonous acids $RAs(OH)_2$ or their anhydrides $(RAsO)_n$. These latter are not arsoneso compounds $RAs=O$ analogous to nitroso compounds (p. 416) but are polymeric. Indeed, all these $As^{III}$ compounds feature pyramidal 3-coordinate As as do the formally $As^I$ compounds $(RAs)_n$ discussed on p. 584. A series of planar 3-coordinate arsenic(I) compounds have also been prepared and these are discussed on p. 597.

**Organoarsenic(V) compounds**

Among the compounds of $AsV$ can be noted the complete series $R_{n-5}AsX_n$ ($n = 0–5$) where $R$ can be alkyl or aryl. Thus $AsPh_5$ (mp 150°) can be prepared by direct reaction of LiPh on either [AsPh$_4$I], $Ph_3AsCl_2$ or $Ph_3As=O$. Similarly, $AsMe_5$ has also been prepared as a colourless, volatile, mobile liquid (mp –6°).\(^{(148)}\)

The preparation is carried out in $Me_2O$ at –60° to avoid formation of the ylide $Me_3As=CH_2$ (mp 35°) by elimination of $CH_4$. $AsMe_5$ decomposes above 100° by one of two routes:

\[
\begin{align*}
AsMe_5 & \xrightarrow{\Delta} C_2H_6 + AsMe_3 \\
& \xrightarrow{\Delta} CH_4 + \{Me_3As=CH_2\} \\
& \xrightarrow{} AsMe_3 + (CH_2)_n
\end{align*}
\]

It is stable in air and hydrolyses only slowly:

\[
\begin{align*}
AsMe_5 & + H_2O \rightarrow [AsMe_4]OH + CH_4 \\
& + HCl \rightarrow [AsMe_4]Cl + CH_4
\end{align*}
\]

The aryl analogues are rather more stable.

Of the quaternary arsonium compounds, methyltriaryl derivatives are important as precursors of arsonium ylides, e.g.

\[
[Ph_3AsMe]Br + NaNH_2 \xrightarrow{thf} Ph_3As=CH_2(mp 74°) + NaBr + NH_3
\]

Such ylides are unstable and react with carbonyl compounds to give both the Wittig product (p. 545) as well as $AsPh_3$ and an epoxide. However, this very reactivity is sometimes an advantage since $As$ ylides often react with carbonyl compounds that are unresponsive to $P$ ylides. Substituted quaternary arsonium compounds are also a useful source of heterocyclic organoarsanes, e.g. thermolysis of 4-(1,7-dibromoheptyl)trimethylarsionium bromide to 1-arsabicyclo[3.3.0]octane:

\[
\begin{align*}
Br(CH_2)_3 & \xrightarrow{\Delta} C-(CH_2)_3Br \xrightarrow{+ Br^-} AsMe_3 \\
& \xrightarrow{3MeBr} + 3MeBr
\end{align*}
\]

Some routes to organoarsenic compounds\(^{137}\)
Arsonic acids $\text{RAsO(OH)}_2$ are amongst the most important organoarsonium compounds. Alkyl arsonic acids are generally prepared by the Meyer reaction in which an alkaline solution of $\text{As}_2\text{O}_3$ is heated with an alkyl halide:

$$\text{As(ONa)}_3 + \text{RX} \xrightarrow{\text{heat}} \text{NaX} + \text{RAsO(OH)}_2$$

Acidify $\rightarrow \text{RAsO(OH)}_2$

Aryl arsonic acids can be made from a diazonium salt by the Bart reaction:

$$\text{As(ONa)}_3 + \text{ArN}_2\text{X} \rightarrow \text{NaX} + \text{N}_2$$

$$+ \text{ArAsO(OH)}_2$$

Similar reactions on alkyl or aryl arsonites yield the arsinic acids $\text{R}_2\text{AsO(OH)}$ and $\text{Ar}_2\text{AsO(OH)}$. Arsine oxides are made by alkaline hydrolysis of $\text{R}_3\text{AsX}_2$ (or $\text{Ar}_3\text{AsX}_2$) or by oxidation of a tertiary arsine with $\text{KMnO}_4$, $\text{H}_2\text{O}_2$ or $\text{I}_2$.

**Physiological activity of arsenicals**

In general $\text{As}^{\text{III}}$ organic derivatives are more toxic than $\text{As}^{\text{V}}$ derivatives. The use of organoarsenicals in medicine dates from the discovery in 1905 by H. W. Thomas that “atoxyl” (first made by A. Béchamp in 1863) cured experimental trypanosomiasis (e.g. sleeping sickness). In 1907 P. Erlich and A. Bertheim showed that “atoxyl” was sodium hydrogen 4-aminophenylarsonate

![Chemical structure of sodium hydrogen 4-aminophenylarsonate](image)

and the field was systematically developed especially when some arsenicals proved effective against syphilis. Today such treatment is obsolete but arsenicals are still used against amoebic dysentery and are indispensable for treatment of the late neurological stages of African trypanosomiasis.

**Organoantimony and organobismuth compounds**

Organoantimony and organobismuth compounds are closely related to organoarsenic compounds but have not been so extensively investigated. Similar preparative routes are available and it will suffice to single out a few individual compounds for comment or comparison. $\text{MR}_3$ (and $\text{MAr}_3$) are colourless, volatile liquids or solids having the expected pyramidal molecular structure. Some properties are in Table 13.13. As expected (p. 198) tertiary stibines are much weaker ligands than phosphines or arsines. Tertiary bismuthines are weaker still: among the very few coordination complexes that have been reported are $[\text{Ag(BiPh}_3]\text{ClO}_4$, $\text{Ph}_3\text{BiNbCl}_5$, and $\text{Ph}_3\text{BiM(CO)}_5$ ($\text{M} = \text{Cr, Mo, W}$).

An intriguing 3-coordinate organoantimony compound, which is the first example of trigonal-planar Sb, has been characterized. The stibinidene complex $[\text{PhSb}[\text{Mn(CO)}_2(\eta^5-\text{C}_5\text{H}_5)]_2]$ has been isolated as shiny golden metallic crystals (mp 128°) from the crown-ether catalysed reaction:

$$[(\eta^5-\text{C}_5\text{H}_5)(\text{CO})_2\text{MnSbPhI}_2] + [(\eta^5-\text{C}_5\text{H}_5)\text{Mn(CO)}_2] \xrightarrow{\text{K/Ph}} \text{K/18-crown-6}$$

$$[\text{PhSb}[\text{Mn(CO)}_2(\eta^5-\text{C}_5\text{H}_5)]_2] + 2\text{KI} + \cdots$$

**Table 13.13** Some physical properties of MMe₃ and MPh₃
Figure 13.28 Planar structure of (a) [PhSb\{Mn(CO)2(\eta^5-C_5H_5)\}2], and (b) [PhAs\{Cr(CO)3\}3]. Note the relatively short Sb–Mn and As–Cr bonds.

The structure is shown in Fig. 13.28a: the interatomic angles and distances suggest that the bridging \{PhSb\} group is stabilized by Sb–Mn \(\pi\) interactions. A similar route leads to 3-coordinate planar organoarsinidine complexes which can also be prepared by the following reaction sequence:

\[
[\text{Cr(CO)}_6] \xrightarrow{\text{PhAsH}_2} [\text{Cr(CO)}_5(\text{AsPhH}_2)] \quad \text{yellow}
\]

\[
\xrightarrow{\text{LiBu}} [\text{Cr(CO)}_5(\text{AsPhL}_2)] \quad \text{orange}
\]

\[
[\{\text{Cr(CO)}_3\}_2\text{AsPh}] \quad \text{dark violet (mp 104\(^\circ\)}
\]

The chloro-derivative \([\text{ClAs}\{\text{Mn(CO)}_2-(\eta^5-C_5H_5)\}2]\) (shiny black crystals, mp 124\(^\circ\)) can now be much more readily obtained by direct reaction of AsCl\(_3\) with \([\text{Mn(CO)}_2-(\eta^5-C_5H_5)]_3\),thf.\(^{150}\)

Halogenostibines \(\text{R}_2\text{SbX}\) and dihalogenostibines \(\text{RSbX}_2\) (\(\text{R} = \text{alkyl, aryl}\)) can be prepared by standard methods. The former hydrolyse to the corresponding covalent molecular oxides \((\text{R}_2\text{Sb})_2\text{O}\), whereas \(\text{RSbX}_2\) yield highly polymeric “stiboso” compounds \((\text{RSbO})_n\). The stibonic acids, \(\text{RSbO(OH)}_2\), and stibinic acids, \(\text{R}_2\text{SbO(OH)}\), differ in structure from phosphonic and phosphinic acids (p. 512) or arsonic and arsinic acids (p. 594) in being high molecular weight materials of unknown structure. They are probably best considered as oxide hydroxides of organoantimony(V) cations. Indeed, throughout its organometallic chemistry Sb shows a propensity to increase its coordination number by dimerization or polymerization. Thus \(\text{Ph}_2\text{SbF}\) consists of infinite chains of F-bridged pseudo trigonalbipyramidal units as shown in Fig. 13.29.\(^{151}\) The compound could not be prepared by the normal methods of fluorinating \(\text{Ph}_2\text{SbCl}\) or phenylating \(\text{SbF}_3\) but can be obtained as a white, air-stable, crystalline solid mp 154\(^\circ\) by the following sequence of steps:

\[
\text{PhSiCl}_3 \xrightarrow{\text{SbF}_3/80^\circ} \text{PhSiF}_3 \xrightarrow{\text{aq NH}_4\text{F}} \text{PhSiF}_3\quad \text{(anhydr)}
\]

\[
\xrightarrow{\text{aq SbF}_3} \text{[NH}_4\text{][PhSiF}_3] \xrightarrow{\text{aq SbF}_3} \text{Ph}_2\text{SbF}
\]

Again, \(\text{Me}_2\text{SbCl}_3\) is monomeric with equatorial methyl groups \((C_2v)\) in solution \((\text{CH}_2\text{Cl}_2, \text{CHCl}_3\) or \(\text{C}_6\text{H}_6\)) but forms Cl-bridged dimers with \textit{trans} methyl groups \((D_{2h})\) in the solid.\(^{152}\)

Figure 13.29  Structure of Ph$_2$SbF$_2$ showing polymeric chains of apex-shared pseudo trigonal bipyramidal units {Ph$_2$FSb...F}.

Figure 13.30  (a) Molecular geometry of SbPh$_5$ showing the slightly distorted square-pyramidal structure.$^{155}$ (b) Similar data obtained at $-96^\circ$ for the slightly more regular square-pyramidal BiPh$_5$.$^{159}$

A similar Cl-bridged dimeric structure was established by X-ray analysis for Ph$_2$SbCl$_3$.$^{153}$ Pentaphenylantimony, SbPh$_5$ (mp 171$^\circ$), has attracted much attention as the first known example of a 10-valence-electron molecule of a main group element that has a square pyramidal structure.$^{154,155}$ rather than the usual trigonal bipyramidal structure (as found in PPh$_5$ and AsPh$_5$). BiPh$_5$ is now also known to have a square pyramidal structure (see below) as does the anion InCl$_5^{2-}$ (p. 238). SbPh$_5$ can conveniently be prepared as colourless crystals from SbPh$_3$ by chlorination to give Ph$_3$SbCl$_2$ and then reaction with LiPh:

$$\text{Ph}_3\text{SbCl}_2 + 3\text{LiPh} \rightarrow 2\text{LiCl} + \text{Li}[\text{SbPh}_6]$$

$$\text{H}_2\text{O} \rightarrow \text{LiOH} + \text{C}_6\text{H}_6 + \text{SbPh}_5$$

The structure, shown in Fig. 13.30(a), is based on a slightly distorted square-pyramidal coordination around the Sb atom (C$_{2v}$ instead of C$_{4v}$), the ipso-C$_{as}$-Sb-C$_{ip}$ angles being alternately 98.3$^\circ$ and 105.4$^\circ$. Vibrational spectroscopy suggests that the molecule retains its square-pyramidal structure even in solution, so the structure is not an artefact of crystal packing forces. The yellow cyclopropyl analogue, Sb(C$_3$H$_5$)$_5$, apparently has the same geometry.$^{156}$ while the solvate SbPh$_5$-0.5C$_6$H$_{12}$

and the \( p \)-tolyl derivative \( \text{Sb}(4-\text{MeC}_6\text{H}_4)_5 \) have almost undistorted trigonal bipyramidal structures.\(^{157}\)

\( \text{BiPh}_5 \) is even more remarkable. Not only is it square pyramidal (Fig. 13.30b) but it is also highly coloured. It can be prepared as violet crystals by the direct reaction of \( \text{Ph}_3\text{BiCl}_2 \) with two moles of \( \text{LiPh} \) in ether at \(-75^\circ\).\(^{158}\) The colour is retained in solution, and is due to a weak broad absorption in the green-yellow region (\( \lambda_{\text{max}} \) 532 nm, \( \log \varepsilon \) 2.4).\(^{159}\) Substitution on the phenyl rings modifies the colour and may also alter the structure, e.g.:\(^{160}\) \( \text{[BiPh}_3(2-\text{FC}_6\text{H}_4)_2] \), which is square pyramidal with the \( o \)-fluorophenyl groups \( \text{trans} \)-basal, forms violet crystals but is reddish in solution, whereas \( \text{[Bi}(4-\text{MeC}_6\text{H}_4)_3(2-\text{F-C}_6\text{H}_4)_2] \) is trigonal bipyramidal with axial fluorophenyl groups; it forms yellow crystals but again gives reddish solutions. The structures and colours have been interpreted in terms of relativistic effects.

\( \text{SbMe}_5 \) is surprisingly stable in view of the difficulty of obtaining \( \text{AsMe}_5 \) and \( \text{BiMe}_5 \); it melts at \(-1^\circ\), boils at 127\(^\circ\), and does not inflame in air, though it oxidizes quickly and is hydrolysed by water. It resembles \( \text{SbPh}_5 \) in reacting with \( \text{LiMe} \) (\( \text{LiPh} \)) to give \( \text{Li}^+[\text{SbR}_5]^− \) and in reacting with \( \text{BPh}_3 \) to give \( [\text{SbR}_4]^+[\text{RBPh}_3]^− \).

Organobismuth(V) compounds are in general similar to their As and Sb analogues but are less stable and there are few examples known; e.g. \( [\text{BiR}_4]X \) and \( R_3\text{BiX}_2 \) are known but not \( R_2\text{BiX}_3 \) or \( R\text{BiX}_4 \), whereas all 4 classes of compound are known for P, As and Sb. Similarly, no pentaalkylbismuth compound is known, though as noted above \( \text{BiPh}_5 \) and its derivatives have been prepared. It decomposes spontaneously over a period of days at room temperature and reacts readily with \( \text{HX} \), \( \text{X}_2 \) or even \( \text{BPh}_3 \) by cleaving 1 phenyl to form quaternary bismuth compounds \( [\text{BiPh}_4]X \) and \( [\text{BiPh}_4][\text{BPh}_3] \); this latter compound (mp 228\(^\circ\)) is the most stable bismuthonium salt yet known.

14

Oxygen

14.1 The Element

14.1.1 Introduction

Oxygen is the most abundant element on the earth’s surface: it occurs both as the free element and combined in innumerable compounds, and comprises 23% of the atmosphere by weight, 46% of the lithosphere and more than 85% of the hydrosphere (~85.8% of the oceans and 88.81% of pure water). It is also, perhaps paradoxically, by far the most abundant element on the surface of the moon where, on average, 3 out of every 5 atoms are oxygen (44.6% by weight).

The “discovery” of oxygen is generally credited to C. W. Scheele and J. Priestley (independently) in 1773–4, though several earlier investigators had made pertinent observations without actually isolating and characterizing the gas. Indeed, it is difficult to ascribe a precise meaning to the word “discovery” when applied to a substance so ubiquitously present as oxygen; particularly when (a) experiments on combustion and respiration were interpreted in terms of the phlogiston theory, (b) there was no clear consensus on what constituted “an element”, and (c) the birth of Dalton’s atomic theory was still far in the future. Moreover, the technical difficulties before the mid-eighteenth century of isolating and manipulating gases compounded the problem still further, and it seems certain that several investigators had previously prepared oxygen without actually collecting it or recognizing it as a constituent of “common air”. Scheele, a pharmacist in Uppsala, Sweden, prepared oxygen at various times between 1771–3 by heating KNO₃, Mg(NO₃)₂, Ag₂CO₃, HgO and a mixture of H₃AsO₄ and

MnO₂. He called the gas “vitriol air” and reported that it was colourless, odourless and tasteless, and supported combustion better than common air, but the results did not appear until 1777 because of his publisher’s negligence. Priestley’s classic experiment of using a “burning glass” to calcine HgO confined in a cylinder inverted over liquid mercury was first performed in Colne, England, on 1 August 1774; he related this to A. L. Lavoisier and others at a dinner party in Paris in October 1774 and published the results in 1775 after he had shown that the gas was different from nitrous oxide. Priestley’s ingenious experiments undoubtedly established oxygen as a separate substance (“dephlogisticated air”) but it was Lavoisier’s deep insight which recognized the new gas as an element and as the key to our present understanding of the nature of combustion. This led to the overthrow of the phlogiston theory and laid the foundations

of modern chemistry.(5) Lavoisier named the element “oxygène” in 1777 in the erroneous belief that it was an essential constituent of all acids (Greek ὀξύς, oxys, sharp, sour; γείνωμαι, geinomai, I produce; i.e. acid forming). Some other important dates in oxygen chemistry are in the Panel.

14.1.2 Occurrence

Oxygen occurs in the atmosphere in vast quantities as the free element \( \text{O}_2 \) (and \( \text{O}_3 \), p. 607) and there are also substantial amounts dissolved in the oceans and surface waters of the world. Virtually all of this oxygen is of biological origin having been generated by green-plant photosynthesis from water (and carbon dioxide).\(^6\)\(^7\) The net reaction can be represented by:

\[
\text{H}_2\text{O} + \text{CO}_2 + h\nu \xrightarrow{\text{chlorophyll enzymes}} \text{O}_2 + (\text{CH}_2\text{O})
\]

(i.e. carbohydrates, etc.)

However, this is misleading since isotope-tracer experiments using \(^{18}\text{O}\) have shown that both of the oxygen atoms in \( \text{O}_2 \) originate from \( \text{H}_2\text{O} \), whereas those in the carbohydrates come from \( \text{CO}_2 \). The process is a complex multistage reaction involving many other species,\(^8\) and requires 469 kJ mol\(^{-1}\) of energy (supplied by the light). The reverse process, combustion of organic materials with oxygen, releases this energy again. Indeed, except for very small amounts of energy generated from wind or water power, or from nuclear reactors, all the energy used by man comes ultimately from the combustion of wood or fossil fuels such as coal, peat, natural gas and oil. Photosynthesis thus converts inorganic compounds into organic material, generates atmospheric oxygen, and converts light energy (from the sun) into chemical energy. The \( 1.5 \times 10^9 \) km\(^3\) of water on the earth is split by photosynthesis and reconstituted by respiration and combustion once every 2 million years or so.\(^9\) The photosynthetically generated gas temporarily enters the atmosphere and is recycled about once every 2000 years at present rates. The carbon dioxide is partly recycled in the atmosphere and oceans after an average residence time of 300 years and is partly fixed by precipitation of CaCO\(_3\), etc. (p. 273).

There was very little, if any, oxygen in the atmosphere 3000 million years ago. Green-plant photosynthesis probably began about 2500 My ago and \( \text{O}_2 \) first appeared in the atmosphere in geochemically significant amounts about 2000 My ago (this is signalled by the appearance of red beds of iron-containing minerals that have been weathered in an oxygen-containing atmosphere).\(^{6-8}\) The \( \text{O}_2 \) content of the atmosphere reached \(~2\%\) of the present level some 800 My ago and \( \sim20\% \) of the present level about 580 My ago. This can be compared with the era of rapid sea-floor spreading to give the separated continents which occurred 110–85 My ago. The concentration of \( \text{O}_2 \) in the atmosphere has probably remained fairly constant for the past 50 My, a period of time which is still extensive when compared with the presence of \( \text{homo sapiens} \), <1 My. The composition of the present atmosphere (excluding water vapour which is present in variable amounts depending on locality, season of the year, etc., is given in Table 14.1.\(^6\) The oxygen content corresponds to 21.04 atom\(\%\) and 23.15 wt\(\%\) (see also ref. 10). The question of atmospheric ozone and pollution of the stratosphere is discussed on p. 608.

\(^{(a)}\)Total mass: 5.136(7) \times 10^{15} tonnes; H\(_2\)O 0.017(1) \times 10^{15} tonnes; dry atmosphere 5.119(8) \times 10^{15} tonnes. Figures in parentheses denote estimated uncertainty in last significant digit.

In addition to its presence as the free element in the atmosphere and dissolved in surface waters, oxygen occurs in combined form both as water, and a constituent of most rocks, minerals, and soils. The estimated abundance of oxygen in the crustal rocks of the earth is 455,000 ppm (i.e. 45.5% by weight): see silicates, p. 347; aluminosilicates, p. 347; carbonates, p. 109; phosphates, p. 475, etc.

14.1.3 Preparation

Oxygen is now separated from air on a vast scale (see below) and is conveniently obtained for most laboratory purposes from high-pressure stainless steel cylinders. Small traces of N\(_2\) and the rare gases, particularly argon, are the most persistent impurities. Occasionally, small-scale laboratory preparations are required and the method chosen depends on the amount and purity required and the availability of services. Electrolysis of degassed aqueous electrolytes produces wet O\(_2\), the purest gas being obtained from 30% potassium hydroxide solution using nickel electrodes. Another source is the catalytic decomposition of 30% aqueous hydrogen peroxide on a platinized nickel foil. Many oxoacid salts decompose to give oxygen when heated (p. 864). A convenient source is KClO\(_3\) which evolves oxygen when heated to 400–500° according to the simplified equation

\[2\text{KClO}_3 \xrightarrow{\Delta} 2\text{KCl} + 3\text{O}_2\]

The decomposition temperature is reduced to 150° in the presence of MnO\(_2\) but then the product is contaminated with up to 3% of ClO\(_2\) (p. 847). Small amounts of breathable oxygen for use in emergencies (e.g. failure of normal supply in aircraft or submarines) can be generated by decomposition of NaClO\(_3\) in “oxygen candles”. The best method for the controlled preparation of very pure O\(_2\) is the thermal decomposition of recrystallized, predried, degassed KMnO\(_4\) in a vacuum line. Mn\(^{VI}\) and Mn\(^{IV}\) are both formed and the reaction can formally be represented as:

\[2\text{KMnO}_4 \xrightarrow{215-235^\circ} \text{K}_2\text{MnO}_4 + \text{MnO}_2 + \text{O}_2\]

Oxygen gas and liquid oxygen are manufactured on a huge scale by the fractional distillation of liquid air at temperatures near -183°C. Although world production exceeds 100 million tonnes pa this is still less than one ten-millionth part of the oxygen in the atmosphere; moreover, the oxygen is continuously being replenished by photosynthesis. Further information on the industrial production and uses of oxygen are in the Panel.
Industrial Production and Uses of Oxygen

Air can be cooled and eventually liquified by compressing it isothermally and then allowing it to expand adiabatically to obtain cooling by the Joule-Thompson effect. Although this process was developed by C. von Linde (Germany) and W. Hampson (UK) at the end of the last century, it is thermodynamically inefficient and costly in energy. Most large industrial plants now use the method developed by G. Claude (France) in which air is expanded isentropically in an engine from which mechanical work can be obtained; this produces a much greater cooling effect than that obtained by the Joule-Thompson effect alone. Because N₂ (bp = 195.8°C) is more volatile than O₂ (bp = 183.0°C) there is a higher concentration of N₂ in the vapour phase above boiling liquid air than in the liquid phase, whilst O₂ becomes progressively enriched in the liquid phase. Fractional distillation of the liquefied air is usually effected in an ingeniously designed double-column dual-pressure still which uses product oxygen from the upper column at a lower pressure (lower bp) to condense vapour for reflux at a higher pressure in the lower column. The most volatile constituents of air (He, H₂, Ne) do not condense but accumulate as a high-pressure gaseous mixture with N₂ at the top of the lower column. Argon, which has a volatility between those of O₂ and N₂, concentrates in the upper column from which it can be withdrawn for further purification in a separate column, whilst the least-volatile constituents (Kr, Xe) accumulate in the oxygen boiler at the foot of the upper column. Typical operating pressures are 5 atm at the top of the lower column and 0.5 atm at the bottom of the upper column. A large plant might produce 1700 tonnes per day of separated products. A rather different design is used if liquid (rather than gaseous) N₂ is required in addition to the liquid and/or gaseous O₂.

From modest beginnings at the turn of the century, oxygen has now become the third largest volume chemical produced in the USA (after H₂SO₄ and N₂ and ahead of ethylene, lime and NH₃, see p. 407). Production in 1995 was 23.3 million tonnes (USA), over 3 Mt (UK), and 100 Mt worldwide. About 20% of the USA production is as liquid O₂. This phenomenal growth derived mainly from the growing use of O₂ in steelmaking; the use of O₂ rather than air in the Bessemer process was introduced in the late 1950s and greatly increased the productivity by hastening the reactions. In many of the major industrial countries this use alone now accounts for 65–85% of the oxygen produced. Much of this is manufactured on site and is simply piped from the air-separation plant to the steel converter.

Oxygen is also used to an increasing extent in iron blast furnaces since enrichment of the blast enables heavy fuel oil to replace some of the more expensive metallurgical coke. Other furnace applications are in ferrous and non-ferrous metal smelting and in glass manufacture, where considerable benefits accrue from higher temperatures, greater productivity, and longer furnace life. Related, though smaller-scale applications, include steel cutting, oxy-gas welding, and oxygen lancing (concrete drilling).

In the chemical industry oxygen is used on a large scale in the production of TiO₂ by the chloride process (p. 959), in the direct oxidation of ethene to ethylene oxide, and in the manufacture of synthesis gas (H₂ + CO), propylene oxide, vinyl chloride, vinyl acetate, etc. Environmental and biomedical uses embrace sewage treatment, river revival, paper-pulp bleaching, fish farming, artificial atmospheres for diving and submarine work, oxygen tents in hospitals, etc. Much of the oxygen for these applications is transported either in bulk liquid carriers or in high-pressure steel cylinders.

A final, somewhat variable outlet for large-scale liquid oxygen is as oxidant in rocket fuels for space exploration, satellite launching and space shuttles. For example, in the Apollo mission to the moon (1979), each Saturn 5 launch rocket used 1270 m³ (i.e. 1.25 million litres or 1450 tonnes) of liquid oxygen in Stage 1, where it oxidized the kerosene fuel (195 000 l, or about 550 tonnes) in the almost unbelievably short time of 2.5 min. Stages 2 and 3 had 315 and 76.3 m³ of liquid O₂ respectively, and the fuel was liquid H₂.

14.1.4 Atomic and physical properties

Oxygen has 3 stable isotopes of which ¹⁶O (relative atomic mass 15.994915) is by far the most abundant (99.762 atom%). Of the others, ¹⁷O (16.999134) has an abundance of only 0.038% and ¹⁸O (17.999160) is 0.200% abundant. These values vary slightly in differing natural sources (the ranges being 0.0350–0.0407% for ¹⁷O and 0.188–0.215% for ¹⁸O) and this variability prevents the atomic weight of oxygen being quoted more precisely than 15.9994 ± 0.0003 (see p. 17). Artificial enrichment of ¹⁷O and ¹⁸O can be achieved by several physical or chemical processes such as the fractional distillation of water, the electrolysis of water, and the thermal diffusion of oxygen gas. Heavy water enriched to 20 atom% ¹⁷O or 98% ¹⁸O is available commercially, as is oxygen gas enriched to 95% in ¹⁷O or 99% in ¹⁸O. The ¹⁸O isotope has been much used in kinetic and

---

mechanistic studies. Ten radioactive isotopes are also known but their very short half-lives make them unsuitable for tracer work. The longest lived, $^{15}\text{O}$, decays by positron emission with $t_\frac{1}{2}$ 222.2 s; it can be made by bombarding $^{16}\text{O}$ with $^3\text{He}$ particles: $^{16}\text{O}(^3\text{He},\alpha)^{15}\text{O}$.

The isotope $^{17}\text{O}$ is important in having a nuclear spin ($I = \frac{5}{2}$) and this enables it to be used in nmr studies. The nuclear magnetic moment is $-1.8930$ nuclear magnetons (very similar to the value for the free neutron, $-1.9132\text{ NM}$) and the relative sensitivity for equal numbers of nuclei is 0.0291, compared with $^1\text{H}$ 1.00, $^{11}\text{B}$ 0.17, $^{13}\text{C}$ 0.016, $^{31}\text{P}$ 0.066, etc. In addition to this low sensitivity, measurements are made more difficult because the quadrupolar nucleus leads to very broad resonances, typically $10^2 - 10^3$ times those for $^1\text{H}$. The observing frequency is $\sim0.136$ times that for proton nmr. The resonance was first observed in 1951 and the range of chemical shifts extended in 1955. The technique has proved particularly valuable for studying aqueous solutions and the solvation equilibria of electrolytes. Thus the hydration numbers for the diamagnetic cations Be$^{2+}$, Al$^{3+}$, and Ga$^{3+}$ have been directly measured as 4, 6 and 6 respectively, and several exchange reactions between "bound" and "free" water have been investigated. Chemical shifts for $^{17}\text{O}$ in a wide range of oxoanions $[\text{XO}_n]^{n-}$ have been studied and it has been found that the shifts for terminal and bridging O atoms in $[\text{Cr}_2\text{O}_7]^{2-}$ differ by as much as 760 ppm. The technique is proving increasingly valuable in the structure determination of complex polyanions in solution; for example all seven different types of O atoms in $[\text{V}_{10}\text{O}_{28}]^{6-}$ (p. 986) have been detected. The exchange of $^{17}\text{O}$ between $\text{H}_2^{17}\text{O}$ and various oxoanions has also been studied. Less work has been done so far on transition metal complexes of CO and NO though advances in techniques are now beginning to yield valuable structural and kinetic data.

The electronic configuration of the free O atom is $1s^22s^22p^4$, leading to a $^3\text{P}_2$ ground state. The ionization energy of O is 1313.5 kJ mol$^{-1}$ (cf. S on p. 662 and the other Group 16 elements on p. 754). The electronegativity of O is 3.5; this is exceeded only by F and the high value is reflected in much of the chemistry of oxygen and the oxides. The single-bond atomic radius of O is usually quoted as 73–74 pm, i.e. slightly smaller than for C and N, and slightly larger than for F, as expected. The ionic radius of $\text{O}^{2-}$ is assigned the standard value of 140 pm and all other ionic radii are derived from this.

Molecular oxygen, $\text{O}_2$, is unique among gaseous diatomic species with an even number of electrons in being paramagnetic. This property, first observed by M. Faraday in 1848, receives a satisfying explanation in terms of molecular orbital theory. The schematic energy-level diagram is shown in Fig. 14.1: this indicates that the 2 least-strongly bound electrons in $\text{O}_2$ occupy degenerate orbitals of $\pi$ symmetry and have parallel spins. This leads to a triplet ground state, $^3\Sigma_g^-$. As there are 4 more electrons in bonding MOs than in antibonding MOs, $\text{O}_2$ can be formally said to contain a double bond. If the 2 electrons, whilst remaining unpaired in separate orbitals, have opposite spin, then a singlet excited state of zero resultant spin results, $^1\Sigma_g^+$. A singlet state also results if the 2 electrons occupy a single $\pi^*$ orbital with opposed spins, $^1\Sigma_g^-$. These 2 singlet states lie 94.72 and 157.85 kJ mol$^{-1}$ above the ground state and are extremely important in gas-phase oxidation reactions (p. 614). The excitation is

---

accompanied by a slight but definite increase in the internuclear distance from 120.74 pm in the ground state to 121.55 and 122.77 pm in the excited states. The bond dissociation energy of O₂ is 493.4(2) kJ mol⁻¹; this is substantially less than for the triply bonded species N₂ (945.4 kJ mol⁻¹) but is much greater than for F₂ (158.8 kJ mol⁻¹). See also the discussion on p. 616.

Oxygen is a colourless, odourless, tasteless highly reactive gas. It dissolves to the extent of 3.08 cm³ (gas at STP) in 100 cm³ H₂O at 20° and this drops to 2.08 cm³ at 50°. Solubility in salt water is slightly less but is still sufficient for the vital support of marine and aquatic life. Solubility in many organic solvents is about 10 times that in water and necessitates careful degassing if these solvents are to be used in the preparation and handling of oxygen-sensitive compounds. Typical solubilities (expressed as gas volumes dissolved in 100 cm³ of solvent at 25°C and 1 atm pressure) are Et₂O 45.0, CCl₄ 30.2, Me₂CO 28.0 and C₆H₆ 22.3 cm³.

Oxygen condenses to a pale blue, mobile paramagnetic liquid (bp −183.0°C at 1 atm). The viscosity (0.199 centipoise at −183.5° and 10.6 atm) is about one-fifth that of water at room temperature. The critical temperature, above which oxygen cannot be liquefied by application of pressure alone, is −118.4°C and the critical pressure is 50.15 atm. Solid oxygen (pale blue, mp −218.8°C) also comprises paramagnetic O₂ molecules but, in the cubic y-phase just below the mp, these are rotationally disordered and the solid is soft, transparent, and only slightly more dense than the liquid. There is a much greater increase in density when the solid transforms to the rhombohedral β-phase at −229.4° and there is a further phase change to the monoclinic α-form at −249.3°C; these various changes and the accompanying changes in molar volume ΔVₘ are summarized in Table 14.2.

The blue colour of oxygen in the liquid and solid phases is due to electronic transitions by which molecules in the triplet ground state are excited to the singlet states. These transitions are normally forbidden in pure gaseous oxygen and, in any case, they occur in the infrared region of the spectrum at 7918 cm⁻¹ (^1Δ₉) and 13 195 cm⁻¹ (^1Σ⁺). However, in the condensed phases a

A single photon can elevate 2 colliding molecules simultaneously to excited states, thereby requiring absorption of energy in the visible (red-yellow-green) regions of the spectrum. For example:

\[ 2\text{O}_2 (\text{Σ}_g^-) + h\nu \rightarrow 2\text{O}_2 (\text{Δ}_g^+); \]
\[ \bar{\nu} = 15,800 \text{ cm}^{-1}, \text{ i.e. } \lambda = 631.2 \text{ nm} \]

\[ 2\text{O}_2 (\text{Σ}_g^-) + h\nu \rightarrow \text{O}_2 (\text{Δ}_g) + \text{O}_2 (\text{Σ}_g^+); \]
\[ \bar{\nu} \sim 21,100 \text{ cm}^{-1}, \text{ i.e. } \lambda = 473.7 \text{ nm} \]

The blue colour of the sky is, of course, due to Rayleigh scattering and not to electronic absorption by O₂ molecules.

14.1.5 Other forms of oxygen

Ozone (20)

Ozone, O₃, is the triatomic allotrope of oxygen. It is an unstable, blue diamagnetic gas with a characteristic pungent odour: indeed, it was first detected by means of its smell, as reflected by its name (Greek ὀζέν, ozein, to smell) coined by C. F. Schönbein in 1840. Ozone can be detected by its smell in concentrations as low as 0.01 ppm; the maximum permissible concentration for continuous exposure is 0.1 ppm but levels as high as 1 ppm are considered non-toxic if breathed for less than 10 min.

The molecule O₃ is bent, as are the isoelectronic species ONCl and ONO⁻. Microwave measurements lead to a bond angle of 116.8 ± 0.5° and an interatomic distance of 127.8 (±0.3) pm between the central O and each of the 2 terminal O atoms as shown in Fig. 14.2a. This implies an O···O distance of only 218 pm between the 2 terminal O atoms, compared with the normal van der Waals O···O distance of 280 pm. A valence-bond description of the molecule is given by the resonance hybrids in Fig. 14.2b and a MO description of the bonding is indicated in Fig. 14.2c: in this, each O atom forms a σ bond to its neighbour using an sp²-type orbital, and the 3 atomic pₜ orbitals can combine to give the 3 MOs shown. There are just sufficient electrons to fill the bonding and nonbonding MOs so that the π system can be termed a 4-electron 3-centre bond. The total bond order for each O–O bond is therefore approximately 1.5 (1 σ bond and half of 1 π-bonding MO). It is instructive to note that SO₂ has a similar structure (angle O–S–O 120°): the much greater stability of this molecule when compared with O₃ has been ascribed, in part, to the possible involvement of d_e orbitals on the S atom which would allow the filled nonbonding orbital in O₃ to become bonding in SO₂ (see also p. 700). Other comparisons of O–O bond orders, interatomic distances and bond energies are in Table 14.4 (p. 616).

Ozone condenses to a deep blue liquid (bp –111.9°C) and to a violet-black solid (mp –192.5°C). The colour is due to an intense absorption band in the red region of the spectrum between 500–700 nm (λ_max 557.4 and 601.9 nm). Both the liquid and the solid are explosive.

---

due to decomposition into gaseous \( \text{O}_2 \). Gaseous ozone is also thermodynamically unstable with respect to decomposition into dioxygen though it decomposes only slowly, even at 200°, in the absence of catalysts or ultraviolet light:

\[
\frac{3}{2} \text{O}_2(\text{g}) \rightarrow \text{O}_3(\text{g}) ; \quad \Delta H_f = +142.7 \text{ kJ mol}^{-1} ; \\
\Delta G_f = +163.2 \text{ kJ mol}^{-1}
\]

Other properties of ozone (which can be compared with those of dioxygen on p. 606) are: density at \(-119.4^\circ\text{C} 1.354 \text{ g cm}^{-3} \) (liquid), density at \(-195.8^\circ\text{C} 1.728 \text{ g cm}^{-3} \) (solid), viscosity at \(-183^\circ\text{C} 1.57 \text{ centipoise} \), dipole moment 0.54 D. Liquid ozone is miscible in all proportions with \( \text{CH}_4 \), \( \text{CCl}_2 \text{F}_2 \), \( \text{CClF}_3 \), \( \text{CO} \), \( \text{NF}_3 \), \( \text{OF}_2 \) and \( \text{F}_2 \) but forms two layers with liquid \( \text{Ar} \), \( \text{N}_2 \), \( \text{O}_2 \) and \( \text{CF}_4 \).

A particularly important property of ozone is its strong absorption in the ultraviolet region of the spectrum between 220–290 nm (\( \lambda_{\text{max}} 255.3 \text{ nm} \)); this protects the surface of the earth and its inhabitants from the intense ultraviolet radiation of the sun. Indeed, it is this absorption of energy, and the consequent rise in temperature, which is the main cause for the existence of the stratosphere in the first place. Thus, the mean temperature of the atmosphere, which is about 20°C at sea level, falls steadily to about \(-55^\circ\) at an altitude of 10 km and then rises to almost 0°C at 50 km before dropping steadily again to about \(-90^\circ\) at 90 km. Concern was expressed in 1974\(^{21}\) that interaction of ozone with man-made chlorofluorocarbons would deplete the equilibrium concentration of ozone with potentially disastrous consequences, and this was dramatically confirmed by the discovery of a seasonally recurring “ozone hole” above Antarctica in 1985.\(^{22}\) A less prominent ozone hole was subsequently detected above the Arctic Ocean. The detailed physical and chemical conditions required to generate these large seasonal depletions of ozone are extremely complex but the main features have now been elucidated (see p. 848). Several accounts of various aspects of the emerging story, and of the consequent international governmental actions to

---

ameliorate or reverse the depletion have been published.\(^{23-27}\)

Ozone is best prepared by flowing \(\text{O}_2\) at 1 atm and 25° through concentric metallized glass tubes to which low-frequency power at 50–500 Hz and 10–20 kV is applied to maintain a silent electric discharge (see also p. 611). The ozonizer tube, which becomes heated by dielectric loss, should be kept cooled to room temperature and the effluent gas, which contains up to 10% \(\text{O}_3\) at moderate flow rates, can be used directly or fractionated if higher concentrations are required. Reaction proceeds via \(\text{O}\) atoms at the surface \(\text{M}\), via excited \(\text{O}_2^+\) molecules, and by dissociative ion recombination:

\[
\text{O}_2 + \text{O} + \text{M} \rightarrow \text{O}_3 + \text{M}^+; \quad \Delta H^\circ_{298} = -109 \text{ kJ mol}^{-1}
\]

\[
\text{O}_2 + \text{O}_2^+ \rightarrow \text{O}_3 + \text{O}
\]

\[
\text{O}_2^+ + \text{O}_2^- \rightarrow \text{O}_3 + \text{O}
\]

However, the reverse reaction of ozone with atomic oxygen is highly exothermic and must be suppressed by trapping out the ozone if good yields are to be obtained:

\[
\text{O}_3 + \text{O} \rightarrow 2\text{O}_2; \quad \Delta H^\circ_{298} = -394 \text{ kJ mol}^{-1}
\]

An alternative route to \(\text{O}_3\) is by ultraviolet irradiation of \(\text{O}_2\): this is useful for producing low concentrations of \(\text{O}_3\) for sterilization of foodstuffs and disinfection, and also occurs during the generation of photochemical smog. The electrolysis of cold aqueous \(\text{H}_2\text{SO}_4\) (or \(\text{HClO}_4\)) at very high anode current densities also affords modest concentrations of \(\text{O}_3\), together with \(\text{O}_2\) and \(\text{H}_2\text{SO}_4\) (p. 712) as byproducts. Other reactions in which \(\text{O}_3\) is formed are the reaction of elementary \(\text{F}_2\) with \(\text{H}_2\text{O}\) (p. 804) and the thermal decomposition of periodic acid at 130° (p. 872).

The concentration of ozone in \(\text{O}_2/\text{O}_3\) mixtures can be determined by catalytic decomposition to \(\text{O}_2\) in the gas phase and measurement of the expansion in volume. More conveniently it can be determined iodometrically by passing the gas mixture into an alkaline boric-acid-buffered aqueous solution of \(\text{KI}\) and determining the \(\text{I}_2\) so formed by titration with sodium thiosulfate in acidified solution:

\[
\text{O}_3 + 2\text{I}^- + \text{H}_2\text{O} \rightarrow \text{O}_2 + \text{I}_2 + 2\text{OH}^-
\]

The reaction illustrates the two most characteristic chemical properties of ozone: its strongly oxidizing nature and its tendency to transfer an \(\text{O}\) atom with coproduction of \(\text{O}_2\). Standard reduction potentials in acid and in alkaline solution are:

\[
\text{O}_3 + 2\text{H}^+ + 2\text{e}^- \leftrightarrow \text{O}_2 + \text{H}_2\text{O}; \quad E^\circ = 2.075 \text{ V}
\]

\[
\text{O}_3 + \text{H}_2\text{O} + 2\text{e}^- \leftrightarrow \text{O}_2 + 2\text{OH}^-; \quad E^\circ = 1.246 \text{ V}
\]

The acid potential is exceeded only by fluorine (p. 804), перокседат (p. 901), atomic \(\text{O}\), the \(\text{OH}\) radical, and a few other such potent oxidants. Decomposition is rapid in acid solutions but the allotrope is much more stable in alkaline solution. At 25° the half-life of \(\text{O}_3\) in 1 M \(\text{NaOH}\) is \(~2\) min; corresponding times for 5 M and 20 M \(\text{NaOH}\) are 40 min and 83 h respectively.

The highly reactive nature of \(\text{O}_3\) is further typified by the following reactions:

\[
\text{CN}^- + \text{O}_3 \rightarrow \text{OCN}^- + \text{O}_2
\]

\[
2\text{NO}_2 + \text{O}_3 \rightarrow \text{N}_2\text{O}_5 + \text{O}_2
\]

\[
\text{PbS} + 4\text{O}_3 \rightarrow \text{PbSO}_4 + 4\text{O}_2
\]

\[
3\text{I}^- + \text{O}_3 + 2\text{H}^+ \rightarrow \text{I}_3^- + \text{O}_2 + \text{H}_2\text{O}
\]

\[
2\text{CO}^{2+} + \text{O}_3 + 2\text{H}^+ \rightarrow 2\text{CO}^{3+} + \text{O}_2 + \text{H}_2\text{O}
\]

An important reaction of ozone is the formation of ozonides \(\text{MO}_3\). The formation of a red coloration when \(\text{O}_3\) is passed into concentrated aqueous alkali was first noted by C. F. Schönbein in 1866, but the presence

\[\text{CN}^- + \text{O}_3 \rightarrow \text{OCN}^- + \text{O}_2\]

\[2\text{NO}_2 + \text{O}_3 \rightarrow \text{N}_2\text{O}_5 + \text{O}_2\]

\[\text{PbS} + 4\text{O}_3 \rightarrow \text{PbSO}_4 + 4\text{O}_2\]

\[3\text{I}^- + \text{O}_3 + 2\text{H}^+ \rightarrow \text{I}_3^- + \text{O}_2 + \text{H}_2\text{O}\]

\[2\text{CO}^{2+} + \text{O}_3 + 2\text{H}^+ \rightarrow 2\text{CO}^{3+} + \text{O}_2 + \text{H}_2\text{O}\]

An important reaction of ozone is the formation of ozonides \(\text{MO}_3\). The formation of a red coloration when \(\text{O}_3\) is passed into concentrated aqueous alkali was first noted by C. F. Schönbein in 1866, but the presence
of $O_3^-$ was not established until 1949.\(^{(28)}\) The compounds are best prepared by action of gaseous $O_3$ on dry, powdered $MOH$ below $-10^\circ$ (or $O_3/O_2$ mixtures on $O_2$) followed by extraction with liquid ammonia (which may also catalyse their formation). The compounds are red-brown paramagnetic solids ($\mu = 1.74-1.80$ BM)\(^{(29)}\) and they decrease in stability in the sequence $Cs > Rb > K > Na$; unsolvated $LiO_3$ has not been prepared but the ammine $LiO_3\cdot4NH_3$ is known. Likewise the stability of $M^{II}(O_3)_2$ decreases in the sequence $Ba > Sr > Ca$. Above room temperature $MO_3$ decomposes to the superoxide $MO_2$ (p. 616) and the compounds are also hydrolytically unstable:

$$\text{Mo}_3 \xrightarrow{\text{warm}} \text{Mo}_2 + \frac{1}{2}O_2$$

$$\text{K}_3 + H_2O \rightarrow \text{KOH} + O_2 + \{\text{OH}\}$$

$$2\{\text{OH}\} \rightarrow H_2O + \frac{1}{2}O_2$$

The ozonide ion $O_3^-$ has the expected $C_{2v}$ symmetry like $O_3$ itself and the isoelectronic, paramagnetic molecule $ClO_2$ (p. 845). Early attempts at X-ray structural analysis were frustrated by the thermal instability of the compounds, their great reactivity, the difficulty of growing single crystals and the tendency to rotational disorder.\(^{(30)}\) However, it is now clear that the $O_3^-$ ion is indeed bent, the most accurate data being obtained on crystals of the surprisingly stable red compound $[\text{NMe}_4]_2O_3$ (decomp. 75\(^\circ\), cf. $CsO_3$ 53\(^\circ\)):\(^{(31)}\) the angle $O-O-O$ is 119.5(5)\(^\circ\), only slightly larger than for $O_3$ itself, and the $O-O$ and $O-O$ distances are 126.4(4) and 222.2(4) pm, respectively (cf. Fig. 14.2).

Ozone adds readily to unsaturated organic compounds\(^{(32)}\) and can cause unwanted cross-linking in rubbers and other polymers with residual unsaturation, thereby leading to brittleness and fracture. Addition to alkenes yields "ozonides" which can be reductively cleaved by $Zn/\text{H}_2O$ (or $I^-/\text{MeOH}$, etc.) to yield aldehydes or ketones. This smooth reaction, discovered by C. D. Harries in 1903, has long been used to determine the position of double bonds in organic molecules, e.g.:

$$\text{EtCH}=\text{CH}_2 \xrightarrow{\text{O}_3} \text{EtCH}-\text{CH}_2 \rightarrow \text{EtCHO} + HCHO$$

$$\text{MeCH}=\text{CHMe} \xrightarrow{\text{O}_3} \text{MeCH}-\text{CHMe} \rightarrow 2\text{MeCHO}$$

Ozonide formation occurs by a three-step mechanism along the lines first proposed in 1951 by R. Criegee:\(^{(33,34)}\)

$$\begin{align*}
\text{C} + \text{O}_3 & \rightarrow \text{C} - \text{O} - \text{O} \\
\left[ \begin{array}{c}
\text{O} \\
\text{O}^- \\
\text{C}^+ \\
\end{array} \right] + \text{O}_3 & \rightarrow \text{C} - \text{O} - \text{O} - \text{C} \\
\end{align*}$$

---

The primary ozonides (1), which are 1,2,3-trioxolanes, are formed by a concerted 1,3-dipolar cycloaddition between ozone and the alkene and are detectable only at very low temperatures. For example, at \(-175^\circ C\) ethene gives \(\text{CH}_2\text{CH}_2\text{OOO}\) which was shown by microwave spectroscopy to be non-planar with O–O 145 pm, angle O–O–O 100° and a dihedral angle between the C–O plane and O3 plane of 51°.\(^{(35)}\) At higher temperatures the primary ozonides spontaneously rearrange to secondary ozonides: these have a 1,2,4-trioxolane structure (2) and can be studied by a variety of techniques including \(^{17}\)O nmr spectroscopy.\(^{(36)}\) Normally, however, the ozonide is not isolated but is reductively cleaved to aldehydes and ketones in solution. Oxidative cleavage (air or \(O_2\)) yields carboxylic acids and, indeed, the first large-scale application of the reaction was the commercial production of pelargonic and azelaic acids from oleic acid:

\[
\begin{align*}
\text{Me(CH)}_2\text{CH}=\text{CH(CH)}_2\text{C(OH)H} & \quad \text{Oleic acid} \\
\text{Me(CH)}_2\text{CH} & \rightarrow \text{O}_3 \\
\text{Me(CH)}_2\text{CH} & \quad \text{Ozone} \\
\text{Me(CH)}_2\text{CH} & \rightarrow \text{O}_2/\text{H}_2\text{O} \\
\text{Me(CH)}_2\text{C(OH)OH} & \quad \text{Pelargonic acid} \\
\text{HO}_2\text{C(CH)}_2\text{C(OH)OH} & \quad \text{Azelaic acid}
\end{align*}
\]

Esters of these acids are used as plasticizers for PVC (polyvinylchloride) and other plastics.

Because of the reactivity, instability and hazardous nature of \(O_3\) it is always generated on site. Typical industrial ozone generators operate at 1 or 2 atm, 15–20 kV, and 50 or 500 Hz. The concentration of \(O_3\) in the effluent gas depends on the industrial use envisaged but yields of up to 10 kg per hour or 150 kg per day from a single apparatus are not uncommon and some plants yield over 1 tonne per day. In addition to pelargonic and azelaic acid production, \(O_3\) is used to make peroxyacetic acid from acetaldehyde and for various inorganic oxidations. At low concentrations it is used (particularly in Europe) to purify drinking water, since this avoids the undesirable taste and smell of chlorinated water, and residual ozone decomposes to \(O_2\) soon after treatment.\(^{(37)}\) Of the 1039 plants operating in 1977 all but 40 were in Europe, with the greatest numbers in France (593), Switzerland (150), Germany (136), and Austria (42). Other industrial uses include the preservation of goods in cold storage, the treatment of industrial waste and the deodorizing of air and sewage gases.\(^{(38)}\)

**Atomic oxygen**

Atomic oxygen is an extremely reactive, fugitive species which cannot be isolated free from other substances. Many methods of preparing oxygen atoms also yield other reactive or electronically excited species, and this somewhat complicates the study of their properties. Passage of a microwave or electric discharge through purified \(O_2\) gas diluted with argon produces O atoms in the \(^3P\) ground state (2 unpaired electrons). Mercury-sensitized photolysis of \(N_2O\) is perhaps a more convenient route to ground state O atoms (plus inert \(N_2\) molecules) though they can also be made by photolysis of \(O_2\) or \(NO_2\). Photolysis of \(N_2O\) in the absence of \(Hg\) gives O atoms in the spin-paired \(^1D\) excited state, and this species can also be obtained by photolysis of \(O_3\) or \(CO_2\).

---

The best method for determining the concentration of O atoms is by their extremely rapid reaction with NO₂ in a flow system:

\[ \text{O} + \text{NO}_2 \rightarrow \text{O}_2 + \text{NO} \]

The NO thus formed reacts more slowly with any excess of O atoms to reform NO₂ and this reaction emits a yellow-green glow.

\[ \text{NO} + \text{O} \rightarrow \text{NO}_2^* \rightarrow \text{NO}_2 + h\nu \]

The system is thus titrated with NO₂ until the glow is sharply extinguished.

As expected, atomic O is a strong oxidizing agent and it is an important reactant in the chemistry of the upper atmosphere.\(^{17,18}\) Typical reactions are:

- \( \text{H}_2 + \text{O} \rightarrow \text{OH} + \text{H} \)
- \( \text{OH} + \text{O} \rightarrow \text{O}_2 + \text{H} \)
- \( \text{O}_2 + \text{O} \rightarrow \text{O}_3 \)
- \( \text{Cl}_2 + \text{O} \rightarrow \text{Cl}_2\text{O}, \text{ClO}_2 \)
- \( \text{CO} + \text{O} \rightarrow \text{CO}_2 \)
- \( \text{CH}_4 + \text{O} \rightarrow \text{CO}_2, \text{H}_2\text{O} \)
- \( \text{HCN} + \text{O} \rightarrow \text{CO}, \text{CO}_2, \text{NO}, \text{H}_2\text{O} \)
- \( \text{H}_2\text{S} + \text{O} \rightarrow \text{H}_2\text{O}, \text{SO}_2, \text{SO}_3, \text{H}_2\text{SO}_4 \)
- \( \text{NaCl} + \text{O} \rightarrow \text{NaClO}_3, \text{Cl}_2, \text{NaOH} \)

Many of these reactions are explosive and/or chemiluminescent.

### 14.1.6 Chemical properties of dioxygen, O₂

Oxygen is an extremely reactive gas which vigorously oxidizes many elements directly, either at room temperature or above. Despite the high bond dissociation energy of O₂ (493.4 kJ mol⁻¹) these reactions are frequently highly exothermic and, once initiated, can continue spontaneously (combustion) or even explosively. Familiar examples are its reactions with carbon (charcoal) and hydrogen. Some elements do not combine with oxygen directly, e.g. certain refractory or noble metals such as W, Pt, Au and the noble gases, though oxo compounds of all elements are known except for He, Ne, Ar and possibly Kr. This great range of compounds was one of the reasons why Mendeleev chose oxides to exemplify his periodic law (p. 20) and why oxygen was chosen as the standard element for the atomic weight scale in the early days when atomic weights were determined mainly by chemical stoichiometry (p. 16).

Many inorganic compounds and all organic compounds also react directly with O₂ under appropriate conditions. Reaction may be spontaneous, or may require initiation by heat, light, electric discharge, chemisorption or various catalytic means. Oxygen is normally considered to be divalent, though the oxidation state can vary widely and includes the values of \( +\frac{1}{2}, 0, -\frac{1}{2}, -1 \) and \(-2\) in isolable compounds of such species as \( \text{O}_2^+, \text{O}_3, \text{O}_3^-, \text{O}_2^-, \text{O}_2^{2-} \) and \( \text{O}^{2-} \) respectively. The coordination number of oxygen in its compounds also varies widely, as illustrated in Table 14.3 and numerous examples of stable compounds are known which exemplify each coordination number from 1 to 8 (with the possible exception of 7, for which unambiguous examples are more difficult to find). Most of these examples are straightforward and structural details will be found at appropriate points in the text. Linear 2-coordinate O occurs in the silyl ether molecule \( [\text{O}(\text{SiPh}_3)_2] \).\(^{39}\) Planar 3-coordinate O occurs in the neutral gaseous molecular species \( \text{OLi}_3 \) and \( \text{ONa}_3 \)\(^{40}\) and in both cationic and anionic complexes (Fig. 14.3a, b). It also occurs in two-dimensional layer lattices such as tunellite, \( [\text{OB}_6\text{O}_6(\text{OH})_2]^{2n-} \) (cf. Fig. 14.3b) and in the three-dimensional rutile structure (p. 961).

Planar 4-coordinate O occurs uniquely in NbO which can be considered as a defect-NaCl-type structure with O and Nb vacancies at (000) and \( (\frac{1}{2}, \frac{1}{2}, \frac{1}{2}) \) respectively, thereby having only 3

| 8   | Cubic          | NBO (rather than 4) per unit cell (see p. 983). Tetrahedral, 4-coordinate O is featured in “basic beryllium acetate” (p. 122) and in many binary oxides as mentioned in Table 14.3. The detailed structure depends both on the stoichiometry and on the coordination geometry of the metal, which is planar in CuO, AgO and PdO, tetrahedral in BeO and ZnO, octahedral in M₂O₃ and cubic in MO₂. Tetrahedral coordination of O also occurs in the unusual species ONa₄ and HONa₃.⁴⁰ The less common see-saw (C₂ᵥ) coordination mode occurs in the “butterfly” oxo cluster anion [Fe₃Mn(CO)₁₂(μ₄-O)]⁻, in which the O atom bridges the [Mn(CO)₃] and [Fe(CO)₃] wingtips and the two [Fe(CO)₃] hinge groups.⁴² Five-fold coordination of O has only recently been established, in the μ₄-hydroxo bridged Cu₄ᴵ cluster, [Cu₄(μ₄-O)(η⁸-L⁺)]⁺, in which the central planar OCu₄ group is surrounded by a circum- annular octadentate macroyclic ligand, L⁺, with the H atom of the OH group vertically above (or below) this plane.⁴³ Square pyramidal coordination of O also occurs in the indium iso-propoxide cluster [(InOPr)]₅(μ₂-O)(μ₂-OPr)₄(μ₃-OPr)₄(4⁴) and in some complicated [Ba₅(μ₅-O)] oxobarium clusters supported by μ₂ and μ₃ phenoxide of t-butoxide ligands.⁴⁵

---

Figure 14.3 Examples of planar 3-coordinate O: (a) the cation in [O(HgCl)₃]Cl, (b) the central O atom in the discrete borate anion [OB₆O₆(OH)₆]²⁻ in macallisterite — the three heterocycles are coplanar but the 6 pendant OH groups lie out of the plane.

A recent addition to the many examples of octahedral coordination of O (Table 14.3) is the unusual volatile, hydrocarbon-soluble, crystalline oxo-alkoxide of barium [H₄Ba₆(μ₆-O)(OCH₂-CH₂OMe)₁₄], which forms rapidly when Ba granules are reacted with MeOCH₂CH₂OH in toluene suspension.⁴⁶

Much of the chemistry of oxygen can be rationalized in terms of its electronic structure (2s² 2p⁴), high electronegativity (3.5) and small size. Thus, oxygen shows many similarities to nitrogen (p. 412) in its covalent chemistry, and its propensity to form H bonds (p. 52) and pπ double bonds (p. 416), though the anionic chemistry of O²⁻ and OH⁻ is much more extensive than for the isoelectronic ions N³⁻, NH²⁻ and NH²-. Similarities to fluorine and fluorides are also notable. Comparisons with the chemical properties of sulfur (p. 662) and the heavier chalcogens (p. 754) are deferred to Chapters 15 and 16.

One of the most important reactions of dioxygen is that with the protein haemoglobin which forms the basis of oxygen transport in blood (p. 1099).⁴⁷ Other coordination complexes of O₂ are discussed in the following section (p. 615).

Another particularly important aspect of the chemical reactivity of O₂ concerns the photochemical reaction of singlet O₂ (p. 605) with unsaturated or aromatic organic compounds.⁴⁸⁻⁵¹ The pioneering work was done in 1931–9 by H. Kautsky who noticed that oxygen could quench the fluorescence of certain irradiated dyes by excitation to the singlet state, and that such excited O₂ molecules could oxidize compounds which did not react with oxygen in its triplet ground state. Although Kautsky gave essentially the correct explanation of his observations, his views were not accepted at the time and the work remained unnoticed by organic chemists for 25 years until the reactivity of singlet oxygen was rediscovered independently by two other groups in 1964 (p. 601). With the wisdom of hindsight it seems remarkable that Kautsky’s elegant experiments were ignored.

---

and careful reasoning failed to convince his contemporaries.

Singlet oxygen, \( ^1\text{O}_2 \), can readily be generated by irradiating normal triplet oxygen, \( ^3\text{O}_2 \) in the presence of a sensitizer, \( S \), which is usually a fluorescein-type dye, a polycyclic hydrocarbon or other strong absorber of light. A spin-allowed transition then occurs:

\[
^3\text{O}_2 + ^1S \xrightarrow{hv} ^1\text{O}_2 + ^3S
\]

Provided that the energy gap in the sensitizer is greater than 94.7 \( \text{kJ mol}^{-1} \), the \( ^1\Delta_g \) singlet state of \( \text{O}_2 \) is generated (p. 605). Above 157.8 \( \text{kJ mol}^{-1} \) some \( ^1\Sigma^+_g \text{O}_2 \) is also produced and this species predominates above 200 \( \text{kJ mol}^{-1} \). The \( ^1\Delta_g \) singlet state can also be conveniently generated chemically in alcoholic solution by the reaction

\[
\text{H}_2\text{O}_2 + \text{ClO}^- \rightarrow \text{Cl} + \text{H}_2\text{O} + \text{O}_2(^1\Delta_g)
\]

Another chemical route is by decomposition of solid adducts of ozone with triaryl and other phosphites at subambient temperatures:

\[
\text{O}_3 + \text{P(OPh)}_3 \xrightarrow{-78^\circ} \text{O}_3\text{P(OPh)}_3 \xrightarrow{-15^\circ} \text{O}_2(^1\Delta_g)
\]

+ \text{OP(OPh)}_3

Reactions of \( ^1\text{O}_2 \) can be classified into three types: 1,2 addition, 1,3 addition and 1,4 addition (see refs. 48–51 for details). In addition to its great importance in synthetic organic chemistry, singlet oxygen plays an important role in autoxidation (i.e. the photodegradation of polymers in air), and methods of improving the stability of commercial polymers and vulcanized rubbers to oxidation are of considerable industrial significance. Reactions of singlet oxygen also feature in the chemistry of the upper atmosphere.

### 14.2 Compounds of Oxygen

#### 14.2.1 Coordination chemistry: dioxygen as a ligand

Few discoveries in synthetic chemistry during the past three decades have caused more excitement or had more influence on the direction of subsequent work than L. Vaska's observation in 1963 that the planar 16-electron complex \( \text{trans-}[\text{Ir(CO)}\text{Cl(PPh}_3)_2] \) can act as a reversible oxygen carrier by means of the equilibrium:\n
\[
[\text{Ir(CO)}\text{Cl(PPh}_3)_2] + \text{O}_2 \rightleftharpoons [\text{Ir(CO)}\text{Cl(O}_2\text{)}(PPh}_3)_2]
\]

Not only were the structures, stabilities and range of metals that could form such complexes of theoretical interest, but there were manifest implications for an understanding of the biochemistry of the oxygen-carrying metalloproteins haemoglobin, myoglobin, haemerythrin and haemocyanin. Such complexes were also seen as potential keys to an understanding of the interactions occurring during homogeneous catalytic oxidations, heterogeneous catalysis and the action of metalloenzymes. Several excellent reviews are available.\(^{47,53–64}\)

Dioxygen–metal complexes in which there is a 1:1 stoichiometry of \( \text{O}_2:M \) are of two main types, usually designated Ia (or superoxo) and IIa (or

---

56 M. J. NOLTE, E. SINGLETON and M. LAING, J. Am. Chem. Soc. 97, 6396–400 (1975). An important paper showing how errors can arise even in careful single crystal X-ray studies, leading to incorrect inferences.
and careful reasoning failed to convince his contemporaries.

Singlet oxygen, $^1\mathrm{O}_2$, can readily be generated by irradiating normal triplet oxygen, $^3\mathrm{O}_2$ in the presence of a sensitizer, $S$, which is usually a fluorescein-type dye, a polycyclic hydrocarbon or other strong absorber of light. A spin-allowed transition then occurs:

$$^3\mathrm{O}_2 + ^1\mathrm{S} \xrightarrow{hv} ^1\mathrm{O}_2 + ^3\mathrm{S}$$

Provided that the energy gap in the sensitizer is greater than 94.7 kJ mol$^{-1}$, the $^1\Delta_g$ singlet state of $\mathrm{O}_2$ is generated (p. 605). Above 157.8 kJ mol$^{-1}$ some $^1\Sigma_g^+$ $\mathrm{O}_2$ is also produced and this species predominates above 200 kJ mol$^{-1}$. The $^1\Delta_g$ singlet state can also be conveniently generated chemically in alcoholic solution by the reaction

$$\mathrm{H}_2\mathrm{O}_2 + \mathrm{ClO}^- \rightarrow \mathrm{Cl} + \mathrm{H}_2\mathrm{O} + \mathrm{O}_2(1\Delta_g)$$

Another chemical route is by decomposition of solid adducts of ozone with triaryl and other phosphites at subambient temperatures:

$$\mathrm{O}_3 + \mathrm{P}($$OPh)$)_3 \xrightarrow{-78^\circ}$ $^3\mathrm{O}_3\mathrm{P}($OPh)$)_3 \xrightarrow{-15^\circ}$ $^1\mathrm{O}_2(1\Delta_g) + \mathrm{OP}($OPh)$)_3$

Reactions of $^1\mathrm{O}_2$ can be classified into three types: 1,2 addition, 1,3 addition and 1,4 addition (see refs. 48–51 for details). In addition to its great importance in synthetic organic chemistry, singlet oxygen plays an important role in autoxidation (i.e. the photodegradation of polymers in air), and methods of improving the stability of commercial polymers and vulcanized rubbers to oxidation are of considerable industrial significance. Reactions of singlet oxygen also feature in the chemistry of the upper atmosphere.

## 14.2 Compounds of Oxygen

### 14.2.1 Coordination chemistry: dioxygen as a ligand

Few discoveries in synthetic chemistry during the past three decades have caused more excitement or had more influence on the direction of subsequent work than L. Vaska's observation in 1963 that the planar 16-electron complex trans-[Ir(CO)Cl(PPh$_3$)$_2$] can act as a reversible oxygen carrier by means of the equilibrium$^{[52]}$

$$\text{[Ir(CO)Cl(O$_2$)(PPh$_3$)$_2$]}$$

Not only were the structures, stabilities and range of metals that could form such complexes of theoretical interest, but there were manifest implications for an understanding of the biochemistry of the oxygen-carrying metalloproteins haemoglobin, myoglobin, haemerythrin and haemocyanin. Such complexes were also seen as potential keys to an understanding of the interactions occurring during homogeneous catalytic oxidations, heterogeneous catalysis and the action of metalloenzymes. Several excellent reviews are available.$^{[47,53--64]}$

Dioxygen–metal complexes in which there is a 1:1 stoichiometry of $\mathrm{O}_2: \text{M}$ are of two main types, usually designated Ia (or superoxo) and IIa (or

---

Figure 14.4 The four main types of $O_2$–M geometry. The bridging modes Ib and IIb appear superficially similar but differ markedly in dihedral angles and other bonding properties. See also footnote to Table 14.5 for the recently established unique $\mu,\eta^1$-superoxide bridging mode.

peroxo) for reasons which will shortly become apparent (Fig. 14.4). Dioxygen can also form 1:2 complexes in which $O_2$ adopts a bidentate bridging geometry, labelled Ib and IIb in Fig. 14.4. Of these four classes of complex, the Vaska-type IIA peroxo complexes, are by far the most widespread amongst the transition metals, though many are not reversible oxygen carriers and some are formed by deprotonation of $H_2O_2$ (p. 636) rather than coordination of molecular $O_2$. By contrast, the bridging superoxo type Ib is known only for the green cobalt complexes formed by 1-electron oxidation of the corresponding IIb peroxo compounds. In all cases complex formation is accompanied by a significant increase in the $O$–$O$ interatomic distances and a considerable decrease in the $\nu(O–O)$ vibrational stretching frequency. Both effects are more marked for the peroxo (type II) complexes than for the superoxo (type I) complexes and have been interpreted in terms of a transfer of electrons from M into the antibonding orbitals of $O_2$ (p. 606) thereby weakening the $O$–$O$ bond. The magnitude of the effects to be expected can be gauged from Table 14.4. Note that the $O$–$O$ bond in $O_2^+$ is stronger than in $O_2$ but this does not mean that $O_2^+$ is more stable than $O_2$ since energy must be supplied to remove an electron from $O_2$ and this energy is greater than that released in forming the stronger bond: it is important not to confuse bond energy with stability. Comparative data for a wide range of dioxygen-metal complexes is in Table 14.5. It will be noted also that the $O$–$O$ distances and vibrational frequencies are rather insensitive to the nature of the metal or its other attached ligands, or, indeed, as to whether the $O_2$ is coordinated to 1 or 2 metal centres. Both classes of superoxo complex, however, have $d(O–O)$ and $\nu(O–O)$ close to the values for the superoxide ion, whereas both classes of peroxo complex have values close to those for the peroxide ion. (However, see footnote to Table 14.5 for an important caveat to this generalization.)

Superoxo complexes having a nonlinear $M$–$O$–$O$ configuration are known at present only for Fe, Co, Rh and perhaps a few other transition metals, whereas the Vaska-type (IIa) complexes are known for almost all the transition metals.

(a) Reaction of K₂O with Al₂Me₆ in the presence of dibenzo-18-crown-6 (p. 96) yields the surprisingly stable anion [(μ-η⁰⁻O₂)(AlMe₃)₂]⁻ in which one O of the superoxo ion bridges the 2 Al atoms (angle Al–O–Al 128°):

In this new type of coordination mode d(O–O) is long (147 pm) and the weakness of the O–O linkage is also shown by the very low value of 851 cm⁻¹ for ν(O–O), both values being more characteristic of peroxo than of superxo complexes.⁶⁶

Figure 14.5 (a) Reaction of N,N′-ethylenebis(3-Bu′-salicylideneiminato)cobalt(II) with dioxygen and pyridine to form the superxo complex [Co(3-Bu′Salen)₂(O₂)py]; the py ligand is almost coplanar with the Co–O–O plane, the angle between the two being 18°.⁶⁷ (b) Reversible formation of the peroxo complex [Ir(CO)Cl(O₂)(PPh₃)₂]. The more densely shaded part of the complex is accurately coplanar.⁶⁸

---

except those in the Sc and Zn groups and possibly Mn, Cr and Fe. The two modes of formation are illustrated in Fig. 14.5 for the two reactions:

\[
\begin{align*}
\text{O}_2/\text{py} & \quad \text{[Co(3-Bu'Salen)]}_2 \rightarrow [\text{Co(3-Bu'Salen)}]_2(\eta^1-\text{O}_2)\text{py}], \quad (\text{Ia}) \\
\text{O}_2/\text{C}_6\text{H}_6 & \quad [\text{Ir(CO)}\text{Cl}(\text{PPh}_3)]_2 \rightarrow [\text{Ir(CO)}\text{Cl}(\eta^2-\text{O}_2)(\text{PPh}_3)]_2, \quad (\text{IIa})
\end{align*}
\]

The sensitivity of the reaction type to the detailed nature of the bonding in the metal complex can be gauged from the fact that neither the PMe$_3$ analogue of Vaska’s iridium complex, nor the corresponding rhodium complex [Rh(CO)Cl(PPh$_3$)$_2$] react with dioxygen in this way. By contrast, the closely related red complex [RhCl(PPh$_3$)$_3$] reacts readily with O$_2$ in CH$_2$Cl$_2$ solution with elimination of PPh$_3$ to give the brown dinuclear doubly bridging complex [(Ph$_3$P)$_2$RhCl(μ-\text{O}_2)]$_2$.CH$_2$Cl$_2$, the structure of which is shown in Fig. 14.6a.$^\text{(69)}$ With [Pt(PPh$_3$)$_4$] reaction also occurs with elimination of PPh$_3$ but the product is the yellow, planar, mononuclear complex [Pt(\eta$^2$-\text{O}_2)(PPh$_3$)$_2$] (Fig. 14.6b)$^\text{(70)}$.

An example of a singly-bridging peroxo complex is the dinuclear cation [(Co(pydien)$_2$-\text{O}_2)]$^{4+}$ where pydien is the pentadentate ligand 1,9-bis(2-pyridyl)-2,5,8-triazanonane, NC$_5$H$_4$-CH$_2$N(CH$_2$CH$_2$N)$_2$CH$_2$C$_3$H$_4$N. The complex is readily formed by mixing ethanolic solutions of CoCl$_2$.6H$_2$O, NaI and the ligand, and then exposing the resulting solution to oxygen.$^\text{(71)}$ Some structural details are in Fig. 14.7. Such

Coordination chemistry: dioxygen as a ligand

μ-O₂ complexes are formed generally among the “Group VIII” metals (Fe, Ru, Os; Co, Rh, Ir; Ni, Pd, Pt. A unique example from main-group element chemistry is in the doubly-bridged R₂Sn(μ-O)(μ::η⁻,η⁺-O₂)SnR₂, (R = CH(SiMe₃)₂), in which O–O is 154 pm, Sn–O₂ 201 pm, angle Sn–O–O 103.3°; Sn–O 198 pm angle Sn–O–Sn 110.3°. (72)

Many mono- and di-nuclear peroxo-type dioxygen complexes can also be made by an alternative route involving direct reaction of transition metal compounds with H₂O₂ and it is, in fact, quite arbitrary to distinguish these complexes from those made directly from O₂. Many such compounds are discussed further on p. 637 and under the chemistry of individual transition metals, but one example calls for special mention since it was the first structurally characterized peroxo derivative to feature a symmetrical, doubly bidentate (side on) bridge linking two metal centres. (73) The local coordination geometry and dimensions of the central planar {LaO₂La} group are shown in Fig. 14.8; the very long O–O distance is particularly notable, being substantially longer than in the O₂⁻ ion itself (p. 616). The compound [La(N(SiMe₃)₂)₂(OPPh₃)]₂O₂, which is colourless, was made by treating [La(N(SiMe₃)₂)₃] with Ph₃PO, but the origin of the peroxo group remains obscure. Similar complexes of Pr (which is also, surprisingly, colourless), Sm (pale yellow), Eu (orange-red) and Lu (colourless), were obtained in good yield either by a similar reaction or by treating [Ln[N(SiMe₃)₂]₂] with a half-molar proportion of (Ph₃PO)₂H₂O₂.

The nature of the metal–oxygen bonding in the various types of dioxygen complex has been the subject of much discussion. (56,58,59,60,65,74) The electronic structure of the O₂ molecule (p. 606) makes it unlikely that coordination would be by the usual donation of an “onium” lone-pair (from O₂ to the metal centre) which forms an important component of most other donor–acceptor adducts (p. 198). Most discussion has centred on the extent of electron transfer from the metal into the partly occupied antibonding orbitals of O₂. There now seems general agreement that there is substantial transfer of electron density from the metal d₂ orbital into the π* antibonding orbitals of O₂ with concomitant increase in the formal oxidation state of the metal, e.g. {Co^{II}} + O₂ → {Co^{III}(O₂⁻)}. Whether the resulting bonding between dioxygen and the metal atom is predominantly ionic or partly covalent may well depend to some extent on the nature of the metal centre and is largely a semantic problem which gradually disappears the more precisely one can define the detailed MOs or the actual electron distribution, (75) cf. the discussion on p. 79.

A dramatic discovery in this area was made in 1996 when a dicopper–dioxygen adduct was found to have two isomeric forms which featured either a side-on bridging unit {Cu(μ::η⁻,η⁺-O₂)-Cu}²⁺ or a cyclic {Cu(μ-O)₂Cu}²⁺ core depending on whether it was crystallized from CH₂Cl₂ or thf, respectively. The two forms could be readily interconverted by reversible O–O bond cleavage and reformation, the O–O distance being ~141 pm and 229 pm in the two isomers. (75a) The

---

Figure 14.8  Schematic representation of the planar central portion of the μ-peroxo complex [La(N(SiMe₃)₂)₂(OPPh₃)]₂O₂.

---

biochemical implications for reductive cleavage of $O_2$ by metalloenzymes and for $O_2$ evolution during photosynthesis are particularly exciting.

In addition to their great importance for structural and bonding studies, dioxygen complexes undergo many reactions. As already indicated, some of these reactions are of unique importance in biological chemistry\(^{76}\) and in catalytic systems. Some of the simpler inorganic reactions can be summarized as follows: aqueous acids yield $H_2O_2$ and reducing agents give coordinatively unsaturated complexes. Frequently the dioxygen complex can oxidize species that do not readily react directly with free molecular $O_2$, e.g. $CO$, $CO_2$, $CS_2$, NO, NO$_2$, SO$_2$, RNC, RCHO, R$_2$CO, PPh$_3$, etc. Illustrative examples of these reactions are:

$$[Pt(O_2)(PPh_3)_2] + CO \rightarrow [(PPh_3)_2Pt] + C=O$$

$$[Pt(O_2)(PPh_3)_2] + CO_2 \rightarrow [(PPh_3)_2Pt] + C=O$$

$$[Pt(O_2)(PPh_3)_2] + CS_2 \rightarrow [Pt(PPh_3)_2(S_2CO)]$$

$$[Pd(O_2)(PPh_3)_2] + NO \rightarrow [Pt(NO_2)_2(PPh_3)_2]$$

$$[Ir(CO)Cl(O_2)(PPh_3)_2] + 2NO_2 \rightarrow [Ir(CO)Cl(NO_3)_2(PPh_3)_2]$$

$$[Ir(CO)Cl(O_2)(PPh_3)_2] + SO_2 \rightarrow [Ir(CO)Cl(PPh_3)_2(SO_4)]$$

$$[RuCl(NO)(O_2)(PPh_3)_2] + SO_2 \rightarrow [RuCl(NO)(PPh_3)_2(SO_4)]$$

$$[Ni(CNBu')_2(O_2)] + 4Bu'NC \rightarrow [Ni(CNBu')_4] + 2RNCO$$

$$[Pt(O_2)(PPh_3)_2] + MeCHO \rightarrow [(PPh_3)_2Pt] + CHMe$$

$$[Ni(CNBu')_2(O_2)] + 4PPPh_3 \rightarrow [Ni(CNBu')_2(PPPh_3)_2] + 2PPh_3PO$$

Explanations that have been advanced to explain the enhanced reactivity of coordinated dioxygen include:

1. The diamagnetic nature of most $O_2$ complexes might facilitate reactions to form diamagnetic products which would otherwise be hindered by the requirement of spin conservation;
2. the metal may hold $O_2$ and the reactant in $cis$ positions thereby lowering the activation energy for oxidation, particularly with coordinatively unsaturated complexes;
3. coordinated $O_2$ is usually partially reduced (towards $O_2^-$ or $O_2^{2-}$) and this increased electron density might activate it.

Detailed kinetic and mechanistic studies will be required to assess the relative importance of these and other possible factors in specific instances.

### 14.2.2 Water

**Introduction**

Water is without doubt the most abundant, the most accessible and the most studied of all chemical compounds. Its omnipresence, its crucial importance for man’s survival and its ability to transform so readily from the liquid to the solid and gaseous states has ensured its prominence in man’s thinking from the earliest times. Water plays a prominent role in most creation myths and has a symbolic purifying or regenerating significance in many great religions even to the present day. In the religion of ancient Mesopotamia, the oldest of which we have written records (ca. 2000 BC), Nammu, goddess of the primaeval sea, was “the mother who gave birth to heaven and earth”; she was also the mother of the god of water, Enki, one of the four main gods controlling the major realms of the universe. In the Judaic-Christian tradition\(^{77}\) “the Spirit of God moved upon the face of the waters” and creation proceeded via “a firmament in the midst of the waters” to divide heaven from

---

\(^{77}\) Holy Bible, Genesis, Chap. 1, verses 1–10.
earth. Again, the Flood figures prominently\(^{(78)}\) as it does in the legends of many other peoples. The activities of John the Baptist\(^{(79)}\) and the obligatory washing practised by Muslims before prayers are further manifestations of the deep ritual significance of water.

Secular philosophers also perceived the unique nature of water. Thus, Thales of Miletus, who is generally regarded as the initiator of the Greek classical tradition of philosophy, ca. 585 BC, considered water to be the sole fundamental principle in nature. His celebrated dictum maintains: “It is water that, in taking different forms, constitutes the earth, atmosphere, sky, mountains, gods and men, beasts and birds, grass and trees, and animals down to worms, flies and ants. All these are but different forms of water. Meditate on water!” Though this may sound quaint or even perverse to modern ears, we should reflect that some marine invertebrates are, indeed, 96–97% water, and the human embryo during its first month is 93% water by weight. Aristotle considered water to be one of the four elements, alongside earth, air and fire, and this belief in the fundamental and elementary nature of water persisted until the epoch-making experiments of H. Cavendish and others in the second half of the eighteenth century (pp. 32, 601) showed water to be a compound of hydrogen and oxygen.\(^{(80)}\)

### Distribution and availability

Water is distributed very unevenly and with very variable purity over the surface of the earth (Table 14.6). Desert regions have little rainfall and no permanent surface waters, whereas oceans, containing many dissolved salts, cover vast tracts of the globe; they comprise 97% of the available water and cover an area of \(3.61 \times 10^8 \text{ km}^2\) (i.e. 70.8% of the surface of the

earth). Less than 2.7% of the total surface water is fresh and most of this is locked up in the Antarctic ice cap and to a much lesser extent the Arctic. The Antarctic ice cap covers some \(1.5 \times 10^7 \text{ km}^2\), i.e. larger than Continental Europe to the Urals \((1.01 \times 10^7 \text{ km}^2)\), the USA including Alaska and Hawaii \((0.94 \times 10^7 \text{ km}^2)\), or Australia \((0.77 \times 10^7 \text{ km}^2)\); it comprises some \(2.5–2.9 \times 10^7 \text{ km}^3\) of fresh water which, if melted, would supply all the rivers of the earth for more than 800 years. Every year some 5000 icebergs, totalling \(10^{12} \text{ m}^3\) of ice (i.e. \(10^{12} \text{ tonnes}\)), are calved from the glaciers and ice shelves of Antarctica. Each iceberg consists (on average) of \(\sim 200 \text{ Mtonnes}\) of pure fresh water and, if towed at 1–2 km h\(^{-1}\), could arrive 30% intact in Australia to provide water at one-tenth of the cost of current desalination procedures.\(^{(81)}\) Transportation of crushed ice by ship from the polar regions is an alternative that was used intermittently towards the end of the last century.

Surface freshwater lakes contain \(1.25 \times 10^5 \text{ km}^3\) of water, more than half of which

---

\(^{(78)}\) Holy Bible, Genesis, Chaps. 6–8.  
\(^{(79)}\) Holy Bible, Gospels according to St. Matthew, Chap. 3; St. Mark, Chap. 1; St. Luke, Chap. 3, St. John, Chap. 1.  
is in the four largest lakes. Though these huge lacustrine sources dwarf the innumerable smaller lakes, springs and rivers of the earth, human habitation depends more on these widely distributed smaller sources which, in total, still far exceed the needs of man and the animal and plant kingdoms. Despite this, severe local problems can arise due to prolonged drought, the pollution of surface waters, or the extension of settlements into more arid regions. Indeed, droughts have been endemic since ancient times, and even pollution of local sources has been a cause of concern and the subject of legislation since at least 1847 (UK). Fortunately, it now appears that the quality of water supplies and amenities is rising steadily in most communities since the nadir of some 40 years ago, and public concern is now increasingly ensuring that funds are available on an appropriate scale to deal with the massive problems of water pollution. (See also p. 478.)

Water purification and recycling is now a major industry. (86) The method of treatment depends on the source of the water, the use envisaged and the volume required. Luckily the human body is very tolerant to changes in the composition of drinking water, and in many communities this may contain 0.5 g l⁻¹ or more of dissolved solids (Table 14.7). Prior treatment may consist of coagulation (by addition of alum or chlorinated FeSO₄ to produce flocs of Al(OH)₃ or Fe(OH)₃), filtration, softening (removal of Ca²⁺ and Mg²⁺ by ion exchange) and disinfection (by chlorination, p. 793, or addition of ozone, p. 611). In most developed countries industrial needs for water are at least 10 times the volume used domestically. Moreover, some industrial processes require much purer water than that for human consumption, and for high-pressure boiler feedwater in particular the purity standard is 99.999998%, i.e. no more than 0.02 ppm impurities. This is far purer than for reactor grade uranium, the finest refined gold or the best analytical reagents, and is probably exceeded only by semiconductor grade germanium and silicon. In contrast to Ge and Si, however, water is processed on a megatonne-per-day scale at a cost of only about £1 per tonne.

The beneficiation of sea water and other saline sources to produce fresh water is also of increasing importance. Normal freshwater supplies from precipitation cannot meet the needs of the increasing world population, particularly in the semi-arid regions of the world, and desalination is being used increasingly to augment normal water supplies, or even to provide all the fresh water in some places such as the arid parts of the Arabian Peninsula. The most commonly used methods are distillation (e.g. multistage flash distillation processes) and ion-exchange techniques, including electrodialysis and reverse osmosis (hyperfiltration). The enormous importance of the field can be gauged from the fact that Gmelin's volume on Water Desalting, (87) which reviewed 14 000 papers published up to 1973/4, has already

\(^{(a)}\) Heavy water (p. 39) is now manufactured on the multikilotonne scale for use both as a coolant and neutron-moderator in nuclear reactors: its absorption cross-section for neutrons is much less than for normal water: $\sigma_\text{H} = 332$, $\sigma_\text{D} = 0.46$ mb (1 millibarn = $10^{-21}$ cm$^2$)

had to be supplemented by a further 360-page volume\(^{(88)}\) dealing with the 4000 papers appearing during the following 4 years. A far cry from the first recorded use of desalination techniques in biblical times.\(^{(89)}\)

**Physical properties and structure**

Water is a volatile, mobile liquid with many curious properties, most of which can be ascribed to extensive H bonding (p. 52). In the gas phase the $\text{H}_2\text{O}$ molecule has a bond angle of 104.5° (close to tetrahedral) and an interatomic distance of 95.7 pm. The dipole moment is 1.84 D. Some properties of liquid water are summarized in Table 14.8 together with those of heavy water $\text{D}_2\text{O}$ and the tritium analogue $\text{T}_2\text{O}$ (p. 41). The high bp is notable (cf. $\text{H}_2\text{S}$, etc.) as is the temperature of maximum density and its marked dependence on the isotopic composition of water. The high dielectric constant and measurable ionic dissociation equilibrium are also unusual and important properties. The ionic mobilities of $[\text{H}_3\text{O}]^+$ and $[\text{OH}]^-$ in water are abnormally high ($350 \times 10^{-4}$ and $192 \times 10^{-4}$ cm$^2$ V$^{-1}$ s$^{-1}$ at 25° compared with $50-75 \times 10^{-4}$ cm$^2$ V$^{-1}$ s$^{-1}$ for most other ions). This has been ascribed to a proton switch and reorientation mechanism involving the ions and chains of H-bonded solvent molecules. Other properties which show the influence of H bonding are the high heat and entropy of vaporization ($\Delta H_{\text{vap}} 44.02$ kJ mol$^{-1}$, $\Delta S_{\text{vap}} 118.8$ J deg$^{-1}$ mol$^{-1}$), high surface tension (71.97 dyne cm$^{-1}$, i.e. 71.97 mN m$^{-1}$) and relatively high viscosity. The strength of the H bonds has been variously estimated at between 5–50 kJ per mol of H bonds and is most probably close to 20 kJ mol$^{-1}$. The structured nature of liquid water in which the molecules are linked to a small number of neighbours (2–3) by H bonds also accounts for its anomalously low density compared with a value of ~1.84 g cm$^{-3}$ calculated for

\(^{(89)}\) Holy Bible, Exodus, Chap. 15, verses 22–25: "... so Moses brought the sons of Israel from the Red Sea and they went into the desert of Sur. And they marched three days in the wilderness and found no water to drink. And then they arrived at Merra and they could not drink from the waters of Merra because they were bitter. ... And the people murmured against Moses saying: What shall we drink? And Moses cried unto the Lord. And the Lord showed him a wood and he put it into the water and the water became sweet".
a normal close-packed liquid with molecules of similar size and mass. Details of the structure of liquid water have been probed for more than six decades since the classic paper of J. D. Bernal and R. H. Fowler proposed the first plausible model. Despite extensive work by X-ray and neutron diffraction, Raman and infrared spectroscopy, and the theoretical calculation of thermodynamic properties based on various models, details are still controversial and there does not even appear to be general agreement on whether water consists of a mixture of two or more species of varying degrees of polymerization or whether it is better described on a continuous model of highly bent H-bond configurations.

When water freezes the crystalline form adopted depends upon the detailed conditions employed. At least nine structurally distinct forms of ice are known and the phase relations between them are summarized in Fig. 14.9. Thus, when liquid or gaseous water crystallizes at atmospheric pressure normal hexagonal ice Ih forms, but at very low temperatures (−120° to −140°) the vapour condenses to the cubic form, ice Ic. The relation between these structures is the same as that between the tridymite and cristobalite forms of SiO2 (p. 342), though in both forms of ice the protons are disordered. Many of the high-pressure forms of ice are also based on silica structures (Table 14.9) and in ice II, VIII and IX the protons are ordered, the last 2 being low-temperature forms of ice VII and III respectively in which the protons are disordered. Note also that the high-pressure polymorphs VI and VII can exist at temperatures as high as 80°C and that, as expected, the high-pressure forms have substantially greater densities than that for ice I. A vitreous form of ice can be obtained by condensing water vapour at temperatures of −160°C or below.

In “normal” hexagonal ice Ih each O is surrounded by a nearly regular tetrahedral arrangement of 4 other O atoms (3 at 276.5 pm and 1, along the c-axis, at 275.2 pm). The O–O–O angles are all close to 109.5° and neutron diffraction shows that the angle H–O–H is close to 105°, implying that the H atoms lie slightly off the O–O vectors. The detailed description of the disordered H atom positions is complex. In the proton-ordered phases II and IX neutron diffraction again indicates an angle H–O–H close to 105° but the O–O–O angles are now 88° and 99° respectively. More details are in the papers mentioned in ref. 92.

(a) Metastable for H₂O, but firmly established for D₂O.
(b) Edingtonite is BaAl₂Si₃O₁₀·₄H₂O (see p. 1037 of ref. 93).
(c) Structure consists of two interpenetrating frameworks.

---

As indicated in Tables 14.8 and 14.9, ice Ih is unusual in having a density less than that of the liquid phase with which it is in equilibrium (a property which is of crucial significance for the preservation of aquatic life). When ice Ih melts some of the H bonds (possibly about 1 in 4) in the fully H-bonded lattice of 4-coordinate O atoms begin to break, and this process continues as the liquid is warmed, thereby enabling the molecules to pack progressively more closely with a consequent increase in density. This effect is opposed by the thermal motion of the molecules which tends to expand the liquid, and the net result is a maximum in the density at 3.98°C. Further heating reduces the density, though only slowly, presumably because the effects of thermal motion begin to outweigh the countervailing influence of breaking more H bonds. Again the qualitative explanation is clear but quantitative calculations of the density, viscosity, dielectric constant, etc., of H2O, D2O and their mixtures remain formidable.

It was previously thought that pure ice had a low but measurable electrical conductivity of about 1 x 10^-10 ohm^-1 cm^-1 at -10°C. However, this conductivity is now thought to arise almost exclusively from surface defects, and when these have been removed ice is essentially an insulator with an immeasurably small conductivity.93

Water of crystallization, aquo complexes and solid hydrates

Many salts crystallize from aqueous solution not as the anhydrous compound but as a well-defined hydrate. Still other solid phases have variable quantities of water associated with them, and there is an almost continuous gradation in the degree of association or “bonding” between the molecules of water and the other components of the crystal. It is convenient to recognize five limiting types of interaction though the boundaries between them are vague and undefined and many compounds incorporate more than one type.

(a) H2O coordinated in a cationic complex. This is perhaps the most familiar class and can be exemplified by complexes such as [Be(OH2)4]SO4, [Mg(OH2)6]Cl2, [Ni(OH2)6]-(NO3)2, etc.; the metal ion is frequently in the +2 or +3 oxidation state and tends to be small and with high coordination power. Sometimes there is further interaction via H bonding between the aquocation and the anion, particularly if this derives from an oxoacid, e.g. the alums ([M(OH2)6]+[Al(OH2)6]3+[SO4]2-) and related salts of Cr³⁺, Fe³⁺, etc. The species H2O⁺, H₃O⁺, H₇O₃⁺ and H₉O₄⁺ are a special case in which the cation is a proton, i.e. [H(OH2)ₙ]⁺, and are discussed on p. 630.

(b) H2O coordinated by H bonding to oxoanions. This mode is relatively uncommon but occurs in the classic case of CuSO4.5H2O and probably also in ZnSO4.7H2O. Thus, in hydrated copper sulfate, 1 of the H2O molecules is held much more tenaciously than the other 4 (which can all be removed over P₄O₁₀ or by warming under reduced pressure); the fifth can only be removed by heating the compound above 350°C (or to 250°C in vacuo). The crystal structure shows that each Cu atom is coordinated by 4H2O and 2SO₄ groups in a trans octahedral configuration (Fig. 14.10) and that the fifth H2O molecule is not bound to Cu but forms H (donor) bonds to 2 SO₄ groups on neighbouring Cu atoms and 2 further H (acceptor) bonds with cis-H2O molecules on 1 of the Cu atoms. It therefore plays a cohesive role in binding the various units of the structure into a continuous lattice.

(c) Lattice water. Sometimes hydration of either the cation or the anion is required to improve the size compatibility of the units comprising the lattice, and sometimes voids in the lattice so formed can be filled by additional molecules of water. Thus, although LiF and NaF are anhydrous, the larger alkali metal fluorides can form definite hydrates MF.nH2O (n = 2 and 4 for K; 1 ½ for Rb; ½ and 1 ½ for Cs). Conversely, for the chlorides: KCl, RbCl and CsCl are always anhydrous whereas LiCl can form hydrates with

1, 2, 3 and 5H₂O, and NaCl·2H₂O is also known. The space-filling role of water molecules is even more evident with very large anions such as those of the heteropoly acids (p. 1013), e.g. H₃[PW₁₂O₄ improve]·29H₂O.

(d) Zeolitic water. The large cavities of the framework silicates (p. 354) can readily accommodate water molecules, and the lack of specific strong interactions enables the "degree of hydration" to vary continuously over very wide ranges. The swelling of ion-exchange resins and clay minerals (p. 353) are further examples of non-specific hydrates of variable composition.

(e) Clathrate hydrates. The structure motif of zeolite "hosts" accommodating "guest" molecules of water can be inverted in an intriguing way: just as the various forms of ice (p. 624) are formally related to those of silica (p. 342), so (H₂O)n can be induced to generate various cage-like structures with large cavities, thereby enabling the water structure itself to act as host to various guest molecules. Thus, polyhedral frameworks, sometimes with cavities of more than one size, can be generated from unit cells containing 12H₂O, 46H₂O, 136H₂O, etc. In

The first of these (Fig. 14.11) there is a cubic array of 24-cornered cavities, each cavity being a truncated octahedron with square faces of O atoms and each H₂O being common to 2 adjacent cavities (i.e. 24/2 = 12H₂O). There is space for a guest molecule G at the centre of each cavity, i.e. at the centre of the cube and at each corner resulting in a stoichiometry G(8G)₁/₈·12H₂O, i.e. G·6H₂O as in HPF₆·6H₂O. The structure should

---

be compared with the aluminosilicate framework in ultramarine (p. 358).

With the more complicated framework of 46H$_2$O there are 6 cavities of one size and 2 slightly smaller. If all are filled one has 46/8H$_2$O per guest molecule, i.e. G.5$\frac{3}{4}$H$_2$O as in the high-pressure clathrates with G = Ar, Kr, CH$_4$ and H$_2$S. If only the larger cavities are filled, the stoichiometry rises to G.7$\frac{1}{4}$H$_2$O: this is approximated by the classic chlorine hydrate phase discovered by Humphry Davy and studied by Michael Faraday. The compound is now known to be Cl$_2$·7$\frac{1}{4}$H$_2$O, implying that up to 20% of the smaller guest sites are also occupied.

With the 136H$_2$O polyhedron there are 8 larger and 16 smaller voids. If only the former are filled, then G.17H$_2$O results (17 = 136/8) as in CHCl$_3$·17H$_2$O and CH$_3$·17H$_2$O, whereas if both sets are filled with molecules of different sizes, compounds such as CHCl$_3$·2H$_2$S·17H$_2$O result. Many more complicated arrays are possible, resulting from partial filling of the voids or partial replacement of H$_2$O in the framework by other species capable of being H-bonded into the network, e.g. [NMe$_4$]F·4H$_2$O, [NMe$_4$]OH·5H$_2$O, Bu$_2$SF·20H$_2$O and [N(i-C$_5$H$_{11}$)$_4$]F·38H$_2$O. Further structural details are in ref. 92, and industrial applications are discussed in the comprehensive ref. 94.

**Chemical properties**

Water is an excellent solvent because of its high dielectric constant and very strong solvating power. Many compounds, whether hydrated or anhydrous, dissolve to give electrolytic solutions of hydrated cations and anions. However, detailed treatments of solubility relations, free energies and enthalpies of ionic hydration, temperature dependence of solubility and the influence of dissolved ions on the H-bonded structure of the solvent, fall outside the scope of the present treatment. Even predominantly covalent compounds such as HCl can dissolve to give ionic solutions by heterolytic cleavage (e.g. to aquated H$_2$O$^+$Cl$^-$), and the process of dissolution sometimes also results in ionic cleavage of the solvent itself, e.g. [H$_3$O$^+$][BF$_3$(OH)$_2$]$^-$ (p. 198). Because of the great affinity that many elements have for oxygen, solvolytic cleavage (hydrolysis) of “covalent” or “ionic” bonds frequently ensues, e.g.:

\[
P_4O_{10}(s) + xH_2O \rightarrow 4H_3PO_4(aq) \quad (p. 505)
\]

\[
AlCl_3(s) + xH_2O \rightarrow [Al(OH_2)_6]^{3+}(aq) + 3Cl^-(aq) \quad (p. 225)
\]

Such reactions are discussed at appropriate points throughout the book as each individual compound is being considered. A particularly important set of reactions in this category is the synthesis of element hydrides by hydrolysis of certain sulfides (to give H$_2$S), nitrides (to give NH$_3$), phosphides (PH$_3$), carbides (C$_n$H$_m$), borides (B$_n$H$_m$), etc. Useful reviews are available on hydrometallurgy (the recovery of metals by use of aqueous solutions at relatively low temperatures), hydrothermal syntheses and the use of supercritical water as a reaction medium for chemistry.

Another important reaction (between H$_2$O, I$_2$ and SO$_2$) forms the basis of the quantitative determination of water when present in small amounts. The reaction, originally investigated by R. Bunsen in 1835, was introduced in 1935 as an analytical reagent by Karl Fischer who believed, incorrectly, that each mole of I$_2$ was equivalent to 2 moles of H$_2$O:

\[
2H_2O + I_2 + SO_2 \xrightleftharpoons{MeOH/py} 2HI + H_2SO_4
\]

In fact, the reaction is only quantitative in the presence of pyridine, and the methanol solvent

---

is also involved leading to a 1:1 stoichiometry between I₂ and H₂O:

\[ \text{H}_2\text{O} + \text{I}_2 + \text{SO}_2 + 3\text{py} \rightarrow 2\text{pyHI} + \text{C}_\text{H}_\text{N} \text{O} \]

The stability of the reagent is much improved by replacing MeOH with MeOCH₂CH₂OH, and this forms the basis of the present-day Karl Fischer reagent.⁹⁵

In addition to simple dissolution, ionic dissociation and solvolysis, two further classes of reaction are of pre-eminent importance in aqueous solution chemistry, namely acid-base reactions (p. 48) and oxidation–reduction reactions. In water, the oxygen atom is in its lowest oxidation state (−2). Standard reduction potentials (p. 435) of oxygen in acid and alkaline solution are listed in Table 14.10⁹⁶ and shown diagrammatically in the scheme opposite. It is important to remember that if H⁺ or OH⁻ appear in the electrode half-reaction, then the electrode potential will change markedly with the pH. Thus for the first reaction in Table 14.10: O₂ + 4H⁺ + 4e⁻ \rightleftharpoons 2H₂O, although \( E^\circ = 1.229 \) V, the actual potential at 25°C will be given by

\[ E / \text{volt} = 1.229 + 0.05916 \log ([\text{H}^+] / \text{mol}^{-1}) \times \sqrt{P_{\text{O}_2} / \text{atm}} \]

which diminishes to 0.401 V at pH 14 (Fig. 14.12). Likewise, for the half-reaction

\[ \text{H}^+ + e^- \rightleftharpoons \frac{1}{2} \text{H}_2, E^\circ \text{ is zero by definition at pH 0, whereas at other concentrations} \]

\[ E / \text{volt} = -0.05916 \log (P_{\text{H}_2} / \text{atm})^{\frac{1}{2}} \]

and the value falls to −0.828 at pH 14. Theoretically no oxidizing agent whose reduction potential lies above the O₂/H₂O line and no reducing agent whose reduction potential falls below the H⁺/H₂ line can exist in thermodynamically stable aqueous solutions. However, for kinetic reasons associated with the existence of over-potentials, these lines can be extended by about 0.5 V as shown by the dotted lines in Fig. 14.12, and these are a more realistic estimate of the region of stability of oxidizing and reducing agents in aqueous solution. Outside these limits more strongly oxidizing species (e.g. F₂, \( E^\circ = 2.866 \) V) oxidize water to O₂ and more strongly reducing agents (e.g. Kmetal, \( E^\circ = -2.931 \) V) liberate H₂. Sometimes even greater activation energies have to be overcome and reaction only proceeds at elevated temperatures (e.g. C + H₂O \rightleftharpoons CO + H₂; p. 307).

The acid-base behaviour of aqueous solutions has already been discussed (p. 48). The ionic self-dissociation of water is well established (Table 14.8) and can be formally represented as

\[ 2\text{H}_2\text{O} \rightleftharpoons \text{H}_3\text{O}^+ + \text{OH}^- \]

On the Brønsted theory (p. 51), solutions with concentrations of H₃O⁺ greater than that in pure water are acids (proton donors), and solutions rich in OH⁻ are bases (proton acceptors). The same classifications follow from the solvent-system theory of acids and bases.

---

since compounds enhancing the concentrations of the characteristic solvent cation (H₂O⁺) and anion (OH⁻) are solvo-acids and solvo-bases (p. 425). On the Lewis theory, H⁺ is an electron-pair acceptor (acid) and OH⁻ an electron-pair donor (base, or ligand) (p. 198). The various definitions tend to diverge only in other systems (either nonaqueous or solvent-free), particularly when aprotic media are being considered (e.g. N₂O₄, p. 456; BrF₃, p. 831; etc.).

In considering the following isoelectronic sequence (8 valence electrons) and the corresponding gas-phase proton affinities (AH⁺/kJ mol⁻¹): ⁹⁷

\[
\begin{align*}
\text{O}_2^\cdot & \rightarrow \text{H}_2 \rightarrow \text{OH}^- \\
& \rightarrow \text{H}_2\text{O} \rightarrow \text{H}_3\text{O}^+
\end{align*}
\]

it will be noted that only the last three species are stable in aqueous solution. This is because the proton affinity of $O_2^-$ is so huge that it immediately abstracts a proton from the solvent to give $OH^-$; as a consequence, oxides never dissolve in water without reaction and the only oxides that are stable to water are those that are effectively completely insoluble in it:

$$O_2^-(s) + H_2O(aq) \rightarrow 2OH^-(aq); \quad K > 10^{22}$$

There has been considerable discussion about the extent of hydration of the proton and the hydroxide ion in aqueous solution. There is little doubt that this is variable (as for many other ions) and the hydration number derived depends both on the precise definition adopted for this quantity and on the experimental method used to determine it. $H_3O^+$ has definitely been detected by vibration spectroscopy, and by $^{17}O$ nmr spectroscopy on a solution of HF/SbF$_5$/H$_2$$^{17}$O in SO$_2$; a quartet was observed at $-15^\circ$ which collapsed to a singlet on proton decoupling, $J(\text{^{17}O-H})$ 106 Hz. In crystalline hydrates there are a growing number of well-characterized hydrates of the series $H_2O^+$, $H_3O^+$, $H_4O_2^+$, $H_5O_3^+$ and $H_5O_6^+$, i.e. $[\text{H(OH}_2)_n]^+ \cdot n = 1-4, 6$. Thus X-ray studies have established the presence of $H_2O^+$ in the monohydrates of HCl, HNO$_3$ and HClO$_4$, and in the mono- and di-hydrates of sulfuric acid, $[H_3O][HSO_4]$ and $[H_2O_2][SO_4]$. As expected, $H_3O^+$ is pyramidal like the isoelectronic molecule $NH_3$, but the values of the angles $H-O-H$ vary considerably due to extensive H bonding throughout the crystal, e.g. $117^\circ$ in the chloride, $112^\circ$ in the nitrate, and $101^\circ$, $106^\circ$ and $126^\circ$ in $[H_3O][HSO_4]$. Likewise the H-bonded distance $O-H \cdots O$ varies: it is $266$ pm in the nitrate, $254-265$ in $[H_3O][HSO_4]$ and $252-259$ in $[H_3O_2][SO_4]$. The most stable hydroxonium salt yet known is the white crystalline complex $[H_3O]^+[SbF_6]^-$, prepared by adding the stoichiometric amount of H$_2$O to a solution of SbF$_5$ in anhydrous HF; it decomposes without melting when heated to 357°C. The analogous compound $[H_3O]^+[AsF_6]^-$ decomposes at 193°C.

The dihydrated proton $[H_5O_2]^+$ was first established in HCl.2H$_2$O (1967) and HClO$_4$.2H$_2$O (1968), and is now known in perhaps two dozen compounds. The structure is shown schematically in the diagram below though the conformation varies from staggered in the perchlorate, through an intermediate orientation for the chloride to almost eclipsed for $[H_5O_2]^+Cl.H_2O$. In the case of $[H_2O_2]^+[PW_{12}O_{40}]^3^-$, an apparently planar arrangement of all 7 atoms in the cation is an artefact of disorder in the crystal. The $O-H \cdots O$ distance is usually in the range 240–245 pm though in the deep-yellow crystalline compound $[NEt_4]]_3[H_5O_2][Mo_2Cl_4H][MoCl_4(OH_2)]$ it is only 234 pm, one of the shortest $O-H \cdots O$ bonds known. The detailed crystal structures of the hydrated hexafluorosilicic acids, $H_2SiF_6.nH_2O$ ($n = 4, 6, 9.5$) have shown them to be, respectively, $[H_5O_2]_2SiF_6$, $[H_5O_2]_2SiF_6.2H_2O$ and $[H_5O_2][H_7O_3]SiF_6.4.5H_2O$. The ions $[H_7O_3]^+$ and $[H_9O_4]^+$ are both featured in the compound HBr.4H$_2$O which has the unexpectedly complicated formulation $[H_9O_4]^+[H_7O_3]^+[Br]_2^2.H_2O$. The structures of the cations are shown schematically in Fig. 14.13.

---

which indicates that a bromide ion has essentially displaced the fourth water molecule of the second cation to give an effectively neutral H-bonded unit \([\{(H_3O)_2H^+Br^-\} \). The discrete \([H_7O_3]^+\) ion is now known in about a dozen complexes of which a good example is the deep-green complex \([\text{NET}_3][H_7O_3][\text{Ru}_3\text{Cl}_12]\) in which the 2 O-H⋯O distances are 245 and 255 pm and the O-O⋯O angle is 115.9°.\(^{104}\) Similar dimensions were found in the hexafluorosilicate.\(^ {103}\)

The largest protonated cluster of water molecules yet definitively characterized is the discrete unit \([H_7O_3]^+\) formed serendipitously when the cage compound \([\text{C}_9\text{H}_{18}\text{N}(\text{NH})_2\text{Cl}][\text{C}_1\text{Cl}_12]\) was crystallized from a 10% aqueous hydrochloric acid solution.\(^ {105}\) The structure of the cage cation is shown in Fig. 14.14 and the unit cell contains 4([C₉H₁₈]₃(NH)₂Cl][Cl][H₇O₃]Cl]. The hydrated proton features a short symmetrical O-H⋯O bond at the centre of symmetry and 4 longer unsymmetrical O-H⋯O bonds to 4

further H₂O molecules, the whole [H₁₃O₆]⁺ unit being connected to the rest of the lattice by H bonds of normal length to surrounding chloride ions. It is clear from these various examples that the stability of the larger proton hydrates is enhanced by the presence of large co-cations and/or counter-anions in the lattice. Stability can also be enhanced by structural features of the cluster cation itself, as beautifully exemplified by the species [H₄₁₀₂₀]⁺ and [H₄₁₂₁]⁺:(106) these stable groupings comprise a central [H] or [H₃O] bonded to an encapsulating pentagonal dodecahedron of H-bonded {(H₂O)₂₀} over which the positive charge can move by proton switching, i.e [H(OH₂)₂₀]⁺ and [H₃O(OH₂)₂₀]⁺.

Hydrated forms of the hydroxide ion have been much less well characterized though the monohydrate [H₃O₂⁻] has been discovered in the mixed salt Na₂[NEt₃Me][Cr(PhC(S)=N-(O))₃].½NaH₂O.18H₂O which formed when [NEt₃Me]I was added to a solution of tris(thiobenzohydroximato)chromate(III) in aqueous NaOH.(107) The compound tended to lose water at room temperature but an X-ray study identified the centro-symmetric [HO–H–OH]⁻ anion shown in Fig. 14.15. The central O–H–O bond is very short indeed (229 pm) and is probably symmetrical, though the central H was not located on the electron density map. It will be noted that [H₃O₂⁻] is isoelectronic with the bifluoride ion [F–H–F]⁻ which also features a very short, symmetrical H bond with F⋯F 227 pm (p. 60).

**Polywater**

The saga of polywater forms a fascinating and informative case history of the massive amount of work that can be done, even in modern times, on the preparation and characterization of a compound which was eventually found not to exist. Between 1966 and 1973 over 500 scientific papers were published on polywater following B. V. Deryagin’s description of work done in the USSR during the preceding years.(108) The supposed compound, variously called anomalous water, orthowater, polywater, superwater, cyclimetric water, superdense water, water-I1 and water-X, was prepared in minute amounts by condensing purified “ordinary water” into fine, freshly drawn glass capillaries of diameter 1–3 μm. The thermodynamic difficulties inherent in the very existence of such a compound were soon apparent and it was proposed that polywater was, in fact, a dispersion of a silica gel leached from the glass despite the specific rejection of this possibility by several groups of earlier workers. The full panoply of physicochemical techniques was brought to bear on the problem, and it was finally conceded that the anomalous properties were caused by a mixture of colloidal silicic acid and dissolved compounds of Na, K, Ca, B, Si, N (nitrate), O (sulfate) and Cl leached from the glass by the aggressive action of freshly condensed water.(109) A very informative annotated bibliography is available

---

which traces the course of this controversy and analyses the reasons why it took so long to resolve.\(^{(111)}\)

### 14.2.3 Hydrogen peroxide

Hydrogen peroxide was first made in 1818 by J. L. Thenard who acidified barium peroxide (p. 121) and then removed excess $\text{H}_2\text{O}$ by evaporation under reduced pressure. Later the compound was prepared by hydrolysis of peroxodisulfates obtained by electrolytic oxidation of acidified sulfate solutions at high current densities:

$$2\text{HSO}_4^-(aq) \xrightarrow{-2e^-} \text{H}_2\text{O} + 2\text{HSO}_4^- + \text{H}_2\text{O}_2$$

Such processes are now no longer used except in the laboratory preparation of $\text{D}_2\text{O}_2$, e.g.:

$$\text{K}_2\text{S}_2\text{O}_8 + 2\text{D}_2\text{O} \rightarrow 2\text{KDOSO}_4 + \text{D}_2\text{O}_2$$

On an industrial scale $\text{H}_2\text{O}_2$ is now almost exclusively prepared by the autoxidation of 2-alkylanthraquinols (see Panel on next page).

### Physical properties

Hydrogen peroxide, when pure, is an almost colourless (very pale blue) liquid, less volatile than water and somewhat more dense and viscous. Its more important physical properties are in Table 14.11 (cf. $\text{H}_2\text{O}$, p. 623). The compound is miscible with water in all proportions and forms a hydrate $\text{H}_2\text{O}_2\cdot\text{H}_2\text{O}$, mp $-52^\circ$. Addition of water increases the already high dielectric constant of $\text{H}_2\text{O}_2$ ($70.7$) to a maximum value of 121 at $\sim 35\%$ $\text{H}_2\text{O}_2$, i.e. substantially higher than the value of water itself ($78.4$ at $25^\circ$).

In the gas phase the molecule adopts a skew configuration with a dihedral angle of $111.5^\circ$ as shown in Fig. 14.16a. This is due to repulsive interaction of the $\text{O}–\text{H}$ bonds with the lone-pairs of electrons on each $\text{O}$ atom. Indeed, $\text{H}_2\text{O}_2$ is the smallest molecule known to show hindered rotation about a single bond, the rotational barriers being 4.62 and 29.45 kJ mol$^{-1}$ for the trans and cis conformations respectively. The skew form persists in the liquid phase, no doubt modified by $\text{H}$ bonding, and in the crystalline state at $-163^\circ$C a neutron diffraction study\(^{(112)}\) gives the dimensions shown in Fig. 14.16b. The dihedral angle is particularly sensitive to $\text{H}$ bonding, decreasing from $111.5^\circ$ in the gas phase to $90.2^\circ$ in crystalline $\text{H}_2\text{O}_2$; in fact, values spanning the complete range from $90^\circ$ to $180^\circ$ (i.e. trans planar) are known for various solid phases containing molecular $\text{H}_2\text{O}_2$ (Table 14.12). The O–O distance in $\text{H}_2\text{O}_2$ corresponds to the value expected for a single bond (p. 616).

### Chemical properties

In $\text{H}_2\text{O}_2$ the oxidation state of oxygen is $-1$, intermediate between the values for $\text{O}_2$ and $\text{H}_2\text{O}$, and, as indicated by the reduction potentials on p. 628, aqueous solutions of $\text{H}_2\text{O}_2$ should spontaneously disproportionate. For the pure

---

Preparation and Uses of Hydrogen Peroxide

Hydrogen peroxide is a major industrial chemical manufactured on a multikilotonne scale by an ingenious cycle of reactions introduced by I. G. Farbenindustrie about 60 years ago. Since the value of the solvents and organic substrates used are several hundred times that of the \( \text{H}_2\text{O}_2 \) produced, the economic viability of the process depends on keeping losses very small indeed. The basic process consists of dissolving 2-ethylanthraquinone in a mixed ester/hydrocarbon or alcohol/hydrocarbon solvent and reducing it by a Raney nickel or supported palladium catalyst to the corresponding quinol. The catalyst is then separated and the quinol non-catalytically reoxidized in a stream of air:

![Diagram of the process](image)

The \( \text{H}_2\text{O}_2 \) is extracted by water and concentrated to \( \sim 30\% \) (by weight) by distillation under reduced pressure. Further low-pressure distillation to concentrations up to \( 85\% \) are not uncommon.

World production expressed as 100% \( \text{H}_2\text{O}_2 \) approached 1.9 million tonnes in 1994 of which half was in Europe and one-fifth in the USA. The earliest and still the largest industrial use for \( \text{H}_2\text{O}_2 \) is as a bleach for textiles, paper pulp, straw, leather, oils and fats, etc. Domestic use as a hair bleach and a mild disinfectant has diminished somewhat. Hydrogen peroxide is also extensively used to manufacture chemicals, notably sodium perborate (p. 206) and percarbonate, which are major constituents of most domestic detergents at least in the UK and Europe. Normal formulations include 15–25% of such peroxoacid salts, though the practice is much less widespread in the USA, and the concentrations, when included at all, are usually less than 10%.

In the organic chemicals industry, \( \text{H}_2\text{O}_2 \) is used in the production of epoxides, propylene oxide, and caprolactones for PVC stabilizers and polyurethanes, in the manufacture of organic peroxy compounds for use as polymerization initiators and curing agents, and in the synthesis of fine chemicals such as hydroquinone, pharmaceuticals (e.g. cephalosporin) and food products (e.g. tartaric acid).

One of the rapidly growing uses of \( \text{H}_2\text{O}_2 \) is in environmental applications such as control of pollution by treatment of domestic and industrial effluents, e.g. oxidation of cyanides and obnoxious malodorous sulfides, and the restoration of aerobic conditions to sewage waters. Its production in the USA for these and related purposes has trebled during the past decade (from 126 kt in 1984 to 360 kt in 1994) and it has substantially replaced chlorine as an industrial bleach because it yields only \( \text{H}_2\text{O} \) and \( \text{O}_2 \) on decomposition. An indication of the proportion of \( \text{H}_2\text{O}_2 \) production used for various applications in North America (1991) is: pulp and paper treatment 49%, chemicals manufacture 15%, environmental uses 15%, textiles 8%, all other uses 13%. The price per kg for technical grade aqueous \( \text{H}_2\text{O}_2 \) in tank-car lots (1994) is $0.54 (30%), $0.75 (50%) and $1.05 (70%), i.e. essentially a constant price of $1.50 per kg on a “100% basis.”

---

peroxonium salts (H$_2$OOH)$^+$, hydroperoxides (OOH)$^-$ and peroxides (O$_2$)$^{2-}$, and (iii) its reactions to give peroxometal complexes and peroxoacid anions.

The ability of H$_2$O$_2$ to act both as an oxidizing and a reducing agent is well known in analytical chemistry. Typical examples (not necessarily of analytical utility) are:

**Oxidizing agent in acid solution:**

\[
2[\text{Fe(CN)}_6]^{3-} + \text{H}_2\text{O}_2 + 2\text{H}^+ \rightarrow 2[\text{Fe(CN)}_6]^{4-} + \text{H}_2\text{O} + 2\text{H}_2\text{O} + \text{O}_2
\]

Likewise \( \text{Fe}^{2+} \rightarrow \text{Fe}^{3+}, \ \text{SO}_3^{2-} \rightarrow \text{SO}_4^{2-}, \)

\( \text{NH}_2\text{OH} \rightarrow \text{HNO}_3 \) etc.

**Reducing agent in acid solution:**

\[
\text{MnO}_4^- + 2\frac{1}{2}\text{H}_2\text{O}_2 + 3\text{H}^+ \rightarrow \text{Mn}^{2+} + 4\text{H}_2\text{O} + 2\frac{1}{2}\text{O}_2
\]

\[
2\text{Ce}^{4+} + \text{H}_2\text{O}_2 \rightarrow 2\text{Ce}^{3+} + 2\text{H}^+ + \text{O}_2
\]

**Oxidizing agent in alkaline solution:**

\[
\text{Mn}^{2+} + \text{H}_2\text{O}_2 \rightarrow \text{Mn}^{4+} + 2\text{OH}^-
\]

**Reducing agent in alkaline solution:**

\[
2[\text{Fe(CN)}_6]^{3-} + \text{H}_2\text{O}_2 + 2\text{OH}^- \rightarrow 2[\text{Fe(CN)}_6]^{4-} + 2\text{H}_2\text{O} + \text{O}_2
\]

\[
2\text{Fe}^{3+} + \text{H}_2\text{O}_2 + 2\text{OH}^- \rightarrow 2\text{Fe}^{2+} + 2\text{H}_2\text{O} + \text{O}_2
\]

\[
\text{KIO}_4 + \text{H}_2\text{O}_2 \rightarrow \text{KIO}_3 + \text{H}_2\text{O} + \text{O}_2
\]

---

It will be noted that \( \text{O}_{2} \) is always evolved when \( \text{H}_{2}\text{O}_{2} \) acts as a reducing agent, and sometimes this gives rise to a red chemiluminescence if the dioxygen molecule is produced in a singlet state (p. 605), e.g.:

**Acid solution:**
\[
\text{HOCI} + \text{H}_{2}\text{O}_{2} \longrightarrow \text{H}_{3}\text{O}^+ + \text{Cl}^- + \text{^1O}_{2}\text{*} \longrightarrow \text{hv}
\]

**Alkaline solution:**
\[
\text{Cl}_2 + \text{H}_{2}\text{O}_{2} + 2\text{OH}^- \longrightarrow 2\text{Cl}^- + 2\text{H}_{2}\text{O} + \text{^1O}_{2}\text{*} \longrightarrow \text{hv}
\]

The catalytic decomposition of aqueous solutions \( \text{H}_{2}\text{O}_{2} \) alluded to on p. 635 can also be viewed as an oxidation–reduction process and, indeed, most homogeneous catalysts for this reaction are oxidation–reduction couples of which the oxidizing agent can oxidize (be reduced by) \( \text{H}_{2}\text{O}_{2} \) and the reducing agent can reduce (be oxidized by) \( \text{H}_{2}\text{O}_{2} \). Thus, using the data on p. 628, any complex with a reduction potential between +0.695 and +1.776 V in acid solution should catalyse the reaction. For example:

\[
\begin{align*}
\text{Fe}^{3+}/\text{Fe}^{2+}, & \quad E^\circ + 0.771 \text{ V} \\
2\text{Fe}^{3+} + \text{H}_{2}\text{O}_{2} & \longrightarrow 2\text{Fe}^{2+} + \text{O}_2 \\
2\text{Fe}^{2+} + \text{H}_{2}\text{O}_{2} & \longrightarrow 2\text{Fe}^{3+} + 2\text{H}_{2}\text{O}
\end{align*}
\]

**Net:**
\[
2\text{H}_{2}\text{O}_{2} \longrightarrow 2\text{H}_{2}\text{O} + \text{O}_2
\]

\[
\begin{align*}
\text{Br}_2/\text{Br}^-, & \quad E^\circ + 1.078 \\
\text{Br}_2 + \text{H}_{2}\text{O}_{2} & \longrightarrow 2\text{Br}^- + \text{O}_2 \\
2\text{Br}^- + \text{H}_{2}\text{O}_{2} & \longrightarrow \text{Br}_2 + 2\text{H}_{2}\text{O}
\end{align*}
\]

**Net:**
\[
2\text{H}_{2}\text{O}_{2} \longrightarrow 2\text{H}_{2}\text{O} + \text{O}_2
\]

In many such reactions, experiments using \(^{18}\text{O} \) show negligible exchange between \( \text{H}_{2}\text{O}_{2} \) and \( \text{H}_{2}\text{O} \), and all the \( \text{O}_2 \) formed when \( \text{H}_{2}\text{O}_{2} \) is used as a reducing agent comes from the \( \text{H}_{2}\text{O}_{2} \), implying that oxidizing agents do not break the \( \text{O}–\text{O} \) bond but simply remove electrons. Not all reactions are heterolytic, however, and free radicals are sometimes involved, e.g. \( \text{Ti}^{3+}/\text{H}_{2}\text{O}_{2} \) and Fenton’s reagent (\( \text{Fe}^{2+}/\text{H}_{2}\text{O}_{2} \)). The most important free radicals are \( \text{OH} \) and \( \text{O}_2\text{H} \).

Hydrogen peroxide is a somewhat stronger acid than water, and in dilute aqueous solutions has \( pK_a(25^\circ) = 11.65 \pm 0.02 \), i.e. comparable with the third dissociation constant of \( \text{H}_3\text{PO}_4 \) (p. 519):

\[
\text{H}_2\text{O} + \text{H}_2\text{O} \rightleftharpoons \text{H}_3\text{O}^+ + \text{OOH}^-;
\]

\[
K_a = \frac{[\text{H}_3\text{O}^+][\text{OOH}^-]}{[\text{H}_2\text{O}_2]} = 2.24 \times 10^{-12} \text{ mol}^{-1}
\]

Conversely, \( \text{H}_2\text{O}_2 \) is a much weaker base than \( \text{H}_2\text{O} \) (perhaps by a factor of \( 10^6 \)), and the following equilibrium lies far to the right:

\[
\text{H}_3\text{O}_2^+ + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{O}_2 + \text{H}_3\text{O}^+
\]

As a consequence, salts of \( \text{H}_3\text{O}_2^+ \) cannot be prepared from aqueous solutions but they have been obtained as white solids from the strongly acid solvent systems anhydrous \( \text{HF}/\text{SbF}_5 \) and \( \text{HF}/\text{AsF}_5 \), e.g.:

\[
\begin{align*}
\text{H}_2\text{O}_2 + \text{HF} + \text{MF}_5 & \longrightarrow [\text{H}_3\text{O}_2]^+[\text{MF}_6^-] \\
\text{H}_2\text{O}_2 + \text{HF} + 2\text{SbF}_5 & \longrightarrow [\text{H}_3\text{O}_2]^+[\text{Sb}_2\text{F}_{11}^-]
\end{align*}
\]

The salts decompose quantitatively at or slightly above room temperature, e.g.:

\[
2[\text{H}_3\text{O}_2][\text{SbF}_6] \overset{45^\circ}{\longrightarrow} 2[\text{H}_3\text{O}][\text{SbF}_6] + \text{O}_2
\]

The ion \([\text{H}_2\text{OOH}]^+ \) is isoelectronic with \( \text{H}_2\text{NOH} \) and vibrational spectroscopy shows it to have the same \( C_\text{s} \) symmetry.

Deprotonation of \( \text{H}_2\text{O}_2 \) yields \( \text{OOH}^- \), and hydroperoxides of the alkali metals are known in solution. Liquid ammonia can also effect deprotonation and \( \text{NH}_3\text{OOH} \) is a white solid, mp 25°; infrared spectroscopy shows the presence of \( \text{NH}_4^+ \) and \( \text{OOH}^- \) ions in the solid phase but the melt appears to contain only the H-bonded species \( \text{NH}_3 \) and \( \text{H}_2\text{O}_2 \). Double deprotonation yields the peroxide ion \( \text{O}_2^{2-} \), and this is a standard route to transition metal peroxides.\(^{(53)}\)

Many such compounds are discussed under the individual transition elements and it is only necessary here to note that the chemical identity of the products obtained is often very sensitive to the conditions employed because of the combination of acid-base and redox reactions in the system. For example, treatment of alkaline aqueous solutions of chromate(VI) with H₂O₂ yields the stable red paramagnetic tetraperoxochromate(V) compounds [Cr₅⁶(V)₂(0₂)₄]³⁻ (μ 1.80 BM), whereas treatment of chromate(VI) with H₂O₂ in acid solution followed by extraction with ether and coordination with pyridine yields the neutral peroxochromate(VI) complex [CrO(0₂)₂py] which has a small temperature-independent paramagnetism of about 0.5 BM. The structure of these two species is in Fig. 14.17 which also includes the structure of the brown diperoxochromium(IV) complex [Cr(IV)(NH₃)₃(0₂)₂] (μ 2.8 BM) prepared by treating either of the other two complexes with an excess of aqueous ammonia or more directly by treating an aqueous ammonical solution of NH₄Cl₂[Cr₂O₇] with H₂O₂. Besides deprotonation of H₂O₂, other routes to metal peroxides include the direct reduction of O₂ by combustion of the electropositive alkali and alkaline earth metals in oxygen (pp. 84, 119) or by reaction of O₂ with transition metal complexes in solution (p. 616). Very recently K₂O₂ has been obtained as a colourless crystalline biproduct of the synthesis of the orthonitrate K₃NO₄ (p. 472) by prolonged heating of KNO₃ and K₂O in a silver crucible at temperatures up to 400°C. The O–O distance was found to be 154.1(6) pm, significantly longer than the values of ~150 pm previously obtained for alkali metal peroxides (Table 14.4, p. 616).

Another recent development is the production of HOOHO (the ozone analogue of H₂O₂) in 40% yield by the simple expedient of replacing O₂ by O₃ in the standard synthesis via 2-ethylthiouraquinone at −78° (cf. p. 634); H₂O₃ begins to decompose appreciably around −40° to give single oxygen, Δ¹O₂, but is much more stable (up to +20°) in MeOBu¹ and similar solvents.

---

Peroxoanions are described under the appropriate element, e.g. peroxoborates (p. 206), peroxonitrates (p. 459), peroxophosphates (p. 512), peroxosulfates (p. 712), and peroxodisulfates (p. 713).

### 14.2.4 Oxygen fluorides

**Figure 14.18** Comparison of the molecular dimensions of various gaseous molecules having O–F and O–H bonds.

Oxygen forms several binary fluorides of which the most stable is OF$_2$. This was first made in 1929 by the electrolysis of slightly moist molten KF/HF but is now generally made by reacting F$_2$ gas with 2% aqueous NaOH solution:

$$2F_2 + 2NaOH \rightarrow OF_2 + 2NaF + H_2O$$

Conditions must be controlled so as to minimize loss of the product by the secondary reaction:

$$OF_2 + 2OH^- \rightarrow O_2 + 2F^- + H_2O$$

Oxygen fluoride is a colourless, very poisonous gas that condenses to a pale-yellow liquid (mp $-223.8^\circ$, bp $-145.3^\circ$C). When pure it is stable to 200$^\circ$ in glass vessels but above this temperature it decomposes by a radical mechanism to the elements. Molecular dimensions (microwave) are given as $\Delta H_f^\circ = 24.5$ kJ mol$^{-1}$, leading to an average O–F bond energy of 187 kJ mol$^{-1}$. Though less reactive than elementary fluorine, OF$_2$ is a powerful oxidizing and fluorinating agent. Many metals give oxides and fluorides, phosphorus yields PF$_5$ plus POF$_3$, sulfur SO$_2$ plus SF$_4$, and xenon gives XeF$_4$ and oxofluorides (p. 900). H$_2$S explodes on being mixed with OF$_2$ at room temperature. OF$_2$ is formally the anhydride of hypofluorous acid, HOF, but there is no evidence that it reacts with water to form this compound. Indeed, HOF had been sought for many decades but has only relatively recently been prepared and fully characterized.\(^{\text{(123)}}\)

HOF was first identified by P. N. Noble and G. C. Pimentel in 1968 using matrix isolation techniques: F$_2$/H$_2$O mixtures were frozen in solid

---

N$_2$ and photolysed at 14–20 K:

$$\text{F}_2 + \text{H}_2\text{O} \rightleftharpoons \text{HOF} + \text{HF}$$

A more convenient larger-scale preparation was devised in 1971 by M. H. Studier and E. H. Appleman, who circulated F$_2$ rapidly through a Kel-F U-tube filled with Räschig rings of polytetrafluoroethylene (Teflon) which had been moistened with water and cooled to $-40^\circ$. An essential further condition was the presence of traps at $-50^\circ$ and $-79^\circ$ to remove H$_2$O and HF (both of which react with HOF), and the product was retained in a trap at $-183^\circ$. HOF is a white solid, melting at $-117^\circ$ to a pale yellow liquid which boils below room temperature. Molecular dimensions are in Fig. 14.18; the small bond angle is particularly notable, being the smallest yet recorded for 2-coordinate 0 in an open chain. HOF is stable with respect to its elements: $\Delta H^\circ_i(298) = -98.2$, $\Delta G^\circ_i(298) = -85.7$ kJ mol$^{-1}$. However, HOF decomposes fairly rapidly to HF and O$_2$ at room temperature $(t_{1/2} \sim 30$ min at 100 mmHg in Kel-F or Teflon). Decomposition is accelerated by light and by the presence of F$_2$ or metal surfaces. HOF reacts rapidly with water to produce HF, H$_2$O$_2$ and O$_2$; with acid solutions H$_2$O is oxidized primarily to H$_2$O$_2$, whereas in alkaline solutions O$_2$ is the principal oxygen-containing product. Ag$^{+}$ is oxidized to Ag$^{II}$ and, in alkaline solution, BrO$_3^-$ yields the elusive perbromate ion BrO$_4^-$ (p. 871). All these reactions parallel closely those of F$_2$ in water, and it may well be that HOF is the reactive species produced when F$_2$ reacts with water (p. 856). No ionic salts of hypofluorous acid have been isolated but covalent hypofluorites have been known for several decades as highly reactive (sometimes explosive) gases, e.g.:

$$\text{KNO}_3 + \text{F}_2 \rightarrow \text{KF} + \text{O}_2\text{NOF} \text{ (bp } -45.9^\circ)$$

$$\text{SO}_2\text{F}_2 + 2\text{F}_2 \xrightarrow{\text{CIF}} \text{F}_5\text{SOF} \text{ (bp } -35.1^\circ)$$

$$\text{HClO}_4(\text{conc}) + \text{F}_2 \rightarrow \text{HF} + \text{O}_2\text{ClOF} \text{ (bp } -15.9^\circ)$$

Dioxygen difluoride, O$_2$F$_2$, is best prepared by passing a silent electric discharge through a low-pressure mixture of F$_2$ and O$_2$; the products obtained depend markedly on conditions, and the yield of O$_2$F$_2$ is optimized by using a 1:1 mixture at 7–17 mmHg and a discharge of 25–30 mA at 2.1–2.4 kV. Alternatively, pure O$_2$F$_2$ can be synthesized by subjecting a mixture of liquid O$_2$ and F$_2$ in a stainless steel reactor at $-196^\circ$ to 3 MeV bremsstrahlung radiation for 1–4 h. O$_2$F$_2$ is a yellow solid and liquid, mp $-154^\circ$, bp $-57^\circ$ (extrapolated). It is much less stable than OF$_2$ and even at $-160^\circ$ decomposes at a rate of some 4% per day. Decomposition by a radical mechanism is rapid above $-100^\circ$. The structure of O$_2$F$_2$ (Fig. 14.18) resembles that of H$_2$O$_2$ but the remarkably short O–O distance is a notable difference in detail (cf. O$_2$ gas 120.7 pm). Conversely, the O–F distance is unusually long when compared to those in OF$_2$ and HOF (Fig. 14.18). These features are paralleled by the bond dissociation energies:

$$D(\text{FO–OF}) \sim 430 \text{ kJ mol}^{-1},$$

$$D(\text{F–OOF}) \sim 75 \text{ kJ mol}^{-1}.$$ Consistent with this, mass spectrometric, infrared and electron spin resonance studies confirm dissociation into F and OOF radicals, and low-temperature studies have also established the presence of the dimer O$_4$F$_2$, which is a dark red-brown solid, mp $-191^\circ$. Impure O$_3$F$_2$ can also be prepared by silent electric discharge but the material previously thought to be O$_3$F$_2$ is probably a mixture of O$_4$F$_2$ and O$_2$F$_2$. Dioxygen difluoride, as expected, is a very vigorous and powerful oxidizing and fluorinating agent even at very low temperatures ($-150^\circ$). It converts ClF to ClF$_3$, BrF$_3$ to BrF$_5$, and SF$_4$ to SF$_6$. Similar products are obtained from HCl, HBr and H$_2$S, e.g.:

$$\text{H}_3\text{S} + 4\text{O}_2\text{F}_2 \rightarrow \text{SF}_6 + 2\text{HF} + 4\text{O}_2$$

Interest in the production of high-energy oxidizers for use in rocket motors has stimulated the study of peroxy compounds bound to highly electronegative groups during the past few decades. Although such applications have not yet materialized, numerous new compounds of this type...
have been synthesized and characterized, e.g.:

\[
2\text{SO}_3 + \text{F}_2 \xrightarrow{\text{160°/AgF}_2 \text{ catalyst}} 90\% \text{ yield} \quad \text{FO}_2\text{SOOSO}_2\text{F}
\]

\[
2\text{SF}_5\text{Cl} + \text{O}_2 \xrightarrow{\text{hv}} \text{F}_5\text{SOOSF}_5 + \text{Cl}_2
\]

\[
2\text{COF}_2 + \text{OF}_2 \xrightarrow{\text{CsF}} \text{F}_3\text{COOOCF}_3
\]

Such compounds are volatile liquids or gases (Table 14.13) and their extensive reaction chemistry has been very fully reviewed.\(^{(124)}\)

### 14.2.5 Oxides

**Various methods of classification**

Oxides are known for all elements of the periodic table except the lighter noble gases and, indeed, most elements form more than one binary compound with oxygen. Their properties span the full range of volatility from difficultly condensable gases such as CO (bp -191.5°C) to refractory oxides such as ZrO\(_2\) (mp 3265°C, bp ~4850°C). Likewise, their electrical properties vary from being excellent insulators (e.g. MgO), through semi-conductors (e.g. NiO), to good metallic conductors (e.g. ReO\(_3\)). They may be precisely stoichiometric or show stoichiometric variability over a narrow or a wide range of composition. They may be thermodynamically stable or unstable with respect to their elements, thermally stable or unstable, highly reactive to common reagents or almost completely inert even at very high temperatures. With such a vast array of compounds and such a broad spectrum of properties any classification of oxides is likely to be either too simplified to be reliable or too complicated to be useful. One classification that is both convenient and helpful at an elementary level stresses the acid–base properties of oxides; this can be complemented and supplemented by classifications which stress the structural relationships between oxides. General classifications based on redox properties or on presumed bonding models have proved to be less helpful, though they are sometimes of use when a more restricted group of compounds is being considered.

The acid–base classification\(^{(125)}\) turns essentially on the thermodynamic properties of hydroxides in aqueous solution, since oxides themselves are not soluble as such (p. 630). Oxides may be:

- **acidic:** e.g. most oxides of non-metallic elements (CO\(_2\), NO\(_2\), P\(_4\)O\(_{10}\), SO\(_3\), etc.);
- **basic:** e.g. oxides of electropositive elements (Na\(_2\)O, CaO, Ti\(_2\)O, La\(_2\)O\(_3\), etc.);
- **amphoteric:** oxides of less electropositive elements (BeO, Al\(_2\)O\(_3\), Bi\(_2\)O\(_3\), ZnO, etc.);
- **neutral:** oxides that do not interact with water or aqueous acids or bases (CO, NO, etc.).

Periodic trends in these properties are well documented (p. 27). Thus, in a given period, oxides progress from strongly basic, through weakly basic, amphoteric, and weakly acidic, to strongly acidic (e.g. Na\(_2\)O, MgO, Al\(_2\)O\(_3\), SiO\(_2\), P\(_4\)O\(_{10}\), SO\(_3\), ClO\(_2\)). Acidity also increases with increasing oxidation state (e.g. MnO < Mn\(_2\)O\(_3\) < MnO\(_2\) < Mn\(_2\)O\(_7\)). A similar trend is

---

the decrease in basicity of the lanthanide oxides with increase in atomic number from La to Lu. In the main groups, basicity of the oxides increases with increase in atomic number down a group (e.g. BeO < MgO < CaO < SrO < BaO), though the reverse tends to occur in the later transition element groups. Acid–base interactions can also be used to classify reaction types of (a) oxides with each other (eg. CaO with SiO₂), (b) oxides with oxysalts (eg. CaO with CaSiO₃), and (c) oxysalts with each other (eg. Ca₂SiO₄ and Ca₃(PO₄)₂), and to predict the products of such reactions.¹²⁶

Structural classifications of oxides recognize discrete molecular species and structures which are polymeric in one or more dimensions leading to chains, layers, and ultimately, to three-dimensional networks. Some typical examples are in Table 14.14; structural details are given elsewhere under each individual element. The type of structure adopted in any particular case depends (obviously) not only on the stoichiometry but also on the relative sizes of the atoms involved and the propensity to form π–π double bonds to oxygen. In structures which are conventionally described as “ionic”, the 6-coordinate radius of O²⁻ (140 pm) is larger than all 6-coordinate cation radii except for Rb⁺, Cs⁺, Fr⁺, Ra⁺, and Tl⁺ though it is approached by K⁺ (138 pm) and Ba⁺ (135 pm).¹²⁹ Accordingly, many oxides are found to adopt structures in which there is a close-packed oxygen lattice with cations in the interstices (frequently octahedral). For “cations”, which have very small effective ionic radii (say <50 pm), particularly if they carry a high formal charge, the structure type and bonding are usually better described in covalent terms, particularly when π interactions enhance the stability of terminal M=O bonds (M = C, N, P⁵⁺, S⁶⁺, etc.). Thus, for oxides of formula MO, a coordination number of 1 (molecular) is found for CO and NO, though the latter tends towards a coordination number of 2 (dimers, p. 446). With the somewhat larger Be⁺⁺ and Zn⁺⁺ the wurtzite (4:4) structure is adopted, whereas monoxides of still larger divalent cations tend to adopt the sodium chloride (6:6) structure (e.g. M⁺⁺ = Mg, Ca, Sr, Ba, Co, Ni, Cd, Eu, etc.).

A similar trend is observed for oxides of M⁴⁺O₂ in Group 14 of the periodic table. The small C atom, with its propensity to form π–π bonds to oxygen, adopts a linear, molecular structure O=C=O. Silicon, being somewhat larger and less prone to double bonding (p. 361), is surrounded by 4 essentially single-bonded O in most forms of SiO₂ (p. 342) and the coordination geometry is thus 4:2. Similarly, GeO₂ adopts the quartz structure; in addition a rutile form (p. 961) is known in which the coordination is 6:3. SnO₂ and PbO₂ also have rutile structures as has TiO₂, but the largest Group 4 cations Zr and Hf adopt the fluorite (8:4) structure (p. 118) in their dioxides. Other large cations with a fluorite structure for MO₂ are Po; Ce, Pr, Tb; Th, U, Np, Pu, Am and Cm. Conversely, the antifluorite structure is found for

the alkali metal monoxides $\text{M}_2\text{O}$ (p. 84). Such simple ideas are capable of considerable further elaboration.\(^{130}\)

**Nonstoichiometry**

Transition elements, for which variable valency is energetically feasible, frequently show nonstoichiometric behaviour (variable composition) in their oxides, sulfides and related binary compounds. For small deviations from stoichiometry a thermodynamic approach is instructive, but for larger deviations structural considerations supervene, and the possibility of thermodynamically unstable but kinetically isolable phases must be considered. These ideas will be expanded in the following paragraphs but more detailed treatment must be sought elsewhere.\(^{131-134}\)

Any crystal in contact with the vapour of one of its constituents is potentially a nonstoichiometric compound since, for true thermodynamic equilibrium, the composition of the solid phase must depend on the concentration (pressure) of this constituent in the vapour phase. If the solid and vapour are in equilibrium with each other ($\Delta G = 0$) at a given temperature and pressure, then a change in this pressure will lead to a change (however minute) in the composition of the solid, provided that the activation energy for the reaction is not too high at the temperature being used. Such deviations from ideal stoichiometry imply a change in valency of at least some of the ions in the crystal and are readily detected for many oxides using a range of techniques such as pressure-composition isotherms, X-ray diffraction, neutron diffraction, electrical conductivity (semi-conductivity), visible and ultraviolet absorption spectroscopy (colour centres)\(^{131}\) and Mössbauer ($\gamma$-ray resonance) spectroscopy.\(^{135}\)

If the pressure of $\text{O}_2$ above a crystalline oxide is increased, the oxide-ion activity in the solid can be increased by placing the supernumerary $\text{O}^{2-}$ ions in the interstitial positions, e.g.:

$$\text{UO}_2 + \frac{x}{2} \text{O}_2 \xrightarrow{1150^\circ\text{C}} \text{UO}_{2+x} \quad 0 < x < 0.25$$

The electrons required to reduce $\frac{1}{2}\text{O}_2$ to $\text{O}^{2-}$ come from individual cations which are thereby oxidized to a higher oxidation state. Alternatively, if suitable interstitial sites are not available, the excess $\text{O}^{2-}$ ions can build on to normal lattice sites thereby creating cation vacancies which diffuse into the crystal, e.g.:

$$x (1-\frac{5}{4}) \text{Cu}_2\text{O} + \frac{x}{4} \text{O}_2 \longrightarrow \text{Cu}_{2-x}\text{O}$$

In this case the requisite electrons are provided by $2\text{Cu}^1$ becoming oxidized to $2\text{Cu}^{II}$.

Conversely, if the pressure of $\text{O}_2$ above a crystalline oxide is decreased below the equilibrium value appropriate for the stoichiometric composition, oxygen "boils out" of the lattice leaving supernumerary metal atoms or lower-valent ions in interstitial positions, e.g.:

$$(1 + x)\text{ZnO} \longrightarrow \text{Zn}_{1+x}\text{O} + \frac{x}{2} \text{O}_2$$

The absorption spectrum of this nonstoichiometric phase forms the basis for the formerly much-used qualitative test for zinc oxide: "yellow when hot, white when cold". Alternatively, anion sites can be left vacant, e.g.:

$$\text{TiO} \longrightarrow \text{TiO}_{1-x} + \frac{x}{2} \text{O}_2$$

In both cases the average oxidation state of the metal is reduced. It is important to appreciate that,

in all such examples, the resulting nonstoichiometric compound is a homogeneous phase which is thermodynamically stable under the prevailing ambient conditions.

Sometimes the lattice defects form clusters amongst themselves rather than being randomly distributed throughout the lattice. A classic example is “ferrous oxide”, which is unstable as FeO at room temperature but exists as Fe$_{1-x}$O ($0.05 < x < 0.12$): the NaCl-type lattice has a substantial number of vacant Fe$^{II}$ sites and these tend to cluster so that Fe$^{III}$ can occupy tetrahedral sites within the lattice as shown schematically in Fig. 14.19. Such clustering can sometimes nucleate a new phase in which “vacant sites” are eliminated by being ordered in a new structure type. For example, PrO$_{2-x}$ forms a disordered nonstoichiometric phase ($0 < x < 0.25$) at 1000°C but at lower temperatures (400–700°C) this is replaced by a succession of intermediate phases with only very narrow (and non-overlapping) composition ranges of general formula Pr$_n$O$_{2n-2}$ with $n = 4, 7, 9, 10, 11, 12$ and $\infty$ as shown in Fig. 14.20 and Table 14.15. There is now compelling evidence that oxide-ion vacancies, $\square$, in these and other such fluorite-related lattices do not exist in isolation but occur as octahedral ‘coordination defects’ of composition [M$_2^{III}$M$_{1.5}^{IV}$O$_6$]. The structure-forming topology of these coordination defects and their role in generating more extensive defects has recently been brilliantly expounded.\(^{136}\)

Oxygen (oxide ions) in crystal lattices can be progressively removed by systematically

Figure 14.20 Part of the Pr–O phase diagram showing the extended nonstoichiometric α phase PrO_{2-x} at high temperatures (shaded) and the succession of phases Pr_{x}O_{2x-2} at lower temperatures.

Replacing corner-shared \{MO_6\} octahedra with edge-shared octahedra. The geometrical principles involved in the conceptual generation of such successions of phases (chemical-shear structures) are now well understood, but many mechanistic details of their formation remain unresolved. Typical examples are the rutile series Ti_{n}O_{2n-1} \((n = 4, 5, 6, 7, 8, 9, 10, \infty)\) between TiO_{1.75} and TiO_2 and the ReO_3 series M_{n}O_{3n-1} which leads to a succession of 6 phases with \(n = 8, 9, 10, 11, 12\) and 14 in the narrow composition range MO_{2.875} to MO_{2.929} (M = Mo or W).

Nonstoichiometric oxide phases are of great importance in semiconductor devices, in heterogeneous catalysis and in understanding photoelectric, thermoelectric, magnetic and diffusional properties of solids. They have been used in thermistors, photovoltaic cells, rectifiers, transistors, phosphors, luminescent materials and computer components (ferrites, etc.). They are crucially implicated in reactions at electrode surfaces, the performance of batteries, the tarnishing and corrosion of metals, and many other reactions of significance in catalysis.\(^{(131-134)}\)

Sulfur

15.1 The Element

15.1.1 Introduction

Sulfur occurs uncombined in many parts of the world and has therefore been known since prehistoric times. Indeed, sulfur and carbon were the only two non-metallic elements known to the ancients. References to sulfur occur throughout recorded history from the legendary destruction of Sodom and Gomorrah by brimstone\(^1\) to its recent discovery (together with \(\text{H}_2\text{SO}_4\)) as a major component in the atmosphere of the planet Venus.

The element was certainly known to the Egyptians as far back as the sixteenth century BC and Homer refers to its use as a fumigant.\(^2\) Pliny the Elder\(^3\) mentioned the occurrence of sulfur in volcanic islands and other Mediterranean locations, spoke of its use in religious ceremonies and in the fumigation of houses, described its use by fullers, cotton-bleachers, and match-makers, and indicated fourteen supposed medicinal virtues of the element.

Gunpowder, which revolutionized military tactics in the thirteenth century, was the sole known propellant for ammunition until the mid-nineteenth century when smokeless powders based on guncotton (1846), nitroglycerine (1846), and cordite (1889) were discovered. Gunpowder, an intimate mixture of saltpeter (\(\text{KNO}_3\)), powdered charcoal and sulfur in the approximate ratios 75:15:10 by weight, was discovered by Chinese alchemists more than 1000 years ago:\(^4\) The earliest known recipe for explosive gunpowder (as distinct from incendiary mixtures and fireworks) appeared in a Chinese military manual of AD 1044 and its use in a gun (bombard) dates from at least as early as 1128. Arab and European formulae and technology were derived from this. The first use of gunpowder

---

\(^1\) Genesis 19, 24: "Then the Lord rained upon Sodom and Gomorrah brimstone and fire from the Lord out of heaven."

\(^2\) Homer, Odyssey, Book 22, 481: "Bring me sulfur, old nurse, that cleanses all pollution and bring me fire, that I may purify the house with sulfur."

\(^3\) G. Pliny (the Elder), AD 23–79, mentions sulfur in several of the many books of his posthumously published major work, Naturalis Historia.

\(^4\) A. R. Butler, Chem. in Britain, 1119–21 (1988); and research by Joseph Needham, Cambridge, UK.
Developments in the Chemistry of Sulfur

Sulfur (brimstone) mentioned frequently in the Bible.\(^{(1)}\)

Fumigating power of burning S mentioned by Homer.\(^{(2)}\)

Occurrence and many uses of S recorded by G. Pliny.\(^{(3)}\)

Sulfuric acid mentioned by Persian writer Abu Bekr al Rases.

Earliest known (Chinese) recipe for explosive gunpowder.\(^{(4)}\)

Gunpowder used by Chinese military in a bombard.

Gunpowder “discovered” independently in Europe by Roger Bacon (England) and Berthold Swam.

Effects of SO\(_2\) pollution in London dramatically described to Charles II by John Evelyn (p. 698).

Lead chamber process for H\(_2\)SO\(_4\) introduced by John Roebuck (Birmingham, UK); this immediately superseded the cumbersome small-scale glass bell-jar process (p. 708).

Elemental character of S proposed by A.-L. Lavoisier though even in 1809 experiments (presumably on impure samples) led Humphry Davy to contend that oxygen and hydrogen were also essential constituents of S.

Sulfur compounds first detected in plants by N. Deyeux—roots of the dock, horse-radish, and cochlearia).

Sulfur detected in the bile and blood of animals by H. A. Vogel.

Xanthates (e.g. EtOCSSK) discovered by W. C. Zeise who also prepared the first mercaptan (EtSH) in 1834 (see also p. 930).

Contact process for SO\(_3\)/H\(_2\)SO\(_4\) patented by P. Philips of Bristol, UK (the original platinum catalyst was subsequently replaced by ones based on V\(_2\)O\(_5\)).

SaN\(_4\) first made by M. Gregory (S\(_2\)Cl\(_2\) + NH\(_3\)); X-ray structure by M. J. Bueger, 1936.

Vulcanization of natural rubber latex by heating it with S discovered by Charles Goodyear (USA).

Prospectors boring for petroleum in Louisiana discovered a great S deposit beneath a 150-m thick layer of quicksand.

H. Frasch developed commercial recovery of S by superheated water process.

E. Beckmann showed that rhombohedral sulfur was S\(_8\) by cryoscoply in molten iodine.

V. B. Goldschmid's geochemical classification includes “chalcophiles” (p. 648).

Isotopes \(^{33}\text{S}\) and \(^{34}\text{S}\) discovered by F. W. Aston who previously (1920) had only detected \(^{32}\text{S}\) in his mass spectrometer.

Molecular structure of cyclo-S\(_8\) established by X-ray methods (B. E. Warren and J. T. Burwell).

Sulfur first produced from sour natural gas; by 1971 this source, together with crude oil, accounted for nearly one-third of world production.

SF\(_4\) first isolated by G. A. Silvery and G. H. Cady.

Sulfur nmr signals (from \(^{33}\text{S}\)) first detected by S. S. Dharmatti and H. E. Weaver.

Sulfur and H\(_2\)SO\(_4\) detected in the atmosphere of the planet Venus by USSR Venera 8 (subsequently confirmed in 1978 by US Venus Pioneer 2).

Si\(_8\) and \(\alpha\)-\(\beta\)-\(\gamma\) synthesized and characterized by M. Schmidt, A. Kutoglu, and their coworkers.

The metallic and superconducting properties of polymeric (SN)\(_x\) discovered independently by two groups in the USA (p. 727).

in a major campaign in the West was at the Battle of Crécy (26 August 1346), but the guns lacked all power of manoeuvre and the devastating victory of Edward III was due chiefly to the long-bow men whom the French were also encountering for the first time. By 1415, however, gunpowder was decisive in Henry V’s siege of Harfleur, and its increasing use in mobile field guns, naval artillery, and hand-held firearms was a dominant feature of world history for the next 500 y. Parallel with these activities, but largely independent of them, was the European development of the alchemy and chemistry of sulfur, and the growth of the emerging chemical industry based on sulfuric acid (p. 708). Some of the key points in this story are summarized in the Panel and a fuller treatment can be found in standard references.\(^{(5–6)}\)

15.1.2 Abundance and distribution

Sulfur occurs, mainly in combined form, to the extent of about 340 ppm in the crustal rocks of the earth. It is the sixteenth element in order of abundance, closely following barium (390 ppm) and strontium (384 ppm), and being about twice as abundant as the next element carbon (180 ppm). Earlier estimates placed its global abundance in the range 300–1000 ppm. Sulfur is widely distributed in nature but only rarely is it sufficiently concentrated to justify economic mining. Its ubiquity is probably related to its occurrence in nature in both inorganic and organic compounds, and to the fact that it can occur in at least five oxidation states: $-2$ (sulfides, $\text{H}_2\text{S}$ and organosulfur compounds), $-1$ (disulfides, $\text{S}_2^{2-}$), 0 (elemental S), $+4$ (SO$_2$) and $+6$ (sulfates). The three most important commercial sources are:

1. elemental sulfur in the caprock salt domes in the USA and Mexico, and the sedimentary evaporite deposits in southeastern Poland;
2. H$_2$S in natural gas and crude oil, and organosulfur compounds in tar sands, oil shales and coal (the latter two also contain pyrites inclusions);
3. pyrites (FeS$_2$) and other metal-sulfide minerals.

Volcanic sources of the free element are also widespread; they have been of great economic importance until this century but are now little used. They occur throughout the mountain ranges bordering the Pacific Ocean, and also in Iceland and the Mediterranean region, notably in Turkey, Italy and formerly also in Sicily and Spain.

Elemental sulfur in the caprock of salt domes was almost certainly produced by the anaerobic bacterial reduction of sedimentary sulfate deposits (mainly anhydrite or gypsum, p. 648). The strata are also associated with hydrocarbons; these are consumed as a source of energy by the anaerobic bacteria, which use sulfur instead of O$_2$ as a hydrogen acceptor to produce CaCO$_3$, H$_2$O and H$_2$S. The H$_2$S may then be oxidized to colloidal sulfur, or may form calcium hydrosulfide and polysulfide, which reacts with CO$_2$ generated by the bacteria to precipitate crystalline sulfur and secondary calcite. Alternatively, H$_2$S may escape from the system and the limestone caprock will then be free of sulfur. Indeed, of over 400 salt-dome structures known to exist in the coastal and offshore area of the Gulf of Mexico, only about 12 contain commercial deposits of sulfur (5 in Louisiana, 5 in Texas and 2 in Mexico). The mining operations are described in the Section 15.1.3.

The great evaporite basin deposits of elemental sulfur in Poland were discovered only in 1953 but have since had a dramatic impact on the economy of that country which, by 1985, was one of the world’s leading producers (p. 649). The sulfur occurs in association with secondary limestone, gypsum and anhydrite, and is believed to be derived from hydrocarbon reduction of sulfates assisted by bacterial action. The H$_2$S so formed is consumed by other bacteria to produce sulfur as waste — this accumulates in the bodies of the bacteria until death, when the sulfur remains.

The next great natural occurrence of sulfur is as H$_2$S in sour natural gas and as organosulfur compounds in crude oil. Again, distribution is widespread. Although commercial production of elemental sulfur from such sources was first effected only in 1944 (in the USA) it now represents a major source of the element in the USA, Canada and France, and this growth has been one of the most significant trends in world sulfur production during the past few decades. Sulfur, of course, also occurs in many plant and animal proteins, and three of the principal amino-acid residues contain sulfur: cysteine, $\text{HSCH}_2\text{CH(NH}_2\text{)}\text{CO}_2\text{H}$; cystine {($\text{SCH}_2\text{CH(NH}_2\text{)}\text{CO}_2\text{H})_2$}; and methionine, $\text{MeSCH}_2\text{CH}_2\text{CH(NH}_2\text{)}\text{CO}_2\text{H}$.

Oil shales represent a further source of sulfur though here (unlike the tar sands which yield crude oil and H$_2$S) the sulfur is predominantly in the form of pyrites. US oil shales contain about 0.7% S of which about 80% is pyritic; other
major reserves are in Brazil, the former USSR, China and Africa, though these do not at present seem to be used as an industrial source of sulfur. Coal also contains about 1–2% S and is thus as huge a potential source of the element as it is an actual present source of air pollution (p. 698). From over $3 \times 10^9$ tonnes of coal mined annually, only some 500,000 tonnes of sulfur are recovered (as H$_2$SO$_4$) from a potential 50 million tonnes.

The third great source of sulfur and its compounds is from the mineral sulfides. V. M. Goldschmidt's geochemical classification of the elements (1923), which has formed the basis of all subsequent developments in the field, proposed four main groups of elements: chalcophile, siderophile, lithophile and atmophile. Of these the chalcophiles (Greek χάλκος, chalcos, copper; φιλος, philos, loving) are associated with copper, specifically as sulfides. Elements which occur mainly as sulfide minerals are predominantly from Groups 11–16 of the periodic table (together with iron, molybdenum and, to a lesser extent, some of the platinum metals as shown in Fig. 15.1). Some examples of the more important sulfide minerals are listed in Table 15.1, and a further discussion of the structural chemistry and reactivity of metal sulfides is on p. 676. Pyrites (fool's gold, FeS$_2$) is one of the most abundant of all sulfur minerals and is a major source of the element (see above). It often occurs in massive lenses but may also appear in veins or in disseminated zones. The largest commercial deposits extend from Seville (Spain) westward into Portugal and, at the Rio Tinto mines in Huelva Province, one of the lenses is 1.5 km long and 240 m wide with a sulfur content of 48% (pure FeS$_2$ has 53.4% S). Other major deposits are in the former USSR, Japan, Italy, Cyprus and Scandinavia. The most important non-ferrous metal sulfides are those of Cu, Ni, Zn, Pb and As.

Finally, sulfur occurs in many localities as the sulfates of electropositive elements (see Chapters 4 and 5) and to a lesser extent as sulfates of Al, Fe, Cu and Pb, etc. Gypsum (CaSO$_4$.2H$_2$O) and anhydrite (CaSO$_4$) are particularly notable but are little used as a source of sulfur because of high capital and operating costs. Similarly, by far the largest untapped source of sulfur is in the oceans as the dissolved sulfates of Mg, Ca and K. It has been estimated that there are some $1.5 \times 10^9$ cubic km of water in the oceans of the world and that 1 cubic km of sea-water contains approximately 1 million tonnes of sulfur combined as sulfate.
