Sulfur is produced commercially from one or more sources in over seventy countries of the world, and production of all forms in 1985 amounted to 54.0 million tonnes. The main producers are shown in Table 15.2. Until the beginning of this century, sulfur was obtained mainly by mining volcanic deposits of the element, but this now accounts for less than 5% of the total. During the first half of this century the prime method of production was the process developed by H. Frasch in 1891–4. This involves forcing superheated water into submerged sulfur-bearing strata and then forcing the molten element to the surface by compressed air (see Panel). This is the method used to obtain sulfur from the caprock of salt domes in the

The Frasch Process for Mining Elemental Sulfur\(^{(19)}\)

The ingenious process of melting subterranean sulfur with superheated water and forcing it to the surface with compressed air was devised and perfected by Herman Frasch in the period 1891–4. Originally designed to overcome the problems of recovering sulfur from the caprock of salt domes far below the swamps and quicksands of Louisiana, the method is now also extensively used elsewhere to extract native sulfur.

The caprock typically occurs some 150–750 m beneath the surface and the sulfur-bearing zone is typically about 30 m thick and contains 20–40% S. Using oil-well drilling techniques a cased 200 mm (8-inch) pipe is sunk through the caprock to the bottom of the S-bearing layer. Its lower end is perforated with small holes. Inside this pipe a 100 mm (4-inch) pipe is lowered to within a short distance of the bottom and, finally, a concentric 25-mm (1-inch) compressed-air pipe is lowered to a point rather more than half-way down to the bottom of the well as shown in Fig. a. Superheated water at 165°C is forced down the two outer pipes and melts the surrounding sulfur (mp 119°C). As liquid sulfur is about twice as dense as water under these conditions, it flows to the bottom of the well; the pumping of water down the 100-mm pipe is discontinued, but the static pressure of the hot water being pumped down the outer 200-mm pipe forces the liquid sulfur some 100 m up the 100-mm pipe as shown in Fig. b. Compressed air is then forced down the central 25-mm pipe to aerate the molten sulfur and carry it to the surface where it emerges from the 100-mm annulus Fig. (c). One well can extract sulfur (~35 000 tonnes) from an area of about 2000 m\(^2\) (0.5 acre) and new wells must continually be sunk. Bleed-water wells must also be sunk to remove the excess of water pumped into the strata.

A Frasch mine can produce as much as 2.5 million tonnes of sulfur per annum. Such massive operations clearly require huge quantities of mining water (up to 5 million gallons daily) and abundant power supplies for the drilling, pumping and superheating operations.

The sulfur can be piped long distances in liquid form or transported molten in ships, barges or rail cars. Alternatively it can be prilled or handled as nuggets or chunks. Despite the vast bulk of liquid sulfur mined by the Frasch process it is obtained in very pure form. There is virtually no selenium, tellurium or arsenic impurity, and the product is usually 99.5–99.9% pure.

--

\(^{(19)}\) W. Haynes, Brimstone: The Stone that Burns, Van Nostrand, Princeton, 1959, 308 pp. (The story of the Frasch sulfur industry.)
Gulf Coast region of the USA and Mexico, and from the evaporite basin deposits in west Texas, Poland, the former USSR and Iran.

Recovery from sour natural gas and from crude oil was first developed in the USA in 1944, and by 1970 these sources exceeded the total volume of Frasch-mined sulfur for the first time. Canada (Alberta) and France are the principal producers from sour natural gas, which contains 15–20% H₂S. The USA and Japan are the largest producers from petroleum refineries. The phenomenal growth of these sources is clear from the following figures (in 10⁶ tonnes): <0.5 (1950); 2.5 (1960); 15 (1972); >25 (1985). Recovery from sour natural gas involves first separating out the H₂S by absorption in mono-ethanolamine and then converting it to sulfur by a process first developed by C. F. Claus in Germany about 1880. In this process one-third of the H₂S is burned to produce SO₂, water vapour, and sulfur vapour; the SO₂ then reacts with the remaining H₂S in the presence of oxide catalysts such as Fe₂O₃ or Al₂O₃ to produce more H₂O and S vapour:

\[
\text{H}_2\text{S} + \frac{1}{2}\text{O}_2 \rightarrow \text{SO}_2 + \text{H}_2\text{O}
\]

\[
2\text{H}_2\text{S} + \text{SO}_2 \xrightarrow{\text{ox} \text{de catalyst/300°}} \frac{3}{2}\text{S}_8 + 2\text{H}_2\text{O}
\]

Overall reaction: \(3\text{H}_2\text{S} + 1\frac{1}{2}\text{O}_2 \rightarrow \frac{3}{2}\text{S}_8 + 3\text{H}_2\text{O}\);

\[-\Delta H = 664 \text{ kJ mol}^{-1}\]

Multiple reactors achieve 95–96% conversion and recovery, and stringent air pollution legislation has now pushed this to 99%. A similar sequence of reactions is used for sulfur production from crude oil except that the organosulfur compounds must first be removed from the refinery feed and converted to H₂S by a hydrogenation process before the sulfur can be recovered.

The third major source of sulfur is pyrite and related sulfide minerals. The ore is roasted to secure SO₂ gas which is then usually used directly for the manufacture of H₂SO₄ (p. 708). Again air pollution by SO₂ gas emissions has been the subject of increasing legislation and control during the past three decades (p. 698).

The proportion of sulfur and S-containing compounds recovered by these various methods has been changing rapidly and frequently depends on the nature of local sources available. The comparative figures for 1985 are: sour natural gas 38%, Frasch S 28%, pyrites 18%, miscellaneous 16% (includes metallurgy, crude oil, coal, gypsum, tar sands and flue gases). Estimated reserves on the basis of present technology and prices are summarized in Table 15.3; these can increase more than tenfold if coal, gypsum, anhydrite and sea-water are included. At present these latter sources are economic only under special conditions though, as we have already seen (p. 648), vast quantities of SO₂ are lost from industrial coal each year. Recovery of useful sulfur compounds from anhydrite (and gypsum) can be achieved by two main routes. The Müller–Kühne process used in the UK and Austria involves the roasting of anhydrite with clay, sand and coke in a rotary kiln at 1200–1400°:

\[2\text{CaSO}_4 + \text{C} \rightarrow 2\text{CaO} + 2\text{SO}_2 + \text{CO}_2\]

The emergent SO₂ is then fed into a contact process for H₂SO₄ (p. 708). Alternatively, ammonia and CO₂ can be passed into a gypsum slurry to give ammonium sulfate for use in fertilizers:

\[\text{CaSO}_4 + (\text{NH}_4)_2\text{CO}_3 \rightarrow \text{CaCO}_3 + (\text{NH}_4)_2\text{SO}_4\]

This double decomposition route was developed in Germany and has been used in the UK since 1971.

The pattern of uses of sulfur and its compounds in the chemical industry is illustrated in the

Most sulfur is converted via $\text{SO}_2/\text{SO}_3$ into sulfuric acid which accounts, for example, for some 88% of the contained sulfur used in the USA. The proportion of sulfur used in making the extensive number of end products is shown in Fig. 15.2. Indeed, the uses of sulfur and its principal compounds are so widely spread throughout industry that a nation's consumption of sulfur is often used as a reliable measure of its economic development. Thus, the USA, the former USSR, Japan and Germany lead the world in industrial production and rank similarly in the consumption of sulfur. Further details of industrial uses will be found in subsequent sections dealing with specific compounds of sulfur, and various review books are available.\(^{20-22}\)

### 15.1.4 Allotropes of sulfur \(^{(23-25)}\)

The allotropy of sulfur is far more extensive and complex than for any other element (except perhaps carbon, after the synthesis of the innumerable fullerene clusters, p. 279). This arises partly because of the great variety of molecular forms that can be achieved by $-\text{S-S-}$ catenation and partly because of the numerous ways in which the molecules so formed can be arranged within the crystal. In fact, $\text{S-S}$ bonds are very variable and flexible: interatomic distances cover an enormous range, 180–260 pm (depending to some extent on the amount of multiple bonding), whilst bond angles $\text{S-S-S}$ vary from $90^\circ$ to $180^\circ$ and dihedral angles $\text{S-S-S-S}$ from $0^\circ$ to $180^\circ$ (Fig. 15.3). Estimated $\text{S-S}$ bond energies may be as high as 430 kJ mol\(^{-1}\) and the unrestrained $-\text{S-S-}$ single-bond energy of 265 kJ mol\(^{-1}\) is exceeded amongst homonuclear single bonds only by those of $\text{H}_2$ (435 kJ mol\(^{-1}\)) and $\text{C-C}$

---

\(^{25}\) M. Schmidt, Chap. 1, pp. 1–12, in ref. 21.
Most sulfur is made into sulfuric acid. The balance is used in its elemental form or in various chemical compounds. While sulfur is essential in almost every segment of the economy, it is generally used as a processing agent and seldom appears in the final product.

Figure 15.2 Sulfur's uses as acid and as non-acid.

Possible alternative orientations of the bonds from the 2 inner S atoms, and possible directions for extensions of the chain from the 2 outer S atoms are indicated by the black lines. (See also p. 656.)

(330 kJ mol⁻¹). Again, the amazing temperature dependence of the properties of liquid sulfur have attracted attention for over a century since the rapid and reversible gelation of liquid sulfur was first observed in the temperature range 160–195°C. Major advances have been achieved during the past 25 y in our knowledge of the molecular structure of many of the crystalline allotropes of sulfur and of the complex molecular equilibria occurring in the liquid and gaseous states. Sulfur is also unique in the extent to which new allotropes can now be purposefully synthesized using kinetically controlled reactions that rely on the great strength of the S–S bond once it is formed, and over a dozen new elemental sulfur rings, cyclo-S₈, have been synthesized. Fortunately, several excellent reviews are available, and these can be consulted for fuller details and further references. It will be convenient to start with some of the classic allotropes (now known to contain cyclo-S₈ molecules), and then to consider in turn other cyclic oligomers (cyclo-S₈) various chain polymers (catena-S₈), certain unstable small molecules Sₙ (n = 2–5) and, finally, the properties of liquid and gaseous sulfur.

The commonest (and most stable) allotrope of sulfur is the yellow, orthorhombic α-form to which all other modifications eventually revert at room temperature. Commercial roll sulfur, flowers of sulfur (sublimed) and milk of sulfur (precipitated) are all of this form. It was shown to contain S₈ molecules by cryoscopy in iodine (E. Beckmann, 1912) and was amongst the first substances to be examined by X-ray crystallography (W. H. Bragg, 1914), but the now familiar crown structure of cyclo-S₈ was not finally established until 1935. Various representations of the idealized D₄d molecular structure are given in Fig. 15.4. The packing of the molecules within the crystal has been likened to a crankshaft arrangement extending in two different directions and leads to a structure which is very complex. Orthorhombic α-S₈ has a density of 2.069 g cm⁻³, is a good electrical insulator when pure, and is an excellent thermal insulator, the extremely low thermal conductivity being similar to those of the very best insulators such as mica (p. 356) and wood. Some solubilities in common solvents are in Table 15.4.

At about 95.3° α-S₈ becomes unstable with respect to β-monoclinic sulfur in which the packing of the S₈ molecules is altered and their...
Allotropes of sulfur

Figure 15.4 Various representations of the molecule cyclo-S\(_8\) found in \(\alpha\)-orthorhombic, \(\beta\)-monoclinic, and \(\gamma\)-monoclinic sulfur.

orientation becomes partly disordered.\(^{(26)}\) This results in a lower density (1.94–2.01 g cm\(^{-3}\)), but the dimensions of the S\(_8\) rings in the two allotropes are very similar. The transition is somewhat sluggish even above 100°, and this enables a mp of metastable single crystals of \(\alpha\)-S\(_8\) to be obtained: a value of 112.8° is often quoted but microcrystals may melt as high as 115.1°. Monoclinic \(\beta\)-S\(_8\) has a “mp” which is usually quoted as 119.6° but this can rise to 120.4° in microcrystals or may be as low as 114.6°. The uncertainty arises because the S\(_8\) ring is unstable above \(\sim\)119° and begins to form other species which progressively depress the mp. The situation is reminiscent of the equilibria accompanying the melting of anhydrous phosphoric acid (p. 518). Monoclinic \(\beta\)-S\(_8\) is best prepared by crystallizing liquid sulfur at about 100° and then cooling it rapidly to room temperature to retard the formation of orthorhombic \(\alpha\)-S\(_8\); under these conditions \(\beta\)-S\(_8\) can be kept for several weeks at room temperature before reverting to the more stable \(\alpha\)-form.

A third crystalline modification, \(\gamma\)-monoclinic sulfur, was first obtained by W. Muthmann in 1890. It is also called nacreous or mother-of-pearl sulfur and can be made by slowly cooling a sulfur melt that has been heated above 150°, or by chilling hot concentrated solutions of sulfur in EtOH, CS\(_2\) or hydrocarbons. However, it is best prepared as pale-yellow needles by the mechanistically obscure reaction of pyridine with copper(I) ethyl xanthate, CuSSCOEt. Like \(\alpha\)- and \(\beta\)-sulfur, \(\gamma\)-monoclinic sulfur comprises cyclo-S\(_8\) molecules but the packing is more efficient and leads to a higher density (2.19 g cm\(^{-3}\)). It reverts slowly to \(\alpha\)-S\(_8\) at room temperature but rapid heating leads to a mp of 106.8°.

We now consider other homocyclic polymorphs of sulfur containing 6–20 S atoms per ring. A rhombohedral form, \(\epsilon\)-sulfur, was first prepared by M. R. Engel in 1891 by the reaction of concentrated HCl on a saturated solution of thiosulfate \(\text{HS}_2\text{O}_3\) at 0°. It was shown to be

hexameric in 1914 but its structure as cyclo-
S₆ was not established until 1958–61. The
allotrope is best prepared by the reaction
\[
\text{H}_2\text{S}_4 + \text{S}_2\text{Cl}_2 \xrightarrow{\text{dil solns in Et}_2\text{O}} 87\% \text{ yield} \rightarrow \text{cyclo-} \text{S}_6 + 2\text{HCl}
\]
The ring adopts the chair form and its dimensions
are compared with those of other polymorphs in
Table 15.5. Note that cyclo-S₆ has the smallest
bond angle and dihedral angle of all poly-sulfur
species for which data are available and this,
together with the small "hole" at the centre of
the molecule and the efficient packing within the
crystal, lead to the highest density of any known
polymorph of sulfur (Table 15.6).
In cyclo-S₆ and cyclo-S₈ all the S atoms are
equivalent with essentially equal interatomic
distances, angles and conformations. This is not
necessarily so for all homocyclic molecules.
Thus, in building up cumulated \( \cdots \text{S}_n \cdots \) bonds,
addition of S atoms to an \( \text{S}_3 \) unit can occur in
three ways: cis (c), d-trans (dt), and l-trans (lt):

![cis and trans conformations](image)

Both \( \text{S}_6 \) (chair) and \( \text{S}_8 \) (crown) are all -cis con-
formations, but larger rings have more complex
motifs.

At least eight further cyclic modifications of
sulfur have been synthesized during the past 25 y

by the elegant work of M. Schmidt and his group. The method is to couple two compounds which have the desired combined number of S atoms and appropriate terminal groups, e.g.:

$$\text{S}_{12-n}\text{Cl}_2 + \text{H}_2\text{S}_n \rightarrow \text{cyclo-S}_{12} + 2\text{HCl}$$

[also for S_5, S_10, S_18, S_20]

$$\text{S}_6\text{Cl}_2 + [\text{Ti}(\eta^5-\text{C}_5\text{H}_5)_2(S_5)] \rightarrow \text{cyclo-S}_{12-5}$$

$$+ [\text{Ti}(\eta^5-\text{C}_5\text{H}_5)_2\text{Cl}_2] \quad \text{[for S}_7, \text{S}_9, \text{S}_{10}, \text{S}_{11}]$$

A variant is the ligand displacement and coupling reaction:

$$2[\text{Ti}(\eta^5-\text{C}_5\text{H}_5)_2(S_3)] + 2\text{SO}_2\text{Cl}_2 \xrightarrow{-78^\circ} \text{cyclo-S}_{10} + 2[\text{Ti}(\eta^5-\text{C}_5\text{H}_5)_2\text{Cl}_2] + 2\text{SO}_2$$

The preparation and structures of the reactants are on p. 683 (H_2S_n), p. 689 (S_iCl_2), and p. 670 [Ti(\eta^5-C_5H_5)_2(S_3)].

Cyclo-S_7 is known in four crystalline modifications; one of these, obtained by crystallization from CS_2 at -78°, rapidly disintegrates to a powder at room temperature, but an X-ray study at -110° showed it to consist of cyclo-S_7 molecules with the dimensions shown in Fig. 15.5(a). Notable features are the very large interatomic distance S(6)-S(7) (218.1 pm) which probably arises from the almost zero dihedral angle between the virtually coplanar atoms S(4) S(6) S(7) S(5), thus leading to maximum repulsion between nonbonding lone-pairs of electrons on adjacent S atoms. As a result of this weakening of S(6)-S(7), the adjacent bonds are strengthened (199.5 pm) and there are further alternations of bond lengths (210.2 and 205.2 pm) throughout the molecule.

The structure of cyclo-S_10 is shown in Fig. 15.5(b). The molecule belongs to the very rare point group symmetry D_2 (three orthogonal twofold axes of rotation as the only symmetry elements). The mean interatomic distance and bond angle are close to those in cyclo-S_12 (Table 15.5) and the molecule can be regarded as composed of two identical S_5 units obtained from the S_12 molecule (Fig. 15.6).

Cyclo-S_12 occupies an important place amongst the cyclic oligomers of sulfur. In a

---

Figure 15.6 Various representations of the molecular structure of cyclo-S$_{12}$ showing S atoms in three parallel planes. The idealized point group symmetry is $D_{2d}$ and the mean dihedral angle is $86.1 \pm 5.5^\circ$. In the crystal the symmetry is slightly distorted to $C_{2h}$ and the central group of 6 S atoms deviate from coplanarity by $\pm 14$ pm.

Classic paper by L. Pauling$^{(29)}$ the molecule had been predicted to be unstable, though subsequent synthesis showed it to be second only to cyclo-S$_8$ in stability. In fact, the basic principles underlying Pauling’s prediction remain valid but he erroneously applied them to two sets of S atoms in two parallel planes whereas the configuration adopted has S atoms in three parallel planes. Several representations of the structure are in Fig. 15.6. Using the nomenclature of p. 656 it can be seen that, unlike S$_6$ and S$_8$, the conformation of all S atoms is not cis: the S atoms in upper and lower planes do indeed have this conformation but the 6 atoms in the central plane are alternately d-trans and l-trans leading to the sequence:

Cyclo-S$_{12}$ was first prepared in 1966 in 3% yield by reacting H$_2$S$_4$ with S$_2$Cl$_2$ but a better route is the reaction between dilute solutions of H$_2$S$_8$ and S$_4$Cl$_2$ in Et$_2$O (18% yield). It can also be extracted from liquid sulfur. The stability of the allotrope can be gauged from its mp (148$^\circ$), which is higher than that of any other allotrope and nearly 30$^\circ$ above the temperature at which the S$_8$ ring begins to decompose.

Two allotropes of cyclo-S$_{18}$ are known. The structure of the first is shown in Fig. 15.7(a): if we take 3 successive atoms out of the S$_{12}$ ring then the 9-atom fragment combines with a second one to generate the structure. Alternatively, the structure can be viewed as two parallel 9-atom helices (see below), one right-handed and one left-handed, mutually joined at each end by the cis atoms S(5) and S(14). Interatomic distances vary between 204–211 pm (mean 206 pm), bond angles between 103.7–108.3$^\circ$ (mean 106.3$^\circ$), and dihedral angles between 79.1–90.0$^\circ$ (mean 84.5$^\circ$). This form of cyclo-S$_{18}$ is formed by the reaction between H$_2$S$_8$ and S$_{10}$Cl$_2$ and forms lemon-coloured crystals, mp 128$^\circ$, which can be stored in the dark for several days without apparent change. The second form of cyclo-S$_{18}$ has the molecular structure shown in Fig. 15.7(b): this has twice the 8-atom repeat motif cis-cis-trans-cis-trans-cis-trans-cis (one with d-trans and the other with l-trans) joined at each end by further bridging single trans-sulfur atoms which constitute the 2 extreme atoms of the elongated ring.

---

§15.1.4 Allotropes of sulfur

Pale yellow crystals of cyclo-S$_{20}$, mp 124\(^\circ\) (decomp), \(d\) 2.016 g cm\(^{-3}\), have been made by the reaction of H$_2$S$_{10}$ and S$_{10}$Cl$_2$. The molecular structure is shown in Fig. 15.8\(^{(31)}\)

The interatomic S–S distances vary between 202.3–210.4 pm (mean 204.2 pm), the angles S–S–S between 104.6–107.7° (mean 106.4°), and the dihedral angles between 66.3–89.9° (mean 84.7°). In this case the conformation motif is -c-lt-lt-lt-c- repeated 4 times and the abnormally long bond required to achieve ring closure is notable; it is also this section of the molecule which has the smallest dihedral angles thereby incurring increased repulsion between adjacent nonbonding lone-pairs of electrons. Consistent with this the adjacent bonds are the shortest in the molecule.

---

**Figure 15.7** (a) The molecular structure of one form of cyclo-S$_{18}$, together with the conformational sequence of the two helical subunits.\(^{(30)}\) (b) The molecular structure of the second form of cyclo-S$_{18}$ showing the \textit{trans}-configuration of the S atoms at the extreme ends of the elongated rings.\(^{(25)}\)

**Figure 15.8** Molecular structure of cyclo-S$_{20}$ viewed along the [001] direction.\(^{(31)}\) The 2 adjacent S atoms with the longest interatomic distance are shown in white.

Solid polycatenasulfur comes in many forms: it is present in rubbery S, plastic (\(\chi\))S, lamina S, fibrous (\(\psi, \phi\)), polymeric (\(\mu\)) and insoluble (\(\omega\))S, supersublimation S, white S and the commercial product Crystex. All these are metastable mixtures of allotropes containing more or less
defined concentrations of helices \( (S_\infty) \), cyclo-
\( S_8 \), and other molecular forms. The various
modifications are prepared by precipitating \( S \)
from solution or by quenching hot liquid \( S \)
(say from 400°C). The best-defined forms are
fibrous (\( d \approx 2.01 \text{ g cm}^{-3} \)) in which the helices
are mainly parallel, and lamella \( S \) in which they
are partly criss-crossed. When carefully prepared
by drawing filaments from hot liquid sulfur,
fibrous rubbery or plastic \( S \) can be repeatedly
stretched to as much as 15 times its normal length
without substantially impairing its elasticity.
All these forms revert to \( \text{cyclo-S}_8(\alpha) \) at room
temperature and this has caused considerable
difficulty in obtaining their X-ray structures.\(^{(23)}\)
However, it is now established that fibrous \( S \)
consists of infinite chains of \( S \) atoms arranged
in parallel helices whose axes are arranged on
a close-packed (hexagonal) net 463 pm apart.
The structure contains both left-handed and right-
handed helices of radius 95 pm and features a
repeat distance of 1380 pm comprising 10 \( S \)
atoms in three turns as shown in Fig. 15.9.
Within each helix the interatomic distance \( S-S \)
is 206.6 pm, the bond angle \( S-S-S \) is 106.0°, and
the dihedral angle \( S-S-S-S \) is 85.3°.
The constitution of liquid sulfur has been
extensively investigated, particularly in the
region just above the remarkable transition at
159.4°. At this temperature virtually all prop-
erties of liquid sulfur change discontinuously,
e.g. specific heat (\( \lambda \) point), density, velocity
of sound, polarizability, compressibility, colour,
electrical conductivity, surface tension and, most
strikingly, viscosity, which increases over 10 000-
fold within the temperature range 160–195°C
before gradually decreasing again. The phe-
nomena can now be interpreted at least semi-
quantitatively by a 2-step polymerization theory
involving initiation and propagation:

\[
\text{cyclo-S}_8 \rightleftharpoons \text{catena-S}_8
\]
\[
\text{catena-S}_8 + \text{cyclo-S}_8 \rightarrow \text{catena-S}_16, \text{ etc.}
\]
The polymerization is photosensitive, involves
diradicals and leads to chain lengths that exceed
200 000 \( S \) atoms at \( \sim 180°C \) before dropping
slowly to \( \sim 1000 \) \( S \) at 400° and \( \sim 100 \) \( S \) at 600°.

Polymeric \( S_\infty \) is dark yellow with an absorption
edge at 350 nm (cf. \( \text{H}_2\text{S}_n \), p. 683) but the colour
is often obscured either by the presence of trace
organic impurities or, in pure \( S \), by the presence
of other highly coloured species such as the
dark cherry-red trimer \( S_3 \) or the deeper-coloured
radical \( S_4 \) and \( S_5 \).
The saturated vapour pressure above solid and
liquid sulfur is given in Table 15.7. The mole-
cular composition of the vapour has long been in
contention but, mainly as a result of the work of
J. Birkowitz and others\(^{(24)}\) is now known to con-
tain all molecules \( S_n \) with \( 2 \leq n \leq 10 \) including
odd-numbered species. The actual concentration

| Table 15.7 Vapour pressure of crystalline cyclo-S_8(\alpha) and liquid sulfur |
|-------------------------|----------|----------|----------|----------|----------|
| \( p/\text{mmHg}^{(a)} \) | 10^{-5}  | 10^{-3}  | 10^{-1}  | 1        | 10       | 100      | 260      |
| \( T/°C \)              | 39.0     | 81.1     | 141      | 186      | 244.9    | 328      | 444.61   |

\(^{(a)}\) \( 1 \text{ mmHg} \approx 133.322 \text{ Pa} \); \( 1 \text{ atm} = 101325 \text{ Pa} \)
of each species depends on both temperature and pressure. In the saturated vapour up to 600°C $S_8$ is the most common species followed by $S_6$ and $S_7$, and the vapour is green. Between 620–720°C $S_7$ and $S_6$ are slightly more prevalent than $S_8$ but the concentration of all three species falls rapidly with respect to those of $S_2$, $S_3$ and $S_4$, and above $S_2$ is the predominant species. At lower pressures $S_2$ is even more prominent, accounting for more than 80% of all vapour species at 530°C and 100 mmHg, and 99% at 730°C and 1 mmHg. This vapour is violet. The vapour above FeS$_2$ at 850°C is also $S_2$.

The best conditions for observing $S_3$ are 440°C and 10 mmHg when 10–20% of vapour species comprise this deep cherry-red bent triatomic species; like ozone, p. 607, it has a singlet ground state. The best conditions for $S_4$ are 450°C and 20 mmHg (concentration ~20%) but the structure is still not definitely established and may, in fact be a strained ring, an unbranched diradical chain, or a branched-chain isostructural with SO$_3$(g) (p. 703).

The great stability of $S_2$ in the gas phase at high temperature is presumably due to the essentially double-bond character of the molecule and to the increase in entropy ($T\Delta S$) consequent on the breaking up of the single-bonded $S_n$ oligomers. As with O$_2$ (p. 606) the ground state is a triplet level $^3\Sigma^-$ but the splitting within the triplet state is far larger than with O$_2$ and the violet colour is due to the transition B$^3\Sigma^+ \leftarrow X^3\Sigma^-$ at 31 689 cm$^{-1}$. The corresponding B$\rightarrow$X emission is observed whenever S compounds are burned in a reducing flame and the transition can be used for the quantitative analytical determination of the concentration of S compounds. There is also a singlet $^1\Delta$ excited state for O$_2$. The dissociation energy $D_0^r(S_2)$ is 421.3 kJ mol$^{-1}$, and the interatomic distance in the gas phase 188.7 pm (cf. Table 15.5).

### 15.1.5 Atomic and physical properties

Several physical properties of sulfur have been mentioned in the preceding section; they vary markedly with the particular allotrope and its physical state.

Sulfur ($Z = 16$) has 4 stable isotopes of which $^{32}\text{S}$ is by far the most abundant in nature (95.02%). The others are $^{33}\text{S}$ (0.75%), $^{34}\text{S}$ (4.21%), and $^{36}\text{S}$ (0.02%). These abundances vary somewhat depending on the source of the sulfur, and this prevents the atomic weight of sulfur being quoted for general use more precisely than 32.066(6) (p. 17). The variability is a valuable geochemical indication of the source of the sulfur and the isotope ratios of sulfur-containing impurities can even be used to identify the probable source of petroleum samples.$^{(15,32)}$

In such work it is convenient to define the abundance ratio of the 2 most abundant isotopes ($R = ^{32}\text{S}/^{34}\text{S}$) and to take as standard the value of 22.22 for meteoritic troilite (FeS). Deviations from this standard ratio are then expressed in parts per thousand (sometimes confusingly called "per mil" or $\delta$):

$$\delta^{34}\text{S} = 1000(R_{\text{sample}} - R_{\text{std}})/R_{\text{std}}$$

On this definition, $^{34}\text{S}$ is zero for meteoritic troilite; dissolved sulfate in ocean water is enriched +20‰ in $^{34}\text{S}$, as are contemporary evaporite sulfates, whereas sedimentary sulfides are depleted in $^{34}\text{S}$ by as much as −50‰ due to fractionation during bacterial reduction to H$_2$S.

In addition to the 4 stable isotopes sulfur has at least 9 radioactive isotopes, the one with the longest half-life being $^{35}\text{S}$ which decays by $\beta^-$ activity ($E_{\text{max}}$ 0.167 MeV, $t_1^1$ 87.5 d). $^{35}\text{S}$ can be prepared by $^{35}\text{Cl}(n,p)$, $^{34}\text{S}(n,\gamma)$ or $^{34}\text{S}(d,p)$ and is commercially available as S$_\text{element}$, H$_2$S, SOC$_2$ and KSCN. The $\beta^-$ radiation has a similar energy to that of $^{14}\text{C}$ ($E_{\text{max}}$ 0.155 MeV) and similar counting techniques can be used (p. 276). The maximum range is 300 mm in air and 0.28 mm in water, and effective shielding is provided by a perspex screen 3–10 mm thick. The preparation of many $^{35}\text{S}$-containing compounds has been

---

reviewed\textsuperscript{(33)} and many of these have been used for mechanistic studies, e.g. the reactions of the specifically labelled thiosulfate ions $\text{S}_2\text{SO}_3^{2-}$ and $\text{S}_3\text{S}_2\text{O}_3^{2-}$. Another ingenious application, which won Barbara B. Askins the US Inventor of the Year award for 1978, is the use of $\text{S}^{35}$ for intensifying under-exposed photographic images: prints or films are immersed in dilute aqueous alkaline solutions of $\text{S}^{35}$-thiourea, which complexes all the silver in the image (including invisibly small amounts), and the alkaline medium converts this to immobile, insoluble Ag$^{35}$S; the film so treated is then overlaid with unexposed film which reproduces the image with heightened intensity as a result of exposure to the $\beta^-$ activity.

The isotope $\text{S}^{33}$ has a nuclear spin quantum number $I = \frac{3}{2}$ and so is potentially useful in nmr experiments (receptivity to nmr detection $17 \times 10^{-5}$ that of the proton). The resonance was first observed in 1951 but the low natural abundance of $\text{S}^{33}(0.75\%)$ and the quadrupolar broadening of many of the signals has so far restricted the amount of chemically significant work appearing on this resonance.\textsuperscript{(34)} However, more results are expected now that pulsed fourier-transform techniques have become generally available.

The $\text{S}$ atom in the ground state has the electronic configuration $[\text{Ne}]3s^23p^4$ with 2 unpaired p electrons ($^3P_1$). Other atomic properties are: ionization energy 999.30 kJ mol$^{-1}$, electron affinities +200 and $-414$ kJ mol$^{-1}$ for the addition of the first and second electrons respectively, electronegativity (Pauling) 2.5, covalent radius 103 pm and ionic radius of $\text{S}^{2-}$ 184 pm. These properties can be compared with those of the other elements in Group 16 on p. 754.

\textbf{15.1.6 Chemical reactivity}

Sulfur is a very reactive element especially at slightly elevated temperatures (which presumably facilitates cleavage of S–S bonds). It unites directly with all elements except the noble gases, nitrogen, tellurium, iodine, iridium, platinum and gold, though even here compounds containing S bonded directly to N, Te, I, Ir, Pt and Au are known. Sulfur reacts slowly with $\text{H}_2$ at 120°, more rapidly above 200°, and is in reversible thermodynamic equilibrium with $\text{H}_2$ and $\text{H}_2\text{S}$ at higher temperatures. It ignites in $\text{F}_2$ and burns with a livid flame to give $\text{SF}_6$; reaction with chlorine is more sedate at room temperature but rapidly accelerates above this to give (initially) $\text{S}_2\text{Cl}_2$ (p. 689). Sulfur dissolves in liquid $\text{Br}_2$ to form $\text{S}_2\text{Br}_2$, which readily dissociates into its elements; iodine has been used as a cryoscopic solvent for sulfur (p. 654) and no binary compound is formed (directly) even at elevated temperature (see, however, p. 691). Oxidation of sulfur by (moist?) air is very slow at room temperature though traces of $\text{SO}_2$ are formed; the ignition temperature of $\text{S}$ in air is 250-260°. Pure dry $\text{O}_2$ does not react at room temperature though $\text{O}_3$ does. Likewise direct reaction with $\text{N}_2$ has not been observed but, in a discharge tube, activated N reacts. All other non-metals (B, C, Si, Ge; P, As, Sb; Se) react at elevated temperatures. Of the metals, sulfur reacts in the cold with all the main group representatives of Groups 1, 2, 13, Sn, Pb and Bi, and also Cu, Ag and Hg (which even tarnishes at liquid-air temperatures). The transition metals (except Ir, Pt and Au) and the lanthanides and actinides react more or less vigorously on being heated with sulfur to form binary metal sulfides (p. 676).

The reactivity of sulfur clearly depends sensitively on the molecular complexity of the reacting species. Little systematic work has been done. Cyclo-$\text{S}_8$ is obviously less reactive than the diradical $\text{catena-S}_8$, and smaller oligomers in the liquid or vapour phase also complicate the picture. In the limit atomic sulfur, which can readily be generated photolytically, is an extremely reactive species. As with atomic oxygen and the various

reviewed\(^{(33)}\) and many of these have been used for mechanistic studies, e.g. the reactions of the specifically labelled thiosulfate ions \(3^{35}\text{SSO}_3^2-\) and \(3^{35}\text{S}_2\text{O}_3^2-\). Another ingenious application, which won Barbara B. Atkin the US Inventor of the Year award for 1978, is the use of \(3^{35}\text{S}\) for intensifying under-exposed photographic images: prints or films are immersed in dilute aqueous alkaline solutions of \(3^{35}\text{S}-\text{thiourea}, which complexes all the silver in the image (including invisibly small amounts), and the alkaline medium converts this to immobile, insoluble \(\text{Ag}^{35}\text{S}\); the film so treated is then overlayed with unexposed film which reproduces the image with heightened intensity as a result of exposure to the \(\beta^-\) activity.

The isotope \(3^{33}\text{S}\) has a nuclear spin quantum number \(I = \frac{3}{2}\) and so is potentially useful in nmr experiments (receptivity to nmr detection \(17 \times 10^{-6}\) that of the proton). The resonance was first observed in 1951 but the low natural abundance of \(3^{33}\text{S}(0.75\%)\) and the quadrupolar broadening of many of the signals has so far restricted the amount of chemically significant work appearing on this resonance.\(^{(34)}\) However, more results are expected now that pulsed fourier-transform techniques have become generally available.

The \(\text{S}\) atom in the ground state has the electronic configuration \([\text{Ne}]3s^23p^4\) with 2 unpaired \(p\) electrons \((3P_1)\). Other atomic properties are: ionization energy 999.30 kJ mol\(^{-1}\), electron affinities +200 and −414 kJ mol\(^{-1}\) for the addition of the first and second electrons respectively, electronegativity (Pauling) 2.5, covalent radius 103 pm and ionic radius of \(\text{S}^{2-}\) 184 pm. These properties can be compared with those of the other elements in Group 16 on p. 754.

### 15.1.6 Chemical reactivity

Sulfur is a very reactive element especially at slightly elevated temperatures (which presumably facilitates cleavage of \(\text{S}-\text{S}\) bonds). It unites directly with all elements except the noble gases, nitrogen, tellurium, iodine, iridium, platinum and gold, though even here compounds containing \(\text{S}\) bonded directly to \(\text{N}, \text{Te}, \text{I}, \text{Ir}, \text{Pt}\) and \(\text{Au}\) are known. Sulfur reacts slowly with \(\text{H}_2\) at 120°, more rapidly above 200°, and is in reversible thermodynamic equilibrium with \(\text{H}_2\) and \(\text{H}_2\text{S}\) at higher temperatures. It ignites in \(\text{F}_2\) and burns with a livid flame to give \(\text{SF}_6\); reaction with chlorine is more sedate at room temperature but rapidly accelerates above this to give (initially) \(\text{S}_2\text{Cl}_2\) (p. 689). Sulfur dissolves in liquid \(\text{Br}_2\) to form \(\text{S}_2\text{Br}_2\), which readily dissociates into its elements; iodine has been used as a cryoscopic solvent for sulfur (p. 654) and no binary compound is formed (directly) even at elevated temperature (see, however, p. 691). Oxidation of sulfur by (moist?) air is very slow at room temperature though traces of \(\text{SO}_2\) are formed; the ignition temperature of \(\text{S}\) in air is 250-260°. Pure dry \(\text{O}_2\) does not react at room temperature though \(\text{O}_3\) does. methylenes, both singlet and triplet states are possible and these have different reactivities. The ground state is \(^3\)P\(_2\), and the singlet state \(^1\)D\(_2\) lies 110.52 kJ mol\(^{-1}\) above this. Triplet state S atoms (with 2 unpaired electrons) can be generated by the Hg-photosensitized irradiation of COS:

\[
\text{Hg} + \text{hv} \ (253.7 \text{ nm}) \longrightarrow \text{Hg}^{(3\, P_1)}
\]

\[
\text{Hg}^{(3\, P_1)} + \text{COS} \longrightarrow \text{Hg} + \text{CO} + \text{S}^{(1\, P)}
\]

Triplet S can also be generated by direct photolysis of CS\(_2\) (\(h\nu < 210 \text{ nm}\)) or ethylene episulfide CH\(_2\)CH\(_2\)S (\(h\nu 210-230 \text{ pm}\)) generates singlet state S atoms (with no unpaired electrons) but the best syntheses of these is the direct primary photolysis of COS in the absence of Hg; this generates mainly singlet S (75%) with the rest being in the triplet state \((^3\, P)\):

\[
\text{COS} + \text{hv} \longrightarrow \text{CO} + \text{S}^{(1\, D_2)}
\]

Generation of (excited state) singlet S in the presence of paraffins yields the corresponding mercaptan by a concerted single-step insertion: RH + S\(^{(1\, D_2)}\) \longrightarrow RSH. By contrast, paraffins are inert to triplet (ground state) S atoms. Singlet S undergoes analogous insertion reactions with MeSiH\(_3\), SiMe\(_4\) and B\(_2\)H\(_6\). Olefins can undergo insertion of singlet S atoms on stereospecific addition of triplet S atoms; according to experimental conditions, the products are alkenyl mercaptans, vinylic mercaptans or episulfides. Analogous reactions with inorganic compounds appear to be a very promising field for future research. Generation of the reactive diatomic species S\(_2\) for synthetic purposes is also currently an active field.(45,46)

Sulfur compounds exhibit a rich and multifarious variety which derives not only from the numerous possible oxidation states of the element (from -2 to +6) but also from the range of bond types utilized (covalent, coordinate, ionic and even metallic) and the multiplicity of coordination geometries adopted by the element. Oxidation states and their interrelationships as codified by oxidation state diagrams are dealt with more fully in the section on oxoacids of sulfur (p. 706) though the existence of several other series of compounds, notably the halides, also illustrates the element's versatility. The range of bond types, as reflected in the physical and chemical properties of the various compounds of the element, will become increasingly apparent throughout the rest of the chapter. The multiplicity of coordination geometries is amply demonstrated by the examples in Table 15.8. Most of these can be readily rationalized by the numerous variants of elementary bonding theory. See ref. 47 for a VSEPR treatment.

**Polyatomic sulfur cations**

As long ago as 1804 C. F. Bucholz observed that sulfur dissolves in oleum to give clear, brightly coloured solutions which could be yellow, deep blue or red (or intermediate colours) depending on the strength of the oleum and the time of the reaction. These solutions are now known to contain S\(_n\)^\(^{2+}\) cations, the structure of which has been elucidated during the past two decades mainly by elegant synthetic, Raman spectroscopic and crystallographic studies.(48-50) Selenium and tellurium behave similarly (p. 759).

Sulfur can most conveniently be quantitatively oxidized using SbF\(_5\) or AsF\(_5\) in an inert solvent such as SO\(_2\), e.g.:

\[
\text{S}_8 + 3\text{AsF}_5 \rightarrow [\text{S}_8]^{2+}[\text{AsF}_6]_2^- + 3\text{AsF}_3
\]

\[
\text{S}_8 + 6\text{AsF}_5 \rightarrow 2[\text{S}_4]^{2+}[\text{AsF}_6]_2^- + 2\text{AsF}_3
\]

---

The bright-yellow solutions contain \( \text{S}_4^{2+} \), a square-planar ring whose structure has been confirmed by an X-ray study on the unusual crystalline compound \( \text{As}_6\text{F}_{36}\text{S}_3\text{S}_{32} \), i.e. \( [\text{S}_4]^{2+}[\text{S}_7\text{I}]^{4+}[\text{AsF}_6]^{-6} \) (p. 692). The S–S interatomic distance is 198 pm compared with 204 pm for a single-bonded species. Note also that \( \text{S}_4^{2+} \) is isoelectronic with the known heterocyclic compound \( \text{S}_2\text{N}_2 \) (p. 725). The pale-yellow compound \( [\text{S}_4]^{2+}[\text{SbF}_6]^{-2} \) has also been isolated.

The deep-blue solutions contain \( \text{S}_8^{2+} \), and the X-ray structure of \( [\text{S}_8]^{2+}[\text{AsF}_6]^{-2} \) reveals that the cation has an exo-endo cyclic structure with a long transannular bond as shown in Fig. 15.10 (see also p. 724). The bright-red solutions were originally thought to contain the \( \text{S}_{16}^{2+} \) cation and a compound thought to be \( \text{S}_{16}(\text{AsF}_6)_2 \) was isolated; however, crystallographic study has shown\(^{51}\) that the compound has the totally unexpected formulation \( [\text{S}_{19}]^{2+}[\text{AsF}_6]^{-2} \) which could not have been distinguished from the earlier stoichiometry on the basis of the original analytical data. This astonishing cation consists of two 7-membered rings joined by a 5-atom chain. As shown in Fig. 15.11, one of the rings has a boat conformation whilst the other is disordered, existing as a 4:1 mixture of chair and boat conformations. S–S distances vary greatly from 187 to 239 pm and S–S–S angles vary from 91.9° to 127.6°. See also p. 692 for \( [\text{S}_7\text{X}]^{1+} \) cations.

Solutions of sulfur in oleum also give rise to paramagnetic species, probably \( \text{S}_n^{+} \), but the

of \( d_{\pi} \) orbitals in bonding to sulfur has also been invoked (see comparison of N and P, p. 416).

Some examples of the S atom as a bridging ligand are given in Fig. 15.12. In the \( \mu_2 \) bridging mode S is usually regarded as a 2-electron donor, though in the linear bridge \([((C_5H_5)(CO)_2Cr)_2S]\) it is probably best regarded as a 6-electron donor.\(^{35}\) In the \( \mu_3 \) triply bridging mode S can be regarded as a 4-electron donor, using both its unpaired electrons and one lone-pair.\(^{52}\) If the 3 bridged metal atoms

---

are different then a chiral tetrahedrane molecule results and this has permitted the recent (1980) resolution of the enantiomers of the first optically active metal cluster compound, the red complex $\left[[\text{Co}(\text{CO})_3][\text{Fe}(\text{CO})_3][\text{Mo}(\eta^5-\text{C}_3\text{H}_5)(\text{CO})_2]\text{S}]\right]$. The pseudo-cubane structure adopted by some of the $\mu_3$-$\text{S}$ compounds is assuming added significance as a crucial structural unit in many biologically important systems, e.g. the $\left[[\text{RS}]\text{FeS}_4\right]$ units which cross-link the polypeptide chains in ferredoxins (p. 1103). In the $\mu_4$-mode 6-electrons are involved, if the bonding is considered to be predominantly covalent, though metal-sulfides are sometimes treated as compounds of $S^{2-}$. No molecular compounds are known in which S bridges 6 or 8 metal atoms though, again, these coordinations are prevalent in solid-state compounds, many of which have interatomic bonding which is far from being purely ionic.

The disulfur ligand $S_2$ (sometimes more helpfully considered as $S_2^{2-}$) is attracting increasing attention since no other simple ligand is as versatile in the variety of its modes of coordination. Moreover, in one particular mode (see Type III, p. 669) it is particularly effective in stabilizing metal clusters. Many of the complexes of $S_2$ were first obtained accidentally, and their seemingly bizarre stoichiometries only became intelligible after structural elucidation by X-ray crystallography. The complexes can be prepared by reacting metals or their compounds with: (a) a positive $S_2$ group as in $S_2\text{Cl}_2$; (b) a neutral $S_2$ group, usually derived from $S_8$; (c) a negative $S_2^{2-}$ group such as an alkaline polysulfide solution. Examples are:

\[
\text{Nb} + S_2\text{Cl}_2 \xrightarrow{\text{heat}} \text{NbS}_2\text{Cl}_2 \quad \text{(see Fig. 15.14a), (p. 671)}
\]

\[
\text{Nb} + \frac{1}{2}S_8 + X_2 \xrightarrow{500^\circ C} \text{NbS}_2X_2 \quad (X = \text{Cl, Br, I})
\]

\[
(\text{NH}_4)_6\text{Mo}_7\text{O}_{24}.4\text{H}_2\text{O} + \text{H}_2\text{S} + (\text{NH}_4)_2\text{S}_n \xrightarrow{\text{aq NH}_4}\quad (\text{NH}_4)_2[\text{Mo}_2(\text{S}_2)_6] \quad \text{(see Fig. 15.13g)}
\]

The $S$--$S$ bond can also be formed by a direct coupling reaction, e.g.:

\[
2[(\text{H}_2\text{O})_5\text{Cr(\text{SH})}]^{2+} + \text{I}_2 \rightarrow [(\text{H}_2\text{O})_5\text{CrSSCr(OH}_2)_3]^{4+} + 2\text{HI}
\]

At least 8 modes of coordination are known (Table 15.9); they are all based on either side-on $S_2$ or bridging $-S-S-$ with possible further ligation via one or two lone-pairs as shown schematically below:

Frequently, more than one type of coordination occurs in a given complex, e.g. Figs. 15.13b, c and g. Interestingly, there appear to be no known example of terminal "end-on" coordination, $M-S-S$ (see dioxygen complexes, p. 615). Detailed descriptions of all the structures and their bonding are beyond the scope of this treatment but it will be noted from Table 15.9 that the $S-S$ interatomic distances in disulfide complexes range from 201 to 209 pm. The following specific points of interest may also be mentioned. The orange-red anion $[\text{Mo}_4(\text{NO})_4\text{S}_{13}]^{4-}$ (Fig. 15.13b) features two triangular arrays of Mo atoms joined by a common edge and with an angle of 127.6° between the two Mo$_3$ planes; each plane has a $\mu_2$-bonded S atom above it (Mo--S 250.1 pm) and there is a further unique $\mu_4$-bonded S atom which is 261.6 pm from each of the 4 Mo atoms. Four of the 5 $S^{2-}$ ligands are simultaneously bonded both end on (Mo--S 246.5 pm) and side on (Mo--S 249.2 pm) whilst the fifth is side-on only. The complex therefore has sulfur in five different bonding states. In the red complex $[\text{Mn}_4(\text{CO})_{15}(\text{S}_2)_2]$ (Fig. 15.13c) the 2 $S^{2-}$ ligands are different (Types Ic and Id); the 4 Mn

atoms are bonded, respectively, to 3, 3, 4 and 5 carbonyl ligands, but each achieves a distorted octahedral coordination by being bonded also to 3, 3, 2 and 1 S atoms respectively. There seems no reason to suppose that the diamagnetic bridged dinuclear anion \([(\text{NC})_2\text{Co}^{II}SS\text{Co}^{III}(\text{CN})_2]^6-\) is not a formal Type IIa disulfido \(S_2^{2-}\) complex, but there is evidence that the superficially analogous paramagnetic dinuclear ruthenium cation in Fig. 15.13d is, in fact, a mixed-valence supersulfido \(S_2^{2-}\) complex: \([(\text{H}~\text{N})_2\text{Ru}^{II}SS\text{Ru}^{III}(\text{NH}_3)_2]^4+\).

The bridged dinuclear cobalt anion undergoes a remarkable aerial oxidation in aqueous ethanol solutions at \(-15°C\); one of the bridging S atoms only is oxidized and this results in the formation of a bridging thiosulfito group \([(\text{NC})\text{Co}SS\text{Co}(\text{CN})_2]^2-\) coordinated through the two S atoms to the two Co atoms.\(^{63}\)

Other recent examples of \(S_2^{2-}\) complexes include \([\text{V}(\eta^5-\text{C}_5\text{Me}_5)_2(\eta^2_2-\text{S}_2)]^{6-}\), \([\text{W}_2(\text{S})_2(\text{SH})(\mu-\eta^2-\text{S}_2)(\eta^2_2-\text{S}_2)]^{-}\), \([\eta^8-\text{C}_5\text{Me}_5)_2\text{Fe}_2(\mu-\eta^2-\eta^2-\text{S}_2)]^{66}\) and \([\text{Ru}_2(\text{POMe})_3_2(\eta^2-\text{C}_5\text{H}_5)_2(\mu-\eta^1-\eta^1-\text{S}_2)]^{67}\).

Not all disulfide complexes are discrete molecular or ionic species and several solid-state compounds of \(S_2^{2-}\) are known in addition to the familiar pyrites and marcasite-type disulfides (p. 680). Examples are the chlorine-bridged polymeric NbS_2Cl_2 mentioned on p. 667 (Fig. 15.14a) and the curious series of brown and red compounds formed by heating Mo or MoS_3 with S_2Cl_2, e.g. \(^{54}\) MoS_2Cl_3, MoS_2Cl_4 (Fig. 15.14b), Mo_2S_4Cl_5 (Fig. 15.14c), Mo_5S_6Cl_3 and Mo_3S_7Cl_4.

Complexes with chelating polysulfide ligands can be made either by reacting complex metal halides with solutions of polysulfides or by reacting hydrido complexes with elemental sulfur, e.g.:

\[
\text{H}_2\text{PtCl}_6 + (\text{NH}_4)_2\text{S}_2(\text{aq}) \xrightarrow{\text{h} \text{oil}} (\text{NH}_4)_2[\text{Pt}^{IV}(\text{S}_5)_2] \]

\[
[\text{Ti}(\eta^5-\text{C}_5\text{H}_5)_2\text{Cl}_2] + \text{Na}_2\text{S}_4 \xrightarrow{} [\text{Ti}^{IV}(\eta^5-\text{C}_5\text{H}_5)_2(\text{S}_5)] + 2\text{NaCl} \]

\[
[\text{W}(\eta^5-\text{C}_5\text{H}_5)_2\text{H}_2] + \frac{5}{8}\text{S}_8 \xrightarrow{} [\text{W}^{IV}(\eta^5-\text{C}_5\text{H}_5)_2(\text{S}_4)] + \text{H}_2\text{S} \]

The red dianion \([\text{PtS}_{15}]^{2-}\) was first made in 1903 but its structure as a chiral tris chelating pentasulfido complex (Fig. 15.15a) was not established until 1969.\(^{68}\) It is a rare example of a "purely inorganic" (carbon-free) optically active species.\(^{69}\) Other examples are S. Heřmánek and J. Plešek’s resolution of the main group element cluster compound \(\text{i}-\text{B}_{18}\text{H}_{22}\), \(^{70}\) A. Werner’s first-row transition-metal complex cation \([\text{Co}(\mu-\text{OH})_2\text{Co}(\text{NH}_3)_4]^{6+}\), \(^{71}\) and F. G. Mann’s second-row complex anion \(\text{cis}-[\text{Rh}(\eta^2-\text{S}_2)(\text{S}_2\text{O}_2)(\text{OH}_2)_2]^{2-}\).\(^{72}\) The structure of the complex \([\text{Ti}(\eta^5-\text{C}_5\text{H}_5)_2(\text{S}_5)]\) is in Fig. 15.15b; it has previously been mentioned in connection with the synthesis of cyclo-polysulfur allotropes (p. 657). The chair conformation of the 6-membered TiS_5 ring undergoes chair-to-chair inversion above room temperature with an activation energy of about 69 kJ mol\(^{-1}\).\(^{73}\) A similar ring inversion in \([\text{Pt}(\text{S}_5)_3]^{2-}\) is even more facile and \(^{195}\)Pt n.m.r. studies lead to a value of 50.5 \(\pm\) 1.3 kJ mol\(^{-1}\) for \(\Delta G^\ddagger\) at 0°C.\(^{74}\) Other recent examples of chelating \(S_n^{2-}\) ligands occur in the dark red-brown dianion \([\eta^2-\text{S}_4\text{Fe}(\mu-S)\text{S}_2\text{Fe}(\eta^2-\text{S}_3)]^{2-}\) and in the intriguing black

dianion $[\text{Mo}_2\text{S}_{10}]^{2-}$ which features 4 different sorts of sulfur ligand and at least 6 different S-atom environments (Fig. 15.15c). More complicated structures, including those featuring multidentate polymers or metal-sulfur clusters are continually being discovered in polysulfides whose apparently simple stoichiometry often conceals an amazing structural complexity. Some recent examples are: $[\sigma^5\text{-C}_5\text{Me}_5\text{Th}(\eta^4\text{-S}_5)]^{2-}$, $[\text{NMMe}_4]^+\text{[Ag(S)_5]}$, $[\text{Cu}_4\text{(S)_2(py)_4}]$.

Other ligands containing sulfur as donor atom

H₂S, the simplest compound of sulfur, differs markedly from its homologue H₂O in complex-forming ability: whereas aquo complexes are extremely numerous and frequently very stable (p. 625), H₂S rarely forms simple adducts due to its ready oxidation to sulfur or its facile deprotonation to SH⁻ or S²⁻. [AlBr₃(SH₂)] has long been known as a stable compound of tetrahedral Al (86) but the few transition metal complexes having some degree of stability at room temperature are of more recent vintage: examples include [Mn(η⁵-C₅H₅)(C₀)₂(SH)I, [w(co>dSH₂)₁, and the triangulo cluster complexes [Ru(CO)(SH)] and [Os₃(CO)₆(SH₂)]. (52, 87) Action of H₂S on acidic aqueous solutions frequently precipitates the metal sulfide (cf. qualitative analysis separation schemes) but, in the presence of a reducing agent such as Eu²⁺, H₂S can displace H₂O from the pale-yellow aquopentammine ruthenium(I) ion:

[Ru(NH₃)₅(OH₂)]²⁺ + H₂S  →  [Ru(NH₃)₅(SH₂)]²⁺;

\[
K_{298} = 1.5 \times 10^3 \text{mol}^{-1}
\]

In the absence of Eu²⁺, oxidative deprotonation of the pale-yellow H₂S complex occurs to give the orange ruthenium(III) complex [Ru(NH₃)₅(SH)]²⁺. Other examples of complexes containing the SH⁻ ligand are [Cr(OH₂)₅(SH)]²⁺, [W(η⁵-C₅H₅)(CO)₃(SH)], [Ni(η⁵-C₅H₅)(PBu₃)²(SH)], trans-[PtH(PET₃)₂(SH)] and trans-[Pt(PET₃)₂(SH₂)]. (52, 87, 89) The S-donor ligands SO, S₂O₂ and SO₂ are mentioned in Section 15.2.5 and S⁻N ligands in Section 15.2.7. Thiocyanate (SCN⁻) tends to be S-bonded rather than N-bonded. Bridging modes are also known (p. 324), including M–SCN–M and the rare S-only bridged MS(CN)M. (90)

Organic thio ligands are well established, examples being the thiols RSH (R = Et, Pr⁺, Bu', Ph), (91) the thioethers SMe₂, SEt₂, tetrahydrothiophene, etc., the chelating dithioethers, e.g. MeS(CH₂)₂SMe, and macro-cyclic ligands such as [(CH₃)₃S]⁻, with n = 3, 4 etc. (92) Thioureia, (H₂N)₂C=S, affords a further example. Factors affecting the stability of the resulting complexes have already been reviewed (p. 198). It is also notable that when B₉H₁₄ reacts with solutions of thioethers in OEt₂, tetrahydrofurran, etc., it is the thio ligand rather than the oxygen-containing species which forms the stable arachno-bis adducts [B₉H₁₂(SR₂)₂] (p. 176). Another large class of S-donor ligands comprises the dithiocarbamates R₂NCS₂⁻ and related anions YCS₂⁻, e.g. dithiocarboxylates RCS₂⁻, xanthates ROCS₂⁻, thiocarbonates SCS₂⁻ and thiophosphinates R₃PS₂⁻ (see p. 509 for applications). Dithiocarbamates can function either as unidentate or bidentate (chelating) ligands:

In the chelating mode they frequently stabilize the metal centre in an unusually high apparent formal oxidation state, e.g. $[\text{Fe}^{IV}(\text{S}_2\text{CNR}_2)_3]^+$ and $[\text{Ni}^{IV}(\text{S}_2\text{CNR}_2)_3]^+$. They also have a propensity for stabilizing novel stereochemical configurations, unusual mixed oxidation states (e.g. of Cu), intermediate spin states (e.g. Fe$^{"{i}}$, S$^{"{i}}$), and for forming a variety of tris chelated complexes of Fe$^{III}$ which lie at the $T_2 - A_1$ spin crossover (p. 1096).(93)

Dithiocarbamates and their analogues have 2 potential S-donor atoms joined to a single C atom and their complexes are sometimes called 1,1-dithiolato complexes. If the 2 S atoms are joined to adjacent C atoms then the equally numerous class of 1,2-dithiolato complexes results. Examples of chelating dithiolenligands (drawn for convenience with localized valence bonds and ionic charges) are:

![Dithiolato complexes](image)

Complexes of these ligands have been extensively studied during the past few decades not only because of the intrinsically interesting structural and bonding problems that they pose but also because of their varied industrial applications.(94—96) These include their use as highly specific analytical reagents, chromatographic supports, polarizers in sunglasses, mode-locking additives in neodymium lasers, semiconductors, fungicides, pesticides, vulcanization accelerators, high-temperature wear-inhibiting additives in lubricants, polymerization and oxidation catalysts and even fingerprint developers in forensic investigations.

Complexes in which dithioleines are the only ligands present can be classified according to six structural types as shown schematically in Fig. 15.16. For bis(dithiolato) complexes the planar structure (a) with $D_{2h}$ local symmetry about the metal is the commonest mode but occasionally 5-coordinate dimers (b) are observed. The very rare metal–metal bonded 5-coordinate dimeric bis(dithiolato) structure (c) has been found for the palladium and platinum complexes $[[\text{M}(\text{S}_2\text{C}_2\text{H}_2)_2]]$ with Pd–Pd 279 pm and Pt–Pt 275 pm. For tris(dithiolato) complexes two limiting geometries are possible: trigonal prismatic (Fig. 15.16d) and octahedral (Fig. 15.16f). The two geometries are related by a 30° twist of one triangular $S_3$ face with respect to the other, and intermediate twists are also known (Fig. 15.16e). As a rough generalization, the less-common trigonal prismatic geometry (local $D_{3h}$ symmetry) is adopted by “ligand-controlled” complexes which are often neutral or highly oxidized [e.g. $\text{M}(\text{S}_2\text{C}_2\text{R}_2)_3$, where $\text{M} = \text{V}, \text{Cr}, \text{Mo}, \text{W}, \text{Re}$], whereas the more usual octahedral ($D_3$) geometry tends to be formed when the central metal dominates the stereochemistry as in the reduced anionic complexes. Thus reduction of the trigonal prismatic $[\text{V}(\text{S}_2\text{C}_2(\text{CN})_2)_3]$ to the dianion $[\text{V}(\text{S}_2\text{C}_2(\text{CN})_2)_3]^{2-}$ results in distortion to an intermediate geometry, whereas the iron analogue $[\text{Fe}(\text{S}_2\text{C}_2(\text{CN})_2)_3]^{2-}$ has the chelated octahedral $D_3$ structure. Intermediate geometries (Fig. 15.16e) have also been found for $[\text{Mo}(\text{S}_2\text{C}_2(\text{CN})_2)_3]^{2-}$ and its W analogue.

There has been much discussion about the detailed bonding in 1,2-dithiolene complexes because of the alternative ways that the ring system can be described, e.g.:

![Dithiolene bonding](image)

The formal oxidation state of the metal differs by 2 in these two limiting formulations (or...
by 6 in a tris complex). On this basis it is unclear whether the complex \([\text{V} \{\text{S}_2\text{C}_2\text{(CN)}_2\}_3]\) mentioned in the preceding paragraph should be formulated as \(\text{V}^\text{VI}\) or \(\text{V}^0\): it seems probable that an intermediate value would be more likely, but the example emphasizes the difficulty of assigning meaningful oxidation numbers to metal atoms in a redox series when the electronic configuration of the ligands themselves may also be undergoing change during reduction. Such reversible oxidation-reduction sequences are a characteristic feature of many 1,2-dithiolene complexes, e.g. for \(L = \{\text{S}_2\text{C}_2\text{(CN)}_2\}\):

\[
\begin{align*}
[\text{CrL}_3]^0 & \xrightleftharpoons{+e} [\text{CrL}_3]^1^- \xrightarrow{-e} [\text{CrL}_3]^2^- \xrightarrow{+e} [\text{CrL}_3]^3^- \\
\text{[NiL}_2]\) & \xrightleftharpoons{+e} [\text{NiL}_2]^2^- \xrightarrow{-e} [\text{NiL}_2]^3- \\
\text{[NiL}_2]^2^- & \xrightarrow{+e} [\text{NiL}_2]^3- \\
\text{[CoL}_2]\) & \xrightleftharpoons{+e} [\text{CoL}_2]^1^- \xrightarrow{-e} [\text{CoL}_2]^2^- \xrightarrow{+2e} 2[\text{CoL}_2]^2-
\end{align*}
\]

and similarly for the Pd, Pt and other analogues.\(^{97}\) Likewise for dimeric species with \(L = \{\text{S}_2\text{C}_2\text{(CF)}_3\}_2\):

\[
\begin{align*}
[[\text{CoL}_2]\) & \xrightleftharpoons{+e} [[\text{CoL}_2]^1- \xrightarrow{-e} [[\text{CoL}_2]^2^- \xrightarrow{+2e} 2[\text{CoL}_2]^2-
\end{align*}
\]

Mixed complexes in which a metal is coordinated by a dithiolene and by other ligands such as \( (\eta^3-C_5H_5) \), CO, NO, \( R_3P \), etc., are also known.

15.2 Compounds of Sulfur

15.2.1 Sulfides of the metallic elements

Many of the most important naturally occurring minerals and ores of the metallic elements are sulfides (p. 648), and the recovery of metals from these ores is of major importance. Other metal sulfides, though they do not occur in nature, can be synthesized by a variety of preparative methods, and many have important physical or chemical properties which have led to their industrial production. Again, the solubility relations of metal sulfides in aqueous solution form the basis of the most widely used scheme of elementary qualitative analysis. These various more general considerations will be briefly discussed before the systematic structural chemistry of metal sulfides is summarized.

General considerations

When sulfide ores are roasted in air two possible reactions may occur:

(a) conversion of the material to the oxide (as a preliminary to metal extraction, e.g. lead sulfide roasting);

(b) formation of water-soluble sulfates which can then be used in hydrometallurgical processes.

The operating conditions (temperature, oxygen pressure, etc.) required to achieve each of these results depend on the thermodynamics of the system and the duration of the roast is determined by the kinetics of the gas–solid reactions.\(^{100}\) According to the Gibbs’ phase rule:

\[ F + P = C + 2 \]

where \( F \) is the number of degrees of freedom (pressure, temperature, etc.), \( P \) is the number of phases in equilibrium and \( C \) is the number of components (independently variable chemical entities) in the system. It follows that, for a 3-component system (metal-sulfur-oxygen) at a given temperature and total pressure of the gas phase, a maximum of three condensed phases can coexist in equilibrium. The ranges of stability of the various solid phases at a fixed temperature can be shown on a stability diagram which plots the equilibrium pressure of \( SO_2 \) against the pressure of oxygen on a log–log graph. An idealized stability diagram for a divalent metal \( M \) is shown in Fig. 15.17a, and actual stability diagrams for copper at 950 K and lead at 1175 K are in Fig. 15.17b, and c. Note that, ideally, all boundaries are straight lines: those between \( M/\text{MO} \) and \( \text{MSNO}_4 \) are vertical whereas the others have slopes of 1.0 (\( M/\text{MS} \)), 1.5 (\( \text{MS}/\text{MO} \)), and \(-0.5 \) (\( \text{MO}/\text{MSNO}_4 \)).\(^{1}\)

The application of these generalizations to the extractive metallurgy of individual metals is illustrated at appropriate points in the text dealing with the chemistry of the various elements.

\(^{1}\) These simple relations can readily be deduced from the equilibria being represented. Thus at constant temperature:

- M/\text{MO} boundary: \( \text{MO} = M + \frac{1}{2} \text{O}_2(g); \quad K = p^{\frac{1}{2}}(\text{O}_2) \).
  Hence \( \log p(O_2) = 2 \log K = \text{constant} \).

- MS/\text{MSNO}_4 boundary: \( \text{MSNO}_4 = M + 2 \text{O}_2(g); \quad K = p^{2}(\text{O}_2) \).
  Hence \( \log p(O_2) = \frac{1}{2} \log K = \text{constant} \).

- M/\text{MS} boundary: \( \text{MS} + \frac{1}{2} \text{O}_2(g) = M + \text{SO}_2(g); \quad K = p(\text{SO}_2)/p(\text{O}_2) \).
  Hence \( \log p(\text{SO}_2) = \log K + \log p(O_2), \text{ i.e. slope } = 1.0 \).

- \text{MS}/\text{MO} boundary: \( \text{MS} + \frac{3}{2} \text{O}_2(g) = \text{MO} + \text{SO}_2(g); \quad K = p(\text{SO}_2)/p^{3/2}(\text{O}_2) \).
  Hence \( \log p(\text{SO}_2) = \log K + \frac{3}{2} \log p(O_2), \text{ i.e. slope } = 1.5 \).

- \text{MO}/\text{MSNO}_4 boundary: \( \text{MO} + \frac{1}{2} \text{O}_2(g) = \text{MO} + \text{SO}_2(g); \quad K = p(\text{SO}_2)/p^{1/2}(\text{O}_2) \).
  Hence \( \log p(\text{SO}_2) = \log K - \frac{1}{2} \log p(O_2), \text{ i.e. slope } = -0.5 \).

As noted above, the roasting of most metal sulfides yields either the oxide or sulfate. However, a few metals can be obtained directly by oxidation of their sulfides, and these all have the characteristic property that their oxides are much less stable than SO\textsubscript{2}. Examples are Cu, Ag, Hg and the platinum metals. In addition, metallic Pb can be extracted by partial oxidation of galena to form a sulfate (the "Scotch hearth" or Newnham process, p. 370). The oversimplified reaction is:

\[
PbS + PbSO_4 \rightarrow 2Pb + 2SO_2
\]

However, as indicated in Fig. 15.17c, the system is complicated by the presence of several stable “basic sulfates” PbSO\textsubscript{4}.\textsubscript{n}PbO (n = 1, 2, 4), and these can react with gaseous PbS at lower metal-making temperatures, e.g.:

\[
PbSO_4.2PbO(s) + 2PbS(g) \rightarrow 5Pb(l) + 3SO_2(g)
\]

Metal sulfides can be prepared in the laboratory or on an industrial scale by a number of reactions; pure products are rarely obtained without considerable refinement and nonstoichiometric phases abound (p. 679). The more important preparative routes include:

(a) direct combination of the elements (e.g. Fe + S \rightarrow FeS);
(b) reduction of a sulfate with carbon (e.g. Na\textsubscript{2}SO\textsubscript{4} + 4C \rightarrow Na\textsubscript{2}S + 4CO);
(c) precipitation from aqueous solution by treatment with either acidified H\textsubscript{2}S (e.g. the platinum metals; Cu, Ag, Au; Cd, Hg; Ge, Sn, Pb; As, Sb, Bi; Se, Te) or alkaline (NH\textsubscript{4})\textsubscript{2}S (e.g. Mn, Fe, Co, Ni, Zn; In, Tl);
(d) saturation of an alkali hydroxide solution with H\textsubscript{2}S to give MHS followed by reaction with a further equivalent of alkali (e.g. KOH(aq) + H\textsubscript{2}S \rightarrow KHS + H\textsubscript{2}O; KHS + KOH \rightarrow K\textsubscript{2}S + H\textsubscript{2}O).

This last method is particularly suitable for water-soluble sulfides, though frequently it is the hydrate that crystallizes, e.g. Na\textsubscript{2}S.9H\textsubscript{2}O, K\textsubscript{2}S.5H\textsubscript{2}O. The hydrogensulfides MHS can also be made by passing H\textsubscript{2}S into solutions of metals in liquid NH\textsubscript{3}. The colourless hygroscopic mixed metal sulfide RbKS was recently made by annealing a mixture of K\textsubscript{2}S and Rb\textsubscript{2}S.\textsuperscript{(100a)}

Industrial applications of metal sulfides span the full time-scale from the earliest rise of the emerging chemical industry in the eighteenth century to the most recent developments of Li/S and Na/S power battery systems (see Panel). Reduction of Na\textsubscript{2}SO\textsubscript{4} by C was the first step in the now defunct Leblanc process (1791) for making Na\textsubscript{2}CO\textsubscript{3} (p. 71). Na\textsubscript{2}S (or NaHS) is still used extensively in the leather industry for removal of hair from hides prior to tanning, for making organo-sulfur dyes, as a reducing agent for organic nitro compounds in the production of amines, and as a flotation agent for copper ores. It is readily oxidized by atmospheric O\textsubscript{2} to give

Sodium-Sulfur Batteries

Alternatives to coal and hydrocarbon fuels as a source of power have been sought with increasing determination over the past three decades. One possibility is the Hydrogen Economy (p. 40). Another possibility, particularly for secondary, mobile sources of power, is the use of storage batteries. Indeed, electric vehicles were developed simultaneously with the first internal-combustion-engined vehicles, the first being made in 1886. In those days, over a century ago, electric vehicles were popular and sold well compared with the then noisy, inconvenient and rather unreliable petrol-engined vehicles. In 1899 an electric car held the world land-speed record at 105 km per hour. In the early years of this century, taxis in New York, Boston and Berlin were mainly electric; there were over 20 000 electric vehicles in the USA and some 10 000 cars and commercial vehicles in London. Even today (silent) battery-powered milk delivery vehicles are still operated in the UK. These use the traditional lead-sulfuric acid battery (p. 371), but this is extremely heavy and rather expensive.

The Na/S system has the potential to store 5-times as much energy (for the same weight) as the conventional lead battery and, in addition, shares with it the advantages of being silent, cheap to run, and essentially pollution-free; in general it is also reliable, has a long life and has extremely low maintenance costs. However, until recently it lacked the mileage range between successive chargings when compared with the highly developed petrol- or diesel-powered vehicles and it has a rather low performance (top speed and acceleration). A further disadvantage is the very long time taken to recharge the batteries (15–20 h) compared with the average time required to refill a petrol tank (1–2 min). Mixed power sources (petrol/electric battery) are a possible mode for development.

Conventional batteries consist of a liquid electrolyte separating two solid electrodes. In the Na/S battery this is inverted: a solid electrolyte separates two liquid electrodes: a ceramic tube made from the solid electrolyte sodium β-alumina (p. 249) separates an inner pool of molten sodium (mp 98°C) from an outer bath of molten sulfur (mp 119°C) and allows Na⁺ ions to pass through. The whole system is sealed and is encased in a stainless steel canister which also serves as the sulfur-electrode current collector. Within the battery, the current is passed by Na⁺ ions which pass through the solid electrolyte and react with the sulfur. The cell reaction can be written formally as

\[ 2\text{Na}(l) + \frac{n}{8}\text{S}_8(l) \rightarrow \text{Na}_2\text{S}_n(l) \]

In the central compartment molten Na gives up electrons which pass through the external circuit and reduce the molten S₈ to polysulfide ions Sₙ²⁻ (p. 681). The open circuit voltage is 2.08 V at 350°C. Since sulfur is an insulator the outer compartment is packed with porous carbon to provide efficient electrical conduction: the electrode volume is partially filled with sulfur when fully charged and is completely filled with sodium sulfide when fully discharged. To recharge, the polarity of the electrodes is changed and the passage of current forces the Na⁺ ions back into the central compartment where they are discharged as Na atoms.

Typical dimensions for the β-alumina electrolyte tube are 380 mm long, with an outer diameter of 28 mm, and a wall thickness of 1.5 mm. A typical battery for automotive power might contain 980 of such cells (20 modules each of 49 cells) and have an open-circuit voltage of 100 V. Capacity exceeds 50 kWh. The cells operate at an optimum temperature of 300–350°C (to ensure that the sodium polysulfides remain molten and that the β-alumina solid electrolyte has an adequate Na⁺ ion conductivity). This means that the cells must be thermally insulated to reduce wasteful loss of heat and to maintain the electrodes molten even when not in operation. Such a system is about one-fifth of the weight of an equivalent lead-acid traction battery and has a similar life (~1000 cycles).

Thiosulfate:

\[ 2\text{Na}_2\text{S} + \text{O}_2 + \text{H}_2\text{O} \rightarrow \text{Na}_2\text{S}_2\text{O}_3 + 2\text{NaOH} \]

World production of Na₂S exceeds 150 000 tonnes pa and that of NaHS approaches 100 000 tpa. Barium sulfide (from BaSO₄ + C) is the largest volume Ba compound manufactured but little of it is sold; almost all commercial Ba compounds are made by first making BaS and then converting it to the required compound.

Metal sulfides vary enormously in their solubility in water. As expected, the (predominantly ionic) alkali metal sulfides and alkaline earth metal sulfides are quite soluble though there is appreciable hydrolysis which results in strongly alkaline solutions (M₂S + H₂O → MSH + MOH). Accordingly, solubilities depend sensitively not only on temperature but also on pH and partial pressure of H₂S. Thus, by varying the acidity, As can be separated from Pb, Pb from Zn, Zn from Ni, and Mn from Mg. In pure water the solubility of Na₂S is said to be 18.06 g per 100 g H₂O and for Ba₂S it is 7.28 g. In the case of some less-basic elements (e.g. Al₂S₃, Cr₂S₃) hydrolysis is complete and action of H₂S on solutions of the metal cation results in the precipitation of the hydroxide; likewise these sulfides (and SiS₂, etc.) react rapidly with water with evolution of H₂S.
Sulfides of the metallic elements

By contrast with the water-soluble sulfides of Groups 1 and 2, the corresponding heavy metal sulfides of Groups 11 and 12 are amongst the least-soluble compounds known. Literature values are often wildly discordant, and care should be taken in interpreting the data. Thus, for black HgS the most acceptable value of the solubility product \([\text{Hg}^{2+}][\text{S}^{2-}]\) is \(10^{-51.8}\) mol² l⁻², i.e.

\[
\text{HgS(s)} \rightleftharpoons \text{Hg}^{2+}(aq) + \text{S}^{2-}(aq); \ pK = 51.8 \pm 0.5
\]

However, this should not be taken to imply a concentration of only \(10^{-51.8}\) mol l⁻¹ for mercury in solution (i.e. less than \(10^{-2}\) of 1 atom of Hg per litre!) since complex formation can simultaneously occur to give species such as \([\text{Hg}(\text{SH})_2]^{-}\) in weakly acid solutions and \([\text{HgS}_2]^{2-}\) in alkaline solutions:

\[
\text{HgS(s)} + \text{H}_2\text{S(1 atm)} \rightleftharpoons [\text{Hg}(\text{SH})_2](aq); \ pK = 6.2
\]

\[
\text{HgS(s)} + \text{S}^{2-}(aq) \rightleftharpoons [\text{HgS}_2]^{2-}(aq); \ pK = 1.5
\]

Hydrolysis also sometimes obtrudes.

Structural chemistry of metal sulfides

The predominantly ionic alkali metal sulfides \(\text{M}_2\text{S}\) (Li, Na, K, Rb, Cs) adopt the antifluorite structure (p. 118) in which each S atom is surrounded by a cube of 8 M and each M by a tetrahedron of S. The alkaline earth sulfides \(\text{MS}\) (Mg, Ca, Sr, Ba) adopt the NaCl-type 6:6 structure (p. 242) as do many other monosulfides of rather less basic metals (\(M = \text{Pb}, \text{Mn}, \text{La}, \text{Ce}, \text{Pr}, \text{Nd}, \text{Sm}, \text{Eu}, \text{ Tb}, \text{Ho}, \text{Th}, \text{U}, \text{Pu}\)). However, many metals in the later transition element groups show substantial trends to increasing covalency leading either to lower coordination numbers or to layer-lattice structures.\(^{101}\) Thus \(\text{MS}\) (Be, Zn, Cd, Hg) adopt the 4:4 zinc blende structure (p. 1210) and \(\text{ZnS, CdS and MnS}\) also crystallize in the 4:4 wurtzite modification (p. 1210). In both of these structures both M and S are tetrahedrally coordinated, whereas \(\text{PtS}\), which also has 4:4 coordination, features a square-planar array of 4 S atoms about each Pt, thus emphasizing its covalent rather than ionic bonding. Group 13 sulfides \(\text{M}_2\text{S}_3\) (p. 252) have defect \(\text{ZnS}\) structures with various patterns of vacant lattice sites.

The final major structure type found amongst monosulfides is the NiAs (nickel arsenide) structure (Fig. 15.18a). Each S atom is surrounded by a trigonal prism of 6 M atoms whilst each M has eightfold coordination, being surrounded octahedrally by \(6\) S atoms and by \(2\) additional M atoms which are coplanar with \(4\) of the S atoms. A significant feature of the structure is the close approach of the M atoms in chains along the (vertical) c-axis (e.g. 260 pm in \(\text{FeS}\)) and the structure can be regarded as transitional between the 6:6 \(\text{NaCl}\) structure and the more highly coordinated structures typical of metals. The NiAs structure is adopted by most first row transition-metal monosulfides \(\text{MS}\) (\(M = \text{Ti}, \text{V}, \text{Cr}, \text{Fe}, \text{Co}, \text{Ni}\)) as well as by many selenides and tellurides of these elements.

The NiAs structure is closely related to the hexagonal layer-lattice \(\text{CdI}_2\) structure shown in Fig. 15.18b, this stoichiometry being achieved simply by leaving alternate M layers of the NiAs structure vacant. Disulfides \(\text{MS}_2\) adopting this structure include those of \(\text{Ti}, \text{Zr}, \text{Hf}, \text{Ta}, \text{Pt}\) and \(\text{Sn}\); conversely, \(\text{Ti}_2\text{S}\) has the anti-\(\text{CdI}_2\) structure. Progressive partial filling of the alternate metal layers leads to phases of intermediate composition as exemplified by the Cr/S system (Table 15.10). For some elements these intermediate phases have quite extensive ranges of composition, the limits depending on the temperature of the system. For example, at \(1000\text{°C}\) there is a succession of non-stoichiometric titanium sulfides \(\text{TiS}_{0.97-1.06}, \text{TiS}_{1.204-1.333}, \text{TiS}_{1.377-1.594}, \text{TiS}_{1.810-1.919}\).\(^{101}\) Many diselenides and ditellurides also adopt the \(\text{CdI}_2\) structure and in some there is an almost continuous nonstoichiometric variation in composition, e.g. \(\text{CoTe} \longrightarrow \text{CoTe}_2\). A related 6:3 layer structure is the \(\text{CdCl}_2\)-type adopted by \(\text{TaS}_2\), and the layer structures of \(\text{MoS}_2\) and \(\text{WS}_2\) are mentioned on p. 1018.

Figure 15.18 Comparison of the nickel arsenide structure (a) adopted by many monosulfides MS with the cadmium iodide structure (b) adopted by some disulfides MS₂. The structures are related simply by removing alternate layers of M from MS to give MS₂.

\(^{(a)}\)Refers to the vacancies in the alternate metal layers.
\(^{(b)}\)CrS has a unique monoclinic structure intermediate between NiAs and PtS types.

Finally, many disulfides have a quite different structure motif, being composed of infinite three-dimensional networks of M and discrete S₂ units. The predominate structural types are pyrites, FeS₂ (also for M = Mn, Co, Ni, Ru, Os), and marcasite (known only for FeS₂ among the disulfides). Pyrites can be described as a distorted NaCl-type structure in which the rod-shaped S₂ units (S–S 217 pm) are centred on the Cl positions but are oriented so that they are inclined away from the cubic axes. The marcasite structure is a variant of the rutile structure (TiO₂, p. 961) in which the columns of edge-shared octahedra are rotated to give close approaches between pairs of S atoms in adjacent columns (S–S 221 pm).

Many metal sulfides have important physical properties.\(^{(98,102)}\) They range from insulators, through semiconductors to metallic conductors of electricity, and some are even superconductors.

\(^{(98,102)}\)F. Hulliger, Struct. Bonding (Berlin) 4, 83–229 (1968). A comprehensive review with 532 references, 65 structural diagrams, and a 34-page appendix tabulating the known phases and their physical properties.
e.g. NbS₂ (<6.2 K), TaS₂ (<2.1 K), Rh₁₇S₁₅ (<5.8 K), CuS (<1.62 K) and CuS₂ (<1.56 K). Likewise they can be diamagnetic, paramagnetic, temperature-independent paramagnetic, ferromagnetic, antiferromagnetic or ferrimagnetic.

The structures of more complex ternary metal sulfides such as BaZrS₃ (perovskite-type, p. 963), ZnAl₂S₄ (spinel type, p. 247), and NaCrS₂ (NaCl superstructure) introduce no new principles. Likewise, thiosalts, which may feature finite anions (e.g. Tl₁₃[VS₄]₁₄), vertex-shared chains (e.g. Ba₂MnS₃), edge-shared chains (e.g. KFeS₂), double chains (e.g. Ba₂ZnS₃), double layers (e.g. KCu₄S₃) or three-dimensional frameworks (e.g. NH₄Cu₇S₄). Finite clusters also abound.

Anionic polysulfides

The pyrites and marcasite structures can be thought of as containing S₂⁻⁻ units though the variability of the interatomic distance and other properties suggest substantial deviation from a purely ionic description. Numerous higher polysulfides Sₙ⁻⁻ have been characterized, particularly for the more electropositive elements Na, K, Ba, etc. They are yellow at room temperature, turn dark red on being heated, and may be thought of as salts of the polysulfanes (p. 683). Typical examples are M₂Sₙ (n = 2–5 for Na, 2–6 for K, 6 for Cs), BaS₂, BaS₃, BaS₄, etc. The polysulfides, unlike the monosulfides, are low melting solids: published values for mps vary somewhat but representative values (°C) are:

\[
\begin{align*}
\text{Na₂S} & : 180° \\
\text{Na₂S₂} & : 484° \\
\text{Na₂S₃} & : 294° \\
\text{Na₂S₄} & : 255° \\
\text{K₂S₃} & : 292° \\
\text{K₂S₄} & : ~145° \\
\text{K₂S₅} & : 211° \\
\text{K₂S₆} & : 196° \\
\text{BaS₃} & : 554°
\end{align*}
\]

Structures are in Fig. 15.19. The S₃⁻⁻ ion is bent (Cᵥ) and is isoelectronic with SC₁₂ (p. 689). The S₄⁻⁻ ion has twofold symmetry, essentially tetrahedral bond angles, and a dihedral angle of 97.8° (see p. 654). The S₅⁻⁻ ion also has approximately twofold symmetry (about the central S atom); it is a contorted but unbranched chain with bond angles close to tetrahedral and a small but significant difference between the terminal and internal S–S distances. The S₆⁻⁻ ion has alternating S–S distances, and bond angles in the range 106.4–110.0° (mean 108.8°). Several of the references in Fig. 15.19 give preparative details: these can involve direct reaction of

---

stoichiometric amounts of the elements in sealed tubes or reaction of MSH with S in ethanol. \(^{(110)}\)

It is interesting that, despite the unequivocal presence of the \(S_3^{2-}\) ion in \(K_2S_3\), \(BaS_3\), etc., a Raman spectroscopic study of molten "Na_2S_3" showed that the ion had disproportionated into \(S_2^{2-}\) and \(S_4^{2-}\). \(^{(111)}\)

**15.2.2 Hydrides of sulfur (sulfanes)**

Hydrogen sulfide is the only thermodynamically stable sulfane; it occurs widely in nature as a result of volcanic or bacterial action and is, indeed, a prime source of elemental S (p. 647). It has been known since earliest times and its classical chemistry has been extensively studied since the seventeenth century. \(^{(112)}\) \(H_2S\) is a foul smelling, very poisonous gas familiar to all students of chemistry. Its smell is noticeable at 0.02 ppm but the gas tends to anaesthetize the olfactory senses and the intensity of the smell is therefore a dangerously unreliable guide to its concentration. \(H_2S\) causes irritation at 5 ppm, headaches and nausea at 10 ppm and immediate paralysis and death at 100 ppm; it is therefore as toxic and as dangerous as HCN.

\(H_2S\) is readily prepared in the laboratory by treating FeS with dilute HCl in a Kipp apparatus. Purfer samples can be made by hydrolysing CaS, BaS or Al_2S_3, and the purest gas is prepared by direct reaction of the elements at 600°C.

Some physical properties are in Table 15.11: \(^{(113)}\) comparison with the properties of water (p. 623) shows the absence of any appreciable H bonding in \(H_2S\). \(^{(114)}\) Comparisons with \(H_2Se\), \(H_2Te\) and \(H_2Po\) are on p. 767.

\(H_2S\) is readily soluble in both acidic and alkaline aqueous solutions. Pure water dissolves 4.65 volumes of the gas at 0°C and 2.61 volumes at 20°C; in other units a saturated solution is 0.1 M at atmospheric pressure and 25°C, i.e.

\[
H_2S(g) \rightleftharpoons H_2S(aq); \quad K = 0.1023 \text{ mol l}^{-1} \text{ atm}^{-1};
\]

\[
pK = 0.99
\]

In aqueous solution \(H_2S\) is a weak acid (p. 49). At 20°C: \(^{(115)}\)

\[
H_2S(aq) \rightleftharpoons H^+(aq) + SH^-(aq);
\]

\[
pK_{a_1} = 6.88 \pm 0.02
\]

\[
SH^-(aq) \rightleftharpoons H^+(aq) + S^{2-}(aq);
\]

\[
pK_{a_2} = 14.15 \pm 0.05
\]

The chemistry of such solutions has been alluded to on p. 678. At low temperatures a hydrate \(H_2S.5\frac{1}{2}H_2O\) crystallizes. In acid solution \(H_2S\) is also a mild reducing agent; e.g. even on standing in air solutions slowly precipitate sulfur. The gas burns with a bluish flame in air to give \(H_2O\) and \(SO_2\) (or \(H_2O\) and S if the air supply is restricted). For adducts, see p. 673.

In very strongly acidic nonaqueous solutions (such as HF/SbF_5) \(H_2S\) acts as a base (proton acceptor) and the white crystalline

---

solid \([\text{SH}_3]^+\text{[SbF}_6]^-\) has been isolated from such solutions.\(^{(116)}\) The compound, which is the first known example of a stable salt of \(\text{SH}_3^+\), can be stored at room temperature in Teflon or Kel-F containers but attacks quartz. Vibrational spectroscopy confirms the pyramidal \(C_{3v}\) structure expected for a species isoelectronic with \(\text{PH}_3\) (p. 492). In the presence of an excess of \(\text{H}_2\text{S}\) at \(-80^\circ\text{C}\), the trimercaptosulfonium salts \([\text{S(SH)}_3]^+\text{AsF}_6^-\) and \([\text{S(SH)}_3]^+\text{SbCl}_6^-\) can be prepared;\(^{(117)}\) the cation is isoelectronic with \(\text{P(PH}_2)_3\) (p. 495) and is expected to have \(C_{3v}\) symmetry.

Polysulfanes, \(\text{H}_2\text{S}_n\), with \(n = 2\)–\(8\) have been prepared and isolated pure, and many higher homologues have been obtained as mixtures with variable \(n\). Our modern knowledge of these numerous compounds stems mainly from the elegant work of F. Fehér and his group in the 1950s. All polysulfanes have unbranched chains of \(n\) sulfur atoms thus reflecting the well-established propensity of this element towards catenation (p. 652). The polysulfanes are reactive liquids whose density \(d\), viscosity \(\eta\), and bp increase with increasing chain length. \(\text{H}_2\text{S}_2\), the analogue of \(\text{H}_2\text{O}_2\), is colourless but the others are yellow, the colour deepening with increasing chain length.

The polysulfanes were at one time made by fusing crude \(\text{Na}_2\text{S}_9\text{H}_2\text{O}\) with various amounts of sulfur and pouring the resulting polysulfide solution into an excess of dilute hydrochloric acid at \(-10^\circ\text{C}\). The resulting crude yellow oil is a mixture mainly of \(\text{H}_2\text{S}_n\) (\(n = 4\)–\(7\)). Polysulfanes can now also be readily prepared by a variety of other reactions, e.g.:

\[
\begin{align*}
\text{Na}_2\text{S}_n(\text{aq}) + 2\text{HCl(aq)} & \rightarrow 2\text{NaCl(aq)} \\
& + \text{H}_2\text{S}_n \ (n = 4\text{–}6) \\
\text{S}_n\text{Cl}_2(\text{l}) + 2\text{H}_2\text{S(1)} & \rightarrow 2\text{HCl(g)} + \text{H}_2\text{S}_n+2(\text{l}) \\
\text{S}_n\text{Cl}_2(\text{l}) + 2\text{H}_2\text{S}_m(\text{l}) & \rightarrow 2\text{HCl(g)} \\
& + \text{H}_2\text{S}_n+2m(\text{H}_2\text{S}_6\text{–H}_2\text{S}_{18})
\end{align*}
\]

Purification is by low-pressure distillation. Some physical properties are in Table 15.12. Polysulfanes are readily oxidized and all are thermodynamically unstable with respect to disproportionation:

\[
\text{H}_2\text{S}_n(\text{l}) \rightarrow \text{H}_2\text{S}(\text{g}) + \frac{n-1}{8}\text{S}_8(\text{s})
\]

This disproportionation is catalysed by alkali, and even traces dissolved from the surface of glass containers is sufficient to effect deposition of sulfur. They are also degraded by sulfite and by cyanide ions:

\[
\text{H}_2\text{S}_n + (n-1)\text{SO}_3^{2-} \rightarrow \text{H}_2\text{S} + (n-1)\text{S}_2\text{O}_3^{2-}
\]

\[
\text{H}_2\text{S}_n + (n-1)\text{CN}^- \rightarrow \text{H}_2\text{S} + (n-1)\text{SCN}^{-}
\]

The former reaction, in particular, affords a convenient means of quantitative analysis by determination of the \(\text{H}_2\text{S}\) (precipitated as \(\text{CdS}\)) and iodometric determination of the thiosulfate produced.

\section*{15.2.3 Halides of sulfur}

\textbf{Sulfur fluorides}

The seven known sulfur fluorides are quite different from the other halides of sulfur in their stability, reactivity and to some extent even in their stoichiometries; it is therefore convenient to

consider them separately. Moreover, they have proved a rich field for both structural and theoretical studies since they form an unusually extensive and graded series of covalent molecular compounds in which S has the oxidation states 1, 2, 3, 4, 5 and 6, and in which it also exhibits all coordination numbers from 1 to 6 (if SF$_5^-$ is also included). The compounds feature a rare example of structural isomerism amongst simple molecular inorganic compounds (FSSF and SSF$_2$) and also a monomer–dimer pair (SF$_2$ and F$_3$SSF). The structures and physical properties will be described first, before discussing the preparative routes and chemical reactions.

**Structures and physical properties.** The molecular structure, point group symmetries, and dimensions of the sulfur fluorides are summarized in Fig. 15.20(119) S$_2$F$_2$ resembles H$_2$O$_2$, H$_2$S$_2$, O$_2$F$_2$ and S$_2$X$_2$, and detailed comparisons of bond distances, bond angles and dihedral angles are instructive. The isomer SSF$_2$ (thionyl fluoride) features 3-coordinate S$^{IV}$ and 1-coordinate S$^{II}$ and it is notable that the formally double-bonded S–S distance is very close to that in the singly bonded isomer. The fugitive species SF$_2$ has the expected bent configuration in the gas phase but is unique in readily undergoing dimerization by insertion of a second SF$_2$ into an S–F bond. The structure of the resulting molecule F$_3$SSF is, in a sense, intermediate between those of S$_2$F$_2$ and SF$_4$, being based on a trigonal bipyramid with the equatorial F atom replaced by an SF$_2$ group. The fact that the $^{19}$F nmr spectrum at $-100^\circ$ shows four distinct F resonances indicates that the 2 axial F atoms are non-equivalent, implying restricted rotation about the S–S bond.

The structure of SF$_4$ is particularly significant. It is based on a trigonal bipyramid with one equatorial position occupied by the lone-pair; this distorts the structure by reducing the equatorial F–S–F bond angle bond angle from 120° to 101.6° and by repelling the axial F$_{ax}$ atoms towards F$_{eq}$. There is also a significant difference between the (long) S–F$_{ax}$ and (short) S–F$_{eq}$ distances. Again, the low-temperature $^{19}$F nmr spectrum is precisely diagnostic of the C$_{2v}$ structure, since the observed doublet of 1:2:1 triplets is consistent only with the two sets of 2 equivalent F atoms in this point group symmetry.

(¹⁹F, like ¹H, has nuclear spin ½). Thus, an axial lone-pair (C₃ᵥ) would lead to a doublet and a quartet of integrated relative intensity 3:1, whereas all other conceivable symmetries (Tₖ, C₄ᵥ, D₄h, D₂d, D₂h) would give a sharp singlet from the 4 equivalent F atoms. Above −98°C the 30 MHz ¹⁹F nmr spectrum of SF₄ gradually broadens and it coalesces at −47°C into a single broad resonance which gradually sharpens again to a narrow singlet at higher temperatures; this is due to molecular fluxionality which permits intramolecular interchange of the axial and equatorial F atoms.

The structure of SF₄ can be rationalized on most of the simple bonding theories; the environment of S has 10 valency electrons and this leads to the observed structure in both valence-bond and electron-pair repulsion models. However, the rather high energy of the 3d orbitals on S make their full participation in bonding via sp³d² unlikely and, indeed, calculations show that there may be as little as 12% d-orbital participation rather than the 50% implied by the scheme sp₃pₓ + p₂d₂. Thus charge-transfer configurations or bonding via sp₃pₓ + p₂ seem to be better descriptions, the p₂ orbital on S being involved in a 3-centre 4-electron bond with the 2 axial F atoms (cf. XeF₂, p. 897).

The regular octahedral structure of SF₆ and the related structure of S₂F₁₀ (Fig. 15.20) call for little comment except to note the staggered (D₄d) arrangement of the two sets of F eq in S₂F₁₀ and the unusually long S–S distance, both features presumably reflecting interatomic repulsion between the F atoms. SF₆ is also of interest in establishing conclusively that S can be hexavalent. Its great stability (see below) contrasts with the non-existence of SH₄ and SH₆ despite the general similarity in S–F and S–H bond strengths; its existence probably reflects (a) the high electronegativity of F (p. 26), which facilitates the formation of either polar or 3-centre 4-electron bonds as discussed above for SF₄, and (b) the lower bond energy of F₂ compared to H₂, which for SH₄ and SH₆ favours dissociation into H₂S + nH₂.(¹²²) For descriptions of the bonding which involve the use of 3d orbitals on sulfur, a net positive charge on the central atom would contract the d orbitals thereby making them energetically and spatially more favourable for overlap with the fluorine orbitals.

Some physical properties of the more stable sulfur fluorides are in Table 15.13. All are colourless gases or volatile liquids at room temperature. SF₆ sublimes at −63.8°C (1 atm) and can only be melted under pressure (−50.8°C). It is notable both for its extreme thermal and chemical stability (see below), and also for having a higher gas density than any other substance that boils below room temperature (5.107 times as dense as air).

**Synthesis and chemical reactions.** Disulfur difluoride, S₂F₂, can be prepared by the mild fluorination of sulfur with AgF in a rigorously dried apparatus at 125°C. It is best handled in the gas phase at low pressures and readily isomerizes to thiothionylfluoride,SSF₂, in the presence of alkali metal fluorides. SSF₂ can be made either by isomerizing S₂F₂ or directly by the fluorination of S₂Cl₂ using KF in SO₂:

\[
2\text{KSO}_2\text{F} + \text{S}_2\text{Cl}_2 \rightarrow \text{SSF}_2 + 2\text{KCl} + 2\text{SO}_2
\]

---

Figure 15.21 Comparison of the structures of three species in which S has 12 valence electrons: (a) the SF$_5^-$ ion in RbSF$_5$, as deduced from X-ray analysis,\textsuperscript{122} (b) OSF$_4$ as deduced from gas-phase electron diffraction\textsuperscript{124} (note the wider angle F$_{eq}$S$_{eq}$ when compared with SF$_4$ (Fig. 15.20) and the shorter distance S–F$_{ax}$, the angle F$_{ax}$S$_{ax}$ is 164.6°), and (c) H$_2$CSF$_4$ (X-ray crystal structure at $-160^\circ$).\textsuperscript{125} The angle F$_{eq}$S$_{eq}$ is significantly smaller than in SF$_4$ as is the angle F$_{ax}$S$_{ax}$ (170.4°); the methylene group is coplanar with the axial SF$_2$ group as expected for p$_z$–d$_z$ C=S overlap and, unlike SF$_4$, the molecule is non-fluxional.

Sulfur tetrafluoride, SF$_4$, though extremely reactive (and valuable) as a selective fluorinating agent, is much more stable than the lower fluorides. It is formed, together with SF$_6$, when a cooled film of sulfur is reacted with F$_2$, but is best prepared by fluorinating SCl$_2$ with NaF in warm acetonitrile solution:

$$3\text{SCl}_2 + 4\text{NaF} \xrightarrow{\text{MeCN}} \text{S}_2\text{Cl}_2 + \text{SF}_4 + 4\text{NaCl}$$

SF$_4$ is unusual in apparently acting both as an electron-pair acceptor and an electron-pair donor (amphoteric Lewis acid-base). Thus pyridine forms a stable 1:1 adduct C$_5$H$_5$NSF$_4$ which presumably has a pseudoctahedral (square-pyramidal) geometry. Likewise CsF (at $125^\circ$) and Me$_4$NF (at $-20^\circ$) form CsSF$_5$ and [NMe$_4]^+\text{[SF}_5^-]_2$ (Fig. 15.21a). By contrast, SF$_4$ behaves as a donor to form 1:1 adducts with many Lewis acids; the stability decreases in the sequence SbF$_5$ > AsF$_5$ > IrF$_5$ > BF$_3$ > PF$_3$ > AsF$_3$. In view of the discussion on

SSF$_2$ can be heated to $250^\circ$ but is, in fact, thermodynamically unstable with respect to disproportionation, being immediately transformed to SF$_4$ in the presence of acid catalysts such as BF$_3$ or HF:

$$2\text{SSF}_2 \rightarrow \frac{3}{4}\text{S}_8 + \text{SF}_4$$

Both S$_2$F$_2$ and SSF$_2$ are rapidly hydrolysed by pure water to give S$_8$, HF and a mixture of polythionic acids H$_2$S$_n$O$_6$ ($n$ 4–6), e.g.:

$$5\text{S}_2\text{F}_2 + 6\text{H}_2\text{O} \rightarrow \frac{3}{4}\text{S}_8 + 10\text{HF} + \text{H}_2\text{S}_4\text{O}_6$$

Alkaline hydrolysis yields predominantly thiosulfate. SSF$_2$ burns with a pale-blue flame when ignited, to yield SO$_2$, SOF$_2$ and SO$_2$F$_2$.

Sulfur difluoride, SF$_2$, is a surprisingly fugitive species in view of its stoichiometric similarity to the stable compounds H$_2$S and SCl$_2$ (p. 689). It is best made by fluorinating gaseous SCl$_2$ with activated KF (from KSO$_2$F) or with HgF$_2$ at $150^\circ$, followed by a tedious fractionation from the other sulfur fluorides (FSSF, SSF$_2$ and SF$_4$) which form the predominant products. The chlorofluorides CISSF and CISSF$_3$ are also formed. The compound can only be handled as a dilute gas under rigorously anhydrous conditions or at very low temperatures in a matrix of solid argon, and it rapidly dimerizes to give F$_3$SSF.

Sulfur tetrafluoride, SF$_4$, though extremely reactive (and valuable) as a selective fluorinating agent, is much more stable than the lower fluorides. It is formed, together with SF$_6$, when a cooled film of sulfur is reacted with F$_2$, but is best prepared by fluorinating SCl$_2$ with NaF in warm acetonitrile solution:

$$3\text{SCl}_2 + 4\text{NaF} \xrightarrow{\text{MeCN}} \text{S}_2\text{Cl}_2 + \text{SF}_4 + 4\text{NaCl}$$

SF$_4$ is unusual in apparently acting both as an electron-pair acceptor and an electron-pair donor (amphoteric Lewis acid-base). Thus pyridine forms a stable 1:1 adduct C$_5$H$_5$NSF$_4$ which presumably has a pseudoctahedral (square-pyramidal) geometry. Likewise CsF (at $125^\circ$) and Me$_4$NF (at $-20^\circ$) form CsSF$_5$ and [NMe$_4]^+\text{[SF}_5^-]_2$ (Fig. 15.21a). By contrast, SF$_4$ behaves as a donor to form 1:1 adducts with many Lewis acids; the stability decreases in the sequence SbF$_5$ > AsF$_5$ > IrF$_5$ > BF$_3$ > PF$_3$ > AsF$_3$. In view of the discussion on

\textsuperscript{125} H. \textsc{Bock}, J. E. \textsc{Boggs}, G. \textsc{Kleemann}, D. \textsc{Lentz}, H. \textsc{Oberhammer}, E. M. \textsc{Peters}, K. \textsc{Seppelt}, A. \textsc{Simon} and B. \textsc{Solouki}, \textit{Angew. Chem. Int. Edn. Engl.} \textbf{18}, 944–5 (1979).
it seems likely that SF₄ is acting here not as an S lone-pair donor but as a fluoride ion lone-pair donor and there is, indeed, infrared evidence to suggest that SF₄BF₃ is predominantly [SF₃⁺][BF₄⁻].

SF₄ rapidly decomposes in the presence of moisture, being instantly hydrolysed to HF and SO₂. Despite this it has been increasingly used as a powerful and highly selective fluorinating agent for both inorganic and organic compounds. In particular it is useful for converting ketonic and aldehyde >C=O groups to >CF₂, and carboxylic acid groups −COOH to −CF₃. Similarly, ≡P=O groups are smoothly converted to ≡PF₂, and >P(O)OH groups to >PF₃. It also undergoes numerous oxidative addition reactions to give derivatives of S⁺⁺. The simplest of these are direct oxidation of SF₄ with F₂ or CIF (at 380°) to give SF₆ and SCIF₅ respectively. Analogous reactions with N₂F₄(hv) and F₅SOOF₅ yield SF₅NF₂ and cis-SF₄(OSF₅)₂ respectively; likewise F₅SOF (p. 688) yields F₅SOSF₅. Direct oxidation of SF₄ with O₂, however, proceeds only slowly unless catalysed by NO₂: the product is OSF₄, which has a trigonal bipyramidal structure like SF₄ itself, but with the equatorial lone-pair replaced by the oxygen atom (Fig. 15.21b). A similar structure is adopted by the more recently prepared methylene compound H₂C=SF₄ (Fig. 15.21c);(125) this is made by treating SF₅–CH₂Br with LiBu° at −110° and is more stable than the isoelectronic P or S ylides or metal carbene complexes, being stable in the gas phase up to 650° at low pressures.

Some other reactions of SF₄ are:

\[ \text{Cl}_2 + \text{CsF} + \text{SF}_4 \xrightarrow{110°} \text{SCIF}_5 + \text{CsCl} \]

\[ \text{I}_2\text{O}_5 + 5\text{SF}_4 \xrightarrow{} 2\text{IF}_5 + 5\text{OSF}_2 \]

\[ 4\text{BCl}_3 + 3\text{SF}_4 \xrightarrow{} 4\text{BF}_3 + 3\text{SCl}_2 + 3\text{Cl}_2 \]

\[ \text{RCN} + \text{SF}_4 \xrightarrow{} \text{RCF}_2\text{N}=\text{SF}_2 \]

\[ \text{NaOCN} + \text{SF}_4 \xrightarrow{} \text{CF}_3\text{N}=\text{SF}_2 + \cdots \]

\[ \text{CF}_3\text{CF}=\text{CF}_2 + \text{SF}_4 \xrightarrow{\text{CsF/150°}} (\text{CF}_3)_2\text{CFSF}_3 \]

\[ \text{(bp ~ 46°)} \]

Disulfur decafluoride, S₂F₁₀, is obtained as a byproduct of the direct fluorination of sulfur to SF₆ but is somewhat tedious to separate and is more conveniently made by the photolytic reduction of SCIF₅ (prepared as above):

\[ 2\text{SCIF}_5 + \text{H}_2 \xrightarrow{hv} \text{S}_2\text{F}_10 + 2\text{HCl} \]

It is intermediate in reactivity between SF₄ and the very inert SF₆. Unlike SF₄ it is not hydrolysed by water or even by dilute acids or alkalis and, unlike SF₆, it is extremely toxic. It disproportionates readily at 150° probably by a free radical mechanism involving SF₅⁺ (note the long, weak S=S bond; Fig. 15.20):

\[ \text{S}_2\text{F}_10 \xrightarrow{150°} \text{SF}_4 + \text{SF}_6 \]

Similarly it reacts readily with Cl₂ and Br₂ to give SCIF₅ and SBrF₅. It oxidizes KI (and I₃⁻) in acetone solution to give iodine (note SF₄ converts acetone to Me₂CF₂). S₂F₁₀ reacts with SO₂ to give F₅SSOF₅ and with NH₃ to give N≡SF₃.

Sulfur hexafluoride is unique in its stability and chemical inertness: it is a colourless, odourless, tasteless, unreactive, non-flammable, non-toxic, insoluble gas prepared by burning sulfur in an atmosphere of fluorine. Because of its extraordinary stability and excellent dielectric properties it is extensively used as an insulating gas for high-voltage generators and switch gear: at a pressure of 2–3 bars it withstands 1.0–1.4 MV across electrodes 50 mm apart without breakdown, and at 10 bars it is used for high-power underground electrical transmission systems at 400 V and above. However, there is now some environmental concern at its use as an electrical transformer fluid and as an inert blanketing gas in magnesium metal casting, since even minute amounts may contribute to an atmospheric greenhouse effect (it is 6800 times as potent as CO₂).

SF₆ can be heated to 500° without decomposition, and is unattacked by most metals, P, As, etc., even when heated. It is also unreactive towards
high-pressure steam presumably as a result of kinetic factors since the gas-phase reaction $\text{SF}_6 + 3\text{H}_2\text{O} \rightarrow \text{SO}_3 + 6\text{HF}$ should release some 460 kJ mol$^{-1}$ ($\Delta G^\circ \sim 200$ kJ mol$^{-1}$). By contrast, reaction with $\text{H}_2\text{S}$ yields sulfur and HF. Hot HCl and molten KOH at 500° are without effect. Boiling Na attacks $\text{SF}_6$ to yield $\text{Na}_2\text{S}$ and NaF; indeed, this reaction can be induced to go rapidly even at room temperature or below in the presence of biphenyl dissolved in glyme (1,2-dimethoxyethane). It is also reduced by Na/liq NH$_3$ and, more slowly, by LiAlH$_4$/Et$_2$O. Al$_2$Cl$_6$ at 200° yields AlF$_3$, Cl$_2$, and sulfur chlorides. Recent experiments$^{(126)}$ indicate that $\text{SF}_6$ becomes much more reactive at higher temperatures and pressures; for example PF$_3$ is quantitatively oxidized to PF$_5$ at 500° and 300 bars, and to a mixture of PF$_5$ and SPF$_3$ at ~380° and 1800–3600 bars.

Derivatives of $\text{SF}_6$ are rather more reactive: $\text{S}_2\text{F}_{10}$ and SCIF$_5$ have already been mentioned. Further synthetically useful reactions of this latter compound are:

$$
\text{RC} \equiv \text{N} \xrightarrow{hv} \text{RC}=\text{N}=\text{NSF}_5
$$

$$
\text{HC} \equiv \text{CH} \xrightarrow{} \text{HCC}=\text{CH}=\text{NSF}_5
$$

$$
\text{RCH}=\text{CH}_2 \xrightarrow{} \text{RCHC}=\text{H}=\text{CH}=\text{NSF}_5
$$

$$
\text{CH}_2=\text{C}=\text{O} \xrightarrow{\text{SCIF}_5} \text{SF}_3\text{CH}=\text{COCl} \xrightarrow{\text{H}_2\text{O}/\text{Ag}^+} \text{SF}_3\text{Me}
$$

$$
\text{SF}_3\text{CH}_2\text{CO}_2\text{Ag} \xrightarrow{\text{Br}_2/\text{CO}_2} \text{SF}_3\text{CH}_2\text{Br} \xrightarrow{\text{LiBu}^-/(-\text{LiF})} \text{SF}_4=\text{CH}_2
$$

$$
\text{SCIF}_5 + \text{O}_2 \xrightarrow{hv} \text{F}_3\text{SOSF}_5 + \text{F}_5\text{SOOSF}_5
$$

SCIF$_5$ is readily attacked by other nucleophiles, e.g. OH$^-$ but is inert to acids. SF$_5$OH and SF$_5$OOH are known.

The very reactive yellow SF$_5$OF, which is one of the few known hypofluorites, can be made by the catalytic reaction:

$$
\text{SOF}_2 + 2\text{F}_2 \xrightarrow{\text{CsF}/25^\circ} \text{SF}_3\text{OF}
$$

In the absence of CsF the product is SOF$_4$ (p. 687) and this can then be isomerized in the presence of CsF to give a second hypofluorite, SF$_3$OF. Derivatives of −SF$_5$ are usually reactive volatile liquids or gases, e.g.:

$^{(a)}$See ref. 127 for $F_5\text{SNCIF}$, $F_5\text{SNHF}$ and $F_5\text{S}=\text{NF}$, and ref. 128 for $F_5\text{SN}=\text{SCIF}$

Of these, ($F_5\text{SO}^-$)$_2$ is an amusing example of a compound accidentally prepared as a byproduct of $\text{SF}_6$ and $\text{S}_2\text{F}_{10}$ due to the fortuitous presence of traces of molecular oxygen in the gaseous fluorine used to fluorinate sulfur. A small amount of material boiling somewhat above $\text{S}_2\text{F}_{10}$ and having a molecular weight some 32 units higher was isolated. [How would you show that it was not $\text{S}_3\text{F}_{10}$, and that its structure was $F_5\text{SOOSF}_5$ rather than one of the 8 possible isomers of $F_5\text{O}(\text{OF})_2$ or $F_5\text{S}(\text{OF})=\text{OSFS}$?].$^{(129)}$

Numerous other highly reactive oxofluorosulfur compounds have been prepared but their chemistry, though sometimes hazardous because of a tendency to explosion, introduces no new principles. Some examples are:

- Thionyl fluorides: OSF$_2$, OSFCl, OSFBr, OSF(OM).
- Sulfuryl fluorides: $\text{O}_2\text{SF}_2$, $\text{F}_2\text{SO}_2\text{O}=\text{SO}_2\text{F}$, $\text{F}_2\text{SO}_2\text{O}=\text{SO}_2\text{O}=\text{SO}_2\text{F}$, $\text{F}_2\text{SO}_2\text{O}=\text{SO}_2\text{F}$, $\text{F}_2\text{SO}_2\text{O}=\text{SO}_5\text{F}_5$.

Other peroxo compounds: \( \text{SF}_2\text{OOC(O)F} \), \( \text{SF}_2\text{OSF}_2\text{OOSF}_3 \), \( \text{SF}_2\text{OSF}_4\text{OOSF}_3 \), \( \text{CF}_3\text{OSF}_4\text{OOSF}_3 \), \( \text{CF}_3\text{OSF}_4\text{OOSF}_4\text{OCF}_3 \), \( \text{HOSO}_2\text{OCOF}_3 \), \( \text{CF}_3\text{OSO}_2\text{OCF}_3 \).

Fluorosulfuric acid: \( \text{FSO}_2\text{(OH)} \), \( \text{FSO}_3^- \).

Of these the most extensively studied is fluorosulfuric acid, made by direct reaction of \( \text{SO}_3 \) and \( \text{HF} \). Its importance derives from its use as a solvent system and from the fact that its mixtures with \( \text{SbF}_5 \) and \( \text{SO}_3 \) are amongst the strongest known acids (superacids, p. 570). Anhydrous \( \text{HSO}_3\text{F} \) is a colourless, dense, mobile liquid which fumes ill moist air: \( \text{mp} -89.0^\circ \), \( \text{bp} 162.7^\circ \), \( d_{25} 1.726 \text{ g cm}^{-3} \), \( \kappa_{25} 1.085 \times 10^4 \text{ ohm}^{-1} \text{ cm}^{-1} \).

Attention should also be directed to the growing number of perfluorocarbon–sulfur species which feature single, double or even triple C–S bonds, e.g.:

Single: \( (\text{F}_2\text{S})_2\text{CF}_2 \), \( (\text{F}_2\text{S})\text{SCF}_2\text{SF}_2\text{CF}_2 \), \( [(\text{F}_2\text{S})\text{C}(\text{CF}_3)_2]^- \), \( [(\text{F}_2\text{S})_2\text{C}(\text{CF}_3)]^- \), \( [\text{F}_2\text{SCF}_2\text{S}(\text{F}_3\text{CF}_3)]^- \); see also footnote on p. 690;

Double: \( (\text{F}_2\text{S})(\text{F}_3\text{C})\text{C} = \text{SF}_2 \), \( (\text{F}_3\text{C})\text{C} = \text{SF}_2 \), \( (\text{F}_2\text{S})\text{C} = \text{SF}_3 \).

Triple: \( (\text{F}_2\text{S})(\text{F}_3\text{C})\text{C} = \text{SF}_3 \), \( (\text{F}_2\text{S})\text{C} = \text{SF}_3 \).

Also notable are sulfur cyanide fluorides such as \( \text{SF}_3\text{CN} \), \( \text{SF}_2\text{(CN)}_2 \), and \( \text{SF}_3\text{CN} \) and the sulfinyl cyanide fluoride \( \text{FS}(\text{O})\text{CN} \).

### Halides of sulfur

Sulfur is readily chlorinated by direct reaction with \( \text{Cl}_2 \) but the simplicity of the products obtained belies the complexity of the mechanisms involved. The reaction was first investigated by C. W. Scheele in 1774 and has been extensively studied since because of its economic importance (see below) and its intrinsic physicochemical interest. Direct chlorination of molten \( \text{S} \) followed by fractional distillation yields disulfur dichloride \( (\text{S}_2\text{Cl}_2) \) a toxic, golden-yellow liquid of revolting smell: \( \text{mp} -76^\circ \), \( \text{bp} 138^\circ \), \( d(20^\circ) 1.677 \text{ g cm}^{-3} \). The molecule has the expected \( \text{C}_2 \) structure (like \( \text{S}_2\text{F}_2 \), \( \text{H}_2\text{O}_2 \), etc.) with \( \text{S-S} 195 \text{ pm} \), \( \text{S-Cl} 206 \text{ pm}, \angle \text{Cl-S-S} 107.7^\circ \), and a dihedral angle of 85.2°. Further chlorination of \( \text{S}_2\text{Cl}_2 \), preferably in the presence of a trace of catalyst such as \( \text{FeCl}_3 \), yields the more-volatile, cherry-red liquid sulfur dichloride, \( \text{SCl}_2 \): \( \text{mp} -122^\circ \), \( \text{bp} 59^\circ \), \( d(20^\circ) 1.621 \text{ g cm}^{-3} \). \( \text{SCl}_2 \) resembles \( \text{S}_2\text{Cl}_2 \) in being foul-smelling and toxic, but is rather unstable when pure due to the decomposition equilibrium \( 2\text{SCl}_2 \rightleftharpoons \text{S}_2\text{Cl}_2 + \text{Cl}_2 \). However, it can be stabilized by the presence of as little as 0.01% \( \text{PCl}_5 \) and can be purified by distillation at atmospheric pressure in the presence of 0.1% \( \text{PCl}_5 \). The sulfur dichloride molecule is nonlinear (\( \text{C}_2\text{v} \)) as expected, with \( \text{S-Cl} 201 \text{ pm} \) and \( \angle \text{Cl-S-Cl} 103^\circ \).

\( \text{S}_2\text{Cl}_2 \) and \( \text{SCl}_2 \) both react readily with \( \text{H}_2\text{O} \) to give a variety of products such as...
H$_2$S, SO$_2$, H$_2$SO$_3$, H$_2$SO$_4$ and the polythionic acids H$_2$S$_x$O$_6$. Oxidation of SCl$_2$ yields thionyl chloride (OSCl$_2$) and sulfuryl chloride (O$_2$SCl$_2$) (see Section 15.2.4). Reaction with F$_2$ produces SF$_4$ and SF$_6$ (p. 686), whereas fluorination with NaF is accompanied by some disproportionation:

$$3\text{SCl}_2 + 4\text{NaF} \rightarrow \text{SF}_4 + 2\text{S}_2\text{Cl}_2 + 4\text{NaCl}$$

As indicated on p. 686, fluorination of S$_2$Cl$_2$ with KF/SO$_2$ occurs with concurrent isomerization to SSF$_2$. Both S$_2$Cl$_2$ and SCl$_2$ react with atomic N (p. 413) to give NSCI as the first step, and this can then react further with S$_2$Cl$_2$ to give the ionic heterocyclic compound S$_3$N$_2$Cl$^+$Cl$^-$ (p. 739). By contrast, reaction of S$_2$Cl$_2$ with NH$_4$Cl at 160$^\circ$C yields colourless crystals of S$_4$N$_4$ (p. 722). Treatment of S$_2$Cl$_2$ with Hg(SCN)$_2$ yields NCS$^-$ and S$_2$Cl$_2$ (p. 657). The compounds SCl$_2$ and S$_2$Cl$_2$ can be thought of as the first two members of an extended series of dichlorosulfanes S$_n$Cl$_2$. The lower electronegativity of Cl (compared with F) and the lower S-Cl bond energy (compared with S-F) enable the natural catenating propensity of S to have full reign and a series of dichlorosulfanes can be prepared in which S-S bonds in sulfur chains (and rings) can be broken and the resulting S$_n$- oligomers stabilized by the formation of chain-terminating S-Cl bonds. The first eight members with $n = 1 - 8$ have been isolated as pure compounds, and mixtures up to perhaps S$_{100}$Cl$_2$ are known.† Specific compounds have been made by F. Fehér's group using the polysulfanes as starting materials (p. 683):\(^{147}\)

$$\text{H}_2\text{S}_x + 2\text{S}_2\text{Cl}_2 \rightarrow 2\text{HCl} + \text{S}_4+n\text{Cl}_2$$

The dichlorosulfanes are yellow to orange-yellow viscous liquids with an irritating odour. They are thermally and hydrolytically unstable. S$_3$Cl$_2$ boils at 31$^\circ$C (10$^{-4}$ mmHg) and has a density of 1.744 g cm$^{-3}$ at 20$^\circ$C. Higher homologues have

\[^{\dagger}\] Several related series of compounds are also known in which Cl is replaced by a pseudohalogen such as CF$_3$ or C$_2$F$_5$, e.g. S$_n$(CF$_3$)$_2$ ($n = 1 - 4$), CF$_3$S$_n$C$_2$F$_5$ ($n = 2 - 4$), and S$_4$(C$_2$F$_5$)$_2$ ($n = 2 - 4$). These can be prepared by the reaction of CF$_3$I and S vapour in a glow discharge followed by fractionation and gcle separation; other routes include reaction of CS$_2$I with IF$_3$ at 60–200$^\circ$C, reaction of CF$_3$I with sulfur at 310$^\circ$C, and fluorination of SCl$_2$ or related compounds with NaF or KF at 150–250$^\circ$C. (See, for example, T. Yasumura and R. J. Lagow, Inorg. Chem. 17, 3108-10 (1978).)

even higher densities:

The higher chlorides of S (unlike the higher fluorides) are very unstable and poorly characterized. There is no evidence for molecular chloro analogues of SF₄, S₂F₁₀ and SF₆, though SCIFS₃ is known (p. 687). Chlorination of SCl₂ by liquid Cl₂ at −78°C yields a powdery off-white solid which begins to decompose when warmed above −30°C. It analyses as SCl₄ and is generally formulated as SC₁₃⁺Cl⁻, but little reliable structural work has been done on it. Consistent with this ionic formulation, reaction of SCl₄ with Lewis acids results in the formation of stable adducts; e.g. AlCl₃ yields the white solid SCl₄.AlCl₃ which has been shown by vibrational spectroscopy on both the solid and the melt (125°C) to be [SCl₃⁺][AlCl₄]⁻. The compound [SCl₃⁺][ICl₅⁻] is also known (p. 693). As expected from a species that is isoelectronic with PCl₃ the cation is pyramidal; dimensions are: S-Cl (average) 198.5 pm, angle Cl-S-Cl 101.3° (cf. PCl₃: P-CI 204.3 pm, angle Cl-P-CI 100.1°). Other compounds containing [SCl₃⁺]⁺ which have been characterized spectroscopically and by X-ray crystallography include those with [SbCl₆]⁻, [UCl₆]⁻ and [AsF₆]⁻. Sulfur bromides are but poorly characterized and there are few reliable data on them. SBr₂ probably does not exist at room temperature but has been claimed as a matrix-isolated product when a mixture of S₂Cl₂/SCl₂:Br₂:Ar in the ratio 1:1:150 is passed through an 80-W microwave and the product condensed on a CsI window at 9 K. The dibromosulfanes SₙBr₂ (n = 2–8) are formed by the action of anhydrous HBr on the corresponding chlorides. The best characterized compound (which can also be made directly from the elements at 100°C) is the garnet-red oily liquid S₂Br₂ isostructural with S₂Cl₂ (S-S 198 pm, S-Br 224 pm, angle Br-S-S 105°, dihedral angle 84 ± 1°). It has mp −46°C, bp(0.18 mmHg) 54°C, and d(20°C) 2.629 g cm⁻³, but even at room temperature S₂Br₂ tends to dissociate into its elements. Interestingly, the higher homologues have progressively lower densities (cf. S₄Cl₂). The unusual ionic compound [BrSSSBr₂⁺][AsF₆]⁻ can be formed by reacting stoichiometric amounts of S, Br₂ and AsF₅ in liquid SO₂.

Sulfur iodides are a topic of considerable current interest, although compounds containing S-I bonds were, in fact, unknown until fairly recently. The failure to prepare sulfur iodides by direct reaction of the elements probably reflects the comparative weakness of the S-I bond: an experimental value is not available but extrapolation from representative values for the bond energies of other S-X bonds leads to a value of ~170 kJ mol⁻¹:

The data indicate that formation of SI₂ from ⁴/₅S₈ + I₂ and the formation of S₂I₂ from ⁴/₅S₈ + I₂ are both endothermic to the extent of ~35 kJ mol⁻¹, implying that successful synthesis of these compounds must employ kinetically controlled routes to obviate decomposition back to the free elements.

Pure S₂I₂ was first isolated (as a dark reddish-brown solid) following the reaction of S₂Cl₂ with

---

HI/N₂ in a freon solvent of −78° in the presence of catalytic amounts of added I₂. The darker brown solid OSI₂ was formed similarly from OSCl₂. S₂I₂ and OSI₂ are both thermally unstable and decompose rapidly above about −30° into S, I₂ (and also SO₂ in the case of OSI₂). S₂I₂ was assigned C₂ symmetry (like S₂F₂, p. 684) on the basis of its vibrational spectrum. The first X-ray crystal structure of a species containing an S–I bond was of the curious and unexpected cation [S₇I]+ which was found in the dark-orange compound [S₇I]+[SbF₆]⁻ formed when iodine and sulfur react in SbF₅ solution. The structure of the cation is shown in Fig. 15.22a and features an S₇ ring with alternating S–S distances and a pendant iodine atom; the conformation of the ring is the same as in S₇, S₈, and S₈O (p. 696). The same cation was found in [S₇I]⁺[S₄]²⁺[AsF₆]⁻ and a similar motif forms part of the iodo-bridged species [(S₇I)₂I]³⁺ (Fig. 15.22b); this latter cation was formed during the reaction of S₈ and I₂ with SbF₅ in the presence of AsF₃ according to the reaction stoichiometry:

\[
3S₈ + 6I₂ + 10SbF₅ \rightarrow 2[S₄I]⁺[SbF₆]⁻ - 2AsF₃ + (SbF₃)₃SbF₅
\]

The very long S–Iᵣ bonds in the linear S–I–S bridge (267.5 pm) are notable and have been interpreted in terms of an S–I bond order of ½. Even weaker S–Iᵣ interactions occur in the cation [S₂I₄]²⁺ which could, indeed, alternatively be regarded as an S₂²⁺ cation coordinated side-on by two I₂ molecules (Fig. 15.23).

15.2.4 Oxohalides of sulfur

Sulfur forms two main series of oxohalides, the thionyl dihalides $\text{OS}^{\text{IV}}\text{X}_2$ and the sulfuryl dihalides $\text{O}_2\text{S}^{\text{VI}}\text{X}_2$. In addition, various other oxofluorides and peroxofluorides are known (p. 688). Thionyl fluorides and chlorides are colourless volatile liquids (Table 15.14); $\text{OSF}_2$ is rather less volatile and is orange-coloured.

All have pyramidal molecules (C₃ point group for OSX₂), and OSFCl is chiral though stereochemically labile. Dimensions are in Table 15.14: the short O—S distance is notable. The unstable compound OSI₂ was mentioned on p. 692.

The most important thionyl compound is OSCl₂—it is readily prepared by chlorination of SO₂ with PCl₅ or, on an industrial scale, by oxygen-atom transfer from SO₃ to SCl₂:

\[
\text{SO}_2 + \text{PCl}_5 \rightarrow \text{OSCl}_2 + \text{OPCl}_3
\]

\[
\text{SO}_3 + \text{SCl}_2 \rightarrow \text{OSCl}_2 + \text{SO}_2
\]

OSCl₂ reacts vigorously with water and is particularly valuable for drying or dehydrating readily hydrolysable inorganic halides:

\[
\text{MX}_n \cdot m\text{H}_2\text{O} + m\text{OSCl}_2 \rightarrow \text{MX}_n + m\text{SO}_2 + 2m\text{HCl}
\]

Examples are MgCl₂.6H₂O, AlCl₃.6H₂O, FeCl₃.6H₂O, etc. Thionyl chloride begins to decompose above its bp (76°) into S₂Cl₂, SO₂, and Cl₂; it is therefore much used as an oxidizing and chlorinating agent in organic chemistry. Fluorination with Sb₂F₅/SbF₅ gives OSF₂; use of NaF/MeCN gives OSFCl or OSF₂ according to conditions. Thionyl chloride also finds some use as a nonaqueous ionizing solvent as does SO₂ (p. 700) and the formally related dimethylsulfoxide (dmso), Me₂SO (mp 18.6°, bp 189°, viscosity \(\eta_{25}\) 1.996 centipoise, dielectric constant \(\varepsilon_{25}\) 46.7). OSF₂ is a useful low-temperature fluorinating agent in organic chemistry: it converts active C—H and P—H groups into C—F and P—F, and replaces N—H with N—S(O)F.(162)

Sulfuryl halides, like their thionyl analogues, are also reactive, colourless, volatile liquids or gases (Table 15.15). The most important compound is O₂SCl₂, which is made on an industrial scale by direct chlorination of SO₂ in the presence of a catalyst such as activated charcoal (p. 274) or FeCl₃. It is stable to 300° but begins to dissociate into SO₂ and Cl₂ above this: it is a useful reagent for introducing Cl or O₂SCl into organic compounds. O₂SCl₂ can be regarded as the acid chloride of H₂SO₄ and, accordingly, slow hydrolysis (or ammonolysis) yields O₂S(OH)₂ or O₂S(NH₂)₂. Fluorination yields O₂SF₂ (also prepared by SO₂ + F₂) and comproportionation of this with O₂SCl₂ and O₂SBr₂ yield the corresponding O₂SFX species.

All these compounds have (distorted) tetrahedral molecules, those of formula $O_2SX_2$ having $C_{2v}$ symmetry and the others $C_s$. Dimensions are in Table 15.15: the remarkably short $O-S$ and $S-F$ distances in $O_2SF_2$ should be noted (cf. above). Indeed, the implied strength of bonding in this molecule is reflected by the fact that it can be made by reacting the normally extremely inert compound $SF_6$ (p. 687) with the fluoro-acceptor $SO_3$:

$$SF_6 + 2SO_3 \rightarrow 3O_2SF_2; \Delta G_{298}^\circ = -202 \text{kJ mol}^{-1}$$

A 20% conversion can be effected by heating the two compounds at $250^\circ$ for 24 h.

### 15.2.5 Oxides of sulfur

At least thirteen proven oxides of sulfur are known to exist\(^{163}\) though this profusion should not obscure the fact that $SO_2$ and $SO_3$ remain by far the most stable and unquestionably the most important economically. The six homocyclic polysulfur monoxides $S_nO (5 < n < 10)$ are made by oxidizing the appropriate cyclo-$S_n$ (p. 656) with trifluoroperoxoacetic acid, $CF_3C(O)OOH$, at $-30^\circ$. The dioxides $S_7O_2$ and $S_6O_2$ are also known. In addition there are the thermally unstable acyclic oxides $S_2O$, $S_2O_2$, $SO$ and the fugitive species $SOO$ and $SO_4$. Several other compounds were described in the older literature (pre-1950s) but these reports are now known to be in error. For example, the blue substance of composition “$S_2O_3$” prepared from liquid $SO_3$ and sulfur now appears to be a mixture of salts of the cations $S_4^{2+}$ and $S_8^{2+}$ (p. 664) with polysulfate anions. Likewise a “sulfur monoxide” prepared by P. W. Schenk in 1933 was shown by D. J. Meschi and R. J. Meyers in 1956 to be a mixture of $S_2O$ and $SO_2$. The well-established lower oxides of $S$ will be briefly reviewed before $SO_2$ and $SO_3$ are discussed in more detail.

![Image](https://www.chemie.de/)

---

---

**Lower oxides**\(^{164}\)

Elegant work by R. Steudel and his group in Berlin has shown that, when cyclo-$S_{10}$, -$S_9$, and -$S_8$ are dissolved in $CS_2$ and oxidized by freshly prepared $CF_3C(O)O_2H$ at temperatures below $-10^\circ$, modest yields (10–20%) of the corresponding crystalline monoxides $S_nO$ are obtained. Similar oxidation of cyclo-$S_7$, and $\alpha$- and $\beta$-$S_6$ in $CH_2Cl_2$ solution yields crystalline $S_7O$, $S_7O_2$, and $\alpha$- and $\beta$-$S_6O$. Crystals of $S_6O_2$ and $S_5O (d > -50^\circ)$ have not yet been isolated but the compounds have been made in solution by the same technique. $S_8O$ had previously been made (1972) by the reaction of $OSCl_2$ and $H_2S_7$ in $CS_2$ at $-40^\circ$: it is one of the most stable compounds in the series and melts (with decomposition) at $78^\circ$. All the compounds are orange or dark yellow and decompose with liberation of $SO_2$ and sulfur when warmed to room temperature or slightly above. Structures are in Fig. 15.24. It will be noted that $S_7O$ is isoelectronic and isostructural with $[S_7I]^+$ (p. 692). This invites the question as to whether $S_7S$ can be prepared as a new structural isomer of cyclo-$S_8$.

$S_8O$ reacts with $SbCl_5$ in $CS_2$ over a period of 9 days at $-50^\circ$ to give a 71% yield of the unstable orange adduct $S_8O.SbCl_5$:\(^{165}\) its structure and dimensions are in Fig. 15.25a. It will be noted that the $S_8O$ unit differs from molecular $S_8O$ in having an equatorially bonded $O$ atom and significantly different $S-O$ and $S-S$ interatomic distances. The X-ray crystal structure was determined at $-100^\circ$C as the adduct decomposes within 5 min at $25^\circ$ to give $OSCl_2$, $SbCl_3$ and $S_8$. When a similar reaction was attempted with $\beta$-$S_6O$, the novel dimer $S_12O_2.2SbCl_5.3CS_2$ was obtained as orange crystals in 10% yield after 1 week at $-50^\circ$\(^{165}\) (Fig. 15.25b). Formation of the centrosymmetric $S_12O_2$ molecule, which is still unknown in the uncoordinated state, can be

---

All these compounds have (distorted) tetrahedral molecules, those of formula $O_2SX_2$ having $C_{2v}$ symmetry and the others $C_1$. Dimensions are in Table 15.15: the remarkably short $O-S$ and $S-F$ distances in $O_2SF_2$ should be noted (cf. above). Indeed, the implied strength of bonding in this molecule is reflected by the fact that it can be made by reacting the normally extremely inert compound $SF_6$ (p. 687) with the fluoro-acceptor $SO_3$:

$$SF_6 + 2SO_3 \rightarrow 3O_2SF_2; \ \Delta G^{298} = -202 \text{kJ mol}^{-1}$$

A 20% conversion can be effected by heating the two compounds at 250° for 24 h.

### 15.2.5 Oxides of sulfur

Sulfur

Figure 15.24  Structures of S₈₋, S₇₋, S₇₋₂ and S₆₋; in each case the O atom adopts an axial conformation. For S₈₋ there is an alternation of S-S distances, the longest being adjacent to the exocyclic O atoms; S-S-S angles are in the range 102°-108° and dihedral angles (p. 654) vary from 95° to 112° (+ and -). For S₇₋ there is again an alternation in S-S distances; ring angles are in the range 97°-106° the smallest angle again being at the S atom carrying the pendant O. The structure of S₇₋₂ was deduced from its Raman spectrum, the interatomic distances (d/pm) being computed from the relation log(d/pm) = 2.881 - 0.213log(v/cm⁻¹). The two modifications α- and β-S₆₋ have the same Raman spectrum in solution.

explained in terms of a dipolar addition reaction (Fig. 15.25c). Its conformation differs drastically from the D₃d symmetry of the parent cyclo-S₁₂ (p. 658).

The fugitive species SO was first identified by its ultraviolet spectrum in 1929 but it is thermodynamically unstable and decomposes completely in the gas phase in less than 1 s. It is formed by reduction of SO₂ with sulfur vapour in a glow discharge and its spectroscopic properties have excited interest because of its relation to O₂ (³Σ⁻ ground state, p. 605). Molecular properties include internuclear distance 148.1 pm, dipole moment 1.55 D, equilibrium bond energy Dₑ 524 kJ mol⁻¹. The use of transition-metal complexes to trap SO has received considerable attention.¹⁶⁶ It can bond in several modes including

4-centre-2 electron (4c–2e) as in \([\text{Fe}_3(\text{CO})_9\text{S}(\mu_3-\text{SO})]\),\(^{167}\) 2c–2e as in \([\text{IrCl(SO)(PR}_3)_2]\),\(^{168}\) and also 3c–4e and 3c–2e in several dinuclear transition-metal complexes.\(^{169,170}\) A novel and unprecedented route to this last class of \(\mu\)-SO complexes involves the direct oxidative addition of \(\text{OSCl}_2\) to the \(\text{Ni}^0\) complex \([\text{Ni}(\text{cod})_2]\) in the presence of \(\text{dppm}\) (\(\text{cod} = \text{cycloocta-1,5-diene}, \text{dppm} = \text{Ph}_2\text{PCH}_2\text{PPh}_2\)) to form the purple crystalline dinickel A-frame complex, \([\text{Ni}_2(\mu\text{-SO})(\text{dppm})_2\text{Cl}_2]\).\(^{171}\) X-ray analysis reveals two slightly differing geometries, with \(\text{SO}\) 144 and 145.9 pm, respectively (both shorter than in the free molecule, 148.1 pm), and with the \(\text{SO}\) ligand being tilted with respect to the Ni–Ni vector.

\(\text{S}_2\text{O}\) is also an unstable species but survives for several days in the gas phase at \(<1\text{mmHg}\) pressure. It is formed by decomposition of \(\text{SO}\) (above) and by numerous other reactions between \(\text{S}\) - and \(\text{O}\)-containing species but cannot be isolated as a pure compound. Typical recipes include: (a) passing a stream of \(\text{OSCl}_2\) at 0.1–0.5 mmHg over heated \(\text{Ag}_2\text{S}\) at 160°, (b) burning \(\text{S}_8\) in a stream of \(\text{O}_2\) at \(\sim 8\text{mmHg}\) pressure, and (c) passing \(\text{SO}_2\) at 120° and \(<1\text{mmHg}\) through a high-voltage discharge (\(\sim 5\text{kV}\)). Spectroscopic studies in the gas phase have shown it to be a nonlinear molecule (like \(\text{O}_3\) and \(\text{SO}_2\)) with angle \(\text{S}-\text{S}-\text{O}\) 118° and the interatomic distances \(\text{S}-\text{S} 188\) and \(\text{S}-\text{O} 146\) pm. \(\text{S}_2\text{O}\) readily decomposes at room temperature to \(\text{SO}_2\) and sulfur. As with \(\text{SO}\), the fugitive \(\text{S}_2\text{O}\) species can be trapped with transition-metal complexes (of \(\text{Mn}\) and \(\text{Ir}\), for

Figure 15.25 Molecular structure and dimensions of (a) the adduct \(\text{S}_8\text{O}\cdot\text{SbCl}_5\) at \(-100^\circ\), and (b) the dimeric unit \(\text{Sb}_2\text{O}_2\cdot2\text{SbCl}_5\) in \(\text{Sb}_2\text{O}_2\cdot2\text{SbCl}_5\cdot3\text{CS}_2\) at \(-115^\circ\). (c) Possible dipolar addition of \(2\text{S}_6\text{O}\) to form \(\text{S}_2\text{O}_2\).
example) wherein it behaves as an $\eta^2$-SS(O) ligand.\(^{172}\)

The unstable molecule $S_2O_2$ was first unambiguously characterized by microwave spectroscopy in 1974. It can be made by subjecting a stream of SO\(_2\) gas at 0.1 mmHg pressure to a microwave discharge (80 W, 2.45 GHz): the effluent gas is predominantly SO\(_2\) but also contains 20–30% SO, 5% S\(_2\)O and 5% S\(_2\)O\(_2\). This latter species has a planar $C_2v$ structure with $r(S-S)$ 202 pm, $r(S-O)$ 146 pm, and angle $S-S-O$ 113°; it decomposes directly into SO with a half-life of several seconds at 0.1 mmHg.

**Sulfur dioxide, SO\(_2\)**

Sulfur dioxide is made commercially on a very large scale either by the combustion of sulfur or H\(_2\)S or by roasting sulfide ores (particularly pyrite, FeS\(_2\)) in air (p. 651). It is also produced as a noxious and undesirable byproduct during the combustion of coal and fuel oil. The ensuing environmental problems and the urgent need to control this pollution are matters of considerable concern and activity (see Panel). Most of the technically produced SO\(_2\) is used in the manufacture of sulfuric acid (p. 708) but it also finds use

---

**Atmospheric SO\(_2\) and Environmental Pollution\(^{173–179}\)**

The pollution of air by smoke and sulfurous fumes is no new problem\(^5\) but the quickening pace of industrial development during the nineteenth century, and the growing concern for both personal health and protection of the environment generally since the 1950s, has given added impetus to measures required to eliminate or at least minimize the hazard.

As indicated on p. 647, there are vast amounts of volatile sulfur compounds in the environment as a result of natural processes. Geothermal activity (especially volcanic) releases large amounts of SO\(_2\) together with smaller quantities of H\(_2\)S, SO\(_3\), elemental S and particulate sulfates. From a global viewpoint, however, this accounts for less than 1% of the naturally formed volatile S compounds (Fig. A). By far the most important source is the biological reduction of S compounds which occurs most readily in the presence of organic matter and under oxygen-deficient conditions. Much of this is released as H\(_2\)S but other compounds such as Me\(_2\)S are probably also implicated. The final natural source of atmospheric S compounds is sea-spray (sulfate is the second most abundant anion in sea-water being about one-seventh the concentration of chloride). Though much sulfur is transported as sulfate by wind-driven sea spray and by river run off, its environmental impact is not severe.

\(^5\) One of the earliest tracts on the matter was John Evelyn’s *Fumifugium, or the Inconvenience of the Aer and Smoke of London Dissipated* which he submitted (with little effect) to Charles II in 1661. Evelyn, a noted diarist and a founder Fellow of the Royal Society, outlined the problem as follows: “For when in all other places the Aer is most Serene and Pure, it is here [in London] Eclipsed with such a Cloud of Sulphure, as the Sun itself, which gives day to all the World besides, is hardly able to penetrate and impart it here; and the weary Traveller, at many Miles distance, sooner smells than sees the City to which he repairs. This is that pernicious Sinoake which sullyes all her Glory, superinducing a sooty Crust or Fur upon all that it lights, spoiling the moveables, tarnishing the Plate, Gildings, and Furniture, and corroding the very Iron-bars and hardest Stones with these piercing and acrimonious Spirits which accompany its Sulphure: and executing more in one year than exposed to the pure Aer of the Country it could effect in some hundreds.”

Panel continues
Much more serious is the effect of volatile S compounds (mainly SO\textsubscript{2}) released into the atmosphere as a result of man’s domestic and industrial activities. This has been estimated to be some 200 million tonnes pa, and is comparable in amount to all the sulfur released by natural processes (\(\sim 310 \times 10^6\) tonnes pa). Unfortunately, by the very nature of its origin, this SO\textsubscript{2} is released in the heart of densely populated areas and does great damage to the respiratory organs of man and animals, to buildings, and perhaps most seriously to plants, lake-waters and aquatic life as a result of “acid rain”. Dispersal by means of high chimney stacks is inadequate since this merely transfers the problem to neighbouring regions. For example, only one-tenth of the serious SO\textsubscript{2}/H\textsubscript{2}SO\textsubscript{4} pollution of lakes and streams in Sweden is as a result of atmospheric SO\textsubscript{2} emissions in Sweden itself; one-tenth is due to emissions from the UK, and the remaining four-fifths is from industrial regions in northern Europe.

In Europe and the USA (and presumably elsewhere) the major source of SO\textsubscript{2} pollution is in coal-based power generation; this, together with other coal consumption and coking operations accounts for some 60% of the emissions. A further 25% arises from oil-refinery operations, oil-fired power generation, and other oil consumption. Copper-smelting (together with much smaller amounts from zinc and lead ore processing) accounts for some 12% of the annual release of SO\textsubscript{2}. The sulfuric acid manufacturing industry, which is the only one designed actually to make SO\textsubscript{2} on a large scale, only contributes <2% to the total, probably because of the efficient design of the process.

![Diagram of sulfur budget for land-ocean system](image)

**Figure A** The sulfur budget for the land-atmosphere-ocean system. Annual turnover rates are indicated in units of \(10^9\) tonnes (as estimated for 1977).\(^{(173)}\)

Ultimately, pollution can only be avoided by complete removal of SO\textsubscript{2} from the effluent gases, but this council of perfection is both technologically and economically unattainable. Many processes are available to reduce the SO\textsubscript{2} concentration to very low figures, but the vast scale of power generation and domestic heating by coal and oil still results in substantial emission. SO\textsubscript{2} can be removed by scrubbing with a slurry of “milk of lime”, Ca(OH)\textsubscript{2}. Alternatively, partial reduction to H\textsubscript{2}S using natural gas (CH\textsubscript{4}), naphtha or coal, followed by catalytic conversion to elemental sulfur by the Claus process can be used:

\[
2\text{H}_2\text{S} + \text{SO}_2 \xrightarrow{\text{activated} \ \text{Al}_2\text{O}_3} 3\text{S} + 2\text{H}_2\text{O}
\]

The detection of SO\textsubscript{2} in the atmosphere has become a refined analytical procedure. Several techniques are available such as (a) absorption in aqueous H\textsubscript{2}SO\textsubscript{4} and titration (or conductometric determination) of the resulting H\textsubscript{2}SO\textsubscript{4} (H\textsubscript{2}O + SO\textsubscript{2} \(\rightarrow\) H\textsubscript{2}SO\textsubscript{4}); and (b) reaction with Na\textsubscript{2}[HgCl\textsubscript{4}] or K\textsubscript{2}[HgCl\textsubscript{4}]:

\[
[\text{HgCl}_4]^{2-} + 2\text{SO}_2 + 2\text{H}_2\text{O} \rightarrow [\text{Hg(SO}_2)_2]^{2-} + 4\text{Cl}^- + 4\text{H}^+
\]

The resulting disulfotelluricurate is determined colorimetrically after addition of acidic paranitroaniline and formaldehyde (P. W. West and G. C. Gucke, 1956). Other methods are (c) flame-photometric monitoring of the gas stream using a reducing H\textsubscript{2}/air flame and emission of S\textsubscript{2} at 394 nm sensitive down to 1 part in \(10^9\) by volume and (d) pulsed fluorescent analyser using radiation in the region of 214 nm; this is specific for SO\textsubscript{2} and response is linear over wide ranges down to 1 in \(10^9\). Commercial instruments are available.

as a bleach, disinfectant (Homer, p. 645), food preservative, refrigerant and nonaqueous solvent. Other chemical uses are in the preparation of sulfites and dithionites (p. 716) and, with \( \text{Cl}_2 \), in the derivatization of hydrocarbons via sulfochlorination reactions. There is also much current interest in its properties as a multimode ligand (p. 701).

\( \text{SO}_2 \) is a colourless, toxic gas with a choking odour. Maximum permitted atmospheric concentration for humans is \( 5 \) ppm but many green plants suffer severe distress in concentrations as low as \( 1 \)–\( 2 \) ppm. \( \text{SO}_2 \) neither burns in air nor supports combustion. Some molecular and physical properties of the compound are in Table 15.16. Comparison of these properties with those of ozone (p. 607) is instructive. Note also that the \( \text{S-O} \) distance of 143.1 pm in \( \text{SO}_2 \) is less than that in unstable \( \text{SO} \) (148.1 pm) whereas the \( \text{O-O} \) distance of 127.8 pm in \( \text{O}_3 \) is greater than that in stable \( \text{O}_2 \) (120.7 pm). Furthermore the mean bond energy in \( \text{SO}_2 \) is 548 kJ mol\(^{-1} \) which is greater than that for \( \text{SO} \) (524 kJ mol\(^{-1} \)) whereas the mean bond energy in \( \text{O}_3 \) is 297 kJ mol\(^{-1} \) which is less than the value for \( \text{O}_2 \) (490 kJ mol\(^{-1} \)). This has been taken to imply an \( \text{S-O} \) bond order of at least 2 in \( \text{SO}_2 \), compared with only 1.5 for \( \text{O-O} \) in \( \text{O}_3 \) (p. 607).

By far the most important chemical reaction of \( \text{SO}_2 \) is its further oxidation to \( \text{SO}_3 \) according to the equilibrium:

\[
\text{SO}_2 + \frac{1}{2} \text{O}_2 \rightleftharpoons \text{SO}_3; \quad \Delta H^\circ = -95.6 \text{ kJ mol}^{-1}
\]

The equilibrium constant, \( K_p = p(\text{SO}_3)/[p(\text{SO}_2) \cdot p(\text{O}_2)^{1/2}] \), decreases rapidly with increasing temperature; for example: \( \log K_p = 3.49 \) at 800°C and \(-0.52 \) at 1100°C. Thus for maximum oxidation during the manufacture of \( \text{H}_2\text{SO}_4 \) it is necessary to work at lower temperatures and to increase the rate of reaction by use of catalysts.

Typical conditions would be to pass a mixture of \( \text{SO}_2 \) and air over Pt gauze or more commonly a \( \text{V}_2\text{O}_5/\text{K}_2\text{O} \) contact catalyst supported on Kieselguhr or zeolite.

Gaseous \( \text{SO}_2 \) is readily soluble in water (3927 cm\(^3 \) \( \text{SO}_2 \) in 100 g \( \text{H}_2\text{O} \) at 20°C). Numerous species are present in this aqueous solution of "sulfurous acid" (p. 717). At 0°C a cubic clathrate hydrate also forms with a composition \( \sim \text{SO}_2.6\text{H}_2\text{O} \); its dissociation pressure reaches 1 atm at 7.1°C. The ideal composition would be \( \text{SO}_2.5\frac{1}{2}\text{H}_2\text{O} \) (p. 627).

In addition to the role of gaseous \( \text{SO}_2 \) in the manufacture of \( \text{H}_2\text{SO}_4 \), pure (liquid) \( \text{SO}_2 \) is manufactured on a large scale for the uses mentioned above. Typical production levels (in 1985) were 162,000 tonnes in USA and 65,000 tonnes in (West) Germany. About half of this is used in the manufacture of \( \text{S} \)-containing chemicals such as sulfites, hydrogen sulfites, thiosulfates, dithionites, salts of hydroxalkane-sulfinic acids and alkane sulfonates. It is also used in cellulose manufacture, in the chemical dressing of Mn-ores, in the removal of \( \text{S} \)-containing impurities from mineral oils, for food disinfection and preservation, and for treatment of water.

Liquid \( \text{SO}_2 \) has been much studied as a nonaqueous solvent.\(^{180}\) Some of the early work (particularly on the physical properties of the solutions) is now known to be in error but

the solvent is especially useful for carrying out a range of inorganic reactions. It is also an excellent solvent for proton nmr studies. In general, covalent compounds are very soluble: e.g. Br₂, ICl, OSX₂, BC1₃, CS₂, PC1₃, OPCI₃ and AsCl₃ are completely miscible, and most organic amines, ethers, esters, alcohols, mercaptans and acids are readily soluble. Many uni-univalent salts are moderately soluble, and those with ions such as the tetramethylammonium halides and the alkali metal iodides are freely so. The low dielectric constant of liquid SO₂ leads to extensive ion-pair and ion-triplet formation but the solutions have limiting molar conductances in the range 190–250 ohm⁻¹ cm² mol⁻¹ at 0°. Solvate formation is exemplified by compounds such as SnBr₄.SO₂ and 2TiC1₄.SO₂ (see below for SO₂ as a ligand). Solvolysis reactions are also documented, e.g.: 

\[
\begin{align*}
\text{NbCl}_5 + \text{SO}_2 & \rightarrow \text{NbOCl}_3 + \text{OSCl}_2 \\
\text{WCl}_6 + \text{SO}_2 & \rightarrow \text{WOCl}_4 + \text{OSCl}_2 \\
\text{UCI}_5 + 2\text{SO}_2 & \rightarrow \text{UO}_2\text{Cl}_2 + 2\text{OSCl}_2
\end{align*}
\]

Several other reaction types have also appeared in the literature but are sometimes purely formal schemes dating from the time when the solvent was (incorrectly) thought to undergo self-ionic dissociation into SO²⁺ and SO₃²⁻ or SO²⁺ and S₂O₅²⁻. More recently it has been shown that, whereas neither SO₂ nor OSMe₂ (dmso) react with first-row transition metals, the mixed solvent smoothly effects dissolution of the metals with simultaneous oxidation of SIV to SVI, thereby enabling the production of crystalline solvated metal disulfates (S₂O₅²⁻) in high yield.\(^{(181)}\) Examples are: colourless \[\text{Ti}^{IV}(\text{OSMe}_2)_6][\text{S}_2\text{O}_7]_2\], green \[\text{V}^{III}(\text{OSMe}_2)_6][\text{S}_2\text{O}_7]_3\] and the salts \[\text{M}^{II}(\text{OSMe}_2)_6][\text{S}_2\text{O}_7]_2\], where \(\text{M} = \text{Mn}\) (yellow), Fe (pale green), Co (pale pink), Ni (green), Cu (pale blue), Zn (white) and Cd (white). This is by far the most convenient way to prepare pure disulfates. Dissolution of metals in SO₂ mixed with other solvents such as dmf, dma, or hmpa also occurs, but in these cases there is no oxidation of the SIV, and the product is usually the metal dithionite, M^{II}[S₂O₄].

**Sulfur dioxide as a ligand**

The coordination chemistry of SO₂ has been extensively studied during the past two decades and at least 9 different bonding modes have been established.\(^{(166)}\) These are illustrated schematically in Fig. 15.26 and typical examples are given in Table 15.17.\(^{(166,182)}\) It is clear that nearly all the transition-metal complexes involve the metals in oxidation state zero or +1. Moreover, SO₂ in the pyramidal \(\eta^1\)-clusters tends to be reversibly bound (being eliminated when

---

The complex is heated to $<200^\circ$ and recombining when the system is cooled to room temperature) whereas this tends not to be the case for the other bonding modes. Facile oxidation of the SO$_2$ by molecular O$_2$ to give coordinated sulfato complexes (SO$_4^{2-}$) is also a characteristic of pyramidal $\eta^1$-SO$_2$ which is not shared by the other types.

In the absence of X-ray crystallographic data vibrational spectroscopy can sometimes provide information concerning the mode of ligation, the position of the two $\nu$(SO) stretching modes in particular often providing a useful but not always reliable diagnostic.$^{182}$

With such structural diversity it is perhaps not surprising that no certain method has been devised for theoretically predicting the mode of bonding to be expected in specific cases, although plausible post hoc rationalization of the observed structure is sometimes possible.

Sometimes coordination of SO$_2$ to an organometallic complex is followed by intramolecular insertion of SO$_2$ into the M-C $\sigma$ bond, e.g.

$$\text{trans-}[\text{PtClPh(PET}_{3}2]\text{+ SO}_2]$$

(4 coordinate Pt)

$$\rightarrow$$

$$\text{[PtClPh(PET}_{3}2](SO}_2\text{Ph})$$

(5-coordinate)

$$\downarrow$$

$$\text{trans-}[\text{PtCl(PET}_{3}2][S(O}_2\text{Ph})]$$

(4-coordinate)

Intermolecular insertion of SO$_2$ can also occur (without prior formation of an isolable complex) and the general reaction can be represented by the equation.$^{183}$

</tbody>
</table>
\[ \text{M} - \text{R} + \text{SO}_2 \rightarrow \text{M} - (\text{SO}_2) - \text{R} \]

where \( \text{M} \) represents a metal atom and its pendant ligands and \( \text{R} \) is an alkyl, aryl or related \( \sigma \)-bonded carbon group. The reaction is more flexible (though less important industrially) than the analogous carbonylation reaction of \( \text{CO} \) (p. 306) and can, in principle, lead to four different types of product:

- S-sulfinate
- O-alkyl-S-sulfoxylate
- O-sulfinate
- O-alkyl-O'-sulfinate

Examples of all except possibly the second mode are known.

**Sulfur trioxide**

\( \text{SO}_3 \) is made on a huge scale by the catalytic oxidation of \( \text{SO}_2 \) (p. 700): it is not usually isolated but is immediately converted to \( \text{H}_2\text{SO}_4 \) (p. 708). It can also be obtained by the thermolysis of sulfates though rather high temperatures are required. \( \text{SO}_3 \) is available commercially as a liquid: such samples contain small amounts (0.03–1.5%) of additives to inhibit polymerization. Typical additives are simple compounds of boron (e.g. \( \text{B}_2\text{O}_3 \), \( \text{B(OH)}_3 \), \( \text{HBO}_2 \), \( \text{BX}_3 \), \( \text{MBF}_4 \), \( \text{Na}_2\text{B}_4\text{O}_7 \)), silica, siloxanes, \( \text{SOCl}_2 \), sulfonic acids, etc. The detailed mode of action of these additives remains obscure. \( \text{SO}_3 \) is also readily available as fuming sulfuric acid (or oleum) which is a solution of 25–65% \( \text{SO}_3 \) in \( \text{H}_2\text{SO}_4 \) (p. 707). Because of its extremely aggressive reaction with most materials, pure anhydrous \( \text{SO}_3 \) is difficult to handle although it is made in the USA (for example) on a scale approaching 90 000 tonnes per annum. It can be obtained on a laboratory scale by the double distillation of oleum in an evacuated all-glass apparatus; a small amount of \( \text{KMnO}_4 \) is sometimes used to oxidize any traces of \( \text{SO}_2 \).

In the gas phase, monomeric \( \text{SO}_3 \) has a planar \( (D_3h) \) structure with \( \text{S-O} \ 142\text{pm} \). This species is in equilibrium with the cyclic trimer \( \text{S}_3\text{O}_9 \) in both the gaseous and liquid phases: \( K_p \approx 1\text{ atm}^{-2} \) at 25°C, \( \Delta H^\circ \approx 125\text{ kJ (mole S}_3\text{O}_9)^{-1} \). Bulk properties therefore often refer to this equilibrium mixture, e.g. bp 44.6°C, \( d(25^\circ) \) 1.903 g cm\(^{-3} \), \( \eta(25^\circ) \) 1.820 centipoise. Below the mp (16.86°), colourless crystals of ice-like orthorhombic \( \gamma\)-\( \text{SO}_3 \) separate and structural studies reveal that the only species present is the trimer \( \text{S}_3\text{O}_9 \) (Fig. 15.27). Traces of water (10\(^{-3}\) mole%) lead to the rapid formation of glistening, white, needle-like crystals of \( \beta\)-\( \text{SO}_3 \) which is actually a mixture of fibrous, polymeric polysulfuric acids \( \text{HO(SO}_2\text{O)}_x\text{H}, \) where \( x \) is very large (≈10\(^5\)). The helical chain structure of \( \beta\)-\( \text{SO}_3 \) is shown in Fig. 15.27 (cf. polyphosphates, p. 528). A third and still more stable form, \( \alpha\)-\( \text{SO}_3 \), also requires traces of moisture or other polymerizing agent for its formation but involves some cross-linking between the chains to give a complex layer structure (mp 62°). The standard enthalpies of formation (\( \Delta H^\circ/\text{kJ mol}^{-1} \)) of the various forms of \( \text{SO}_3 \) at 25°C are: gas –395.2, liquid –437.9, \( \gamma\)-crystals –447.4, \( \beta\)-crystals –449.6, \( \alpha\)-solid –462.4.

\( \text{SO}_3 \) reacts vigorously and extremely exothermically with water to give \( \text{H}_2\text{SO}_4 \). Substoichiometric amounts yield oleums and mixtures of various polysulfuric acids (p. 712). Hydrogen halides give the corresponding halogenosulfuric acids \( \text{HSO}_3\text{X} \). \( \text{SO}_3 \) extracts the elements of \( \text{H}_2\text{O} \) from carbohydrates and other organic matter leaving a carbonaceous char. It acts as a strong Lewis acid towards a wide variety of inorganic and organic ligands to give adducts: e.g. oxides give \( \text{SO}_4^{2-} \), \( \text{Ph}_3\text{P} \) gives \( \text{Ph}_3\text{P} \cdot \text{SO}_3 \) (with a rather long P–S bond, 217.6 pm\(^{184}\)).

Ph₃AsO gives Ph₃AsO·SO₃ etc. Frequently further reaction ensues: thus, under various conditions reaction with NH₃ yields H₂NSO₃H, HN(SO₃H)₂, HN(SO₃NH₄)₂, NH₄N(SO₃NH₄)₂, etc. SO₃ can also act as a ligand towards strong electron-pair acceptors such as AsF₃, SbF₃ and SbCl₃. It is reduced to SO₂ by activated charcoal or by metal sulfides. The reaction with metal oxides (particularly Fe₃O₄) to give sulfates is used industrially to rid stack-gases of unwanted byproduct SO₃.

**Higher oxides**

The reaction of gaseous SO₂ or SO₃ with O₂ in a silent electric discharge gives colourless polymeric condensates of composition SO₃₊ₓ (0 < x < 1). These materials are derived from β-SO₃ by random substitution of oxo-bridges by peroxy-bridges:

\[
\begin{array}{c}
\text{O} \\
\| \\
\text{O}--\text{S}--\text{O}--\text{O}--\text{S}--\text{O}--
\end{array}
\]

Hydrolysis of the polymers yields H₂SO₄ and H₂SO₅ (p. 712), with H₂O₂ and O₂ as secondary products.

Monomeric neutral SO₄ can be obtained by reaction of SO₃ and atomic oxygen; photolysis of SO₃/ozone mixtures also yields monomeric SO₄, which can be isolated by inert-gas matrix techniques at low temperatures (15–78 K). Vibration spectroscopy indicates either an open peroxy \( C_s \) structure or a closed peroxy \( C_{2v} \) structure, the former being preferred by the most recent study, on the basis of agreement between observed and calculated frequencies and reasonable values for the force constants.\(^{185}\)

*Acids marked with an asterisk do not exist in the free state but are known as salts.
15.2.6 Oxoacids of sulfur

Sulfur, like nitrogen and phosphorus, forms many oxoacids though few of these can be isolated as the free acid and most are known either as aqueous solutions or as crystalline salts of the corresponding oxoacid anions. Sulfuric acid, H$_2$SO$_4$, is the most important of all industrial chemicals and is manufactured on an enormous scale, greater than for any other compound of any element (p. 407). Other compounds, such as thiosulfates, sulfites, disulfites and dithionites, are valuable reducing agents with a wide variety of applications. Nomenclature is somewhat confusing but is summarized in Table 15.18 which also gives an indication of the various oxidation states of S and a schematic representation of the structures. Previously claimed species such as “sulfoxylic acid” (H$_2$SO$_2$), “thiosulfurous acid” (H$_2$S$_2$O$_2$), and their salts are now thought not to exist.

Many of the sulfur oxoacids and their salts are connected by oxidation-reduction equilibria: some of the more important standard reduction potentials are summarized in Table 15.19 and displayed in graphic form as a volt-equivalent diagram (p. 435) in Fig. 15.28. By use of the couples in Table 15.19 data for many other oxidation-reduction equilibria can readily be calculated. (Indeed, it is an instructive exercise to check the derivation of the numerical data.

Figure 15.28  Volt-equivalent diagram for sulfur-containing species in acid solution.

given in parentheses in Fig. 15.28 from the data given in Table 15.19 and to calculate the standard reduction potentials of other couples, e.g. HSO₄⁻/H₂S 0.289 V, HSO₄⁻/H₂SO₃ 0.119 V, H₂SO₃/S₂O₅²⁻ 0.433 V, etc.) Several important points emerge which are immediately apparent from inspection of Fig. 15.28. For example, it is clear that, in acid solutions, the gradient between H₂S and S₈ is less than between S₈ and any positive oxidation state, so that H₂S is thermodynamically able to reduce any oxoacid of sulfur to the element. Again, as all the intermediate oxoacids lie above the line joining HSO₄⁻ and S₈, it follows that all can ultimately disproportionate into sulfuric acid and the element. Similarly, any moderately powerful oxidizing agent should be capable of oxidizing the intermediate oxoacids to sulfuric acid (sometimes with concurrent precipitation of sulfur) though by suitable choice of conditions it is often possible to obtain kinetically stable intermediate oxidation states (e.g. the polythionates with the stable S=S linkages). It follows that all the oxoacids except H₂SO₄ are moderately strong reducing agents (see below).

The formal interrelationship between the various oxoacids of sulfur can also be illustrated in a scheme(186) which places less emphasis on oxidation-reduction reactions but which is useful in suggesting possible alternative synthetic routes to these oxoacids. Thus successive addition of SO₃ or SO₂ to H₂O can be represented by the scheme:

\[
\begin{align*}
H₂O & \rightarrow H₂SO₃ \\
H₂SO₃ & \rightarrow H₂SO₄ \\
H₂SO₄ & \rightarrow SO₃ \\
SO₃ & \rightarrow H₂S₂O₅
\end{align*}
\]

Likewise addition of SO₃ to H₂O₂, H₂S and H₂Sₙ generates the formulae of the other oxoacids as follows:

\[
\begin{align*}
H₂O₂ & \rightarrow H₂SO₃ \\
H₂SO₃ & \rightarrow H₂SO₄ \\
H₂SO₄ & \rightarrow SO₃
\end{align*}
\]

\[
\begin{align*}
H₂S & \rightarrow H₂S₂O₅ \\
H₂S₂O₅ & \rightarrow SO₃ \\
SO₃ & \rightarrow H₂S₃O₇
\end{align*}
\]

\[
\begin{align*}
H₂Sₙ & \rightarrow H₂Sₙ₊₁O₃ \\
H₂Sₙ₊₁O₃ & \rightarrow SO₃ \\
SO₃ & \rightarrow H₂Sₙ₊₂O₅
\end{align*}
\]

It should be emphasized that not all the processes in these schemes represent viable syntheses, and other routes are frequently preferred. The following sections give a fuller discussion of the individual oxoacids and their salts.

(1) In the gas phase H₂SO₄ and D₂SO₄ adopt the C₂ conformation with r(O-H) 97 pm, r(S-OH) 157.4 pm, r(S-O) 142.2 pm; the various interatomic and dihedral angles were also determined and the molecular dipole moment calculated to be 2.73 D. 187
Industrial Manufacture of Sulfuric Acid

Sulfuric acid is the world's most important industrial chemical and is the cheapest bulk acid available in every country of the world. It was one of the first chemicals to be produced commercially in the USA (by John Harrison, Philadelphia, 1793); in Europe the history of its manufacture goes back even further — by at least two centuries. Concentrated sulfuric acid ("oil of vitriol") was first made by the distillation of "green vitriol", FeSO₄·nH₂O and was needed in quantity to make Na₂SO₄ from NaCl for use in the Leblanc Process (p. 71). This expensive method was replaced in the early eighteenth century by the burning of sulfur and Chile saltpetre (NaNO₃) in the necks of large glass vessels containing a little water. The process was patented in 1749 by Joshua Ward (the Quack of Hogarth's Harlot's Progress) though it had been in use for several decades previously in Germany, France and England. The price plummeted 20-fold from £2 to 2 shillings per pound. It dropped by a further factor of 10 by 1830 following firstly John Roebuck's replacement (ca. 1755) of the fragile glass jars by lead-chambers of 200 ft³ (5.7 m³) capacity, and, secondly, the discovery (by N. Clement and C. B. Désormes in 1793) that the amount of NaNO₃ could be substantially reduced by admitting air for the combustion of sulfur. By 1860 James Muspratt (UK) was using lead chambers of 56000 ft³ capacity (1585111~) and the process was continuous. The maximum concentration of acid that could be produced by this method was about 78% and until 1870 virtually the only source of oleum was the Nordhausen works (distillation of FeSO₄·nH₂O). Today both processes have been almost entirely replaced by the modern contact process. This derives originally from Peregrine Philips' observation (patented in 1831) that SO₂ can be oxidized to SO₃ by air in the presence of a platinum catalyst.

The modern process uses a potassium-sulfate-promoted vanadium(V) oxide catalyst on a silica or kieselguhr support. The SO₂ is obtained either by burning pure sulfur or by roasting sulfide minerals (p. 651) notably iron pyrite, or ores of Cu, Ni and Zn during the production of these metals. On a worldwide basis about 65% of the SO₂ comes from the burning of sulfur and some 35% by the roasting of sulfide ores but in some countries (e.g. the UK) over 95% comes from the former.

The oxidation of SO₂ to SO₃ is exothermic and reversible:

\[
\text{SO}_2 + \frac{1}{2} \text{O}_2 \rightarrow \text{SO}_3; \quad \Delta H^\circ = -98 \text{ kJ mol}^{-1}
\]

According to le Chatelier's principle the yield of SO₃ will increase with increase in pressure, increase in excess O₂ concentration, and removal of SO₂ from the reaction zone; each of these factors will also increase the rate of conversion somewhat (by the law of mass action). Reaction rate will also increase substantially with increase in temperature but this will simultaneously decrease the yield of the exothermic forward reaction. Accordingly, a catalyst is required to accelerate the reaction without diminishing the yield. Optimum conditions involve an equimolar feed of O₂/SO₂ (i.e. air/SO₂:5/1) and a 4-stage catalytic converter operating at the temperatures shown in the Figure. (The V₂O₅ catalyst is inactive below 400°C and breaks down above 620°C; it is dispersed as a thin film of molten salt on the catalyst support.) Such a converter may be 13 m high, 9 m in diameter, contain 80 tonnes of catalyst pellets and produce 500 tonnes per day of acid. The gas temperature rises during passage through the catalyst bed and is recooled by passage through external heat-exchanger loops between the first three stages. In the most modern "double-absorption" plants (IPA) the SO₃ is removed at this stage before the residual SO₂/O₂ is passed through a fourth catalyst bed for final conversion. The SO₃ gas cannot be absorbed directly in water because it would first come into contact with the water-vapour above the absorbant and so produce a stable mist of fine droplets of H₂SO₄ which would then pass right through the absorber and out into the atmosphere. Instead, absorption is effected by 98% H₂SO₄ in ceramic-packed towers and sufficient water is added to the circulating acid to maintain the required concentration. Commercial conc H₂SO₄ is generally 96–98% to prevent undesirable solidification of the product. The main construction materials of the sulfur burner, catalytic converter, absorption towers and ducting are mild steel and stainless steel, and the major impurity in the acid is therefore Fe⁺⁺ (10 ppm) together with traces of SO₂ and NOₓ.

Some idea of the accelerating demand for sulfuric acid can be gained from the following UK production figures:

<table>

</tbody>
</table>

---

Figures for France, Germany and the USA were lower than these until the turn of the century, but then the USA began to outstrip the rest. At about the same time superphosphate manufacture overtook the Leblanc soda process as the main user of $\text{H}_2\text{SO}_4$. $\text{H}_2\text{SO}_4$ production is now often taken as a reliable measure of a nation's industrial strength because it enters into so many industrial and manufacturing processes. Thus in 1900 production was equivalent to 4.05 million tonnes of 100% $\text{H}_2\text{SO}_4$ distributed as follows (%):
By 1976 world production was 113 million tonnes and the distribution changed to the following (%):

<table>
<thead>
<tr>
<th>Country</th>
<th>UK</th>
<th>USA</th>
<th>Germany</th>
<th>France</th>
<th>Austria</th>
<th>Belgium</th>
<th>Russia</th>
<th>Japan</th>
</tr>
</thead>
<tbody>
<tr>
<td>1976</td>
<td>25.9</td>
<td>25.6</td>
<td>41.0</td>
<td>34.5</td>
<td>4.9</td>
<td>4.0</td>
<td>3.1</td>
<td>1.2</td>
</tr>
</tbody>
</table>

This had increased to 145 million tonnes by 1986 (Europe 44%, USA/Canada 24%, Asia/Oceania 18%, Africa 9%, Latin America 5%). Such vast quantities require huge plants; these frequently have a capacity in excess of 2000 tonnes per day in the USA but are more commonly in the range 300–750 tonnes per day in Europe and smaller still in less industrialized countries. Even so, the energy flows are enormous as can be appreciated by scaling up the following reactions:

\[
\begin{align*}
S + O_2 & \rightarrow SO_2, \quad \Delta H^\circ = -297 \text{ kJ mol}^{-1} \\
SO_2 + \frac{1}{2} O_2 & \rightarrow SO_3, \quad \Delta H^\circ = -9.8 \text{ kJ mol}^{-1} \\
SO_3 + H_2O \text{ (in 98% H}_2\text{SO}_4) & \rightarrow H_2\text{SO}_4, \quad \Delta H^\circ = -130 \text{ kJ mol}^{-1}
\end{align*}
\]

For example, the oxidation of S to SO\(_3\) liberates nearly \(4 \times 10^{7}\) J per tonne of H\(_2\)SO\(_4\) of which \(\sim 3\) GJ can be sold as energy in the form of steam and much of the rest used to pump materials around the plant, etc. A plant producing 750 tonnes per day of H\(_2\)SO\(_4\) produces \(\sim 25\) MW of byproduct thermal energy, equivalent to \(\sim 7\) MW of electricity if the steam is used to drive generators. Effective utilization of this energy is an important factor in minimizing the cost of sulfuric acid which remains a remarkably cheap commodity despite inflation (of the order of \$150 per tonne in 1994).

Environmental legislation in the USA requires that sulfur emitted from the stack (SO\(_2\) and persistent H\(_2\)SO\(_4\) mist) must not exceed 0.3% of the sulfur burned (0.5% in the UK). Despite this, because of the vast scale of the industry, large quantities of unconverted SO\(_2\) are vented to the atmosphere each year (say 0.3% of \(145 \times 10^6\) tonnes \(\times \frac{30}{55} = 284,000\) tonnes SO\(_2\) per year). It is a testament to the efficiency of the process that this represents a global impact of only some 780 tonnes SO\(_2\) per day, which is minute compared with other sources of this pollution (p. 698).

The pattern of use of H\(_2\)SO\(_4\) varies from country to country and from decade to decade. Current US usage is dominated by fertilizer production (70%) followed by chemical manufacture, metallurgical uses, and petroleum refining (\(\sim 5\)% each). In the UK the distribution of uses is more even: only 30% of the H\(_2\)SO\(_4\) manufactured is used in the fertilizer industry but 18% goes on paints, pigments and dyestuff intermediates, 16% on chemicals manufacture, 12% on soaps and detergents, 10% on natural and manmade fibres, and 2.5% on metallurgical applications.

**Sulfuric acid, H\(_2\)SO\(_4\)**

Anhydrous sulfuric acid is a dense, viscous liquid which is readily miscible with water in all proportions: the reaction is extremely exothermic (\(\sim 880\) kJ mol\(^{-1}\) at infinite dilution) and can result in explosive spattering of the mixture if the water is added to the acid; it is therefore important always to use the reverse order and add the acid to the water, slowly and with stirring. The large-scale preparation of sulfuric acid is a major industry in most countries and is described in the preceding Panel.

Some physical properties of anhydrous H\(_2\)SO\(_4\) (and D\(_2\)SO\(_4\)) are in Table 15.20 (p. 707).\(^{(191,192)}\) In addition, several congruently melting hydrates, H\(_2\)SO\(_4\).\(_n\)H\(_2\)O, are known with \(n = 1, 2, 3, 4\) (mps 8.5°, -39.5°, -36.4° and -28.3°, respectively). Other compounds in the H\(_2\)O/SO\(_3\) system are H\(_2\)S\(_2\)O\(_7\) (mp 36°) and H\(_2\)S\(_4\)O\(_13\) (mp 4°). Anhydrous H\(_2\)SO\(_4\) is a remarkable compound with an unusually high dielectric constant, and a very high electrical conductivity which results from the ionic self-dissociation (autoprotolysis) of the compound coupled with a proton-switch mechanism for the rapid

---

conduction of current through the viscous H-bonded liquid. For example, at 25° the single-ion conductances for H$_3$SO$_4^+$ and HS$_3$O$_4^-$ are 220 and 150 respectively, whereas those for Na$^+$ and K$^+$ which are viscosity-controlled are only 3–5. Anhydrous H$_2$SO$_4$ thus has many features in common with anhydrous H$_3$PO$_4$ (p. 518) but the equilibria are reached much more rapidly (almost instantaneously) in H$_2$SO$_4$:

$$2\text{H}_2\text{SO}_4 \rightleftharpoons \text{H}_3\text{SO}_4^+ + \text{HSO}_4^-$$

$$K_{ap}(25^\circ) = [\text{H}_3\text{SO}_4^+][\text{HSO}_4^-] = 2.7 \times 10^{-4}$$

This value is compared with those for other acids and protonic liquids in Table 15.21, the extent of autoprotolysis in H$_2$SO$_4$ is greater than in water by a factor of more than 10$^{10}$ and is exceeded only by anhydrous H$_3$PO$_4$ and [HBF$_3$(OH)] (p. 198). In addition to autoprotolysis, H$_2$SO$_4$ undergoes ionic self-dehydration:

$$2\text{H}_2\text{SO}_4 \rightleftharpoons \text{H}_3\text{O}^+ + \text{HS}_2\text{O}_7^-; K_{ap}(25^\circ) = 5.1 \times 10^{-5}$$

This arises from the primary dissociation of H$_2$SO$_4$ into H$_2$O and SO$_3$ which then react with further H$_2$SO$_4$ as follows:

$$\text{H}_2\text{O} + \text{H}_2\text{SO}_4 \rightleftharpoons \text{H}_3\text{O}^+ + \text{HSO}_4^-;$$

$$K_{ap}(25^\circ) = [\text{H}_3\text{O}^+][\text{HSO}_4^-]/[\text{H}_2\text{O}] \sim 1$$

$$\text{SO}_3 + \text{H}_2\text{SO}_4 \rightleftharpoons \text{H}_2\text{S}_2\text{O}_7$$

$$\text{H}_2\text{S}_2\text{O}_7 + \text{H}_2\text{SO}_4 \rightleftharpoons \text{H}_3\text{SO}_4^+ + \text{HS}_2\text{O}_7^-;$$

$$K_{ap}(25^\circ) = [\text{H}_3\text{SO}_4^+][\text{HS}_2\text{O}_7^-]/[\text{H}_2\text{S}_2\text{O}_7]$$

$$= 1.4 \times 10^{-2}$$

It is clear that “pure” anhydrous sulfuric acid, far from being a single substance in the bulk liquid phase, comprises a dynamic equilibrium involving at least seven well-defined species. The concentration of the self-dissociation products in H$_2$SO$_4$ and D$_2$SO$_4$ at 25° (expressed in millimoles of solute per kg solvent) are:

As the molecular weight of H$_2$SO$_4$ is 98.078 it follows that 1 kg contains 10.196 mol; hence the predominant ions are present to the extent of about 1 millimole per mole of H$_2$SO$_4$ and the total concentration of species in equilibrium with the parent acid is 4.16 millimole per mole. Many of the physical and chemical properties of anhydrous H$_2$SO$_4$ as a nonaqueous solvent stem from these equilibria.

In the sulfuric acid solvent system, compounds that enhance the concentration of the solvo-cation HSO$_4^-$ will behave as bases and those that give rise to H$_3$SO$_4^+$ will behave as acids (p. 425). Basic solutions can be formed in several ways of which the following examples are typical:

(a) Dissolution of metal hydrogen sulfates:

$$\text{KH}_3\text{SO}_4 \rightleftharpoons \text{K}^+ + \text{HSO}_4^-$$

(b) Solvolysis of salts of acids that are weaker than H$_2$SO$_4$:

$$\text{KNO}_3 + \text{H}_2\text{SO}_4 \rightleftharpoons \text{K}^+ + \text{HSO}_4^- + \text{HNO}_3$$

$$\text{NH}_3\text{ClO}_4 + \text{H}_2\text{SO}_4 \rightleftharpoons \text{NH}_4^++ \text{HSO}_4^- + \text{HClO}_4$$

(c) Protonation of compounds with lone-pairs of electrons:

$$\text{H}_2\text{O} + \text{H}_2\text{SO}_4 \rightleftharpoons \text{H}_3\text{O}^+ + \text{HSO}_4^-$$

$$\text{Me}_2\text{CO} + \text{H}_2\text{SO}_4 \rightleftharpoons \text{Me}_2\text{COH}^+ + \text{HSO}_4^-$$

Table 15.21 Autoprotolysis constants at 25°.
The reaction with HNO₃ is quantitative, and the presence of large concentrations of the nitronium ion, NO₂⁺, in solutions of HNO₃, MNO₃ and N₂O₅ in H₂SO₄ enable a detailed interpretation to be given of the nitrations of aromatic hydrocarbons by these solutions.

Because of the high acidity of H₂SO₄ itself, bases form the largest class of electrolytes and only few acids (proton donors) are known in this solvent system. As noted above, H₂S₂O₇ acts as a proton donor to H₂SO₄ and HSO₃F is also a weak acid:

\[ \text{HSO}_3\text{F} + \text{H}_2\text{SO}_4 \rightleftharpoons \text{H}_3\text{SO}_4^{+} + \text{SO}_3\text{F}^- \]

One of the few strong acids is tetra(hydrogen sulfato)boric acid HB(HSO₄)₄; solutions of this can be obtained by dissolving boric acid in oleum:

\[ \text{B(OH)}_3 + 3\text{H}_2\text{S}_2\text{O}_7 \rightarrow \text{H}_3\text{SO}_4^{+} + \{\text{B(HSO}_4\text{)}_4\}^- + \text{H}_2\text{SO}_4 \]

Other strong acids are H₂Sn(HSO₄)₆ and H₂Pb(HSO₄)₆.

Sulfuric acid forms salts (sulfates and hydrogen sulfates) with many metals. These are frequently very stable and, indeed, they are the most important mineral compounds of several of the more electropositive elements. They have been discussed in detail under the appropriate elements. Sulfates can be prepared by:

(a) dissolution of metals in aqueous H₂SO₄ (e.g. Fe);
(b) neutralization of aqueous H₂SO₄ with metal oxides or hydroxides (e.g. MOH);
(c) decomposition of salts of volatile acids (e.g. carbonates) with aqueous H₂SO₄;
(d) metathesis between a soluble sulfate and a soluble salt of the metal whose (insoluble) sulfate is required (e.g. BaSO₄);
(e) oxidation of metal sulfides or sulfites.

The sulfate ion is tetrahedral (S–O 149 pm) and can act as a monodentate, bidentate (chelating) or bridging ligand. Examples are in Fig. 15.29. Vibrational spectroscopy is a useful diagnostic, as the progressive reduction in local symmetry of the SO₄ group from Tₖ to C₃ᵥ and eventually C₂ᵥ increases the number of infrared active modes from 2 to 6 and 8 respectively, and the number of Raman active modes from 4 to 6 and 9.¹¹³ The effects of crystal symmetry and the overlapping of bands complicates the analysis but correct assignments are frequently still possible.)

Pairs of corner-shared SO₄ tetrahedra are found in the disulfates, S₂O₇²⁻ (S–Oₖ–S 124°, S–Oₖ 164.5 pm, S–Oₗ 144 pm); they are made by thermal dehydration of MHSO₄. Likewise the trisulfate ion S₃O₁₀²⁻ is known and also the pentasulfate ion, S₅O₁₆²⁻ whose structure indicates an alternation of S–O interatomic distances and very long O–S distances to the almost planar terminal SO₃ groups:

![Diagram of sulfate structure](image)

**Peroxosulfuric acids, H₂SO₅ and H₂S₂O₈**

Anhydrous peroxomonosulfuric acid (Caro’s acid) can be prepared by reacting chlorosulfuric acid with anhydrous H₂O₂:

\[ \text{HOOH} + \text{ClSO}_2\text{(OH)} \rightarrow \text{HOOSO}_2\text{(OH)} + \text{HCl} \]

$\text{MeCOOH} + \text{H}_2\text{SO}_4 \rightarrow \text{MeC(OH)}_2^- + \text{HSO}_4^-$

(d) Dehydration reactions:
$\text{HNO}_3 + 2\text{H}_2\text{SO}_4 \rightarrow \text{NO}_2^+ + \text{H}_3\text{O}^+ + 2\text{HSO}_4^-$
$\text{N}_2\text{O}_5 + 3\text{H}_2\text{SO}_4 \rightarrow 2\text{NO}_2^+ + \text{H}_3\text{O}^+ + 3\text{HSO}_4^-$

The reaction with $\text{HNO}_3$ is quantitative, and the presence of large concentrations of the nitronium ion, $\text{NO}_2^+$, in solutions of $\text{HNO}_3$, $\text{MNO}_3$ and $\text{N}_2\text{O}_5$ in $\text{H}_2\text{SO}_4$ enable a detailed interpretation to be given of the nitration of aromatic hydrocarbons by these solutions.

Because of the high acidity of $\text{H}_2\text{SO}_4$ itself, bases form the largest class of electrolytes and only few acids (proton donors) are known in this solvent system. As noted above, $\text{H}_2\text{S}_2\text{O}_7$ acts as a proton donor to $\text{H}_2\text{SO}_4$ and $\text{HSO}_3\text{F}$ is also a weak acid:
$\text{HSO}_3\text{F} + \text{H}_2\text{SO}_4 \rightleftharpoons \text{H}_3\text{SO}_4^+ + \text{SO}_3\text{F}^-$

One of the few strong acids is tetra(hydrogen sulfato)boric acid $\text{HB(HSO}_4)_4$; solutions of this can be obtained by dissolving boric acid in oleum:
$\text{B(OH)}_3 + 3\text{H}_2\text{S}_2\text{O}_7 \rightarrow \text{H}_3\text{SO}_4^+ + [\text{B(HSO}_4)_4]^-$
$+ \text{H}_2\text{SO}_4$

Other strong acids are $\text{H}_2\text{Sn(HSO}_4)_6$ and $\text{H}_2\text{Pb(HSO}_4)_6$.

Sulfuric acid forms salts (sulfates and hydrogen sulfates) with many metals. These are frequently very stable and, indeed, they are the most important mineral compounds of several of the more electropositive elements. They have been discussed in detail under the appropriate elements. Sulfates can be prepared by:

(a) dissolution of metals in aqueous $\text{H}_2\text{SO}_4$ (e.g. Fe);
(b) neutralization of aqueous $\text{H}_2\text{SO}_4$ with metal oxides or hydroxides (e.g. MOH);
(c) decomposition of salts of volatile acids (e.g. carbonates) with aqueous $\text{H}_2\text{SO}_4$;
(d) metathesis between a soluble sulfate and a soluble salt of the metal whose (insoluble) sulfate is required (e.g. $\text{BaSO}_4$);
(e) oxidation of metal sulfides or sulfites.

The sulfate ion is tetrahedral ($\text{S-O} 149\text{pm}$) and can act as a monodentate, bidentate (chelating) or bridging ligand. Examples are in Fig. 15.29. Vibrational spectroscopy is a useful diagnostic, as the progressive reduction in local symmetry of the SO$_4$ group from $T_d$ to $C_{3v}$, and eventually $C_{2v}$, increases the number of infrared active modes from 2 to 6 and 8 respectively, and the number of Raman active modes from 4 to 6 and 9. The effects of crystal symmetry and the overlapping of bands complicates the analysis but correct assignments are frequently still possible.

Pairs of corner-shared SO$_4$ tetrahedra are found in the disulfates, S$_2$O$_7^{2-}$ ($\text{S-O}_\mu-\text{S} 124^\circ$, S-O$_\mu$ 164.5 pm, S-O 144 pm); they are made by thermal dehydration of $\text{MHSO}_4$. Likewise the trisulfate ion S$_3$O$_{10}^{2-}$ is known and also the pentasulfate ion, S$_5$O$_{16}^{2-}$ whose structure indicates an alternation of S-O interatomic distances and very long O-S distances to the almost planar terminal SO$_3$ groups:

![Peroxosulfuric acids, H$_2$SO$_5$ and H$_2$S$_2$O$_8$](image)

**Peroxosulfuric acids, H$_2$SO$_5$ and H$_2$S$_2$O$_8$**

Anhydrous peroxomonosulfuric acid (Caro’s acid) can be prepared by reacting chlorosulfuric acid with anhydrous $\text{H}_2\text{O}_2$:
$\text{HOOH} + \text{ClSO}_2\text{(OH)} \rightarrow \text{HOOSO}_2\text{(OH)} + \text{HCl}$

It is colourless, beautifully crystalline, and melts at 45°, but should be handled carefully because of the danger of explosions. It can also be made by the action of conc H$_2$SO$_4$ on peroxodisulfates and is formed as a by-product during the preparation of H$_2$S$_2$O$_8$ by electrolysis of aqueous H$_2$SO$_4$ (N. Caro, 1898). Its salts, which are preferably called trioxoperoxosulfates(2-) rather than peroxomonosulfates,(194) are unstable and the compound has few uses except those dependent on the formation of the H$_2$O$_2$ during its decomposition. The structure of the anion [HOOSO$_3$]$^-$, which is the active principle of Caro's acid, has been determined by X-ray analysis of the hydrated salt KHSO$_5$H$_2$O; selected dimensions are O–O 140.0, S–O$_2$ 163.2, S–O$_1$ 143.5–144.4 pm, angle OOS 109.4°.(195)

Peroxodisulfuric acid, H$_2$S$_2$O$_8$, is a colourless solid mp 65° (with decomposition). The acid is soluble in water in all proportions and its most important salts, (NH$_4$)$_2$S$_2$O$_8$ and K$_2$S$_2$O$_8$, are also freely soluble. These salts are, in fact, easier to prepare than the acid and both are made on an industrial scale by anodic oxidation of the corresponding sulfates under carefully controlled conditions (high current density, $T < 30°$, bright Pt electrodes, protected cathode). The structure of the peroxodisulfate ion [now preferably called hexaoxo-µ-peroxodisulfate(2-)](194) is O$_3$SOOSO$_3^{2-}$ with O–O 131 pm and S–O 150 pm. The compounds are used as oxidizing and bleaching agents. Thus, as can be seen from Table 15.19, the standard reduction potential S$_2$O$_8^{2-}$/HSO$_4^-$ is 2.123 V, and $E^\circ$ (S$_2$O$_8^{2-}$/SO$_4^{2-}$) is similar (2.010 V); these are more positive than for any other aqueous couples except H$_2$N$_2$O$_2$, 2H$^+$/N$_2$, 2H$_2$O (2.85 V), F$_2$/2F$^-$ (2.87 V) and F$_2$,2H$^+$/2HF(aq) (3.06) — see also O(g), 2H$^+/H_2$O (2.42 V), OH,H$^+/H_2$O (2.8 V).

---

**Thiosulfuric acid, H₂S₂O₃**

Attempts to prepare thiosulfuric acid by acidification of stable thiosulfates are invariably thwarted by the ready decomposition of the free acid in the presence of water. The reaction is extremely complex and depends on the conditions used, being dominated by numerous redox interconversions amongst the products: these can include sulfur (partly as \( \text{CyCbs}_6 \)), \( \text{SO}_2 \), \( \text{H}_2\text{S} \), \( \text{H}_2\text{S}_n \), \( \text{H}_2\text{SO}_4 \) and various polythionates. In the absence of water, however, these reactions are avoided and the parent acid is more stable: it decomposes quantitatively below 0° according to the reaction \( \text{H}_2\text{S}_2\text{O}_3 \rightarrow \text{H}_2\text{S} + \text{SO}_3 \) (cf. the analogous decomposition of \( \text{H}_2\text{SO}_4 \) to \( \text{H}_2\text{O} \) and \( \text{SO}_3 \) above its bp \( \sim 300° \)). Successful anhydrous syntheses have been devised by M. Schmidt and his group (1959–61), e.g.:

\[
\begin{align*}
\text{H}_2\text{S} + \text{SO}_3 & \xrightarrow{\text{Et}_2\text{O}/-78°} \text{H}_2\text{S}_2\text{O}_3.n\text{Et}_2\text{O} \\
\text{Na}_2\text{S}_2\text{O}_3 + 2\text{HCl} & \xrightarrow{\text{Et}_2\text{O}/-78°} 2\text{NaCl} + \text{H}_2\text{S}_2\text{O}_3.2\text{Et}_2\text{O} \\
\text{HSO}_3\text{Cl} + \text{H}_2\text{S} & \xrightarrow{\text{no solvent}} \text{HCl} + \text{H}_2\text{S}_2\text{O}_3 \\
& \xrightarrow{\text{low temp}} \text{(solvent-free acid)}
\end{align*}
\]

Combination of stoichiometric amounts of \( \text{H}_2\text{S} \) and \( \text{SO}_3 \) at low temperature yields the white crystalline adduct \( \text{H}_2\text{S}_2\text{SO}_3 \) which is isomeric with thiosulfuric acid.

In contrast to the free acid, stable thiosulfate salts can readily be prepared by reaction of \( \text{H}_2\text{S} \) on aqueous solutions of sulfites:

\[
2\text{HS}^- + 4\text{HSO}_3^- \rightarrow 3\text{S}_2\text{O}_3^{2-} + 3\text{H}_2\text{O}
\]

The reaction appears to proceed first by the formation of elemental sulfur which then equilibrates with more \( \text{HSO}_3^- \) to form the product:

\[
2\text{HS}^- + \text{HSO}_3^- \rightarrow 3\text{S} + 3\text{OH}^- \\
3\text{S} + 3\text{HSO}_3^- \rightarrow 3\text{S}_2\text{O}_3^{2-} + 3\text{H}^+
\]

---

197 See p. 723 of ref. 103 for detailed references.
This reaction is the basis for the use of thiosulfates as “antichlorine” in the bleaching industry where they are used to destroy any excess of Cl₂ in the fibres. Bromine, being intermediate between iodine and chlorine, can cause S₂O₃²⁻ to act either as a 1-electron or an 8-electron reducer according to conditions. For example, in an amusing and instructive experiment, if concentrated aqueous solutions of S₂O₃²⁻ and Br₂ are titrated, and the titration is then repeated after having diluted both the S₂O₃²⁻ and Br₂ solutions 100-fold, then the titre will be found to have increased by a factor of exactly 8.

**Figure 15.30** Structure of the thiosulfate ion and its various modes of coordination: (a) uncoordinated S₂O₃²⁻; (b) monodentate (η¹-S) in the anion of the orange complex [Pd⁰(en)₂][Pd⁰(en)(S₂O₃)₂]; (c) monohapto bidentate bridging (μ,η¹-S) in the polymeric anion of the pale-violet mixed valence copper complex Na₄[Cu⁰(NH₃)₄][Cu¹(S₂O₃)₂]; and (d) dihapto chelating (η²-S, O) in the thiourea nickel complex [Ni(S₂O₃)(tu)₄].H₂O.

**Dithionic acid, H₂S₂O₆**

In dithionic acid and dithionates, S₂O₆²⁻, the oxidation state of the 2 S atoms has been reduced from VI to V by the formation of an S–S bond (Table 15.18, p. 705). The free acid has not been obtained pure, but quite concentrated aqueous solutions can be prepared by treatment of the barium salt with the stoichiometric amount of H₂SO₄:

$$\text{BaS}_2\text{O}_6(\text{aq}) + \text{H}_2\text{SO}_4(\text{aq}) \rightarrow \text{H}_2\text{S}_2\text{O}_6(\text{aq}) + \text{BaSO}_4\downarrow$$
Crystalline dithionates are thermally stable above room temperature (e.g. $K_2S_2O_6$ decomposes to $K_2SO_4 + SO_2$). They are commonly made by oxidizing the corresponding sulfite. On a technical scale aqueous solutions of $SO_2$ are oxidized by a suspension of hydrated $MnO_2$ or $Fe_2O_3$:

$$2MnO_2 + 3SO_2 \rightarrow MnSO_4 + MnS_2O_6$$

$$Fe_2O_3 + 3SO_2 \rightarrow \{Fe^{II}(SO_3)_3\} \rightarrow Fe^{II}SO_3 + Fe^{II}S_2O_6$$

All the dithionates are readily soluble in water and can be made by standard metathesis reactions. For example, addition of an excess of $Ba^{II}$ ions to the $Mn^{II}$ solution above precipitates $BaSO_4$, after which $BaS_2O_6.2H_2O$ can be crystallized. The $[O_3S(SO_3)]^{2-}$ ion is centrosymmetric (staggered) $D_{3d}$ in $Na_2S_2O_6.2H_2O$ but in the anhydrous potassium salt some of the $S_2O_6^{2-}$ ions have an almost eclipsed configuration for the two $SO_3$ groups ($D_{4b}$). Dimensions are unremarkable: $S-S 215$ pm, $S-O 143$ pm, and angle $S-S-O 103^\circ$. In a curious reaction between dibenzenechromium(0) and dry, oxygen-free $SO_2$ in toluene, a red precipitate is formed which subsequently turns black. The unexpected product is $[(\eta^6-C_6H_6)Cr]_2[S_4O_{10}]$, which contains the dianion $[S_4O_{10}]^{2-}$ formed by coordination of two $SO_2$ molecules to a dithionate ion, $[O_2S \rightarrow OS(O_2S)O \rightarrow SO_2]^{2-}$ with $S-S 221.8$ pm, $S-O 243.3$ pm and angle $S-O-S 129.3^\circ$ (198).

Dithionates are relatively stable towards oxidation in solution though strong oxidants such as the halogens, dichromate and permanganate oxidize them to sulfate. Powerful reductants (e.g. $Na/Hg$) reduce dithionates to sulfites and dithionites ($S_2O_3^{2-}$). In neutral and slightly acidic aqueous solutions dithionate itself decomposes by pH-dependent routes to thiosulfite ($S_2O_3^{2-}$), sulfite ($SO_3^{2-}$), sulfide ($S^{2-}$), etc. These, and the products of the reactions of dithionites with polythionates ($S_nO_6^{2-}, n = 3-5$) have been studied by ion-pair chromatography (199).

$$S_2O_4^{2-} + S_nO_6^{2-} + 2H_2O \rightarrow S_2O_3^{2-} + S_{n-3}SO_3^{2-} + 4H^+ + 2SO_3^{2-}$$

The numerous acids and salts in this group have a venerable history and the chemistry of systems in which they occur goes back to John Dalton's studies (1808) of the effect of $H_2S$ on aqueous solutions of $SO_2$. Such solutions are now named after H. W. F. Wackenroder (1846) who subjected them to systematic study. Work during the following 60-80 y indicated the presence of numerous species including, in particular, the tetrathionate $S_4O_6^{2-}$ and pentathionate $S_5O_6^{2-}$ ions. New perceptions have emerged during the past few decades as a result of the work of H. Schmidt and others in Germany: just as $H_2S$ can react with $SO_3$ or $HSO_3Cl$ to yield thiosulfuric acid, $H_2S_2O_3$ (p. 714), so reaction with $H_2S_2$ yields “disulfane monosulfonic acid”, $HS_2SO_3H$; likewise polysulfanes $H_2S_n (n = 2-6)$ yield $HS_nSO_3H$. Reaction at both ends of the polysulfane chain would yield “polysulfane disulfonic acids” $H_03SSnSO_3H$ which are more commonly called polythionic acids ($H_2Sn+2O_6$). Many synthetic routes are available, though mechanistic details are frequently obscure because of the numerous simultaneous and competing redox, catenation and disproportionation reactions that occur. Typical examples include:

(a) Interaction of $H_2S$ and $SO_2$ in Wackenroder’s solution (see above).

(b) Reaction of chlorosulfanes with $HSO_3^-$ or $HS_2O_3^-$, e.g.:

$$SCl_2 + 2HSO_3^- \rightarrow [O_3SSSO_3]^{2-} + 2HCl$$

$$S_2Cl_2 + 2HSO_3^- \rightarrow [O_3SS_2SO_3]^{2-} + 2HCl$$

Oxoids of sulfur 717

(c) Oxidation of thiosulfates with mild oxidants (p. 714) such as I₂, Cu²⁺, S₂O₈²⁻, H₂O₂.

(d) Specific syntheses as noted below.

Sodium trithionate, Na₂S₃O₆, can be made by oxidizing sodium thiosulfate with cooled hydrogen peroxide solution

\[ 2\text{Na}_2\text{S}_2\text{O}_3 + 4\text{H}_2\text{O}_2 \rightarrow \text{Na}_2\text{S}_3\text{O}_6 + \text{Na}_2\text{SO}_4 + 4\text{H}_2\text{O} \]

The potassium (but not the sodium) salt is obtained by the obscure reaction of SO₂ on aqueous thiosulfate. Aqueous solutions of the acid H₂S₃O₆ can then be obtained from K₂S₃O₆ by treatment with tartaric acid or perchloric acid.

Sodium (and potassium) tetrathionate, M₂S₄O₆, can be made by oxidation of thiosulfate by I₂ (p. 714) and the free acid liberated (in aqueous solution) by addition of the stoichiometric amount of tartaric acid.

Potassium pentathionate, K₂S₅O₆, can be made by adding potassium acetate to Wackenroder’s solution and solutions of the free acid H₂S₅O₆ can then be obtained by subsequent addition of tartaric acid.

Potassium hexathionate, K₂S₆O₆, is best synthesized by the action of KNO₂ on K₂S₂O₃ in conc HCl at low temperatures, though the ion is also a constituent of Wackenroder’s solution.

Anhydrous polythionic acids can be made in ether solution by three general routes:

\[ \text{HS}_n\text{SO}_3\text{H} + \text{SO}_3 \rightarrow \text{H}_2\text{S}_{n+2}\text{O}_6 \]

\[ (n + 2 = 3, 4, 5, 6, 7, 8) \]

\[ \text{H}_2\text{S}_n + 2\text{SO}_3 \rightarrow \text{H}_2\text{S}_{n+2}\text{O}_6 \]

\[ (n + 2 = 3, 4, 5, 6, 7, 8) \]

\[ 2\text{HS}_n\text{SO}_3\text{H} + \text{I}_2 \rightarrow \text{H}_2\text{S}_{2n+2}\text{O}_6 + 2\text{HI} \]

\[ (2n + 2 = 4, 6, 8, 10, 12, 14) \]

The structure of the trithionate ion (in K₂S₃O₆) is shown in Fig. 15.31a and calls for little comment (cf. the disulfate ion O₃SOSO₃²⁻, p. 712). The tetrathionate ion (in BaS₄O₆·2H₂O and Na₂S₄O₆·2H₂O) has the configuration shown in Fig. 15.31b with dihedral angles close to 90° and a small, but definite, alternation in S–S distances. The pentathionate ion in BaS₅O₆·2H₂O has the cis configuration in which the S₅ unit can be regarded as part of an S₈ ring (p. 655) from which 3 adjacent S atoms have been removed (Fig. 15.31c). By contrast, in the potassium salt K₂S₅O₆·1½H₂O the pentathionate ion adopts the trans configuration in which the two terminal SO₄ groups are on opposite sides of the central S₃ plane (Fig. 15.31d).

These structural differences persist in the seleno- and telluro-analogues O₃S²SeS₄O₃²⁻ and O₃S²TeSSO₃²⁻, the dihydrated Ba salts being cis and the potassium hemihydrates being trans. There are three possible rotamic forms of the hexathionate ion S₆O₆²⁻: the extended trans-trans form analogous to spiral chains of fibrous sulfur (p. 660) occurs in the trans-[Co⁺⁺(en)₂Cl₂]⁺ salt (Fig. 15.31e), whereas the cis-cis form (analogous to cyclo-S₈) occurs in the potassium barium salt (Fig. 15.31f); the cis-trans form of S₆O₆²⁻ has not yet been observed in crystals but presumably occurs in equilibrium with the other two forms in solution since the energy barrier to rotation about the S–S bonds is only some 40 kJ mol⁻¹.

Sulfurous acid, H₂SO₃

Sulfurous acid has never been isolated as a pure compound, although it has recently been detected in the gas phase by neutralization reionization mass spectrometry (NRMS) following the facile dissociative ionization (70 eV) of either diethyl sulfite or ethanesulfonic acid: \(^{200}\)

---

The experimental finding was substantiated by high-level \textit{ab initio} calculations. The unionized acid exists in only minute concentrations (if at all) in aqueous solutions of SO$_2$. However, its salts, the sulfites, are quite stable and many are known.
§15.2.6 Oxoacids of sulfur

in crystalline form; a second series of salts, the hydrogen sulfites HSO₃⁻, are known in solution. Spectroscopic studies of aqueous solutions of SO₂ suggest that the predominant species are various hydrates, SO₂.nH₂O; depending on the concentration, temperature and pH, the ions present are H₃O⁺, HSO₃⁻ and S₂O₄²⁻ together with traces of SO₃²⁻. The undissociated acid OS(OH)₂ has not been detected:

\[
\text{SO}_2.n\text{H}_2\text{O} \leftrightarrow \text{H}_2\text{SO}_3(\text{aq}); \quad K \ll 10^{-9}
\]

The first acid dissociation constant of “sulfurous acid” in aqueous solution is therefore defined as:

\[
\text{H}_2\text{O} + \text{SO}_2.n\text{H}_2\text{O} \leftrightarrow \text{H}_3\text{O}^+ + \text{HSO}_3^-(\text{aq});
\]

\[
K_1(25^\circ) = 1.6 \times 10^{-2} \text{ mol}^{-1}
\]

where

\[
K_1 = \frac{[\text{H}_3\text{O}^+][\text{HSO}_3^-]}{[\text{total dissolved SO}_2] - [\text{HSO}_3^-] - [\text{SO}_3^{2-}]}
\]

The second dissociation constant is given by the equation

\[
\text{HSO}_3^- + \text{H}_2\text{O} \leftrightarrow \text{H}_3\text{O}^+ + \text{SO}_3^{2-};
\]

\[
K_2(25^\circ) = 1.0 \times 10^{-7} \text{ mol}^{-1}
\]

The sulfite ion SO₃²⁻ is pyramidal with C₃ᵥ symmetry: angle O-S-O 106°, S-O 151 pm. The hydrogen sulfite ion also appears to have C₃ᵥ symmetry both in the solid state and in solution, i.e. protonation occurs at S rather than O to give H-SO₃⁻ rather than HO-SO₃⁻ (C₃ᵥ symmetry). However, recent ¹⁷O nmr studies appear to provide evidence for the existence in solution of a dynamic equilibrium between the two isomers: H-SO₃⁻ ≡ HO-SO₃⁻.²⁰³

The sulfite ion also coordinates through S in transition-metal complexes, e.g. [Pd(NH₃)₃(η¹-SO₃)]⁻, cis- and trans-[Pt(NH₃)₂(η¹-SO₃)]²⁻.

The structure of hydrogen-sulfito complex trans-[Ru(H₂(NH₃)₄(SO₃H)₂] is also S-bonded, implying a 1,2 proton shift to give M[S₂O₄(OH)]⁻.²⁰⁴

Sulfites and hydrogen sulfites are moderately strong reducing agents (p. 706) and, depending on conditions, are oxidized either to dithionate or sulfate. The reaction with iodine is quantitative and is used in volumetric analysis:

\[
\text{HSO}_3^- + \text{I}_2 + \text{H}_2\text{O} \rightarrow \text{H}_2\text{SO}_4^- + 2\text{H}^+ + 2\text{I}^-
\]

Conversely, sulfites can act as oxidants in the presence of strong reducing agents; e.g. sodium amalgam yields dithionite, and formates (in being oxidized to oxalates) yield thiosulfate:

\[
2\text{SO}_2^{2-} + 2\text{H}_2\text{O} + 2\text{NaHg} \rightarrow \text{S}_2\text{O}_4^{2-} + 4\text{OH}^- + 2\text{Na}^+
\]

\[
2\text{SO}_3^{2-} + 4\text{HCO}_3^- \rightarrow \text{SSO}_3^{2-} + 2\text{C}_2\text{O}_4^{2-} + 2\text{OH}^- + \text{H}_2\text{O}
\]

Thiosulfates also result from reduction of SO₃²⁻ or HSO₃⁻ with elemental sulfur (p. 714), whereas reduction with H₂S in Wackenroder’s solution (pp. 716-7) yields polythionates. It is also notable that the sulfite ion is involved in the 6-electron sulfite reductase reaction: SO₃²⁻ + 6H⁺ + 6e⁻ → S²⁻ + 3H₂O; E° = 0.380 V. Indeed, there are three such 6e⁻ reductions known in the whole of biology, the other two being nitrite reductase (NO₂⁻ + 7H⁺ + 6e⁻ → NH₃ + 2H₂O) and nitrogenase (N₂ + 6H⁺ + 6e⁻ → 2NH₃).

On a technical scale, solutions of sodium hydrogen sulfite are prepared by passing SO₂ to give H-SO₃⁻ rather than HO-SO₃⁻ (C₃ᵥ symmetry). However, recent ¹⁷O nmr studies appear to provide evidence for the existence in solution of a dynamic equilibrium between the two isomers: H-SO₃⁻ ≡ HO-SO₃⁻.²⁰³

into aqueous Na₂CO₃. As shown in the Scheme above, addition of a further equivalent of Na₂CO₃ allows the normal sulfite to be crystallized, whereas addition of more SO₂ yields the disulfite (see the next subsection below).

Crystallization of Na₂SO₃ above 37°C gives the anhydrous salt; below this temperature Na₂SO₃.7H₂O is obtained. World production of the anhydrous salt exceeds 1 million tonnes pa; most is used in the paper pulp industry, but other applications are as an O₂ scavenger in boiler-water treatment, and as a reducing agent in photography. Similarly, K₂SO₃.2H₂O is obtained by passing SO₂ into aqueous KOH until samples of the solution are neutral to phenolphthalein. For a compilation of critically evaluated solubility data, see ref. 205

**Disulfurous acid, H₂S₂O₅**

Like “sulfurous acid”, disulfurous acid is unknown either in the free state or in solution. However, as indicated in the preceding section, its salts, are readily obtained from concentrated solutions of hydrogen sulfite:

\[ 2\text{HSO}_3^- \rightleftharpoons S_2\text{O}_5^{2-} + \text{H}_2\text{O} \]

Unlike disulfates (p. 712), diphosphates (p. 522), etc., disulfites condense by forming an S–S bond. As indicated in Fig. 15.32a this S–S bond is rather long, but the S–O distances are unexceptional.

Acidification of solutions of disulfites regenerates HSO₃⁻ and SO₂ again, and the solution chemistry of S₂O₅²⁻ is essentially that of the normal sulfites and hydrogen sulfites, despite the formal presence of S⁵⁺ and S³⁺ (rather than S⁴⁺) in the solid state.

**Dithionous acid, H₂S₂O₄**

Dithionites, S₂O₄²⁻ are quite stable when anhydrous, but in the presence of water they disproportionate (slowly at pH ≥ 7, rapidly in acid solution):

\[ 2\text{S}_2\text{O}_4^{2-} + \text{H}_2\text{O} \rightarrow 2\text{HSO}_3^- + \text{SSO}_3^{2-} \]

The parent acid has no independent existence and has not been detected in aqueous solution either. Sodium dithionite is widely used as an industrial reducing agent and can be prepared by reduction of sulfite using Zn dust, Na/Hg or electrolytically, e.g.:

\[ 2\text{HSO}_3^- + \text{SO}_2.n\text{H}_2\text{O} + 2\text{Zn} \rightarrow \text{ZnSO}_3 \]

\[ \text{III} + \text{ZnS}_2\text{O}_4 + (n + 2)\text{H}_2\text{O} \]

The dihydrate Na₂S₂O₄.2H₂O can be precipitated by “salting out” with NaCl. Air and oxygen must be excluded at all stages in the process to avoid reoxidation. The dithionite ion can also be produced in situ on an industrial scale by reaction
between NaHSO₃ and NaBH₄ (p. 167). Its main use is as a reducing agent in dyeing, bleaching of paper pulp, straw, clay, soaps, etc., and in chemical reductions (see below). Current worldwide demand is about 300,000 tonnes per annum.

The dithionite ion has a remarkable eclipsed structure of approximate \( C_{2v} \) symmetry (Fig. 15.32b). The extraordinarily long S–S distance (239 pm) and the almost parallel SO₂ planes (dihedral angle 30°) are other unusual features. Electron-spin-resonance studies have shown the presence of the SO₂⁻ radical ion in solution (~300 ppm), suggesting the establishment of a monomer-dimer equilibrium \( S_2O_4^{2-} \rightleftharpoons 2SO_2 \). Consistent with this, air-oxidation of alkaline dithionite solutions at 30–60° are of order one-half with respect to \([S_2O_4^{2-}]\). Acid hydrolysis (second order with respect to \([S_2O_4^{2-}]\)) yields thiosulfate and hydrogen sulfite, whereas alkaline hydrolysis produces sulfite and sulfide:

\[
2S_2O_4^{2-} + H_2O \rightarrow S_2O_3^{2-} + 2HSO_3^- \\
3Na_2S_2O_4 + 6NaOH \rightarrow 5Na_2SO_3 + Na_2S + 3H_2O
\]

Hydrated dithionites can be dehydrated by gentle warming, but the anhydrous salts themselves decompose on further heating. For example, \( Na_2S_2O_4 \) decomposes rapidly at 150° and violently at 190°:

\[
2Na_2S_2O_4 \rightarrow Na_2S_2O_3 + Na_2SO_3 + SO_2
\]

Dithionites are strong reducing agents and will reduce dissolved \( O_2, H_2O_2, I_2, IO_3^- \) and \( MnO_4^- \). Likewise \( Cr^{VI} \) is reduced to \( Cr^{III} \) and \( TiO^{2+} \) to \( Ti^{III} \). Heavy metal ions such as \( Cu^{I}, Ag^{I}, Pb^{II}, Sb^{III} \) and \( Bi^{III} \) are reduced to the metal. Many of these reactions are useful in water-treatment and pollution control.

15.2.7 Sulfur–nitrogen compounds (206–210)

The study of S–N compounds is one of the most active areas of current inorganic research: many novel cyclic and acyclic compounds are being prepared which have unusual structures and which pose considerable problems in terms of simple bonding theory. The discovery in 1975 that the polymer \((SN)_x\) is a metal whose conductivity increases with decrease in

---

between NaHSO₃ and NaBH₄ (p. 167). Its main use is as a reducing agent in dyeing, bleaching of paper pulp, straw, clay, soaps, etc., and in chemical reductions (see below). Current worldwide demand is about 300,000 tonnes per annum.

The dithionite ion has a remarkable eclipsed structure of approximate $C_{2v}$ symmetry (Fig. 15.32b). The extraordinarily long S–S distance (239 pm) and the almost parallel SO$_2$ planes (dihedral angle 30°) are other unusual features. Electron-spin-resonance studies have shown the presence of the SO$_2^-$ radical ion in solution (~300 ppm), suggesting the establishment of a monomer-dimer equilibrium $S_2O_4^{2-} \rightleftharpoons 2SO_2^-$. Consistent with this, air-oxidation of alkaline dithionite solutions at 30–60° are of order one-half with respect to [S$_2$O$_4^{2-}$]. Acid hydrolysis (second order with respect to [S$_2$O$_4^{2-}$]) yields thiosulfate and hydrogen sulfite, whereas alkaline hydrolysis produces sulfite and sulfide:

$$2S_2O_4^{2-} + H_2O \rightarrow S_2O_3^{2-} + 2HSO_3^-$$

$$3Na_2S_2O_4 + 6NaOH \rightarrow 5Na_2SO_3 + Na_2S + 3H_2O$$

Hydrated dithionites can be dehydrated by gentle warming, but the anhydrous salts themselves decompose on further heating. For example, Na$_2$S$_2$O$_4$ decomposes rapidly at 150° and violently at 190°:

$$2Na_2S_2O_4 \rightarrow Na_2S_2O_3 + Na_2SO_3 + SO_2$$

Dithionites are strong reducing agents and will reduce dissolved O$_2$, H$_2$O$_2$, I$_2$, IO$_3^-$ and MnO$_4^-$. Likewise Cr$^{VI}$ is reduced to Cr$^{III}$ and TiO$_2^+$ to Ti$^{III}$. Heavy metal ions such as Cu$^I$, Ag$^I$, Pb$^{II}$, Sb$^{III}$ and Bi$^{III}$ are reduced to the metal. Many of these reactions are useful in water-treatment and pollution control.

### §15.2.7 Sulfur–nitrogen compounds

The study of S–N compounds is one of the most active areas of current inorganic research: many novel cyclic and acyclic compounds are being prepared which have unusual structures and which pose considerable problems in terms of simple bonding theory. The discovery in 1975 that the polymer (SN)$_x$ is a metal whose conductivity increases with decrease in

---

temperature and which becomes superconducting below 0.33 K aroused tremendous additional interest and has stimulated still further the already substantial activity in this area of synthetic and structural chemistry. The field is not new. S₄N₄ was first prepared in an impure form by W. Gregory in 1835, though the stoichiometry and tetrameric nature of the pure compound were not established until 1851 and 1896 respectively, and its cyclic, pseudo-cluster structure was not revealed until 1944. Other important compounds containing S–N bonds that date from the first half of the nineteenth century include sulfamic acid H[H₂NSO₃], imidosulfonic acid HSO₃N=NH, sulfamide SO₂(NH₂)₂, nitrolitrisulfonic acid N(HSO₃)₃, hydroxy nitrilosulfonic acids HSO₃NH(OH) and (HSO₃)₂N(OH), and their many derivatives. It will be convenient to describe first the binary sulfur nitrides SₐN₆ and then the related cationic and anionic species, SₐN₇⁺, SₐN₇⁻. The sulfur imides and other cyclic S–N compounds will then be discussed and this will be followed by sections on S–N–halogen and S–N–O compounds. Several compounds which feature isolated S–N, S–N, S=N and S=N bonds have already been mentioned in the section on SF₄; e.g. F₄S=NCS₂H₅, F₅S–NF₂, F₃S=NCF₃, and F₃S≡N (p. 687). However, many SN compounds do not lend themselves to simple bond diagrams, and formal oxidation states are often unhelpful or even misleading.

Binary sulfur nitrides

There is little structural similarity between the sulfur nitrides and the oxides of nitrogen (p. 443). The instability of NS when compared with the great stability of NO, and the paucity of thionitrosyl complexes have already been mentioned (p. 453), as has the difference between diatomic O₂ and oligomeric or polymeric S₈. The compounds to be considered in this section are S₄N₄, cyclo-S₂N₂ and catena-(SN), polymer, together with cyclo-S₄N₂, bicyclo-S₃N₂, and the higher homologues S₁₅N₂, S₁₆N₂, S₁₇N₂ and S₁₉N₂. More recently, crystalline S₅N₆ (the first binary sulfur nitride with more atoms of N than S) has been synthesized. The fugitive radicals SN⁺ and S₃N; have also been characterized. (a) Tetrasulfur tetranitride, S₄N₄. This is the most readily prepared sulfur nitride and is an important starting point for the preparation of many S–N compounds. It is obtained as orange-yellow, air-stable crystals by passing NH₃ gas into a warm solution of S₂Cl₂ (or SC₁₂) in CCl₄ or benzene; the overall stoichiometries of the mechanistically obscure reactions are:

\[ 6S₂Cl₂ + 16NH₃ \rightarrow 50^\circ \rightarrow S₄N₄ + 8S + 12NH₄Cl \]
\[ 6SCl₂ + 16NH₃ \rightarrow S₄N₄ + 2S + 14NH₄Cl \]

Alternatively, NH₄Cl can be heated with S₂Cl₂ at 160°C:

\[ 6S₂Cl₂ + 4NH₄Cl \rightarrow 26\% \text{ yield} \rightarrow S₄N₄ + 8S + 16HCl \]

References:

The compound also results from the reversible equilibrium reaction of sulfur with anhydrous liquid ammonia:

$$10S + 4NH_3 \rightleftharpoons S_4N_4 + 6H_2S$$

The $H_2S$, of course, reacts with further ammonia to form ammonium sulfides but the reaction can be made to proceed in the forward direction as written by addition of (soluble) AgI to precipitate AgS and form NH$_4$I.

$S_4N_4$ is kinetically stable in air but is endothermic with respect to its elements ($\Delta H_f$ 460 ± 8 kJ mol$^{-1}$) and may detonate when struck or when heated rapidly. This is due more to the stability of elemental sulfur and the great bond strength of $N_2$ rather than to any inherent weakness in the $S$-$N$ bonds. On careful heating $S_4N_4$ melts at 178.2°. The structure (Fig. 15.33a) is an 8-membered heterocycle in the extreme cradle configuration; it has $D_{2d}$ symmetry and resembles that of As$_2$S$_4$ (p. 579) but with the sites of the Group 15 and Group 16 elements interchanged. The $S$-$N$ distance of 162 pm is rather short when compared with the sum of the covalent radii (178 pm) and this, coupled with the equality of all the $S$-$N$ bond distances in the molecule, has been attributed to some electron delocalization in the heterocycle. The trans-annular $S$-$S$ distances (258 pm) are intermediate between bonding $S$-$S$ (208 pm) and nonbonding van der Waals (330 pm) distances; this suggests a weak but structurally significant bonding interaction between the pairs of $S$ atoms. A study by gas-phase electron diffraction yields similar dimensions except that the trans-annular $S$-$S$ distance is slightly longer (266.6 pm) probably because of the absence of constraining crystal packing forces.\(^{[213]}\)

It is not possible to write down a single, satisfactory, classical bonding diagram for $S_4N_4$ and, in valence-bond theory, numerous resonance hybrids must be considered of which the following are typical:

\[\begin{array}{c}
\begin{array}{c}
N-S\equiv N \\
S \quad S \\
N-S\equiv N \\
\end{array}
\end{array}\]

The extent to which each hybrid is incorporated into the full bonding description of the molecule will depend on the extent to which 3d orbitals

\[^{[213]}\text{A. J. DOWNS, T. L. JEFFERY and K. HAGEN, Polyhedron 8, 2631–6 (1989).}\]
on S are involved and the extent of trans-annular S–S bonding. More recent MO-calculations lead to semiquantitative estimates of these features and to electron charge densities on the individual atoms.\(^{(212)}\) It is also instructive to compare the structure of the 44-(valence)electron species \(S_4N_4\) with those of the 46-electron species \(S_8^{2+}\) (p. 665) and the 48-electron species \(S_8\) (p. 655): successive formal addition of 2 and then 4 electron results in the progressive opening of the \(S_4N_4\) pseudocluster first to the \(bicyclic\)-\(S_8^{2+}\) with a single weak trans-annular S–S bond and then to the open-crown structure of \(S_8\) with no trans-annular bonding at all.

Interestingly, in the N-donor adducts \(S_4N_4BF_3\) and \(S_4N_4SbCl_3\), the \(S_4N_4\) ring adopts the alternative \(D_{2d}\) configuration of \(As_4S_4\), with the 4 S atoms now coplanar instead of the 4 N atoms; the mean S–N distance increases slightly to 168 pm but the (nonbonding) trans-annular S–S distances are 380 pm. The same interchange occurs in \(S_4N_4SO_3\) and Fig. 15.33b shows the substantial alternations in S–N distances and angles that are concurrently introduced into the ring. Likewise in the burgundy red salt \([S_4N_4H]^+\left[BF_4\right]^{-}\), formed by direct protonation of \(S_4N_4\) by \(HBF_4\cdot Et_2O\) (S–N 157 pm, S–NH\(^+\) 165 pm),\(^{(214)}\) By contrast, in \(S_4N_4CuCl\) the heterocycle acts as a bridging ligand between zigzag chains of \((-Cu–Cl-)\)\(_{\infty}\); the \(S_4N_4\) retains the same conformation and almost the same dimensions as in the free molecule, with 2 of the 4 planar N atoms acting as a \(cisoid\) bridge and the 2 trans-annular S–S distances remaining short (259 and 263 pm).\(^{(215)}\) It is not yet clear in detail what factors determine the ring conformation adopted (see also p. 656). Other complexes are mentioned below.

\(S_4N_4\) is insoluble in and unreactive towards water but readily undergoes base hydrolysis with dilute NaOH solutions to give thiosulfate, trithionate and ammonia:

\[
2S_4N_4 + 6OH^- + 9H_2O \rightarrow S_2O_3^{2-} + 2S_3O_6^{2-} + 8NH_3
\]

More concentrated alkali yields sulfite instead of trithionate:

\[
S_4N_4 + 6OH^- + 3H_2O \rightarrow S_2O_3^{2-} + 2SO_3^{2-} + 4NH_3
\]

Milder bases such as Et\(_2\)NH leave some of the S–N bonds intact to yield, for example, \(S(\text{NEt}_2)_2\). The value of \(S_4N_4\) as a synthetic intermediate can be gauged from the representative reactions in the Scheme below\(^{(210)}\) and in Table 15.22. It can be seen that these reactions embrace:

(a) conservation of the 8-membered heterocycle and attachment of substituents to S or N (or subrogation of N by S);
(b) ring contraction to a 7-, 6-, 5- or 4-membered heterocycle with or without attachment of substituents;
(c) ring fragmentation into non-cyclic S–N groups (which sometimes then coordinate to metal centres);
(d) complete cleavage of all S–N bonds;
(e) formation of more complex heterocycles with 3 (or more) different heteroatoms.

Table 15.22 Some further reactions of $\text{S}_4\text{N}_4$\textsuperscript{(206-210)}

</table>

The molecular structures of the products are described as indicated at appropriate points in the text. $\text{S}_3\text{N}_2$O$_2$ was at one time thought to be cyclic but X-ray diffraction analysis has revealed an open chain structure (Fig. 15.34a).\textsuperscript{(217)} The structure of $\text{[Pt($\text{S}_2$N$_2$H)$_2$]}$ (Fig. 15.34b) is typical of several such compounds. When $\text{S}_4\text{N}_4$ reacts with metal carbonyls in aprotic media, the products are the structurally similar $\text{[M($\text{S}_2$N$_2$H)$_2$]}$ (M = Fe, Co, Ni). The pyramidal Pb$^\text{II}$ complex (Fig. 15.34c) is also notable, and features unequal S-N distances consistent with the bonding indicated. Still further reaction types are continually being discovered. For example, with the diphosphines $\text{Ph}_2$P($\text{X}$)PPh$_2$ ($\text{X} = \text{CH}_2\text{CH}_2$ or NC$_2$H$_4$), $\text{S}_4\text{N}_4$ yields ($\text{N}_3$S$_3$)-NPPh$_2$/PPh$_2$N-($\text{S}_3$N$_3$)$\textsuperscript{(218)}$ whereas with platinum-metal complexes it forms adducts of the tridentate S,S,N-ligand $\text{[PtCl}_2($\text{S}_4$\text{N}_4$)-(PMe$_2$Ph)$]$ (Fig 15.34e).\textsuperscript{(220)}

(b) Disulfur dinitrogen, $\text{S}_2\text{N}_2$. When $\text{S}_4\text{N}_4$ is carefully depolymerized by passing the heated vapour over Ag wool at 250-300° and 0.1-1.0 mmHg, the unstable cyclic dimer $\text{S}_2\text{N}_2$ is obtained. The main purpose of the silver is to remove sulfur generated by the thermal decomposition of $\text{S}_4\text{N}_4$; the Ag$_2$S so formed then catalyses the depolymerization of further $\text{S}_4\text{N}_4$.

$$\text{S}_4\text{N}_4 + 8\text{Ag} \rightarrow 4\text{Ag}_2\text{S} + 2\text{N}_2$$

In the absence of Ag/$\text{Ag}_2$S the product is contaminated with $\text{S}_4\text{N}_2$ (p. 728) formed by the reaction of the excess sulfur with either $\text{S}_4\text{N}_4$ or $\text{S}_2\text{N}_2$. (See next subsection for discussion of possible mechanisms.) $\text{S}_2\text{N}_2$ forms large colourless crystals which are insoluble in water but soluble in many organic solvents. The molecular structure is a square-planar ring ($\text{D}_{2h}$) analogous to the isoelectronic cation

$\text{S}_2\text{N}_2^2$ (D$_{4h}$, p. 665). Figure 15.35 shows the structure obtained by X-ray diffraction at $-130^\circ$\textsuperscript{221} together with typical valence-bond representations.$^{212}$

Undoubtedly the most exciting reaction of $\text{S}_2\text{N}_2$ is its slow spontaneous polymerization in the solid state at room temperature to give crystalline (SN)$_n$. Crystals up to several millimetres in length can be grown. Not only is this an unusually facile topochemical reaction for a solid at low temperature but it results in an unprecedented metallic superconducting polymer, as discussed in the following subsection.

(c) Polythiazyl, (SN)$_x$.(222) Polymeric sulfur nitride, also known as polythiazyl, was first prepared by F. B. Burt in 1910 using a method that is still often used today — the solid-state polymerization of crystalline S$_2$N$_2$ at room temperature (or preferably at 0°C over several days). Despite the bronze colour and metallic lustre of the polymer, over 50 y were to elapse before its metallic electrical conductivity, thermal conductivity and thermoelectric effect were investigated. By 1973 it had been established that (SN)$_x$ was indeed a metal down to liquid helium temperatures, and in 1975 the polymer was shown to be a superconductor below 0.26 K. (For higher-quality crystals the transition temperature rises to 0.33 K.) Values of the conductivity $\sigma$ depend on the purity and crystallinity of the polymer and on the direction of measurement, being much greater along the fibres ($b$-axis) than across them. At room temperature typical values of $\sigma_{\parallel}$ are 1000–4000 ohm$^{-1}$ cm$^{-1}$, and this increases by as much as 1000-fold on cooling to 4.2 K. Typical values of the anisotropy ratio $\sigma_{\parallel}/\sigma_{\perp}$ are $\sim$50 at room temperature and $\sim$1000 at 40 K.

The mechanism of formation of S$_2$N$_2$ from S$_4$N$_4$ and of the subsequent polymerization to (SN)$_x$ have been much studied and are very sensitive to the exact conditions employed.(223) The use of the explosive intermediates S$_4$N$_4$ and S$_2$N$_2$ can be avoided by various alternative high-yield syntheses employing nonaqueous solvents. For example, (SN)$_x$ can be made in 65% yield by the reaction of SiMe$_3$(N$_3$) with N$_3$S$_3$Cl$_3$, N$_2$S$_3$Cl$_2$ or N$_2$S$_3$Cl (pp. 738, 739) in MeCN solution at $-15^\circ$C or by the reaction of N$_3$S$_3$Cl$_3$ with an excess of NaN$_3$.(224) More recently still, the electrolytic reduction of S$_5$N$_5^+$Cl$^-$ (p. 732) in liquid SO$_2$ using a silver electrode has been used to deposit thin films of (SN)$_x$ on a variety of surfaces.(225)

(SN)$_x$ is much more stable than its precursor S$_2$N$_2$. When heated in air it decomposes explosively at about 240°C but it sublimes readily in vacuum at about 135°C. The crystal structure reveals an almost planar chain polymer with the dimensions shown in Fig. 15.36. The S and N atoms deviate by about 17 pm from the mean plane. The structure should be compared

Figure 15.37 Structures of (a) $S_3N_2$ showing the “half-chair” conformation with the central S of the $S_3$ unit tilted out of the plane of the SNSNS group by 55°; (b) $S_{11}N_2$ showing the two planar N atoms; (c) $S_{14+n}N_2$ ($x = 1, 2, 3, 5$) — for $x = 2$ the linking $S-S$ distance is 190 pm and $S-N$ is 170 pm; for $x = 3$ the linking $S-S$ is 204 pm and $S-N$ 171 pm.

with that of helical $S_\infty$ (p. 660), the (formal) replacement of alternate S atoms by N resulting both in a conformational change in the position of the atoms and an electronic change whereby 1 valence electron is removed for each SN unit in the chain. Polymerization is thought to occur by a one-point ring cleavage of each $S_2N_2$ molecule followed by the formation of the cis-trans-polymer along the $a$-axis of the $S_2N_2$ crystal which thereby transforms to the $b$-axis of the $(SN)_x$ polymer.

There is intense current interest in these one-dimensional metals and several related partially halogenated derivatives have also been made, some of which have an even higher metallic conductivity, e.g. partial bromination of $(SN)_x$ with Br$_2$ vapour yields blue-black single crystals of $(SNBr_{0.4})_x$ having a room-temperature conductivity of $2 \times 10^{-14}$ ohm$^{-1}$ cm$^{-1}$ i.e. an order of magnitude greater than for the parent $(SN)_x$ polymer. An even more facile preparation involves direct bromination of $S_4N_4$ crystals ($\sigma \sim 10^{-14}$ ohm$^{-1}$ cm$^{-1}$ at 25$^\circ$C) with Br$_2$ vapour at 180 mmHg over a period of hours; subsequent pumping at room temperature gives stoichiometries in the range $(SNBr_{1.5})_x$ to $(SNBr_{0.4})_x$ and further pumping at 80$^\circ$C for 4 h reduces the halogen content to $(SNBr_{0.25})_x$. Similar highly conducting nonstoichiometric polymers can be obtained by treating $S_4N_4$ with ICl, IBr and I$_2$, the increase in conductivity being more than 16 orders of magnitude.

(d) Other binary sulfur nitrides. Six further sulfur nitrides can be briefly mentioned: $S_4N_2$, $S_{11}N_2$ and $(S_7N)_2S_x$ ($x = 1, 2, 3, 5$); as can be seen from Fig. 15.37, these belong to three distinct structural classes. (For a fourth structure class, exemplified by $S_3N_6$, see p. 729.)

$S_4N_2$ is usually prepared by heating $S_4N_4$ with a solution of sulfur in CS$_2$ under pressure at 100–120$^\circ$C, though a more convenient laboratory preparation is now available by the reaction of activated Zn on $N_3S_4$Cl.$^{226}$ The compound also results from the thermolytic loss of N$_2$ from $S_4N_4$ which occurs when $S_4N_4$ is heated under reflux in xylene for some hours. An alternative preparation (42% yield), which involves neither high pressure or high temperature, is the smooth reaction of solutions of $Hg_5(NS)_8$ and $S_2Cl_2$ in CS$_2$:

$$Hg_5(NS)_8 + 4S_2Cl_2 \xrightarrow{CS_2/20^\circC} Hg_2Cl_2 + 3HgCl_2 + 4S_4N_2$$

In all these reactions only the 1,3-diazaheterocycle (Fig. 15.37a) is obtained: the 1,1- and

---

1,4-heterocycles and acyclic isomers are unknown (cf. N2O4, p. 455). S4N2 forms opaque red-grey needles or transparent dark red prisms which melt at 25° to a dark-red liquid resembling Br2. It decomposes explosively above 100°. S4N2 appears to be a weaker ligand than either S4N4 or S2N2: it does not react with BCl3 in CS2 solution, and SbCl5 gives a complex reaction mixture which contains S4N4.SbCl5 and [S4N3]+[SbCl6]− in addition to a poorly defined 1:1 adduct.

S11N2 is obtained as pale amber-coloured crystals by the double condensation of 1,3-(NH)2 with an equimolar amount of S2Cl2 in the presence of pyridine:

Some polymer is also formed but this can be converted into the bicyclic S11N2 by refluxing in CS2. The X-ray crystal structure (Fig. 15.37b) shows that the 2 N atoms are planar. This has been interpreted in terms of sp2 hybridization at N, with some delocalization of the pπ lone-pair of electrons into S-based orbitals, thus explaining the considerably diminished donor power of the molecule. S11N2 is stable at room temperature but begins to decompose when heated above 145°.

The sulfur nitrides S15N2 and S16N2 are (formally) derived from cyclo-S8 (or S7NH) and can be prepared by reacting S7NH with SCl2 and S3Cl2 respectively:

$$2S7NH + S3Cl2 \rightarrow S7N-S7-NH2 + 2HCl$$

Both are yellow crystalline materials, stable at room temperature, and readily soluble in CS2 (Fig. 15.37c). Compounds with x = 3 and 5 can be prepared similarly.

Finally, in this subsection we mention the discovery of S5N6 which is best prepared (73% yield) by the reaction of S4N5− (p. 733) with Br2 in CH2Cl2 at 0°C for several hours. Iodine reacts similarly but chlorine affords S4N5Cl (p. 731). S5N6 forms orange crystals which are stable for prolonged periods at room temperature in an inert atmosphere, though they immediately blacken in air. It can be sublimed unchanged at 45° (10−2 mmHg) and decomposes above 130°. The structure (Fig. 15.38) features a molecular basket in which an −N=S−N− group bridges 2 S atoms of an S4N4 cradle. Comparison with S4N4 itself (p. 723) shows little change in the S-N distances in the cradle (161 pm) but the trans-annular S⋯S distances are markedly different: one is opened up from 258 pm to 394 pm (nonbonding) whereas the other contracts to 243 pm suggesting stronger trans-annular bonding between these 2 S atoms and the incipient formation of 2 fused 5-membered S3N2 rings.

Figure 15.38 Structure of S5N6.
(ii) Sulfur–nitrogen cations and anions

Numerous charged sulfur–nitrogen species have been synthesized in recent years, particularly those having an odd number of N atoms which would otherwise be paramagnetic. However, thioanalogues of nitrites (NO₂⁻, p. 461) and nitrates (NO₃⁻, p. 465) are unknown.

The simplest stable sulfur–nitrogen species is the cation [SN]⁺ which was first prepared by the direct fluoride-ion transfer reaction between NSF and AsF₅ or [NS⁺][AsF₆⁻] can also be prepared by reaction of an excess of AsF₅ with S₃N₃F₃ or by thermal decomposition of [S~N~F~⁺][AsF~₆⁻], but the simplest high-yield synthesis is by the reaction of S₃N₃Cl₃ with an excess of AgAsF₆ in liquid SO₂:²³¹

\[
\text{AgAsF}_6 + \frac{1}{3}\text{S}_3\text{N}_3\text{Cl}_3 \longrightarrow \text{AgCl} + [\text{SN}]^+ [\text{AsF}_6^-] \quad (75\% \text{ yield})
\]

The cation has considerable synthetic potential for a wide range of S/N compounds, e.g.²³²

\[
[\text{SN}]^+ [\text{AsF}_6^-] + \frac{1}{8}\text{S}_8 \longrightarrow [\text{S}_2\text{N}]^+ [\text{AsF}_6^-] \quad (50\% \text{ yield})
\]

\[
[\text{SN}]^+ [\text{AsF}_6^-] + \text{CsF} \overset{110^\circ}{\longrightarrow} \text{NSF} + \text{CsAsF}_6 \quad (80\% \text{ yield})
\]

\[
[\text{SN}]^+ [\text{SbF}_6^-] + [\text{Re}(\text{CO})_5\text{Br}] \longrightarrow [\text{Re}(\text{CO})_5\text{NS}]^+ [\text{SbF}_6^-] \quad (100\% \text{ yield})
\]

Thionitrosyl complexes have already been briefly mentioned on p. 453 and have recently been reviewed.²³³ They were first made by reacting azido complexes directly with

\[
\text{[S}_2\text{N}^2\text{]+, which is the sulfur analogue of the nitronium cation (p. 458), was first prepared as the crystalline salt [S}_2\text{N}^2\text{][SbCl}_6\text{]} by the complex oxidative reaction of S}_2\text{NH, S}_7\text{NBCl}_2 or 1,4-S}_6\text{(NH)}_2\text{ (p. 735) with SbCl}_3.(²³⁶) It can be more conveniently prepared, in 30% yield, by reaction of S}_3\text{N}_3\text{Cl}_3 with 3SbCl}_5 + \frac{3}{8}\text{S}_8 using OClCl or CH}_2\text{Cl}_2 as solvent.(²³⁷) An X-ray structure determination on [S}_2\text{N}^2\text{][SbCl}_6\text{] showed the cation to be linear (D}_∞_h) as expected for a species isoelectronic with CS}_2 and NO}_2^+(²³⁶) The rather short N–S distance of 146.4 pm is consistent with the formulation [S=N=S]^+.
\]

The radical cation S}_3\text{N}_2^+ is formed in high yield from the oxidation of S}_4\text{N}_4 with the anhydride (CF}_3\text{SO}_2)\text{O}_2(²³⁸)

\[
(\text{CF}_3\text{SO}_2)\text{O}_2 + S}_4\text{N}_4 \longrightarrow [S}_3\text{N}_2^+] [\text{CF}_3\text{SO}_3]^- + \text{CF}_3\text{SO}_2\text{S}_3\text{N}_3
\]

The product is a black-brown solid that is very sensitive to oxygen. The same cation can be obtained by oxidation of S}_4\text{N}_4 with AsF}_5 and is unusual in being the only sulfur–nitrogen (paramagnetic) radical that has been obtained as a stable crystalline salt. X-ray diffraction analysis shows the structure to be a planar 5-membered ring with approximate

Figure 15.39 Structures of (a) the planar radical cation \(S_3N_2^+\), (b) its dimer \(S_4N_4^{2+}\) and (c) the corresponding planar diamagnetic dication \(S_4N_2^{2+}\).

C\(_{2v}\) symmetry (Fig. 15.39a). The corresponding diamagnetic dimer \(S_4N_4^{2+}\) was obtained in low yield by oxidation of \(S_3N_2\)Cl with Cl\(\text{SO}_3\)H: its structure (Fig. 15.39b) consists of 2 symmetry-related planar \(S_3N_2^+\) units linked by 2 very long S–S bonds. Alternatively, the central S\(_4\) unit can be thought of as being bound by a 4-centre 6-electron bond. Even more remarkably, a diamagnetic 6\(\pi\)-electron dication, \([S_3N_2]^2+\), which is less stable than its paramagnetic 7\(\pi\)-electron analogue \([S_3N_2]^+\), has been prepared and characterized as the crystalline salt \([S_3N_2]^2+\)[As\(\text{F}_6\)]\(^-\).\(^{239}\) The planar conformation of the ring is retained, but the dimensions are significantly different (Fig. 15.39c) most notably in the shortening of the S–S and adjacent S–N bonds. The dication is only stable in the crystalline phase; in \(\text{SO}_2\) solutions it reversibly dissociates into the paramagnetic species \([\text{SN}]^+\) and \([\text{SNS}]^+\), the cycloaddition in the solid state apparently being driven by the high lattice energy of the 1:2 salt.

Cations containing 4 S atoms include \(S_4N_3^+,\) \(S_4N_4^{2+}\) and \(S_4N_5^+\), as well as the unique radical cation \(S_4N_4^+\). The structures are in Fig. 15.40 and typical preparative routes are:\(^{240-241}\)

\[
S_3N_3\text{Cl}_2 + S_2\text{Cl}_2 \rightarrow [S_4N_3]^+\text{Cl}^- + 3\text{SCl}_2
\]

\[
S_4N_4 + 4\text{SbF}_5 \rightarrow [S_4N_4]^2+\{\text{SbF}_6\}^{-}\{\text{Sb}_2\text{F}_{14}\}^{-}
\]

\[
S_2N_3\text{Cl}_3 + (\text{Me}_3\text{SiN})_2\text{S} \rightarrow [S_4N_3]^+\text{Cl}^- + \ldots
\]

\[
S_3N_3\text{Cl}_3 + \text{FeCl}_3 \rightarrow [S_4N_4]^+\text{FeCl}_4^- + \ldots
\]

These compounds contain some fascinating and subtle structural and bonding problems. For example, the compound \([S_4N_4]^2+\)[Sb\(\text{F}_6\)]\(^-\)[Sb\(\text{F}_3\)]\(^-\) shows two structurally distinct cations, one with essentially equal S–N distances around the planar ring (Fig. 15.40b) and the other, also planar, but with alternating S–N distances of ca. 153 and 162 pm and with bond angles at S and N of 127° and 143°, respectively. By contrast, a non-planar boat-shaped structure was found for the dication in \([S_4N_4]^2+\)[Sb\(\text{Cl}_6\)]\(^-\).\(^{240}\) The unusual radical cation \([S_4N_4]^+\) occurs in the brown, moisture-sensitive compound \([S_4N_4]^+\)[Fe\(\text{Cl}_4\)]\(^-\) and features a puckered 8-membered ring in which the four S atoms form an almost perfect square and all the S–N

Figure 15.40 Structure of (a) planar $\text{S}_4\text{N}_3^+$; (b) planar $\text{S}_4\text{N}_4^{2+}$ (see text); (c) puckered $\text{S}_4\text{N}_4^+$; (d) a portion of the polymeric structure of $[\text{S}_4\text{N}_5]^+\text{Cl}^-$ showing the trans-annular bridging $\text{N}$ atom.

distances are essentially equal at 154 pm, but in which the four $\text{N}$ atoms are located alternately 34, $-59$, 45 and $-38$ pm above and below the plane of the four $\text{S}$ atoms. The original papers should be consulted for further details.

An interesting structural problem also emerges from the study of the final sulfur–nitrogen cation to be considered, $\text{S}_5\text{N}_5^+$. First made in 1972, this was originally thought to contain a planar, heart shaped 10-membered heterocycle on the basis of X-ray diffraction studies on $[\text{S}_5\text{N}_5]^+\text{[AlCl}_4^-]$; however, it now seems likely that this is an artefact of disorder within the crystals and that the structure of the cation is as in Fig. 15.41\(^{(243)}\) which is the

conformation observed in \([S_5N_5]^+[S_3N_3O_4]^-\) and \([S_5N_5]^+[SnCl_3(POCl_3)]^-\). Salts such as the yellow \([S_5N_5]^+[AlCl_4]^-\) and dark-orange \([S_5N_5]^+[FeCl_4]^-\) can readily be prepared in high yield by adding AlCl_3 (or FeCl_3) to \(S_3N_3Cl_3\) in SOCl_2 solution and then treating the adduct so formed with \(S_4N_4\); the overall stoichiometry can be represented as:

\[
\frac{1}{2}(SNC\_1)_3 + AlCl_3 \rightarrow "[NS]^+[AlCl_4]^" \\
S_4N_4 \rightarrow [S_5N_5]^+[AlCl_4]^- 
\]

though the reaction is undoubtedly more complex and proceeds via the adduct \((SNCl)_3.2AlCl_3\).\(^{(244)}\)

Treatment of \([S_5N_5]^+[AlCl_4]^-\) with THF yields pure \([S_5N_5]Cl\) from which \([S_5N_5]^+[BF_4]^-\) can readily be prepared.\(^{(245)}\) The planar azulene-shaped cation also occurs in the crystalline adduct \([S_3N_3]^+[AlCl_4]^-\).\(^{(246)}\) Uncoordinated sulfur–nitrogen anions are less common than S–N cations and all are of recent preparation:\(^{(247)}\) \(bicyclo-S_4N_5^-\) (1976), \(cyclo-S_3N_3^-\) (1977) and \(catena-S_4N^-\) (1979), as well as the more fugitive species \(S_3N^-\) and \(S_7N^-\). Structures are in Fig. 15.42. \(S_4N_5^-\) occurs as the product in a variety of reactions of \(S_4N_4\) with nucleophiles: \(^{(248)}\) e.g., liquid NH_3 or ethanolic solutions of R_2NH, MN_3 (M = Li, Na, K, Rb), KCN or even Na_2S. The course of these reactions suggests the initial formation of \(S_3N_3^-\) which then reacts with further \(S_4N_4\) to give \(S_4N_5^-\). The ammonium salt \([NH_4]^+[S_4N_5]^-\) is a ubiquitous product of the reaction of ammonia with \(S_4N_4\), (SNCl)_3, S_2Cl_2, SCl_2 or SCl_4.\(^{(249)}\) Yet another route is the methanalysis of \((Me_3SiN)_2S\):

\[
Me_3Si-N=S=N-SiMe_3 \rightarrow [NH_4]^+[S_4N_5]^- 
\]

Subsequent metathesis with \(Bu_3NOH\) yielded yellow crystals suitable for X-ray structure analysis. The structure of \([S_4N_5]^-\) (Fig. 15.42a)

Planar S-N heterocycles having 4–10 ring atoms respond to salts of S3N3- and S4N- (50% yield). An X-ray crystallographic analysis of the dark-blue air-stable product \([\text{N(PPh}_3)_2\text{]+}[\text{S}_4\text{N}_4\text{]}^-\) revealed the presence of the unique acyclic anion \(\text{S}_3\text{N}_3^-\) whose structure is in Fig. 15.42b. The anion is planar with interesting bonding implications. Thus each S in a heterocycle forms a σ bond to each of its neighbours (thereby using 2 electrons) and it also has an exocyclic lone-pair of electrons: this leaves 2 electrons to contribute to the π system of the heterocycle (which might or might not involve S 3d orbitals). Likewise, each N atom has 2 electrons in σ bonds, one exocyclic lone pair, and contributes one electron to the π system. Planar S–N heterocycles having 4–10 ring atoms are now known and all except the radical cation \(\text{S}_3\text{N}_2^+\) have \(4n + 2\)π electrons where \(n = 1, 2, 3\) as shown below:

Thermal decomposition of \([\text{N(PPh}_3)_2\text{]+}[\text{S}_4\text{N}_4\text{]}^-\) in MeCN yields sequentially the corresponding salts of \(\text{S}_3\text{N}_3^-\) and \(\text{S}_4\text{N}^-\) (50% yield). An X-ray crystallographic analysis of the dark-blue air-stable product \([\text{N(PPh}_3)_2[\text{S}_4\text{N}_4\text{]}^-\) revealed the presence of the unique acyclic anion \([\text{SSNSSN}^-\) whose structure is in Fig. 15.42c. The anion is planar with cis-trans configuration, although a different geometrical configuration occurs in the \([\text{AsPh}_4]^+\) salt. The existence of \([\text{S}_4\text{N}]^-\) as well as of \([\text{S}_3\text{N}]^-\) and small amounts of \([\text{S}_3\text{N}]^-\) in sulfur-ammonia solutions has been demonstrated by \(^{14}\text{N} \text{nmr spectroscopy}.\)

The coordination chemistry of sulfur–nitrogen anions is also a burgeoning field. Some complexes have already been mentioned (pp. 725–6) and others for which X-ray structural data are available include the chelate \([\text{Pt(PPh}_3)_2(\eta^3-\text{SNSN})][\text{S}_4\text{N}_4\text{]}^2-\) and the bridged dimer \([((\text{Ph}_3\text{P})_2\text{Pt})_2-\langle\mu,\mu^2-\text{S}_2\text{N}_2\rangle_2\)] in which each Pt atom is chelated by \(\text{SNSN}^-\) and then bridged to the other Pt atom by the coordinated N atom to form a central planar Pt2N2 ring. For coordinated \([\text{S}_3\text{N}_2]^{2-}\) and \([\text{S}_4\text{N}_4]^{2-}\) examples include the chelated titanocene derivatives \,[\text{Ti}(\eta^5-\text{C}_5\text{H}_5)_3-\langle\eta^2-\text{S}_2\text{N}_2\rangle]\) and \,[\text{Ti}(\eta^5-\text{C}_5\text{H}_5)_2\langle\eta^2-\text{S}_2\text{N}_4]\)] which feature the 6- and 8-membered ring systems \(\text{TiSSNSN}\) and \(\text{TiNSNSNSN}\), respectively. The chelating trianion \([\text{S}_2\text{N}_3]^{3-}\) occurs in the 6-coordinate mixed ligand trisbidentate vanadium(V) complex \([\text{V}(\text{dtbc})(\text{phen})(\eta^2-\text{N}_2\text{S}_2)]\) (dtbc = di-t-butylcatecholate, \(\text{Bu}_2\text{C}_6\text{H}_4\text{O}_2\)–; \(\text{phen} = 1,10\)-phenanthroline) and in the

---

anionic complex \([\text{WC}_2\text{F}_2(\eta^2-\text{N}_3\text{S}_2)]^-\). Copper(I) and silver complexes of the \([\text{S}_3\text{N}]^-\) ion are of older vintage, e.g. \([\text{Cu}(\text{PPh}_3)_2(q^2-\text{SSNS})]^-\) and \([\text{Cu}(\eta^2-\text{SSNS})_2]^-\).

**(iii) Sulfur imides, \(\text{S}_{8-n} (\text{NH})_n\)**

The NH group is "isoelectronic" with S and so can successively subrogate S in cyclo-\(\text{S}_8\). Thus we have already seen that reduction of \(\text{S}_4\text{N}_4\) with dithionite or with \(\text{SnCl}_2\) in boiling ethanol/benzene yields \(\text{S}_4(\text{NH})_4\). Again, whereas reaction of \(\text{S}_2\text{Cl}_2\) or \(\text{SCl}_2\) with \(\text{NH}_3\) in non-polar solvents yields \(\text{S}_4\text{N}_4\), heating these 2 reactants in polar solvents such as dimethylformamide affords a range of sulfur imides. In a typical reaction 170 g \(\text{S}_2\text{Cl}_2\) and the corresponding amount of \(\text{NH}_3\) yielded:

\[
\begin{align*}
\text{S}_8 & (32 \text{ g}) \\
1.3-\text{S}_6(\text{NH})_2 & (0.98 \text{ g}) \\
1.3.5-\text{S}_5(\text{NH})_3 & (0.08 \text{ g}) \\
\text{S}_7\text{NH} & 1.4-\text{S}_6(\text{NH})_2 (2.3 \text{ g}) \\
& 1.3.6-\text{S}_5(\text{NH})_3 (0.32 \text{ g}) \\
& (15.4 \text{ g}) \\
1.5-\text{S}_6(\text{NH})_2 & (0.82 \text{ g})
\end{align*}
\]

In no case have adjacent NH groups been observed.

\(\text{S}_7\text{NH}\) is a stable pale-yellow compound, mp 113.5°; the structure is closely related to that of cyclo-\(\text{S}_8\) as shown in Fig. 15.43a. The proton is acidic and undergoes many reactions of which the following are typical (see also p. 729):

\[
\begin{align*}
\text{BX}_3 & \rightarrow \text{S}_7\text{N}-\text{BX}_2 + \text{HX} \quad (\text{X} = \text{Cl, Br}) \\
\text{NaCPh}_3 & \rightarrow \text{S}_7\text{NNa} + \text{Ph}_3\text{CH} \\
(\text{Me}_3\text{Si})_2\text{NH} & \rightarrow \text{S}_7\text{N}-\text{SiMe}_3 + \text{NH}_3 \\
\text{Hg(MeCO}_2)_2 & \rightarrow \text{Hg(NS}_7)_2 + \text{MeCO}_2\text{H}
\end{align*}
\]

![Figure 15.43](image-url) Structures of the various cyclo sulfur imides.
anionic complex \([\text{WC}_2\text{F}_2(\eta^2-\text{N}_3\text{S}_2)]^-\). Copper(I) and silver complexes of the \([\text{S}_3\text{N}]^-\) ion are of older vintage, e.g. \([\text{Cu}(\text{PPh}_3)_2(\eta^2-\text{SSNS})]\) and \([\text{Cu}(\eta^2-\text{SSNS})_2]^-\).

(iii) Sulfur imides, \(\text{S}_{8-n}(\text{NH})_n\)

The NH group is “isoelectronic” with S and so can successively subrogate S in cyclo-\(\text{S}_8\). Thus we have already seen that reduction of \(\text{S}_4\text{N}_4\) with dithionite or with SnCl\(_2\) in boiling ethanol/benzene yields \(\text{S}_4(\text{NH})_4\). Again, whereas reaction of \(\text{S}_2\text{Cl}_2\) or \(\text{SCl}_2\) with \(\text{NH}_3\) in non-polar solvents yields \(\text{S}_4\text{N}_4\), heating these 2 reactants in polar solvents such as dimethylformamide affords a range of sulfur imides. In a typical reaction 170 g \(\text{S}_2\text{Cl}_2\) and the corresponding amount of \(\text{NH}_3\) yielded:

\[
\begin{align*}
\text{S}_8 & \quad (32 \text{ g}) & 1.3-\text{S}_6(\text{NH})_2 & \quad (0.98 \text{ g}) & 1.3,5-\text{S}_5(\text{NH})_3 & \quad (0.08 \text{ g}) \\
\text{S}_7\text{NH} & \quad 1.4-\text{S}_6(\text{NH})_2 & \quad (2.3 \text{ g}) & 1.3,6-\text{S}_5(\text{NH})_3 & \quad (0.32 \text{ g}) \\
& \quad (15.4 \text{ g}) & 1.5-\text{S}_6(\text{NH})_2 & \quad (0.82 \text{ g})
\end{align*}
\]

In no case have adjacent NH groups been observed.

\(\text{S}_7\text{NH}\) is a stable pale-yellow compound, mp 113.5°; the structure is closely related to that of cyclo-\(\text{S}_8\) as shown in Fig. 15.43a. The proton is acidic and undergoes many reactions of which the following are typical (see also p. 729):

\[
\begin{align*}
\text{BX}_3 & \quad \rightarrow \text{S}_7\text{N}−\text{BX}_2 + \text{HX} & (X = \text{Cl}, \text{Br}) \\
\text{NaCPh}_3 & \quad \rightarrow \text{S}_7\text{NNa} + \text{Ph}_3\text{CH} \\
(\text{Me}_3\text{Si})_2\text{NH} & \quad \rightarrow \text{S}_7\text{N}−\text{SiMe}_3 + \text{NH}_3 \\
\text{Hg(MeCO}_2)_2 & \quad \rightarrow \text{Hg(NS}_7)_2 + \text{MeCO}_2\text{H}
\end{align*}
\]

Figure 15.43  Structures of the various cyclo sulfur imides.
The 3 isomeric compounds $S_6(NH)_2$ form stable colourless crystals and have the structures illustrated in Fig. 15.43b, c, and d. The 1,3-, 1,4-, and 1,5-isomers melt at 130°, 133°, and 155° respectively. The 1,3,5- and 1,3,6-triimides melt with decomposition at 128° and 133° (Fig. 15.43e and f). The tetraimide, $S_4(NH)_4$ (mp 145°) is structurally very similar (Fig. 15.43g); the N atoms are each essentially trigonal planar and the heterocycle is somewhat flattened, the distance between the planes of the 4 N atoms and 4 S atoms being only 57 pm. The influence of extensive intermolecular H-bonding on the structure has been studied by electron deformation density techniques.

Alkyl derivatives such as 1,4-$S_6(NR)_2$ and $S_4(NR)_4$ can be synthesized by reacting $S_2Cl_2$ with primary amines RNH$_2$ in an inert solvent. Compounds such as 1,4-$S_2(NR)_4$ ($R = -CO_2Et$) are now also well characterized. The bis-adduct $[Ag(S_4N_4H_4)_2]$ has been isolated as its perchlorate; this has a sandwich-like structure and is unique in being S-bonded rather than N-bonded to the metal ion.

(iv) Other cyclic sulfur–nitrogen compounds

Incorporation of a third heteroatom into S–N compounds is now well established, e.g. for C, Si; P; As; O; Sn and Pb, together with the $S_2N_2$ chelates of Fe, Co, Ni, Pd and Pt mentioned on p. 725. The field is very extensive but introduces no new concepts into the general scheme of covalent heterocyclic molecular chemistry. Illustrative examples are in Fig. 15.44 and fuller details including X-ray structures for many of the compounds are in the references cited above. A selenium analogue of the dimer $S_6N_2^{2+}$ (p. 731) has also been prepared and structurally characterized, viz. $[SN_2Se_2Se_2N_2]^{2+}$.

(v) Sulfur–nitrogen halogen compounds

As with sulfur–halogen compounds (pp. 683–93) the stability of N–S–X compounds decreases with increase in atomic weight of the halogen. There are numerous fluoro and chloro derivatives but bromo and iodo derivatives are virtually unknown except for the nonstoichiometric (SNX)$_n$ polymers (p. 728) and S(NX)$_2$ (p. 740). Unlike the H atoms in the sulfur imides (p. 735) the halogen atoms are attached to S rather than N. Fluoro derivatives have been known since 1965 but some of the chloro compounds have been known for over a century. The simplest compounds are the nonlinear thiazyl halides N=S−F and N=S−Cl: these form a noteworthy contrast to the nonlinear nitrosyl halides O=N−X. In all cases, the pairs of elements directly bonded are consistent with the rule that the most electronegative atom of the trio bonds to the least electronegative, i.e. {S(NH)}$_4$, {N(SF)}$_{1,3,4}$, {N(SCl)}$_{1,3}$, O(NF), O(NCl) (formal Pauling electronegativities: H 2.1, S 2.5, N 3.0, Cl 3.0, O 3.5, F 4.0).

Thiazyl fluoride, NSF, is a colourless, reactive, pungent gas (mp $-89°$, bp $+0.4°$). It is best prepared by the action of HgF$_2$ on a slurry of $S_4N_4$ and CCl$_4$ but it can also be made by a variety of other reactions:

$$\text{S}_4\text{N}_4 + 4\text{HgF}_2 (\text{or AgF}_2) \xrightarrow{\text{CCL}_4} 4\text{NSF} + 2\text{Hg}_2\text{F}_2$$

$$\text{S}_4\text{N}_4 \xrightarrow{\text{IF}_5} \{\text{S}_4\text{N}_4(\text{NSF})_4\} \xrightarrow{50°} \text{S}_4\text{N}_4 + 4\text{NSF}$$

Some heterocyclic S–N compounds incorporating a third heteroelement.

\[
\begin{align*}
\text{SF}_4 + \text{NH}_3 & \rightarrow \text{NSF} + 3\text{HF} \\
\text{NF}_3 + 3\text{S} & \rightarrow \text{NSF} + \text{SSF}_2
\end{align*}
\]

\(\text{S}_4\text{N}_4\) can also be fluorinated to NSF (and other products) using \(\text{F}_2\) at \(-75^\circ\), \(\text{SeF}_4\) at \(-10^\circ\), or \(\text{SF}_4\). The molecular dimensions of NSF have been determined by microwave spectroscopy: \(\text{N}–\text{S} 145\text{pm}, \text{S}–\text{F} 164\text{pm}, \) angle at \(\text{S} 116.5^\circ\). The angle at \(\text{S}\) is very close to the angle at \(\text{N}\) in \(\text{ONX}\) (110–117°, p. 442). NSF can be stored at room temperature in copper or teflon vessels but it slowly decomposes in glass (more rapidly at 200°) to form a mixture of \(\text{OSF}_2, \text{SO}_2, \text{SiF}_4, \text{S}_4\text{N}_4\) and \(\text{N}_2\). At room temperature and at pressures above 1 atm it trimerises to \(\text{cyclo-N}_3\text{S}_3\text{F}_3\) (see below) but at lower pressures it affords \(\text{S}_4\text{N}_4\) admixed with yellow-green crystals of \(\text{S}_3\text{N}_2\text{F}_2\); this latter is of unknown structure but may well be the nonlinear acyclic species \(\text{FSN}≡\text{S}≡\text{NSF}\). \(\text{N}_3\text{S}_3\text{F}_3\) is best made by fluorinating \(\text{cyclo-N}_3\text{S}_3\text{Cl}_3\) with \(\text{AgF}_2/\text{CCl}_4\). The tetramer \(\text{cyclo-N}_4\text{S}_4\text{F}_4\) is not obtained by polymerization of NSF monomer but can be readily made by fluorinating \(\text{S}_4\text{N}_4\) with a hot slurry of \(\text{AgF}_2/\text{CCl}_4\). Some physical properties of these and other \(\text{N}–\text{S}–\text{F}\) compounds (p. 725) are compared in the following table:

The structures of \(\text{N}_3\text{S}_3\text{F}_3\) and \(\text{N}_4\text{S}_4\text{F}_4\) are in Fig. 15.45. The former features a slightly puckered 6-membered ring (chair conformation) with essentially equal S–N distances around the ring and 3 eclipsed axial F atoms. By contrast,
**Figure 15.45** Molecular structures of (a) \( \text{N}_3\text{S}_3\text{F}_3 \), (b) \( \text{N}_4\text{S}_4\text{F}_4 \) (side view), and (c) \( \text{N}_4\text{S}_4\text{F}_4 \) (top view).

**Figure 15.46** Molecular structure of (a) \( \text{N}_3\text{S}_3\text{Cl}_3 \), (b) \( \alpha\text{-N}_3\text{S}_3\text{Cl}_3\text{O}_3 \) (cis), and (c) \( \text{trans}\cdot\text{N}_3\text{S}_3\text{F}_3\text{O}_3 \).  

\( \text{N}_4\text{S}_4\text{F}_4 \) shows a pronounced alternation in S–N distances and only 2 of the F atoms are axial; it will also be noted that the conformation of the \( \text{N}_4\text{S}_4 \) ring is very different to that in \( \text{S}_4\text{N}_4 \) (p. 723) or \( \text{S}_4(\text{NH})_4 \) (p. 735). It is an interesting intellectual exercise to attempt to rationalize these striking structural differences.\(^{270}\) The chemistry of these various NSF oligomers has not been extensively studied. \( \text{N}_3\text{S}_3\text{F}_3 \) is stable in dry air but is hydrolysed by dilute aqueous NaOH to give \( \text{NH}_4\text{F} \) and sulfate. \( \text{N}_4\text{S}_4\text{F}_4 \) is reported to form an N-bonded 1:1 adduct with BF\(_3\) whereas with \( \text{AsF}_5 \) or \( \text{Sbf}_5 \) fluoride ion transfer occurs (accompanied by dethiazylation of the ring) to give \( [\text{N}_3\text{S}_3\text{F}_2]^+[\text{MF}_6^-] \) and \( [\text{NS}]^+[\text{MF}_6^-] \).

In the chloro series, the compounds to be considered are \( \text{N}=\text{S}=\text{Cl} \), \( \text{cyclo-N}_3\text{S}_3\text{Cl}_3 \), \( \text{cyclo-N}_4\text{S}_4\text{Cl}_2 \); the ionic compounds \( [\text{S}_4\text{N}_3]^+\text{Cl}^- \) and \( [\text{cyclo-N}_2\text{S}_3\text{Cl}]^+\text{Cl}^- \) and \( [\text{catena-N(ScI)}_2]^+[\text{BCl}_4^-] \); together with various isomeric oxo- and fluoro-chloro derivatives. Thi-azyl chloride, \( \text{NSCl} \), is best obtained by pyrolysis of the trimer in vacuum at 100°. It can also be made by the reaction of \( \text{Cl}_2 \) on NSF (note that NSF + \( \text{F}_2 \rightarrow \text{NSF}_3 \)) and by numerous other reactions.\(^{267}\) It is a yellow-green gas that rapidly trimerizes at room temperature, and is isostructural with NSF.  

By far the most common compound in the series is \( \text{N}_3\text{S}_3\text{Cl}_3 \) (yellow needles, mp 168°) which can be prepared by the direct action of \( \text{Cl}_2 \) (or \( \text{SOCl}_2 \)) on \( \text{S}_4\text{N}_4 \) in \( \text{CCl}_4 \), and which is also obtained in all reactions leading to \( \text{NSCl} \). The structure (Fig. 15.46a) is very

similar to that of N₃S₃F₃ and comprises a slightly puckered ring with equal S–N distances of 160.5 pm and the N atoms only 18 pm above and below the plane of the 3 S atoms. N₃S₃Cl₃ is sensitive to moisture and is oxidized by SO₃ above 100° to N₃S₃Cl₃O₃; at lower temperatures the adduct N₃S₃Cl₃.6SO₃ is formed and this dissociates at 100° to N₃S₃Cl₃.3SO₃. A more efficient preparation of N₃S₃Cl₃O₃ is by thermal decomposition of the product obtained by the reaction of amidosulfuric acid with PCl₅:

\[
\text{H}_2\text{NSO}_3\text{H} + 2\text{PCl}_5 \rightarrow 3\text{HCl} + \text{OPCl}_3 + \text{ClISO}_2\text{N} = \text{PCl}_3
\]

\[
3\text{ClISO}_2\text{N} = \text{PCl}_3 \rightarrow 3\text{OPCl}_3 + (\text{NSClO})_3
\]

The compound is obtained in two isomeric forms from this reaction: \(\alpha\), mp 145° and \(\beta\), mp 43°. The structure of the \(\alpha\)-form is in Fig. 15.46b and is closely related to that of (NSCl)₃ with uniform S–N distances around the ring. The \(\beta\)-form may have a different ring conformation but more probably involves cis-trans isomerism of the pendant Cl and O atoms. Fluorination of \(\alpha\)-N₃S₃Cl₃O₃ with KF in CCl₄ yields the two isomeric fluorides cis-N₃S₃F₃O₃ (mp 17.4°) and trans-N₃S₃F₃O₃ (mp −12.5°) (Fig. 15.46c). The structural assignment of the 2 isomers was made on the basis of \(^{19}\text{F} \text{nmr. Fluorination with SbF₅ under reduced pressure yields both the monofluoro and difluoro derivatives N₃S₃Cl₂FO₃ and N₃S₃ClF₂O₃, each having 3 isomers which can be separated chromatographically and assigned by \(^{19}\text{F} \text{nmr as indicated schematically in Fig. 15.47. Numerous other derivatives are known in which one or more halogen atom is replaced by} \text{−NH}_2, \text{−N=SF}_2, \text{−N=PCl}_3, \text{−N=CHPh, −OSiMe}_3, \text{etc.}

A different structure motif occurs in S₄N₃Cl. This very stable yellow compound features the S₄N₃⁺ cation (p. 732) and is obtained by many reactions, e.g.:

\[
\text{3S}_4\text{N}_4 + 2\text{S}_2\text{Cl}_2 \overset{\text{CCl}_4/\text{heat}}{\rightarrow} 4[\text{S}_4\text{N}_3]^+\text{Cl}^-\]

The chloride ion is readily replaced by other anions to give, for example, the orange-yellow [S₄N₃]Br, bronze-coloured [S₄N₃]SCN, [S₄N₃]NO₃, [S₄N₃]HSO₄, etc.

Chlorination of S₄N₄ with NOCl or SOCl₂ in a polar solvent yields S₃N₂Cl₂: S₄N₄ + 2NOCl \(\rightarrow\) S₃N₂Cl₂ + \(\frac{1}{2}\)S₂Cl₂ + 2N₂O

The crystal structure again reveals an ionic formulation, [N₂S₃Cl]⁺Cl⁻, this time with a slightly puckered 5-membered ring carrying a single pendant Cl atom as shown in Fig. 15.48a; the alternation of S–N distances and the rather small angles at the 2 directly linked S atoms are notable features. Reaction of [N₂S₃Cl]⁺Cl⁻ with bis(trimethylsilyl)cyanamide, (Me₃Si)₂NCN, in MeCN yields dark red crystals of N₂S₃NCN (i.e. \(\text{SNNSN} = \text{NCN}\)) in which the essentially linear NCN group (176.4°) lies diagonally above the N₂S₃-ring with the angle S=NC being 119.0°. Yet a further chloride can be obtained by the partial chlorination of S₄N₄ with Cl₂ in CS₂ solution below room temperature: one of the

---

trans-annular $S\cdots S$ “bonds” is opened to give yellow crystals of $N_4S_4Cl_2$ (Fig. 15.48b) and this derivatized heterocycle can be used to prepare several other compounds.\(^{(272)}\)

Reaction of NSF\(_3\) with BC\(_3\) yields the acyclic cation $[N(SCl)\_2]^+$ as its BCl\(_4^-\) salt (Fig. 15.4\%); the compound is very hygroscopic and readily decomposes to BC\(_3\), SC\(_2\), S\(_2\)Cl\(_2\), and N\(_2\).

The formation of highly conducting nonstoichiometric bromo and iodo derivatives of polythiazyl has already been mentioned (p. 728). It has been found that, whereas bromination of solid S\(_4\)N\(_4\) with gaseous Br\(_2\) yields conducting $[SNBr\_2]$\(^+\)$ as its BCl\(_4^-\) salt, reaction with liquid bromine leads to the stable tribromide $[S_4N_3]^-[Br_3]^-$\(^{(273)}\). In contrast, the reaction of S\(_4\)N\(_4\) with Br\(_2\) in CS\(_2\) solution results in a (separable) mixture of $[S_4N_3]^+[Br_3]^-$, $[S_4N_3]^+Br^-$ and the novel ionic compound $CS_3N_2Br_2$ which may be $[S=\overset{-}\equiv C=S=N=S=N]^+2[Br^-]_2^-$ or $[S=\overset{\equiv C-S=N-S(Br)=N]^+Br^-]$. The binary halides $SN_2Br_2$ and $SN_2I_2$ are also known. Thus SF\(_4\) reacts with (Me\(_3\)Si)\(_2\)NI in C\(_2\)F\(_4\)Cl\(_2\) at $0^\circ$C to give $S(NI)_2$ as a shock-sensitive yellow crystalline powder composed of I$-N=S=N-I$ molecules in syn-anti configuration\(^{(274)}\).

This is a classic area of inorganic chemistry dating back to the middle of the last century and only a brief outline will be possible. It will be convenient first to treat the sulfur nitrogen oxides and then the amides, imides and nitrides of sulfuric acid. Hydrazides and hydroxylamides of sulfuric acid will also be considered. Some of these compounds have remarkable properties and some are implicated in the lead-chamber process for the manufacture of H\(_2\)SO\(_4\) (p. 708). The field is closely associated with the names of the great German chemists E. Frémy (~1845), A. Claus (~1870), F. Raschig (~1885–1925), W. Traube (~1890–1920), F. Ephraim (~1910), P. Baumgarten (~1925) and, in more recent years, M. Becke-Goehring (~1955) and F. Seel (~1955–65).

(a) Sulfur–nitrogen oxides. Trisulfur dinitrogen dioxide, $S_3N_2O_2$, is best made by treating $S_4N_4$ with boiling OS\(_2\)Cl\(_2\) under a stream of SO\(_2\):

$$S_4N_4 + 2OSCl_2 \longrightarrow S_3N_2O_2 + 2Cl_2 + S_2N_2 + S$$

It is a yellow solid with an acyclic structure (Fig. 15.49a), cf N\(_2\)O\(_5\) (p. 458). Moist air converts $S_3N_2O_2$ to SO\(_2\) and $S_4N_4$ whereas SO\(_3\)
oxidizes it smoothly to $S_3N_2O_5$:

$$S_3N_2O_2 + 3SO_3 \rightarrow S_3N_2O_5 + 3SO_2$$

The pentoxide $S_3N_2O_5$ can also be made directly from $S_4N_4$ and $SO_3$. It forms colourless, strongly refracting crystals which readily hydrolyse to sulfamic acid:

$$S_3N_2O_5 + 3H_2O \rightarrow 2H_2NSO_3H + SO_2$$

It has a cyclic structure and may be regarded as a substituted diamide of disulfuric acid, $H_2S_2O_7$ (Fig. 15.49b).

An alternative synthetic strategy for sulfur-nitrogen oxides is exemplified by the more recent reaction:

$$S_3N_2Cl_2 + SO_2(NH_2)_2 \xrightarrow{CCl_4, \text{reflux}} S_4N_4O_2$$

The product forms orange-yellow crystals, mp 166 (d), having a structure in which 1 S atom of an $S_4N_4$ ring carries both O atoms. X-ray diffractometry shows substantial deviation from the parent $S_4N_4$ structure, a notable feature being the coplanarity of the $S_3N_2$ moiety furthest removed from the SO$_2$ group (Fig. 15.49c). If $S_4N_4O_2$ is allowed to react with 2 mol of SO$_3$ in liquid SO$_2$, two further compounds are formed: the known $S_3N_2O_5$ (Fig. 15.49b) and the novel greenish-black $S_6N_5O_4$, which is composed of separately stacked tricyclic radical cation dimers $[(S_3N_2)_2]^{2+}$ (Fig. 15.39b)) and the cyclic anion $S_3N_2O_4^-$, i.e. $[O_2SNSNS(O)_2]^{-}$.(276) Numerous other cyclic- and polycyclic-N/S/O species have recently been prepared and structurally characterized.(277)

(b) Amides of sulfuric acid. Amidosulfuric acid (better known as sulfamic acid, $H[OHNSO_3]$), is a classical inorganic compound and an important industrial chemical. Formal replacement of both hydroxyl groups in sulfuric acid leads to sulfamide ($H_2N)_2SO_2$ (p. 742) which is also clearly related structurally to the sulfonyl halides $X_2SO_2$ (p. 694).

Sulfamic acid can be made by many routes, including addition of hydroxylamine to SO$_2$ and addition of NH$_3$ to SO$_3$:

$$H_2NOH + SO_2 \rightarrow H[OHNSO_3]$$
$$NH_3 + SO_3 \rightarrow H[OHNSO_3]$$

The industrial synthesis uses the strongly exothermic reaction between urea and anhydrous $H_2SO_4$ (or dilute oleum):

$$(H_2N)_2CO + 2H_2SO_4 \rightarrow CO_2$$
$$+ H[OHNSO_3] + NH_4[HSO_4]$$

Salts are obtained by direct neutralization of the acid with appropriate oxides, hydroxides, or carbonates. Sulfamic acid is a dry, non-volatile, non-hygroscopic, colourless, white, crystalline solid of considerable stability. It melts at 205°, begins to decompose at 210°, and at 260° rapidly gives a mixture of $\text{SO}_2$, $\text{SO}_3$, $\text{N}_2$, $\text{H}_2\text{O}$, etc. It is a strong acid (dissociation constant $1.01 \times 10^{-1}$ at 25° solubility $\sim 25 \text{ g per 100 g H}_2\text{O}$) and, because of its physical form and stability, is a convenient standard for acidimetry. Over 50,000 tonnes are manufactured annually and its principal applications are in formulations for metal cleaners, scale removers, detergents and stabilizers for chlorine in aqueous solution.\(^{278}\) Its salts are used in flame retardants, weed killers and for electroplating.

In the solid state sulfamic acid forms a strongly H-bonded network which is best described in terms of zwitterion units $^{+}\text{H}_2\text{NSO}_3^-$ rather than the more obvious formulation as aminosulfuric acid, $\text{H}_2\text{NSO}_3(\text{OH})$. The zwitterion has the staggered configuration shown in Fig. 15.50a and the S–N distance is notably longer than in the sulfamate ion or sulfamide.

Dilute aqueous solutions of sulfamic acid are stable for many months at room temperature but at higher temperatures hydrolysis to $\text{NH}_4[\text{HSO}_4]$ sets in. Alkali metal salts are stable in neutral and alkaline solutions even at the bp. Sulfamic acid is a monobasic acid in water (see Fig. 15.50b for structure of the sulfamate ion). In liquid ammonia solutions it is dibasic and, with Na for example, it forms $\text{NaNH}_2\text{SO}_3\text{Na}$. Sulfamic acid is oxidized to nitrogen and sulfate by $\text{Cl}_2$, $\text{Br}_2$ and $\text{ClO}_3^-$, e.g.:

$$2\text{H}[\text{H}_2\text{NSO}_3] + \text{KClO}_3 \rightarrow \text{N}_2 + 2\text{H}_2\text{SO}_4$$

$$+ \text{KCl} + \text{H}_2\text{O}$$

Concentrated $\text{HNO}_3$ yields pure $\text{N}_2\text{O}$ whilst aqueous $\text{HNO}_2$ reacts quantitatively to give $\text{N}_2$:

$$\text{H}[\text{H}_2\text{NSO}_3] + \text{HNO}_3 \rightarrow \text{H}_2\text{SO}_4 + \text{H}_2\text{O} + \text{N}_2$$

$$\text{H}[\text{H}_2\text{NSO}_3] + \text{NaNO}_2 \text{ acidify } \rightarrow \text{NaHSO}_4 + \text{H}_2\text{O} + \text{N}_2$$

This last reaction finds use in volumetric analysis. The use of sulfamic acid to stabilize chlorinated water depends on the equilibrium formation of $N$-chlorosulfamic acid, which reduces loss of chlorine by evaporation, and slowly re-releases hypochlorous acid by the reverse hydrolysis:

$$\text{Cl}_2 + \text{H}_2\text{O} \underset{\text{acidify}}{\overset{\text{HCl}}{\rightleftharpoons}} \text{HOCl} + \text{HCl}$$

$$\text{H}[\text{H}_2\text{NSO}_3] + \text{HOCl} \rightarrow \text{HN(Cl)}\text{SO}_3\text{H} + \text{H}_2\text{O}$$

$$\text{HOCl} \rightarrow \text{HCl} + \frac{1}{2}\text{O}_2$$

Sulfamide, ($\text{H}_2\text{N})_2\text{SO}_2$, can be made by ammonolysis of $\text{SO}_3$ or $\text{O}_2\text{SCl}_2$. It is a colourless crystalline material, mp $93^\circ$, which begins to decompose above this temperature. It is soluble in water to give a neutral non-electrolytic solution but in boiling water it decomposes to ammonia and sulfuric acid. The structure (Fig. 15.50c)

---

can be compared with those of sulfuric acid, \((\text{HO})_2\text{SO}_2\) (p. 710) and the sulfuryl halides \(\text{X}_2\text{SO}_2\) (p. 694).

(c) **Imido and nitrido derivatives of sulfuric acid.** In the preceding section the sulfamate ion and related species were regarded as being formed by replacement of an OH group in \((\text{HO})\text{SO}_3^-\) or \((\text{HO})_2\text{SO}_3\) by an NH\(_2\) group. They could equally well be regarded as sulfonates of ammonia in which each H atom is successively replaced by SO\(_3^-\) (or SO\(_3\)H):

```
\[
\begin{align*}
\text{NH}_3 & \quad \text{HN} \left(\text{SO}_3\right)_2 \\
& \quad \text{HN} \left(\text{SO}_3\right)_3
\end{align*}
\]
```

Both sets of names are used in the literature. Free imidodisulfuric acid \(\text{HN(SO}_3\text{H})_2\) (which is isoelectronic with disulfuric acid \(\text{H}_2\text{S}_2\text{O}_7\), p. 705) and free nitridotrisulfuric acid \(\text{N(SO}_3\text{H})_3\) are unstable, but their salts are well characterized and have been extensively studied.

Imidodisulfuric acid derivatives can be prepared from urea by using less sulfuric acid than required for sulfamic acid (p. 741):

\[
4(\text{H}_2\text{N})_2\text{CO} + 5\text{H}_2\text{SO}_4 \xrightarrow{\text{warm}} 4\text{CO}_2 + 2\text{HN(SO}_3\text{NH}_4)_2 + (\text{NH}_4)_2\text{SO}_4
\]

Addition of aqueous KOH liberates NH\(_3\) and affords crystalline \(\text{HN(SO}_3\text{K})_2\) on evaporation. All 3 H atoms in \(\text{HN(SO}_3\text{H})_2\) can be replaced by NH\(_4\) or M\(^1\), e.g. the direct reaction of NH\(_3\) and SO\(_3\) yields the triammonium salt:

\[
4\text{NH}_3 + 2\text{SO}_3 \xrightarrow{} \text{NH}_4[\text{N(SO}_3\text{NH}_4)_2]
\]

Imidodisulfates can also be obtained by hydrolysis of nitridotrisulfates (see below). Figure 15.51 compares the structure of the imidodisulfate and parent disulfate ions, as determined from the potassium salts. Comparison with the hydroxylamine derivative \(\text{K}[\text{HN(OH)}\text{SO}_3]\) (below) is also instructive.

Fluoro and chloro derivatives of imidodisulfuric acid can be made by reacting \(\text{HSO}_3\text{F}\) or \(\text{HSO}_3\text{Cl}\) (rather than \(\text{H}_2\text{SO}_4\)) with urea:

\[
(\text{H}_2\text{N})_2\text{CO} + 3\text{HSO}_3\text{F} \xrightarrow{} \text{CO}_2 + \text{HN(SO}_2\text{F})_2 + [\text{NH}_4][\text{HSO}_4] + \text{HF}
\]

\(\text{HN(SO}_2\text{F})_2\) melts at 17\(^{\circ}\), boils at 170\(^{\circ}\) and can be further fluorinated with elemental F\(_2\) at room temperature to give \(\text{FN(SO}_2\text{F})_2\), mp \(-79.9^{\circ}\), bp 60\(^{\circ}\). The chloro derivative \(\text{HN(SO}_2\text{Cl})_2\) is a white crystalline compound, mp 37\(^{\circ}\): it is made in better yield from sulfamic acid by the following reaction sequence:

\[
2\text{PCl}_5 + 2\text{NH}_2\text{HSO}_3 \xrightarrow{} \text{Cl}_3\text{P} = \text{NSO}_2\text{Cl} + \text{OPCl}_3 + \text{HCl}
\]

\[
\text{Cl}_3\text{P} = \text{NSO}_2\text{Cl} + \text{ClISO}_3\text{H} \xrightarrow{} \text{HN(SO}_2\text{Cl})_2 + \text{OPCl}_3
\]

Salts of nitridotrisulfuric acid, \(\text{N(SO}_3\text{M})_3\), are readily obtained by the exothermic reaction of nitrites with sulfites or hydrogen sulfites in hot aqueous solution:

\[
\text{KNO}_2 + 4\text{KHSO}_3 \xrightarrow{} \text{N(SO}_3\text{K})_3 + \text{K}_2\text{SO}_4 + 2\text{H}_2\text{O}
\]
The dihydrate crystallizes as the solution cools. Such salts are stable in alkaline solution but hydrolyse in acid solution to imidodisulfate (and then more slowly to sulfamic acid):

\[
[N(SO_3)_3]^3^- + H_3O^+ \rightarrow [HN(SO_3)_2]^{2^-} + H_2SO_4
\]

(d) Hydrazine and hydroxylamine derivatives of sulfuric acid. Hydrazine sulfonic acid, \(H_2NNH.HSO_3\) is obtained as its hydrazinium salt by reacting anhydrous \(N_2H_4\) with diluted gaseous \(SO_3\) or its pyridine adduct:

\[
C_5H_5NSO_3 + 2N_2H_4 \rightarrow C_5H_5N + [N_2H_5]^+[H_2NNHSO_3]^-
\]

The free acid is monobasic, \(pK 3.85\); it is much more easily hydrolysed than sulfamic acid and has reducing properties comparable with those of hydrazine. Like sulfamic acid it exists as a zwitterion in the solid state: \(+H_3NNHSO_3^-\).

Symmetrical hydrazine disulfonic acid can be made by reacting a hydrazine sulfonate with a chlorosulfate:

\[
H_2NNHSO_3^- + CIOSO_3^- \rightarrow HCl + [O_3SNHNHSO_3]^2-.
\]

Oxidation of the dipotassium salt with \(HOCI\) yields the azodisulfonate \(KO_3SN=NSO_3K\). Numerous other symmetrical and unsymmetrical hydrazine polysulfonate derivatives are known.

With hydroxylamine, \(HONH_2\), 4 of the 5 possible sulfonate derivatives have been prepared as anions of the following acids:

- HONH(SO_3H)_2: hydroxylamine \(N,N\)-disulfonic acid
- (HSO_3)ONHSO_3H: hydroxylamine \(O,N\)-disulfonic acid
- (HSO_3)ON(SO_3H)_2: hydroxylamine trisulfonic acid

The first of these can be made by careful hydrolysis of the \(N,N\)-disulfonate which is itself made by the reaction of \(SO_2\) and a nitrite in cold alkaline solution:

\[
KNO_2 + KHSO_3 + SO_2 \rightarrow HON(SO_3K)_2
\]

The potassium salt readily crystallizes from the cold solution thus preventing further reaction with the hydrogen sulfite to give nitridotrisulfate (p. 743). The structure of the hydroxylamine \(N\)-sulfonate ion is shown in Fig. 15.52a. The closely related \(N\)-nitrosohydroxylamine \(N\)-sulfonate ion (Fig. 15.52b) can be made directly by absorbing NO in alkaline \(K_2SO_3\) solution: the 6 atoms ONN(O)SO all lie in one plane and the interatomic distances suggest an \(S-N\) single bond but considerable additional \(\pi\) bonding in the \(N-N\) bond.

Oxidation of hydroxylamine \(N,N\)-disulfonate with permanganate or \(PbO_2\) yields the intriguing

**Figure 15.52** Structures of various \(S-N\) oxoanions: (a) hydroxylamine-\(N\)-sulfonate, (b) \(N\)-nitrosohydroxylamine \(N\)-sulfonate and (c) the dimeric anion in Frémy’s salt \([K_2[ON(SO_3)_2]]_2\).
nitrosodisulfonate $K_2[\text{ON(SO}_3\text{)}_2]$; this was first isolated by Frémy as a yellow solid which was subsequently shown to be dimeric and diamagnetic due to the formation of long $\text{N} \cdots \text{O}$ bonds in the crystal (Fig. 15.52c). However, in aqueous solution the anion dissociates reversibly into the deep violet, paramagnetic monomer $[\text{ON(SO}_3\text{)}_2]^{2-}$.

Hydroxylamine trisulfonates, e.g. $(\text{KO}_3\text{S}) \text{ON}-\text{(SO}_3\text{K)}_2$ are made by the reaction of $K_2\text{SO}_3$ with potassium nitrosodisulfonate (Frémy's salt). Acidification of the product results in rapid hydrolysis to the $O,N$-disulfonate which can be isolated as the exclusive product:

$$(\text{KO}_3\text{S})\text{ON(SO}_3\text{K)}_2 + \text{H}_2\text{O} \rightarrow (\text{KO}_3\text{S})\text{ONH(SO}_3\text{K)} + \text{KHSO}_4$$

Sulfonic acids containing nitrogen have long been implicated as essential intermediates in the synthesis of $\text{H}_2\text{SO}_4$ by the lead-chamber process (p. 708) and, as shown by F. Seel and his group, the crucial stage is the oxidation of sulfite ions by the nitrosyl ion $\text{NO}^+$:

$$\text{SO}_3^{2-} + \text{NO}^+ \rightarrow [\text{ONSO}_3]^- \rightarrow 2\text{NO} + \text{SO}_3$$

The $\text{NO}^+$ ions are thought to be generated by the following sequence of reactions:

$$\text{NO} + \frac{1}{2}\text{O}_2 \rightarrow \text{NO}_2 \quad \text{gas phase}$$

$$\text{NO}_2 + \text{NO} + \text{H}_2\text{O} \rightarrow 2\{\text{ONO}\}$$

$$\left\{\text{surface reactions}\right\}$$

$$\text{SO}_2 + \text{H}_2\text{O} \rightarrow \text{H}_2\text{SO}_3$$

$$\text{H}_2\text{SO}_3 \rightarrow \text{H}^+ + \text{HSO}_3^-$$
\[
(\text{ONOH}) + H^+ \rightarrow \text{NO}^+ + H_2O
\]

The nitrososulfonate intermediate \([\text{ONSO}_3^-]\) can also react with \(\text{SO}_3^{2-}\) to give the hydroxylamine disulfonate ion which can likewise be oxidized by \(\text{NO}^+\):

\[
[\text{ON(SO}_3)_2]^{3-} + \text{NO}^+ \rightarrow \text{N}_2\text{O} + \text{SO}_3 + \text{SO}_4^{2-}
\]

In a parallel reaction the \([\text{ONSO}_3^-]\) intermediate can react with \(\text{SO}_2\) to form nitrilotrisulfonate:

\[
[\text{ON(SO}_3)_2]^{3-} + \text{SO}_2 \rightarrow \text{[N(SO}_3)_3]^{3-}
\]

This then reacts with \(\text{NO}^+\) to form \(\text{N}_2\), \(\text{SO}_3\) and \(\text{SO}_4^{2-}\).

(c) Selected other sulfur–nitrogen compounds. There are innumerable organo–sulfur–nitrogen compounds which fall outside the scope of the present treatment. Even without the presence of skeletal carbon atoms, a rich variety of novel reactions and structural types is being explored as briefly indicated on the preceding page by a selection of examples which is itself far from complete.\(^{279-282}\) (\(E = \text{S, Se}\)).

Selenium, Tellurium and Polonium

16.1 The Elements

16.1.1 Introduction: history, abundance, distribution

Tellurium was the first of these three elements to be discovered. It was isolated by the Austrian chemist F. J. Müller von Reichenstein in 1782 a few years after the discovery of oxygen by J. Priestley and C. W. Scheele (p. 600), though the periodic group relationship between the elements was not apparent until nearly a century later (p. 20). Tellurium was first observed in ores mined in the gold districts of Transylvania; Müller called it "metallum problematicum" or "aurum paradoxum" because it showed none of the properties of the expected antimony. The name tellurium (Latin tellus, earth) is due to another Austrian chemist, M. H. Klaproth, the discoverer of zirconium and uranium.

Selenium was isolated some 35 y after tellurium and, since the new element resembled tellurium, it was named from the Greek σελήνη, selene, the moon. The discovery was made in 1817 by the Swedish chemist J. J. Berzelius (discoverer of Si, Ce and Th) and J. G. Gahn (discoverer of Mn); they observed a reddish-brown deposit during the burning of sulfur obtained from Fahlun copper pyrites, and showed it to be volatile and readily reducible to the new element.

The discovery of polonium by Marie Curie in 1898 is a story that has been told many times. The element was isolated in 1898 by Madame Curie and her husband Pierre. They were searching for a new radioactive element and discovered it while working with pitchblende ore, a type of uranium ore. The element was named polonium (from the Latin word for Poland, where Pierre Curie was born) in honor of his homeland.

---

times. The immense feat of processing huge quantities of uranium ore and of following the progress of separation by the newly discovered phenomenon of radioactivity (together with her parallel isolation of radium by similar techniques, p. 108), earned her the Nobel Prize for Chemistry in 1911. She had already shared the 1902 Nobel Prize for Physics with H. A. Becquerel and her husband P. Curie for their joint researches on radioactivity. Indeed, this was the first time, though by no means the last, that invisible quantities of a new element had been identified, separated, and investigated solely by means of its radioactivity. The element was named after Marie Curie’s home country, Poland.

Selenium and tellurium are comparatively rare elements, being sixty-sixth and seventy-third respectively in order of crustal abundance; polonium, on account of its radioactive decay, is exceedingly unabundant. Selenium comprises some 0.05 ppm of the earth’s crust and is therefore similar to Ag and Hg, which are each about 0.08 ppm, and Pd (0.015 ppm). Tellurium, at about 0.002 ppm can be compared with Au (0.004 ppm) and Ir (0.001 ppm). Both elements are occasionally found native, in association with sulfur, and many of their minerals occur together with the sulfides of chalcophilic metals (p. 648), e.g. Cu, Ag, Au; Zn, Cd, Hg; Fe, Co, Ni; Pb, As, Bi. Sometimes the minerals are partly oxidized, e.g. MSeO3, 2H2O (M = Ni, Cu, Pb); PbTeO3, Fe2(2TeO3)3, 2H2O, FeTeO4, Hg2TeO4, Bi2TeO4(OH)4, etc. Selenolite, SeO2, and tellurite, TeO2, have also been found.

Polonium has no stable isotopes, all 27 isotopes being radioactive; of these only 210Po occurs naturally, as the penultimate member of the radium decay series:

\[
\begin{align*}
^{210}\text{Pb} & \xrightarrow{\beta^-} ^{210}\text{Bi} \\
^{210}\text{Bi} & \xrightarrow{\beta^-} ^{210}\text{Po} \\
^{210}\text{Po} & \xrightarrow{\alpha} ^{206}\text{Pb}
\end{align*}
\]

Because of the fugitive nature of 210Po, uranium ores contain only about 0.1 mg Po per tonne of ore (i.e. 10⁻⁴ ppm). The overall abundance of Po in crustal rocks of the earth is thus of the order of 3 × 10⁻¹⁰ ppm.

### 16.1.2 Production and uses of the elements

The main source of Se and Te is the anode slime deposited during the electrolytic refining of Cu (p. 1175); this mud also contains commercial quantities of Ag, Au and the platinum metals. Direct recovery from minerals is not usually economically viable because of their rarity. Selenium is also recovered from the sludge accumulating in sulfuric acid plants and from electrostatic precipitator dust collected during the processing of Cu and Pb. Detailed procedures for isolation and purification depend on the relative concentrations of Se, Te and other impurities, but a typical sequence involves oxidation by roasting in air with soda ash followed by leaching:

\[
\begin{align*}
\text{Ag}_2\text{Se} + \text{Na}_2\text{CO}_3 + \text{O}_2 & \xrightarrow{650^\circ} 2\text{Ag} + \text{Na}_2\text{SeO}_3 + \text{CO}_2 \\
\text{Cu}_2\text{Se} + \text{Na}_2\text{CO}_3 + 2\text{O}_2 & \xrightarrow{--} 2\text{CuO} + \text{Na}_2\text{SeO}_3 + \text{CO}_2 \\
\text{Cu}_2\text{Te} + \text{Na}_2\text{CO}_3 + 2\text{O}_2 & \xrightarrow{--} 2\text{CuO} + \text{Na}_2\text{TeO}_3 + \text{CO}_2
\end{align*}
\]

In the absence of soda ash, SeO2 can be volatilized directly from the roast:

\[
\begin{align*}
\text{Cu}_2\text{Se} + \frac{3}{2}\text{O}_2 & \xrightarrow{300^\circ} \text{CuO} + \text{CuSeO}_3 \\
\text{Cu}_2\text{Se} + \frac{3}{2}\text{O}_2 & \xrightarrow{650^\circ} \text{2CuO} + \text{SeO}_2
\end{align*}
\]

Separation of Se and Te can also be achieved by neutralizing the alkaline selenite and tellurite leach with H₂SO₄; this precipitates the tellurium as a hydrous dioxide and leaves the more acidic selenous acid, H₂SeO₃, in solution from which 99.5% pure Se can be precipitated by SO₂:

\[ \text{H}_2\text{SeO}_3 + 2\text{SO}_2 + \text{H}_2\text{O} \longrightarrow \text{Se} + 2\text{H}_2\text{SO}_4 \]

Tellurium is obtained by dissolving the dioxide in aqueous NaOH followed by electrolytic reduction:

\[ \text{Na}_2\text{TeO}_3 + \text{H}_2\text{O} \longrightarrow \text{Te} + 2\text{NaOH} + \text{O}_2 \]

The NaOH is regenerated and only make-up quantities are required. However, the detailed processes adopted industrially to produce Se and Te are much more complex and sophisticated than this outline implies.²⁻³⁻⁷⁻

World production of refined Se in 1995 was ~2000 tonnes the largest producers being Japan (600 t), USA (360 t) and Canada (300 t). The pattern of use no doubt varies somewhat from country to country, but in the USA the largest single use of the element (35%) is as a decolorizer of glass (0.01 -0.15 kg/tonne). Higher concentrations (1 -2 kg/tonne) yield delicate pink glasses. The glorious selenium ruby glasses, which are the most brilliant reds known to glass-makers, are obtained by incorporating solid particles of cadmium sulfoselenide in the glass; the deepest ruby colour is obtained when Cd(S,Se) has about 10% CdS, but as the relative concentration of CdS increases the colour moderates to red (40% CdS), orange (75%) and yellow (100%). Cadmium sulfoselenides are also widely used as heat-resistant red pigments in plastics, paints, inks and enamels. Another very important application of elemental Se is in xerography, which has developed during the past four decades into the pre-eminent process for document copying, as witnessed by the ubiquitous presence of xerox machines in offices and libraries (see Panel). Related uses are as a photoconductor (selenium photovoltaic cells) and as a rectifier in semiconductor devices (p. 258). Small amounts of ferroselenium are used to improve the casting, forging and machinability of stainless steels, and the dithiocarbamate [Se(S₂CNEt₂)₄] finds some use in the processing of natural and synthetic rubbers. Selenium pharmaceuticals comprise a further small outlet. In addition to Se, Fe/Se, Cd(S,Se) and [Se(S₂CNEt₂)₄] the main commercially available compounds of Se are SeO₂, Na₂SeO₃, Na₂SeO₄, H₂SeO₄ and SeOCl₂ (q.v.).

Production of Te is on a much smaller scale: ca. 350 tonnes in 1978, dominated by USA, Canada and Japan. More than 70% of the Te is used in iron and steel production and in non-ferrous metals and alloys, and 25% for chemicals. A small amount of TeO₂ is used in tinting glass, and Te compounds find some use as catalysts and as curing agents in the rubber industry. In addition to Te, Fe/Te and TeO₂, commercially important compounds include Na₂TeO₄ and [Te(S₂CNEt₂)₄].

Polonium, because of its very low abundance and very short half-life, is not obtained from natural sources. Virtually all our knowledge of the physical and chemical properties of the element come from studies on ²¹⁰Po which is best made by neutron irradiation of ²⁰⁹Bi in a nuclear reactor:

\[ ^{209}\text{Bi}(n,\gamma)^{210}\text{Bi} \xrightarrow{t\frac{1}{2}5.01\text{ d}} ^{210}\text{Po} \xrightarrow{t\frac{1}{2}138.38\text{ d}} \ldots \]

It will be recalled that ²⁰⁹Bi is 100% abundant and is the heaviest stable nuclide of any element (p. 550), but it is essential to use very high purity Bi to prevent unwanted nuclear side-reactions which would contaminate the product ²¹⁰Po; in particular Sc, Ag, As, Sb and Te must be <0.1 ppm and Fe <10 ppm. Polonium can be obtained directly in milligram amounts by fractional vacuum distillation from the metallic bismuth. Alternatively, it can be deposited spontaneously by electrochemical replacement onto the surface of a less electropositive metal.

---

² Very pure Se can be obtained by heating the crude material in H₂ at 650° and then decomposing the H₂Se so formed by passing the gas through a silica tube at 1000°. Any H₂S present, being more stable than H₂Se, passes through the tube unchanged, whereas hydrides which are less stable than H₂Se, such as those of Te, P, As, Sb, are not formed in the initial reaction at 650°.
Xerography

The invention of xerography by C. F. Carlson (USA) in the period 1934–42 was the culmination of a prolonged and concerted attack on the problem of devising a rapid, cheap and dry process for direct document copying without the need for the intermediate formation of a permanent photographic "negative", or even the use of specially prepared photographic paper for the "print". The discovery that vacuum-deposited amorphous or vitreous selenium was the almost ideal photoconductor for xerography was made in the Battelle Memorial Institute (Ohio, USA) in 1948. The dramatic success of these twin developments is witnessed by the vast number of xerox machines in daily use throughout the world today. However, early xerox equipment was not automatic. Models introduced in 1951 became popular for making offset masters, and rotary xerographic machines were introduced in 1959, but it was only after the introduction of the Xerox 914 copier in the early 1960s that electrophotography came of age. The word "xerography" derives from the Greek ἕρω, xero dry, γραφή, graphē, writing.

The sequential steps involved in commercial machines which employ reusable photoreceptors for generating xerox copies are shown in the figure and further elucidated below.

1. Sensitization of the photoreceptor. The photoreceptor consists of a vacuum-deposited film of amorphous Se, \(~50\mu m\) thick, on an Al substrate; this is sensitized by electrostatic charging from a corona discharge using a field of \(~10^5\) V cm\(^{-1}\).

2. Exposure and latent image formation. The sensitized photoreceptor is exposed to a light and dark image pattern; in the light areas the surface potential of the photoconductor is reduced due to a photoconductive discharge. Since current can only flow perpendicular to the surface, this step produces an electrostatic-potential distribution which replicates the pattern of the image.

3. Development of the image. This is done using a mixture of black (or coloured) toner particles, typically 10\mu m in diameter, and spherical carrier beads (~100\mu m diameter). The toner particles become charged triboelectrically (i.e. by friction) and are preferentially attracted either by the surface fringe field at light–dark boundaries or (in systems with a developing electrode) by the absolute potential in the dark areas; they adhere to the photoreceptor, thus forming a visible image corresponding to the latent electrostatic image.

4. Image transfer. This is best done electrostatically by charging the print paper to attract the toner particles.

5. Fixing. The powder image is made permanent by fusing or melting the toner particles into the surface of the paper, either by heat, by heat and pressure, or by solvent vapours.

6. Cleaning. Any toner still left on the photoreceptor after the transfer process is removed with a cloth web or brush, or by a combination of electrostatic and mechanical means.

7. Image erasure. The potential differences due to latent image formation are removed by flooding the photoreceptors with a sufficiently intense light source to drive the surface potential to some uniformly low value (typically \(~100\) V corresponding to fields of \(~10^4\) V cm\(^{-1}\)); the photoreceptor is then ready for another print cycle.

The elegance, cheapness and convenience of xerography for document copying has led to rapid commercial development on a colossal scale throughout the world.

such as Ag. Solution techniques are unsuitable except on the trace scale (submicrogram amounts) because of the radiation damage caused by the intense radioactivity (p. 753). All applications of Po depend on its radioactivity: it is an almost pure \(\alpha\)-emitter (\(E_\alpha\) 5.30 MeV) and only 0.0011% of the activity is due to \(\gamma\)-rays (\(E_{\max}\) 0.803 MeV). Because of its short
half-life (138.38 d) this entails a tremendous energy output of 141 W per gram of metal: in consequence, there is considerable self-heating of Po and its compounds. The element can therefore be used as a convenient light-weight heat source, or to generate spontaneous and reliable thermoelectric power for space satellites and lunar stations, since no moving parts are involved. Polonium also finds limited use as a neutron generator when combined with a light element of high $\alpha$,n cross-section such as beryllium: $^9$Be($\alpha$,n)$^{12}$C. The best yield (93 neutrons per $10^6\alpha$-particles) is obtained with a BeO target.

16.1.3 Allotropy

At least eight structurally distinct forms of Se are known: the three red monoclinic polymorphs ($\alpha$, $\beta$ and $\gamma$) consist of $\text{Se}_8$ rings and differ only in the intermolecular packing of the rings in the crystals. Other ring sizes have recently been synthesized in the red allotropes cyclo-$\text{Se}_6$ and cyclo-$\text{Se}_7$, and the heterocyclic analogues cyclo-$\text{Se}_5$S and cyclo-$\text{Se}_3$S$_2$.(8) The grey, "metallic", hexagonal crystalline form features helical polymeric chains and these also occur, somewhat deformed, in amorphous red Se. Finally, vitreous black Se, the ordinary commercial form of the element, comprises an extremely complex and irregular structure of large polymeric rings having up to 1000 atoms per ring.

The $\alpha$- and $\beta$-forms of red crystalline $\text{Se}_8$ are obtained respectively by the slow and rapid evaporation of CS$_2$ or benzene solutions of black vitreous Se and more recently a third ($\gamma$) form of red crystalline $\text{Se}_8$ was obtained from the reaction of dipiperidinotetraselane with solvent CS$_2$:(9)

$$\left[\text{Se}_4(\text{NC}_3\text{H}_10)\right]_2 2\text{CS}_2 \rightarrow \left[\text{Se}(\text{S}_2\text{CNC}_3\text{H}_10)\right]_2 + \frac{3}{2}\text{Se}_8$$

All three allotropes consist of almost identical puckered $\text{Se}_8$ rings similar to those found in cyclo-$\text{S}_8$ (p. 658) and of average dimensions Se-Se 233.5 pm, angle Se-Se-Se 105.7°, dihedral angle 101.3° (Fig. 16.1a). The intermolecular packing is most efficient for the $\alpha$-form. It is interesting to note that $\beta$-$\text{Se}_8$ was at one time thought, on the basis of an X-ray crystal structure determination, to be an 8-membered chain with the configuration of a puckered ring in which 1 Se-Se bond had been broken; the error was corrected in a very perceptive paper by L. Pauling and his co-workers.(10) Both $\alpha$- and $\beta$-$\text{Se}_8$ (and presumably also $\gamma$-$\text{Se}_8$) are appreciably soluble in CS$_2$ to give red solutions.

Grey, hexagonal, “metallic” selenium is thermodynamically the most stable form of the element and can be formed by warming other modifications; it can also be obtained by slowly cooling molten Se or by condensing Se vapour at a temperature just below the mp (220.5°). It is a photoconductor (p. 750) and is the only modification which conducts electricity. The structure (Fig. 16.1b) consists of unbranched helical chains with Se-Se 237.3 pm, angle Se-Se-Se 103.1°, and a repeat unit every 3 atoms (cf. fibrous sulfur, p. 660). The closest Se...Se distance between chains is 343.6 pm, which is very close to that in Te$_x$ (350 pm) (see below). Grey Se$_8$ is insoluble in CS$_2$ and its density, 4.82 g cm$^{-3}$, is the highest of any modification of the element. A related allotrope is red amorphous Se, formed by condensation of Se vapour onto a cold surface or by precipitation from aqueous solutions of tellurous acid by treatment with SO$_2$ (p. 755) or other reducing agents such as hydrazine hydrate. It is slightly soluble in CS$_2$, and has a deformed chain structure but does not conduct electricity. The heat of transformation to the stable hexagonal

---

grey form has been variously quoted but is in the region of 5–10 kJ per mole of Se atoms.

Vitreous, black Se is the ordinary commercial form of the element, obtained by rapid cooling of molten Se; it is a brittle, opaque, bluish-black lustrous solid which is somewhat soluble in CS$_2$. It does not melt sharply but softens at about 50° and rapidly transforms to hexagonal grey Se when heated to 180° (or at lower temperatures when catalysed by halogens, amines, etc.). There has been much discussion about the structure but it seems to comprise rings of varying size up to quite high molecular weights. Presumably these rings cleave and polymerize into helical chains under the influence of thermal soaking or catalysts. The great interest in the various allotropes of selenium and their stabilization or interconversion, stems from its use in photocells, rectifiers, and xerography (p. 750).²

Tellurium has only one crystalline form and this is composed of a network of spiral chains similar to those in hexagonal Se (Fig. 16.1c and d). Although the intra-chain Te–Te distance of 284 pm and the $c$ dimension of the crystal (593 pm) are both substantially greater than for Se$_x$ (as expected), nevertheless the closest interatomic distance between chains is almost identical for the 2 elements (Te ⋯ Te 350 pm). Accordingly the elements form a continuous range of solid solutions in which there is a random

Figure 16.1 Structures of various allotropes of selenium and the structure of crystalline tellurium: (a) the Se$_8$ unit in $\alpha$, $\beta$- and $\gamma$-red selenium; (b) the helical Se chain along the $c$-axis in hexagonal grey selenium; (c) the similar helical chain in crystalline tellurium shown in perspective; and (d) projection of the tellurium structure on a plane perpendicular to the $c$-axis.

alternation of Se and Te atoms in the helical chains.\(^{11}\) The homogeneous alloys Se$_x$Te$_{1-x}$ can also, most remarkably, be prepared directly by hydrazine reduction of glycol solutions of $x$SeO$_2$ and $(1-x)$TeO$_2$ or other compounds of Se$^{IV}$ and Te$^{IV}$ such as dialkylselenites and tetraalkoxytelluranes; the lattice parameters and mp of the alloys vary steadily between those of the two end members Se and Te.\(^{12}\) The rapid diminution in allotropic complexity from sulfur through selenium to tellurium is notable.

Polonium is unique in being the only element known to crystallize in the simple cubic form (6 nearest neighbours at 335 pm). This $\alpha$-form distorts at about 36$^\circ$ to a simple rhombohedral modification in which each Po also has 6 nearest neighbours at 335 pm. The precise temperature of the phase change is difficult to determine because of the self-heating of crystalline Po (p. 751) and it appears that both modifications can coexist from about 18$^\circ$ to 54$^\circ$. Both are silvery-white metallic crystals with substantially higher electrical conductivity than Te.

16.1.4 Atomic and physical properties

Selenium, Te and Po are the three heaviest members of Group 16 and, like their congenors O and S, have two $p$ electrons less than the next following noble gases. Selenium is normally said to have 6 stable isotopes though the heaviest of these ($^{82}$Se, 8.73% abundant) is actually an extremely long-lived $\beta^-$ emitter, $t_{1/2} 1.4 \times 10^{20}$ y. The most abundant isotope is $^{80}$Se (49.61%), and all have zero nuclear spin except the 7.63% abundant $^{77}$Se ($I = \frac{1}{2}$), which is finding increasing use in nmr experiments.\(^{13}\) Because of the plethora of isotopes the atomic weight is only known to about 1 part in 2600 (p. 16). Tellurium, with 8 naturally occurring stable isotopes, likewise suffers some imprecision in its atomic weight (1 part in 4300). The most abundant isotopes are $^{130}$Te (33.87%) and $^{128}$Te (31.70%), and again all have zero nuclear spin except the nmr active isotopes $^{123}$Te (0.905%) and $^{125}$Te (7.12%), which have spin $\frac{1}{2}$.\(^{13}\) $^{125}$Te also has a low-lying nuclear isomer $^{125m}$Te which decays by pure $\gamma$ emission ($E_{\gamma}$ 35.48 keV, $t_{1/2}$ 58 d) — this has found much use in Mössbauer spectroscopy.\(^{14}\) Polonium, as we have seen (p. 748), has no stable isotopes. The 3 longest lived, together with their modes of production and other properties, are as shown in Table 16.1.

Several atomic and physical properties of the elements are given in Table 16.2. The trends to larger size, lower ionization energy and lower electronegativity are as expected. The trend to metallic conductivity is also noteworthy; indeed, Po resembles its horizontal neighbours Bi, Pb and TI not only in this but in its moderately high density and notably low mp and bp.

\(^{(a)}\) The 2-coordinate covalent radius is 119 pm for elemental Se and 142 pm for Te; the 6-coordinate metallic radius of Po is 168 pm.

\(^{(b)}\) Depends markedly on purity, temperature and photon flux; resistivity of liquid Se at 400\(^{°}\) is 1.3 \times 10^5 ohm cm.

16.1.5 Chemical reactivity and trends

The elements in Group 16 share with the preceding main-group elements the tendency towards increasing metallic character as the atomic weight increases within the group. Thus O and S are insulators, Se and Te are semiconductors and Po is a metal. Parallel with this trend is the gradual emergence of cationic (basic) properties with Te, and these are even more pronounced with Po. For example, Se is not appreciably attacked by dilute HCl whereas Te dissolves to some extent in the presence of air; Po dissolves readily to yield pink solutions of Po\(^{II}\) which are then rapidly oxidized further to yellow Po\(^{IV}\) by the products of radiolytic decomposition of the solvent. Likewise, the structure and bonding of the halides of these elements depends markedly on both the electronegativity of the halogen and on the oxidation state of the central element, thereby paralleling the “ionic-covalent” transition which has already been discussed for the halides of P (p. 499), As and Sb (p. 558), and S (p. 691).

Selenium, Te and Po combine directly with most elements, though less readily than do O and S. The most stable compounds are (a) the selenides, tellurides and polonides (M\(^{2−}\)) formed with the strongly positive elements of Groups 1, 2 and the lanthanides, and (b) the compounds with the electronegative elements O, F and Cl in which the oxidation states are +2, +4 and +6. The compounds tend to be less stable than the corresponding compounds of S (or O), and there are few analogues of the extensive range of sulfur–nitrogen compounds (p. 721). A similar trend (also noted in the preceding groups) is the decreasing thermal stability of the hydrides: H\(_2\)O > H\(_2\)S > H\(_2\)Se > H\(_2\)Te > H\(_2\)Po. Selenium and tellurium share to a limited extent sulfur’s great propensity for catenation (see allotropy of the elements, polysulfanes, halides, etc.).

As found in preceding groups, there is a diminution in the stability of multiple bonds (e.g. to C, N, O) and a corresponding decrease in their occurrence as the atomic number of the group element increases. Thus O==C==O and (to a lesser extent) S==C==S are stable, whereas
Se=C=Se polymerizes readily, Se=C=Te is unstable and Te=C=Te is unknown. Again, SO$_2$ is a (nonlinear) gaseous molecule, whereas SeO$_2$ is a chain polymer $-O-Se(=O)-$ (p. 779) and TeO$_2$ features 4-coordinate pseudo-trigonal-bipyramidal units $\{TeO_4\}$ which are singly-bonded into extended layer or 3D structures (p. 779); in PoO$_2$ the coordination number increases still further to 8 and the compound adopts the typical “ionic” fluorite structure (p. 118). It can be seen that double bonds are less readily formed between 2 elements the greater the electronegativity difference between them and the smaller the sum of their individual electronegativities; this is paralleled by a diminution in double-bond formation with increasing size of the more electropositive element and the consequent decrease in bond energy.

The redox properties of the elements also show interesting trends. In common with several elements immediately following the first (3d) transition series (especially Ge, As, Se, Br) selenium shows a marked resistance to oxidation up to its group valency, i.e. Se$^{VI}$. For example, whereas HNO$_3$ readily oxidizes S to H$_2$SO$_4$, selenium gives H$_2$SeO$_3$. Again dehydration of H$_2$SO$_4$ with P$_2$O$_5$ yields SO$_3$ whereas H$_2$SeO$_4$ gives SeO$_2$ + $\frac{3}{2}$O$_2$. Likewise S forms a wide range of sulfones, R$_2$SO$_2$, but very few selenones are known; thus, Ph$_2$SeO is not oxidized either by HNO$_3$ or by acidified K$_2$Cr$_2$O$_7$, and alkaline KMnO$_4$ is required to produce Ph$_2$SeO$_2$ (mp 155°). As noted in the isolation of the element (p. 749), SO$_2$ precipitates Se from acidified solutions of Se$^{IV}$.

The standard reduction potentials of the elements in acid and alkaline solutions are summarized in the schemes below.\(^{15}\) It is

[a]CrL₆ = [Cr(η⁵-C₅H₅)(CO)₂]

instructive to plot these data, and the equivalent values for sulfur, as volt-equivalents vs oxidation state (pp. 435–8), when the following trends (in acid solution) become obvious:

(i) the decreasing stability of H₂M from H₂S to H₂Po;
(ii) the greater stability of M⁴⁺ relative to M⁰ and M⁶⁺ for Se, Te and Po (but not for S, p. 706), as shown by the concavity of the graph;
(iii) the anomalous position of Se in its higher oxidation states, as mentioned in the preceding paragraph.

The known coordination geometries of Se, Te and Po are summarized in Table 16.3 together with typical examples. Most of the common geometries are observed for Se and Te, though twofold (linear) is rare and fivefold (trigonal bipyramidal) is conspicuous by its absence. The smaller range of established geometries for compounds of Po undoubtedly reflects the paucity of structural data occasioned by the rarity of this element and the extreme difficulty of obtaining X-ray crystallographic or other structural information. There appears, however, to be a clear preference for higher coordination numbers, as expected from the larger size of the Po atom. The various examples will be discussed more fully in subsequent sections but the rare pentagonal planar coordination formed in the ethyl xanthato complex [Te(η²-S₂COEt)₂(η¹-S₂COEt)]⁻ should be noted (Fig. 16.2a);(17) Other unusual stereochemistries are the pentagonal pyramidal

---

6-coordinate Te$^{IV}$ in [MeTe(I){S$_2$CNEt$_2$}]$_2$ and pentagonal bipyramidal 7-coordinate Te$^{IV}$ in [PhTe{S$_2$CNEt$_2$}]$_2$[S$_2$P(OEt)$_2$]). In both cases the crystallographic data suggest the presence of a stereochemically active lone pair of electrons which distorts the regular geometry of the coordination sphere. This structure is consistent with a pentagonal bipyramidal set of orbitals on Te$^{II}$, 2 of which are occupied by stereochemically active lone-pairs directed above and below the TeS$_5$ plane. By contrast, the single lone-pairs in Se$^{IV}$X$_6^{2-}$, Te$^{IV}$X$_6^{2-}$ and Po$^{IV}$I$_6^{5-}$ are sterically inactive and the 14-(valence)electron anions are accurately octahedral (see p. 776), as in molecular Se$^{VI}$F$_6$, which has only 12 valence electrons.

Other less-symmetrical coordination geometries for Se and Te occur in the $\mu$-Se$_2$ and $\mu$-Te$_2$ complexes and the polyatomic cluster cations Se$_{10}^{2+}$ and Te$_6^{4+}$, as mentioned below.

The coordination chemistry of complexes in which Se is the donor atom has been extensively studied. Ligands with Te as donor atom have been less widely investigated but both sets of ligands resemble S-donor ligands (p. 673) rather than O-donor ligands in favouring b-class acceptors such as Pd$^{II}$, Pt$^{II}$ and Hg$^{II}$. The linear selenocyanate ion SeCN$^-$, like the thiocyanate ion (p. 324) is ambidentate, bonding via Se to heavy metals and via N (isoselenocyanate) to first-row transition metals, e.g. [Ag$^{II}$(SeCN)$_3$]$^{2-}$, [Cd$^{II}$(SeCN)$_4$]$^{2-}$, [Pb$^{II}$(SeCN)$_6$]$^{4-}$, but [Cr$^{III}$(NCSe)$_6$]$^{3-}$ and [Ni(NCSe)$_4$]$^{2-}$. The isoselenocyanate ligand often features nonlinear coordination

\[
\begin{align*}
N &= \text{C} \equiv \text{Se} \\
M &
\end{align*}
\]

but in the presence of bulky ligands it tends to become linear M–N$^+ \equiv \text{C} \equiv \text{Se}$. A bidentate bridging mode is also well established, e.g. [Cd–Se–C–N–Cd] and [Ag–Se–C–N–Cr].

Monodentate organoselenium ligands include

$^{23}$ M. G. B. DREW, G. W. A. FOWLES, E. M. PAGE and D. A. RICE, J. Am. Chem. Soc. 101, 5827–8 (1979). The dark green rhodium complex [Rh$_2$(µ-$\eta^2$-C$_5$Me$_5$)$_2$(µ-Se)(µ-Se$_2$)] and the violet-brown osmium analogue [Os$_2$(µ-$\eta^2$-C$_5$Me$_5$)$_2$(µ-Se)(µ-Se$_2$)] have a similar structure.$^{(23)}$

Polyatomic cations, $M_{x}^{n+}$

The brightly coloured solutions obtained when sulfur is dissolved in oleums (p. 664) are paralleled by similar behaviour of Se and Te. Indeed, the bright-red solutions of Te in $H_2SO_4$ were noted by M. H. Klaproth in 1798 and the coloured solutions of Se in the same solvent were reported by G. Magnus in 1827. Systematic studies in a range of nonaqueous solvents have since shown that the polycations of Se and Te are less electropositive than their $S$ analogues and can be prepared in a variety of strong acids such as $H_2SO_4$, $H_2S_2O_7$, $HSO_3F$, $SO_3/AsF_5$, $SO_2/SbF_5$ and molten $AlCl_3$. Typical reactions for Se are:

$$\text{Se}^{2+} + \text{acid} \rightarrow \text{polyseleonic acid}$$

against certain cancers. The average dietary intake of Se in the USA is said to be $\sim 150 \mu g$ daily, usually in meat and sea food. Considerable caution should be taken in handling compounds of Se and Te, but the hazards should also be kept in perspective — no human fatalities directly attributable to either Se or Te poisoning have ever been recorded. The biochemistry and dietary aspects of Se have been reviewed.\(^{30}\)

Polonium is extremely toxic at all concentrations and is never beneficial. Severe radiation damage of vital organs follows ingestion of even the minutest concentrations and, for the most commonly used isotope, $^{210}$Po, the maximum permissible body burden is $0.03 \mu Ci$, i.e. $1100$ Bq ($\equiv 1100$ s\(^{-1}\)), equivalent to $\sim 7 \times 10^{-12}$ g of the element. Concentrations of airborne Po compounds must be kept below $4 \times 10^{-11}$ mg m\(^{-3}\).

## §16.1.6

**Polyatomic cations, $M_{x}^{n+}$**

The brightly coloured solutions obtained when sulfur is dissolved in oleums (p. 664) are paralleled by similar behaviour of Se and Te. Indeed, the bright-red solutions of Te in $H_2SO_4$ were noted by M. H. Klaproth in 1798 and the coloured solutions of Se in the same solvent were reported by G. Magnus in 1827. Systematic studies in a range of nonaqueous solvents have since shown that the polycations of Se and Te are less electropositive than their $S$ analogues and can be prepared in a variety of strong acids such as $H_2SO_4$, $H_2S_2O_7$, $HSO_3F$, $SO_3/AsF_5$, $SO_2/SbF_5$ and molten $AlCl_3$. Typical reactions for Se are:

$$\text{Se}^{2+} + \text{acid} \rightarrow \text{polyseleonic acid}$$

against certain cancers. The average dietary intake of Se in the USA is said to be $\sim 150 \mu g$ daily, usually in meat and sea food. Considerable caution should be taken in handling compounds of Se and Te, but the hazards should also be kept in perspective — no human fatalities directly attributable to either Se or Te poisoning have ever been recorded. The biochemistry and dietary aspects of Se have been reviewed.\(^ {30}\)

Polonium is extremely toxic at all concentrations and is never beneficial. Severe radiation damage of vital organs follows ingestion of even the minutest concentrations and, for the most commonly used isotope, $^{210}$Po, the maximum permissible body burden is $0.03 \mu Ci$, i.e. $1100$ Bq ($\equiv 1100$ s\(^{-1}\)), equivalent to $\sim 7 \times 10^{-12}$ g of the element. Concentrations of airborne Po compounds must be kept below $4 \times 10^{-11}$ mg m\(^{-3}\).
Figure 16.4 (a) Structure of $[\text{Se}_4]^{2+}$; (b) and (c) views of $[\text{Se}_8]^{2+}$.

Figure 16.5 Structure of the $[\text{Se}_{10}]^{2+}$ cation in $\text{Se}_{10}(\text{SbF}_5)_2$ along the $b$- and $c$-axes of the crystal; angles Se(2)-Se(1)-Se(9) and Se(5)-Se(6)-Se(10) are each 101.7°.

$4\text{Se} + \text{S}_2\text{O}_8\text{F}_2 \xrightarrow{\text{HSO}_3\text{F}} [\text{S}_4]^{2+} [\text{SO}_3\text{F}]^{-2}$ (yellow)

$[\text{Se}_4]^{2+} + 4\text{Se} \xrightarrow{\text{HSO}_3\text{F}} [\text{Se}_8]^{2+}$ (green)

$\text{Se}_8 + 6\text{AsF}_5 \xrightarrow{\text{SO}_3/80^\circ} 2[\text{S}_4]^{2+} [\text{AsF}_6]^{-2}$ (yellow)

$\text{Se}_8 + 5\text{SbF}_5 \xrightarrow{\text{SO}_3/-23^\circ} [\text{Se}_{10}]^{2+} [\text{Sb}_2\text{F}_{11}]^{-2}$ (green)

$7\frac{1}{2}\text{Se} + \frac{1}{2}\text{SeCl}_4 + 2\text{AlCl}_3 \xrightarrow{\text{fuse at } 250^\circ} [\text{Se}_8]^{2+} [\text{AlCl}_4]^{-2}$ (green-black)

X-ray crystal structure studies on $[\text{Se}_4]^{2+}$, $[\text{HS}_2\text{O}_7]^{-2}$ show that the cation is square planar (like $\text{S}_4^{2+}$, p. 665) as in Fig. 16.4a. The Se–Se distance of 228 pm is significantly less than the value of 234 pm in $\text{Se}_8$ and 237 pm in $\text{Se}_{10}$, consistent with some multiple bonding. The structure of $[\text{Se}_8]^{2+}$ in the salt $[\text{Se}_8]^{2+} [\text{AlCl}_4]^{-2}$ is in Fig. 16.4b and c; it comprises a bicyclic $C_7$ structure with the endo-exo configuration with a long trans-annular link of 284 pm. Other Se–Se distances are very similar to those in $\text{Se}_8$ itself, but the Se–Se–Se angles are significantly smaller in the cation, being ~96° rather than 106°. More recently, the deep-red crystalline compound $\text{Se}_{10}(\text{SbF}_5)_2$ has been isolated from the reaction of $\text{SbF}_5$ with an excess of $\text{Se}$ in $\text{SO}_2$ under pressure at ~50°. Two views of the bicyclic cation are shown in Fig. 16.5; it features a 6-membered boat-shaped ring linked across the middle of a zigzag chain of 4 further Se atoms. The Se–Se distances vary from 225 to 240 pm and Se–Se–Se angles range from

Polyatomic cations, \( M_{x}^{n+} \)

97° to 106°, with 6 angles at the bridgehead atoms Se(1) and Se(6) being significantly smaller than the other 8 in the linking chains. The low-temperature disproportionation of Se\(_{10}\)\(^{2+}\) into Se\(_{8}\)\(^{2+}\) and a second species, probably Se\(_{17}\)\(^{2+}\), i.e. \([\text{Se}_{8}-\text{Se}-\text{Se}_{8}]^{2+}\), has been studied by \(^{77}\)Se nmr spectroscopy.\(^{34}\) Heteronuclear species such as \([\text{S}_{4}\text{Se}_{4}^{-}]^{2+}\) have also been identified by nmr techniques and characterized by X-ray structure analysis.\(^{35}\) Analogous Se/Te heteronuclear cations are described below.

Polyatomic tellurium cations can be prepared by similar routes. The bright-red species Te\(_{4}\)\(^{2+}\), like S\(_{4}\)\(^{2+}\) and Se\(_{4}\)\(^{2+}\), is square planar with the Te–Te distance (266 pm) somewhat less than in the element (284 pm) (Fig. 16.6a). Oxidation of Te with AsF\(_{5}\) in AsF\(_{3}\) as solvent yields the brown crystalline compound Te\(_{6}\)(AsF\(_{6}\))\(_{4}\). AsF\(_{3}\); X-ray studies reveal the presence of \([\text{Te}_{6}]^{3+}\) which is the first example of a simple trigonal prismatic cluster cation (Fig. 16.6b). The Te–Te distances between the triangular faces (313 pm) are substantially larger than those within the triangle (267 pm).\(^{36}\) No Te analogue of S\(_{8}\)\(^{2+}\) and Se\(_{8}\)\(^{2+}\) had been identified until 1997 when the reaction of ReCl\(_{4}\) with Te and TeCl\(_{4}\) at 230° yielded silvery crystals of \([\text{Te}_{8}]^{2+}[\text{ReCl}_{6}]^{2-}\) with Te–Te 272 pm (av), the shortest Te–Te distance being 315 pm.\(^{36a}\)

Previously (1990), oxidation of Te with WCl\(_{6}\) had yielded \([\text{Te}_{8}][\text{WCl}_{6}]_{2}\) in which the Te\(_{8}\)\(^{2+}\) dication was found to have a more pronounced bicyclic structure of C\(_{2}\) symmetry with Te–Te 275.2 pm and the central transannular link being 299.3 pm.\(^{36a}\)

Mixed Se/Te polatomic cations are also known. For example, when Se and Te are dissolved in 65% oleum at room temperature the resulting orange-brown solutions were shown by \(^{125}\)Te and \(^{123}\)Te nmr spectroscopy to contain the four species \([\text{Te}_{n}\text{Se}_{4-}\text{n}]^{2+}\) \(n = 1–4\) and the species \([\text{Se}_{4}]^{2+}\) was also presumably present.\(^{37}\) Likewise \(^{77}\)Se and \(^{125}\)Te multinuclear magnetic resonance studies on solutions obtained by oxidizing equimolar mixtures of Se and Te with AsF\(_{5}\) in SO\(_{2}\) reveal not only \([\text{Se}_{4}]^{2+}\), \([\text{Te}_{4}]^{2+}\) and \([\text{Te}_{6}]^{2+}\) but also \([\text{TeSe}_{3}]^{2+}\), cis- and trans-\([\text{Te}_{2}\text{Se}_{2}]^{2+}\), \([\text{Te}_{3}\text{Se}]^{2+}\), \([\text{Te}_{2}\text{Se}_{4}]^{2+}\) and \([\text{Te}_{3}\text{Se}_{3}]^{2+}\).\(^{38}\) The molecular structures of the sulfur analogue \([\text{Te}_{3}\text{S}_{3}]^{2+}\) and of \([\text{Te}_{2}\text{Se}_{4}]^{2+}\) have also been determined by X-ray diffractionmetry and found to have a boat-shaped 6-membered heterocyclic structure with a cross-ring bond as shown in Fig. 16.7. As expected, these M\(_{6}\)\(^{2+}\) species are more open than the corresponding Te\(_{6}\)\(^{4+}\) cluster because of the presence of 2 extra valency-shell electrons (p. 724). Other mixed species that have been characterized include \([\text{Te}_{2}\text{Se}_{6}]^{2+}\) (cube, with diagonally placed Te)\(^{39}\)

---

and \([\text{Te}_4\text{S}_4]^{2+}\) (electron-rich \(\text{S}_4\text{N}_4\) cluster but with coplanar \(\text{S}\) atoms as in \(\text{As}_4\text{S}_4\)).\(^{40}\)

The mixed anionic species \([\text{TI}_2\text{Te}_2]^{2-}\) (20 valence electrons) is butterfly-shaped with \(\text{TI}_2\) at the “hinge” and \(2\text{Te}\) at the “wing tips”,\(^{41}\) in contrast to the 22 valence-electron cationic species \(\text{Te}_4^{2+}\) and \(\text{Se}_4^{2+}\) which are square planar. The remarkable cationic cluster species \(((\text{NbI}_2)\text{TeO}^+\text{(Te}_2\text{)}\text{I}_2\text{)}^+\) should also be noted: this was formed serendipitously in low yield as the monoiiodide during the high-temperature reaction between \(\text{NbOI}_3\), \(\text{Te}\) and \(\text{I}_2\) and features the bridging groups \((\mu,\eta^2:\eta^2\text{-Te}_4^{2+}\) and two \((\mu,\eta^2\text{-Te}_2^{2+}\) in addition to \((\mu_3\text{-O})^{2-}\) and six terminal \(\text{I}^-\). This implies a mixed \(\text{Nb}^{III}\) \(\text{Nb}^{IV}\) oxidation state with two localized \(\text{Nb}--\text{Nb}\) single bonds.\(^{42}\)

### 16.1.7 Polyatomic anions, \(M_x^{2-}\)

The synthesis, structural characterization and coordination chemistry of polyselenides, \(\text{Se}_x^{2-}\), and polytellurides, \(\text{Te}_x^{2-}\), is a burgeoning field which has sprung into prominence during the past decade. The seminal studies by E. Zintl and his group during the 1930s showed that such species could be prepared by reduction of the elements with alkali metals in liquid ammonia, but it was the advent of \(^{77}\text{Se}\) and \(^{125}\text{Te}\) nmr techniques, and the use of crown and crypt complexes (p. 96) to prepare crystalline derivatives for X-ray structural analysis which provided the firm bases for further advances. The rich reaction chemistry and coordination properties soon followed. Comparisons with polysulfides and polysulfanes (pp. 681–3) are instructive. Thus, little is known about \(\text{H}_2\text{Se}_2\) and \(\text{H}_2\text{Te}_2\), and nothing at all about the higher homologues \(\text{H}_2\text{Se}_x\) and \(\text{H}_2\text{Te}_x\); however, compounds containing the anions \(\text{Se}_x^{2-}\) \((x = 2–11)\) and \(\text{Te}_x^{2-}\) \((x = 2–5, 8...\) are considerably more stable both in solution and in the crystalline state than are the parent hydrides.

Reaction of \(\text{Na}_2\text{Se}\) and \(\text{Na}_2\text{Se}_2\) with \(\text{Se}\) in the presence of ethanolic solutions of tetraalkyl-ammonium halides and catalytic amounts of \(\text{I}_2\) yields dark green or black crystalline polyselendes \((x = 3, 5–9)\) depending on the conditions used and the particular cation selected.\(^{43}\) Tetrphenylphosphonium salts and crown ether complexes of alkali or alkaline earth cations in dimethylformamid solution can also be used.\(^{44}\)

Typical structures and dimensions of the resulting polyseleneide dianions are shown in Fig. 16.8, though it should be emphasized that torsion angles, interatomic angles and even to some extent interatomic distances may depend on the countercation chosen. Detailed references have been tabulated.(45) The triselenide ion, $\text{Se}_3^{2-}$, has been identified as a moderately stable species in solution and in the solid state, but its $X$-ray structure has not been reported; it is presumably angular like $S_2^{2-}$ and $Te_2^{2-}$. The evolution of the chains up to $Se_{25}^{2-}$ is clear.

The structure of $Ses_2^{2-}$ has also been determined in $[\text{Na(crown)}]^+\text{[Se}_8]^{2-}(\text{Se}_6,\text{Se}_7)$ which features a curious packing of the cation and the anion with an equimolar amount of neutral cyclo-Se$_n$ comprising variable amounts of $\text{Se}_6$ and $\text{Se}_7$.\(^{46}\)

The structure of catena-$\text{Se}_x^{2-}$ has a relatively long central $\text{Se}–\text{Se}$ bond (247 pm) which forms, at one end, a sharp angle of 93° to the adjacent $\text{Se}$ atom; the $\text{Se}$ at other end of the bond is approached rather closely by one of the terminal $\text{Se}$ atoms (295 pm) to form an incipient 6-membered ring. The process continues in $\text{Se}_{11}^{2-}$ which has a centrosymmetric spiro-bicyclic structure involving a central square-planar $\text{Se}$ atom common to the two chair-conformation rings. The central bonds are again rather long (266–268 pm) and the structure may be described as a central $\text{Se}^{2+}$ chelated by two $\eta^2$-$\text{Se}_5^{2-}$ ligands (see below). The structure also has similarities with the anion in $\text{Cs}^+\text{[Se}_{16}]^{4-}$,\(^{47}\) which has a central planar formal $\text{Se}^{2+}$ coordinated by one chelating $\eta^2$-$\text{Se}_5^{2-}$ ligand ($\text{Se}–\text{Se}$ 243 pm) and by two monohapto $\eta^1$-$\text{Se}_5^{2-}$ ligands ($\text{Se}–\text{Se}$ 299 pm), i.e. $[\text{Se}(\eta^2$-$\text{Se}_5)(\eta^1$-$\text{Se}_5)_2]^{2-}$.

Several of the catena-$\text{Se}_x^{2-}$ anions have proved to be effective chelating ligands to both main-group and transition metals. Synthesis of the complexes is usually via direct reaction with the preformed anion or by synthesis of the anion in the presence of the appropriate metal centre. Examples are $[\text{Sn}(\eta^2$-$\text{Se}_4)_3]^{2-}$,\(^{48}\) $[\text{M}(\eta^2$-$\text{Se}_4)_2]^{2-}$ ($\text{M} = \text{Zn}, \text{Cd}, \text{Hg}, \text{Ni}, \text{Pb}^{II}$),\(^{49}\) $[\text{Mo}^{VI}(\eta^2$-$\text{Cs}_3\text{H}_5)(\eta^2$-$\text{Se}_4)_2]^{2-}$ and $[\text{M}_3(\text{Se}_4)_6]^{2-}$, i.e. $[(\text{M}(\text{Se}_4)_3)(\text{M}((\text{Se}_4)_3\text{M})]^{2-}$ ($\text{M} = \text{Cr}$,\(^{50}\) $\text{Co}$\(^{51}\) in which the two terminal $\text{M}^{III}$ atoms have approximately tris-tetraselenide chelate coordination whilst the central $\text{M}^{III}$ atom (also approximately octahedral) has $(\mu$-$\text{Se})_6$ coordination, achieved by sharing one ‘terminal’ $\text{Se}$ atom from each of the six $\text{Se}_4$ groups. The complex $[\text{Ti}(\eta^2$-$\text{Cs}_3\text{H}_5)(\eta^2$-$\text{Se}_5)]$ reacts with $\text{SCL}_2$, $\text{S}_2\text{Cl}_2$ and $\text{SeCL}_2$ to form, respectively, $\text{Se}_5\text{S}$, $\text{Se}_5\text{S}_2$ and $\text{Se}_7$.\(^{52}\) Heterocyclic chelating ligands are also known, e.g. in $[\text{PtCl}(\text{PM}_3\text{Ph})(\eta^2$-$\text{Se}_3\text{N})]$\(^{53}\) Note also the extraordinary 1900 pm long hexameric anion, $[\text{GaSe}_{14}]^{10-}$, which is composed of a linear array of edge-sharing $\{\text{GaSe}_4\}$_n units, i.e. $[\text{Se}_2(\text{Ga}(\mu$-$\text{Se}_2)]_5\text{GaSe}_2]^{10-}$.\(^{54}\)

Polytellurides, $\text{Te}_x^{2-}$, are less straightforward and often form complex units coordinated to metal centres.\(^{55}\) The isolated ions $\text{Te}_2^{2-}$ and $\text{Te}_3^{2-}$ are usually preformed anions or by synthesis of the anion in the presence of the appropriate metal centre.

---

Te$_2^{2-}$ are found in K$_2$Te$_2$, Rb$_2$Te$_2$ and [K(crypt)$_2$]$_2$Te$_3$ — see Fig. 16.9. Likewise, Te$_4^{2-}$ has been characterized in salts of crown ether complexes of Ca, Sr and Ba, and Te$_5^{2-}$ as its salt with [PPh$_3$NPPh$_3$]$^{+}$ — see Fig. 16.9. The bicyclic polytellurides Te$_2^{2-}$ and Te$_8^{2-}$ are also known (Fig. 16.9). However, simple stoichiometry often conceals structural complexity as in the many alkali metal tellurides MTe$_x$ ($x = 1, 1.5, 2.5, 3, 4$). The soluble cluster anion NbTe$_{10}^{3-}$ is also notable; its structure has been determined in the black, crystalline tetraphenylphosphonium salt. Cubane-like clusters occur

---

Selenides, tellurides and polonides

16.2 Compounds of selenium, tellurium and polonium

16.2.1 Selenides, tellurides and polonides

All three elements combine readily with most metals and many non-metals to form binary chalcogenides. Indeed, selenides and tellurides are the most common mineral forms of these elements (p. 748). Nonstoichiometry abounds, particularly for compounds with the transition elements (where electronegativity differences are minimal and variable valency is favoured), and many of the chalcogenides can be considered...
Selenides, tellurides and polonides

16.2 Compounds of selenium, tellurium and polonium

16.2.1 Selenides, tellurides and polonides

All three elements combine readily with most metals and many non-metals to form binary chalcogenides. Indeed, selenides and tellurides are the most common mineral forms of these elements (p. 748). Nonstoichiometry abounds, particularly for compounds with the transition elements (where electronegativity differences are minimal and variable valency is favoured), and many of the chalcogenides can be considered

as metallic alloys. Many such compounds have important technological potentials for solid-state optical, electrical and thermoelectric devices and have been extensively studied. For the more electropositive elements (e.g. Groups 1 and 2), the chalcogenides can be considered as “salts” of the acids, \( \text{H}_2\text{Se}, \text{H}_2\text{Te}, \) and \( \text{H}_2\text{Po} \) (see next subsection).

The alkali metal selenides and tellurides can be prepared by direct reaction of the elements at moderate temperatures in the absence of air, or more conveniently in liquid ammonia solution. They are colourless, water soluble, and readily oxidized by air to the element. The structures adopted are not unexpected from general crystallochemical principles. Thus \( \text{Li}_2\text{Se}, \text{Na}_2\text{Se} \) and \( \text{K}_2\text{Se} \) have the antifluorite structure (p. 118); \( \text{MgSe}, \text{CaSe}, \text{SrSe}, \text{BaSe}, \text{SeSe}, \text{YSe}, \text{LuSe}, \text{etc.}, \) have the rock-salt structure (p. 242); \( \text{BeSe}, \text{ZnSe} \) and \( \text{HgSe} \) have the zinc-blende structure (p. 1210); and \( \text{CdSe} \) has the wurtzite structure (p. 1210). The corresponding tellurides are similar, though there is not a complete 1:1 correspondence. Polonides can also be prepared by direct reaction and are amongst the stabllest compounds of this element: \( \text{Na}_2\text{Po} \) has the antifluorite structure; the \( \text{NaCl} \) structure is adopted by the polonides of \( \text{Ca}, \text{Ba}, \text{Hg}, \text{Pb} \) and the lanthanide elements; \( \text{BePo} \) and \( \text{CdPo} \) have the \( \text{ZnS} \) structure and \( \text{MgPo} \) the nickel arsenide structure (p. 556). Decomposition of these polonides are about 600 ± 50°C except for the less-stable \( \text{HgPo} \) (decomp 300°C) and the extremely stable lanthanide derivatives which do not decompose even at 1000°C (e.g. \( \text{PrPo} \) mp 1253°C, \( \text{TmPo} \) mp 2200°C).

Transition-element chalcogenides are also best prepared by direct reaction of the elements at 400–1000°C in the absence of air. They tend to be metallic nonstoichiometric alloys though intermetallic compounds also occur, e.g. \( \text{Ti}_{1-2}\text{Se}, \text{Ti}_{2-3}\text{Se}, \text{TiSe}_{0.95}, \text{TiSe}_{1.05}, \text{Ti}_{0.9}\text{Se}, \text{Ti}_{1.0}\text{Se}, \text{Ti}_{0.7}\text{Se}, \text{Ti}_{5}\text{Se}, \text{TiSe}_{2}, \text{TiSe}_{3}, \text{etc.} \)

Fuller details of these many compounds are in the references cited.

Most selenides and tellurides are decomposed by water or dilute acid to form \( \text{H}_2\text{Se} \) or \( \text{H}_2\text{Te} \) but the yields, particularly of the latter, are poor.

Polyhalogenides are less stable than polysulphides (p. 681). Reaction of alkali metals with \( \text{Se} \) in liquid ammonia affords \( \text{M}_2\text{Se}_2, \text{M}_2\text{Se}_3 \) and \( \text{M}_2\text{Se}_4 \), and analogous polytellurides have also been reported (see preceding section). However many of these compounds are rather unstable thermally and tend to be oxidized in air.

### 16.2.2 Hydrides

\( \text{H}_2\text{Se} \) (like \( \text{H}_2\text{O} \) and \( \text{H}_2\text{S} \)) can be made by direct combination of the elements (above 350°C), but \( \text{H}_2\text{Te} \) and \( \text{H}_2\text{Po} \) cannot be made in this way because of their thermal instability. \( \text{H}_2\text{Se} \) is a colourless, offensive-smelling poisonous gas which can be made by hydrolysis of \( \text{Al}_2\text{Se}_3 \), the action of dilute mineral acids on \( \text{FeSe} \) or the surface-catalysed reaction of gaseous Se and \( \text{H}_2 \):

\[
\text{Al}_2\text{Se}_3 + 6\text{H}_2\text{O} \rightarrow 3\text{H}_2\text{Se} + 2\text{Al(OH)}_3
\]

\[
\text{FeSe} + 2\text{HCl} \rightarrow \text{H}_2\text{Se} + \text{FeCl}_2
\]

\[
\text{Se} + \text{H}_2 \rightarrow \text{H}_2\text{Se}
\]

In this last reaction, conversion at first rises with increase in temperature and then falls because of increasing thermolysis of the product: conversion exceeds \( \sim 40\% \) between 350–650°C and is optimum (64%) at 520°C.

\( \text{H}_2\text{Te} \) is also a colourless, foul-smelling toxic gas which is best made by electrolysis of 15–50% aqueous \( \text{H}_2\text{SO}_4 \) at a \( \text{Te} \) cathode at \(-20^\circ, 4.5 \text{ A} \) and 75–110 V. It can also be made by hydrolysis of \( \text{Al}_2\text{Te}_3 \), the action of hydrochloric acid on the tellurides of Mg, Zn or Al, or by reduction of \( \text{Na}_2\text{TeO}_3 \) with \( \text{TiCl}_3 \) in a buffered solution. The compound is unstable above 0°C and decomposes in moist air and on exposure to light. \( \text{H}_2\text{Po} \) is even less stable and has only been made in trace amounts (\( \sim 10^{-10} \text{ g scale} \)) by reduction of \( \text{Po} \) using Mg foil/dilute \( \text{HCl} \) and the reaction followed by radioactive tracer techniques.

Physical properties of the three gases are compared with those of H\(_2\)O and H\(_2\)S in Table 16.4. The trends are obvious, as is the "anomalous" position of water (p. 623). The densities of liquid and solid H\(_2\)Se are 2.12 and 2.45 g cm\(^{-3}\). H\(_2\)Te condenses to a colourless liquid (\(d = 4.4 \text{ g cm}^{-3}\)) and then to lemon-yellow crystals. Both gases are soluble in water to about the same extent as H\(_2\)S, yielding increasingly acidic solutions (cf. acetic acid \(K_1 ~ 2 \times 10^{-5}\)). Such solutions precipitate the selenides and tellurides of many metals from aqueous solutions of their salts but, since both H\(_2\)Se and H\(_2\)Te are readily oxidized (e.g. by air), elementary Se and Te are often formed simultaneously.

H\(_2\)Se and H\(_2\)Te burn in air with a blue flame to give the dioxide (p. 779). Halogens and other oxidizing agents (e.g. HNO\(_3\), KMnO\(_4\)) also rapidly react with aqueous solutions to precipitate the elements. Reaction of H\(_2\)Se with aqueous SO\(_2\) is complex, the products formed depending critically on conditions (cf. Wackenroder’s solution, p. 716): addition of the selenide to aqueous SO\(_2\) yields a 2:1 mixture of S and Se together with oxoacids of sulfur, whereas addition of SO\(_2\) to aqueous H\(_2\)Se yields mainly Se:

\[
\begin{align*}
\text{H}_2\text{Se} + 5\text{SO}_2 + 2\text{H}_2\text{O} & \rightarrow 2\text{S} + \text{Se} + 3\text{H}_2\text{SO}_4 \\
\text{H}_2\text{Se} + 6\text{SO}_2 + 2\text{H}_2\text{O} & \rightarrow 2\text{S} + \text{Se} + \text{H}_2\text{S}_2\text{O}_6 \\
& \quad + 2\text{H}_2\text{SO}_4 \\
\text{H}_2\text{Se} + 6\text{SO}_2 + 2\text{H}_2\text{O} & \rightarrow \text{Se} + \text{H}_2\text{S}_4\text{O}_6 \\
& \quad + 2\text{H}_2\text{SO}_4
\end{align*}
\]

H\(_2\)Te undergoes oxidative addition to certain organometallic compounds, e.g. \([\text{Re}(\eta^5-C_5\text{Me}_5)-(\text{CO})_2(\text{thf})]\) reacts in thf solution at 25°C to give \([\text{HRe}(\eta^5-C_5\text{Me}_5)(\text{CO})_2(\text{TeH})]\) and related dinuclear complexes.\(^{73}\) The Te analogue of the hydroxide ion, TeH\(^-\), has been reported from time to time but has only recently been properly characterized crystallographically, in \([\text{PPh}_4]^+\text{[TeH]}^-\).\(^{74}\)

16.2.3 Halides

As with sulfur, there is a definite pattern to the stoichiometries of the known halides of the heavier chalcogens. Selenium forms no binary iodides whereas the more electropositive Te and Po do. Numerous chlorides and bromides are known for all 3 elements, particularly in oxidation states +1, +2 and +4. In the highest oxidation state, +6, only the fluorides MF\(_6\) are known for the 3 elements; in addition SeF\(_4\) and TeF\(_4\) have been characterized but no fluorides of lower oxidation states except the fugitive FSeSeF, Se=SeF\(_2\) and SeF\(_2\) which can be trapped out at low temperature.\(^{75,76}\) The compound previously thought to be Te\(_2\)F\(_{10}\) is now known to be O(SeF\(_3\))\(_2\).\(^{76,77}\) (p. 778). Finally, Te forms a range of curious lower halides which

\(^{74}\) J. C. Huffman and R. C. Haushalter, Polyhedron 8, 531–2 (1989).

are structurally related to the Te₅ chains in elementary tellurium. The known compounds are summarized in Table 16.5 which also lists their colour, mp, bp and decomposition temperature where these have been reported. It will be convenient to discuss the preparation, structure and chemical properties of these various compounds approximately in ascending order of formal oxidation state. For comparable information on the halides of S, see pp. 683–93.

Lower halides

The phase relations in the tellurium-halogen systems have only recently been elucidated

</table>
and the results show a series of subhalides with various structural motifs based on the helical-chain structure of Te itself. These are summarized in Fig. 16.11. Thus, reaction of Te and Cl₂ under carefully controlled conditions in a sealed tube results in Te₃Cl₂ (Fig. 16.11b) in which every third Te atom in the chain is oxidized by addition of 2 Cl atoms, thereby forming a series of 4-coordinate pseudo-trigonal-bipyramidal groups with axial Cl atoms linked by pairs of unmodified Te atoms -Te–Te–TeCl₂–Te–TeCl₂–.  

Te₂Br and Te₂I consist of zigzag chains of Te in planar arrangement (Fig. 16.11c); along the chain is an alternation of trigonal pyramidal (pseudo-tetrahedral) and square-planar (pseudo-octahedral) Te atoms. These chains are joined in pairs by cross-linking at the trigonal pyramidal Te atoms, thereby forming a ribbon of fused 6-membered Te rings in the boat configuration. A similar motif occurs in β-TeI (Fig. 16.11d) which is formed by rapidly cooling partially melted α-TeI (see below) from 190°; in this case the third bond from the trigonal pyramidal Te atoms carries an I atom instead of being cross-linked to a similar chain. The second, more stable modification, α-TeI, features tetrameric molecules Te₄I₄ which are themselves very loosely associated into chains by Te–I–Te links (Fig. 16.11e); the non-planar Te₄ ring comprises two non-adjacent 3-coordinate trigonal pyramidal Te atoms bridged on one side by a single 2-coordinate Te atom and on the other by a 4-coordinate planar >Te₂ group. An unrelated structure motif is found in the unusual intercalation compound, [(Te₂)₂(I₂)ₓ] (x = 0.42–1.0), which is obtained as shiny, metallic-black air-stable crystals by hydrothermal reaction of 67% HI (aq.) on a 1:1 mixture of Te and GeTe at ca. 170° followed by slow cooling (18 h). The structure comprises planar double layers of Te₂ units intercalated by I₂ up to the limiting formula [(Te₂)₂I₂]. The Te atoms within the double layers exhibit distorted tetragonal pyramidal coordination with one short and four longer Te–Te distances (271.3 and 332.3 pm, respectively; cf. distances in Fig. 16.11). The I–I distance within the I₂ molecules is 286.6 pm (cf. 271.5 pm in solid iodine, p. 803). The semiconductivity and nonlinear optical properties of these various tellurium subhalides have been much studied for possible electronic applications.

The only other “monohalides” of these chalcogens are the highly coloured heavy liquids Se₂Cl₂ (d₂₅ 2.774 g cm⁻³) and Se₂Br₂ (d₁₅ 3.604 g cm⁻³). Both can be made by reaction of the stoichiometric amounts of the elements or better, by adding the halogen to a suspension of powdered Se in CS₂. Reduction of Se₄Br₂ with 3Se in a sealed tube at 120° is also effective. Se₂Br₂ has a structure similar to that of S₂Cl₂ and S₂F₂ (pp. 689, 684) with a dihedral angle of 94°, angle Br–Se–Se 104° and a rather short Se–Se bond (224 pm, cf. 233.5 pm in monoclinic Se₈ and 237.3 pm in hexagonal Se₈∞). The structure of Se₂Cl₂ has not been determined but is probably similar. Se₂Br₂ is, in fact, the metastable molecular form (also known as β-SeBr); the structure of the more stable α-SeBr is as yet unknown.

Several mixed species have been identified in nonaqueous solutions by ⁷⁷Se nmr spectroscopy. These include BrSeSeCl, Se₃X₂ and Se₄X₂; and ClSeCl, BrSeCl, ClSeBr and ClSeI. 

---

Figure 16.11  Structural relations between tellurium and its subhalides: (a) tellurium, (b) Te₂Cl₂, (c) Te₂Br and Te₂I, (d) β-TeI, and (e) α-TeI.
BrSeBr.\(^{85}\) ClSeCl, formed by mixing solutions of S\(_2\)Cl\(_2\) and Se\(_2\)Cl\(_2\), has been reacted with titanocene pentasulfide \((p. 672)\) to give mainly S\(_7\), SeS\(_6\) and 1,2-Se\(_2\)S\(_3\), plus smaller amounts of 6-, 8-, 9- and 12-membered Se/S ring molecules.\(^{86}\) The related reaction with SeBr\(_2\) (SeBr\(_4\) + Se) in MeCN yields similar Se/S heterocycles.\(^{87}\)

It is also convenient to mention here several cationic subhalide species that have recently been synthesized. Reaction of Se with [NO][SbCl\(_6\)] in liquid SO\(_2\) yields lustrous dark red crystals of [Se\(_9\)Cl\(_2\)][SbCl\(_6\)]\(^-\) which is the first example of a 7-membered Se ring, [cyclo-Se\(_7\)-SeSeCl]\(^+\) \((\text{Fig. 16.12a})\).\(^{88}\) Again, reaction of stoichiometric amounts of Se (or S), Br\(_2\) and AsF\(_5\) in liquid SO\(_2\) yields dark red crystals or [Br\(_2\)Se-SeSeBr\(_3\)]\(^+\) [AsF\(_6\)]\(^-\) \((\text{Fig. 16.12b})\)\(^{89}\) or its S analogue. The first known binary Se/I species (albeit cationic rather than neutral) have been prepared\(^{90}\) by reaction of Se\(_4\)\(^{2+}\) and I\(_2\) in SO\(_2\): The species SeI\(_3\)\(^+\), Se\(_2\)I\(_4\)\(^{2+}\), Se\(_6\)I\(_2\)\(^{2+}\) were identified by \(^{77}\)Se nmr spectroscopy and subsequently assigned the definitive structures shown in Fig. 16.12c,d,e after X-ray diffraction analysis.\(^{91}\) The polymeric cation [Se\(_6\)I\(_{\infty}\)]\(^+\) is also shown, (f).

Paradoxically, the most firmly established dihalides of the heavier chalcogens are the dark ruby-red PoCl\(_2\) and the purple-brown PoBr\(_2\) \((\text{Table 16.5})\). Both are formed by direct reaction of the elements or more conveniently by reducing PoCl\(_4\) with SO\(_2\) and PoBr\(_4\) with H\(_2\)S at 25\(^\circ\).
Doubt has been cast on "TeCl₂" and "TeBr₂" mentioned in the older literature since no sign of these was found in the phase diagrams.(79) However, this is not an entirely reliable method of establishing the existence of relatively unstable compounds between covalently bonded elements (cf. P/S, p. 506, and S/I, p. 691). It has been claimed that TeCl₂ and TeBr₂ are formed when fused Te reacts with CCl₂F₂ or CBrF₃,(92) though these materials certainly disproportionate to TeX₄ and Te on being heated and may indeed be eutectic-type phases in the system. SeCl₂ and SeBr₂ are unknown in the solid state but are thought to be present as unstable species in the vapour above SeX₄ and have been identified in equilibrium mixtures in nonaqueous solutions (see preceding paragraph).

**Tetrahalides**

All 12 tetrahalides of Se, Te and Po are known except, perhaps, for SeI₄. As with PX₅ (p. 498) and SX₄ (p. 691) these span the "covalent-ionic" border and numerous structural types are known; the stereochemical influence of the lone-pair of electrons (p. 377) is also prominent. SeF₄ is a colourless reactive liquid which fumes in air and crystallizes to a white hygroscopic solid (Table 16.5). It can be made by the controlled fluorination of Se (using F₂ at 0°, or AgF) or by reaction of SF₄ with SeO₂ above 100°. SeF₄ can be handled in scrupulously dried borosilicate glassware and is a useful fluorinating agent. Its structure in the gas phase, like that of SF₄ (p. 684), is pseudo-trigonal-bipyramidal with C₂ᵥ symmetry; the dimensions shown in Fig. 16.13a were obtained by microwave spectroscopy. The same structure persists in solution but, with increasing concentration there is an increasing tendency to association via intermolecular F-bridges. The structure in the crystalline phase also has Se bonded to 4F atoms in a distorted pseudo-trigonal bipyramidal configuration as shown in Fig. 16.13b (Se-Fₐx 180 pm, Se-Fₑq 167 pm, with axial and equatorial angles subtended at Se of 169.3° and 96.9°, respectively).(93) However, these pseudo-tbp molecules are arranged in layers by weaker intermolecular interactions to neighbouring molecules so as to form an overall distorted octahedral environment with two further Se···F at 266 pm (Fig. 16.13b) somewhat reminiscent of the structure found earlier for TeF₄ (see Fig. 16.13c and below).

TeF₄ can be obtained as colourless, hygroscopic, sublimable crystals by controlled fluorination of Te or TeX₂ with F₂/N₂ at 0°, or more conveniently by reaction of SeF₄ with TeO₂ at 80°. It decomposes above 190° with formation of TeF₆ and is much more reactive than SeF₄. For example, it readily fluorinates SiO₂ above room temperature and reacts with Cu, Ag, Au and Ni at 185° to give the metal tellurides and fluorides. Adducts with BF₃, AsF₅ and SbF₅ are known (see also p. 776). Although probably monomeric in the gas phase, crystalline TeF₄ comprises chains of cis-linked square-pyramidal TeF₅ groups (Fig. 16.13c) similar to those in the isoelectronic (SbF₄⁻)ₙ ions (p. 565). The lone-pair is alternately above and below the mean basal plane and each Te atom is displaced some 30 pm in the same direction. However, the local Te environment is somewhat less symmetrical than implied by this idealized description, and the Te-F distances span the range 183–228 pm.(93)

The other tetrahalides can all readily be made by direct reactions of the elements. Crystalline SeCl₄, TeCl₄ and β-SeBr₄ are isotypic and the structural unit is a cubane-like tetramer of the same general type as [Me₃Pt(μ₃-Cl)]₄ (p. 1168). This is illustrated schematically for TeCl₄ in Fig. 16.13d: each Te is displaced outwards along a threefold axis and thus has a distorted octahedral environment. This can be visualized as resulting from repulsions due to the Te lone-pairs directed towards the cube centre and, in the limit, would result in the separation into

---

TeCl$_3^+$ and Cl$^-$ ions. Accordingly, the 3 tetrahalides are good electrical conductors in the fused state, and salts of SeX$_3^+$ and TeCl$_3^+$ can be isolated in the presence of strong halide ion acceptors, e.g. [SeCl$_3^+$][GaCl$_4^-$], [SeBr$_3^+$][AlBr$_4^-$], [TeCl$_3^+$][AlCl$_4^-$]. In solution, however, the structure depends on the donor properties of the solvent: in donor solvents such as MeCN, Me$_2$CO and EtOH the electrical conductivity and vibrational spectra indicate the structure [L$_2$TeCl$_3^+$]Cl$^-$, where L is a molecule of solvent, whereas in benzene and toluene the compound dissolves as a non-conducting molecular oligomer which is tetrameric at a concentration of 0.1 molar but which is in equilibrium with smaller oligomeric units at lower concentrations. Removal of one TeCl$_3^+$ unit from the cubane-like structure of Te$_4$Cl$_{16}$ leaves the trinuclear anion Te$_3$Cl$_{13}^-$ which can be isolated from benzene solutions as the salt of the large counter-cation Ph$_3$C$^+$; the anion has the expected $C_{3v}$ structure.

---

---
comprising three edge-shared octahedra with a central triply bridging Cl atom. Removal of a further TeCl$_3^+$ unit yields the edge-shared bi-octahedral dianion Te$_2$Cl$_{10}^2-$ which was isolated as the crystalline salt [AsP$_3$]$_2[Te$_2$Cl$_{10}^2$]. Notional removal of a final TeCl$_4$ unit leaves the octahedral anion TeCl$_6^{2-}$ (p. 776) as in the scheme above.

Numerous crystal structures have been published of compounds containing the pyramidal cations Se$_7$Cl$_3^+$, Se$_7$Br$_3^+$, Te$_7$Cl$_3^+$, etc., and the anions Se$_7$Cl$_4^{2-}$, Se$_7$Cl$_6^{2-}$; Se$_7$Cl$_8^-$, Se$_7$Br$_7^-$; Se$_7$Br$_{10}^-$, TeCl$_5^-$, TeCl$_6^{2-}$, etc. The anion structures are much as expected with the Se$_7$ species featuring square planar (pseudooctahedral) units, and the trinuclear Se$_7$ anions as in the tellurium analogue above. See also p. 776. There are, in addition, a fascinating series of bromoselenate(II) dianions based on fused planar [SeBr$_4$] units, e.g. Se$_3$Br$_8^{2-}$, Se$_4$Br$_{14}^{2-}$, and Se$_5$Br$_{12}^{2-}$, (see Fig. 16.14a,b,c). Access has also been gained to a series of novel mixed-valence bromopolytellurate(II,IV) dianions by exploiting the dissociation equilibria $\frac{1}{2}$Se$_4$Br$_{16} \rightleftharpoons$ Se$_4$Br$_4 \rightleftharpoons$ Se$_4$Br$_2 + Br_2$ and $2$Se$_2$Br$_2 \rightleftharpoons$ Se$_2$Br$_4 + Br_2$. Careful addition of Br$_2$ to such solutions in weakly polar organic solvents displaces these equilibria and permits the isolation of tetraalkylammonium or tetraphenylphosphonium salts of Se$_2$Br$_8^{2-}$, Se$_3$Br$_{10}^{2-}$, and Se$_4$Br$_{12}^{2-}$, as dark red crystalline salts featuring fused square planar and octahedral units as illustrated in Fig. 16.15a,b,c.

Se$_4$Br$_4$ itself is dimorphic: the $\alpha$-form, like $\beta$-Se$_4$Br$_4$ mentioned on p. 772, has a cubane-like tetrameric unit (Se–Br$_4$ 237 pm, Se–Br$_4$ 297 pm) but the two forms differ in the spacial arrangement of the tetramers. Te$_4$ has yet another structure which involves a tetrameric arrangement of edge-shared {Te$_4$} octahedra not previously encountered in binary inorganic compounds (Fig. 16.13e). The molecule is close to idealized $C_{2h}$ symmetry with each terminal octahedron sharing 2 edges with the 2 neighbouring central octahedra.

---

and each central octahedron sharing 3 edges with its 3 neighbours (Te–I, 277 pm, Te–Iμ2 311 pm, Te–Iμ3 323 pm). There is no significant intermolecular I⋯I bonding. Comparison of the structures and bond data for the homologous series TeF4, TeCl4(TeBr4), TeI4 reveals an increasing delocalization of the TeIV lone-pair. This effect is also observed in the compounds of other ns2 elements (e.g. SnII, PbII, AsIII, SbIII, BiIII, I V; see pp. 380, 383, 568) and correlates with the gradation of electronegativities and the polarizing power of the halogens.

The detailed structures of Po& are unknown. Some properties are in Table 16.5. PoF4 is not well characterized. PoCl4 forms bright-yellow monoclinic crystals which can be melted under an atmosphere of chlorine, and PoBr4 has a fcc lattice with a0 = 560 pm. These compounds and PoI4 can be made by direct combination of the elements or indirectly, e.g. by the chlorination of PoO2 with HCl, PCl5 or SOCl2, or by the reaction of PoO2 with HI and 200°. Similar methods are used to prepare the tetrahalides of Se and Te, e.g.:

TeCl4: Cl2 + Te; SeCl2 on Te, TeO2 or TeCl2; CCl4 + TeO2 at 500°
TeBr4: Te + Br2 at room temp; aq HBr on TeO2
TeI4: Heat Te + I2; Te + MeI; TeBr4 + EtI

The two mixed tellurium(IV) halides listed in Table 16.5 were prepared by the action of liquid Br2 on TeCl2 to give the yellow solid TeBr2Cl2, and by the action of I2 on TeBr2 in ether solution to give the red crystalline TeBr2I2; their structures are as yet unknown.

**Hexahalides**

The only hexahalides known are the colourless gaseous fluorides SeF6 and TeF6 and the volatile
liquids TeClF₅ and TeBrF₅. The hexafluorides are prepared by direct fluorination of the elements or by reaction of BrF₃ on the dioxides. Both are octahedral with Se−F 167−170 pm and Te−F 184 pm. SeF₆ resembles SF₆ in being inert to water but it is decomposed by aqueous solutions of KI or thiosulfate. TeF₆ hydrolyses completely within 1 day at room temperature.

The mixed halides TeClF₅ and TeBrF₅ are made by oxidative fluorination of TeCl₄ or TeBr₄ in a stream of F₂ diluted with N₂ at 25°. Under similar conditions TeI₄ gave only TeF₆ and IF₅. TeClF₅ can also be made by the action of ClF on TeF₄, TeCl₄ or TeO₂ below room temperature; it is a colourless liquid, mp −28°, bp 13.5°, which does not react with Hg, dry metals or glass at room temperature.

**Halide complexes**

It is convenient to include halide complexes in this section on the halides of Se, Te and Po and, indeed, some have already been alluded to above. In addition, pentafluoroselenates(IV) can be obtained as rather unstable white solids MSeF₅ by dissolving alkali metal fluorides or Tlf in SeF₄. The crystal structure of Me₄NSeF₅ features square-pyramidal SeF₅⁻ ions, with Se−Fₐpex 171 pm Se−Fₖₜ₆ 185 pm and the angle Fₐpex−Se−Fₖₜ₆ 84°, implying that the Se atom and its lone pair of electrons lies some 20 pm below the basal plane (cf. Fig. 16.13b). The tellurium analogues are best prepared by dissolving MF and TeO₂ in aqueous HF or SeF₄; they are white crystalline solids. The TeF₅⁻ ion (like SeF₅⁻) has a distorted square-based pyramidal structure (C₄ᵥ) in which the Te atom (and pendant lone-pair of electrons) is about 30 pm below the basal plane with Te−Fₐpex 184 pm, Te−Fₖₜ₆ 196 pm and the angle Fₐpex−Te−Fₖₜ₆ 81°(104) (cf. TeF₄, Fig. 16.13c). The resemblance to other isoelectronic MF₅⁻,ₗ⁺ species is illustrated in Table 16.6; in each case, the fact that the distance M−Fₖₜ₆ is greater than M−Fₐpex and that the angle Fₐpex−M−Fₖₜ₆ is less than 90° can be ascribed to repulsive interaction of the basal M−F bonds with the lone-pair of electrons.

Attempts to prepare compounds containing the TeF₆²⁻ ion have not been successful though numerous routes have been tried. However, reaction of Me₄NF with TeF₆ in anhydrous MeCN affords the novel 7- and 8-coordinated species TeF₆⁻ (D₅ₖ, pentagonal bipyramid)(105,106) and TeF₆⁻² (D₄d, square antiprism).

were noted for octahedral Sn" (p. 380) and Sb" (p. 568).

16.2.4 Oxohalides and pseudohalides

Numerous oxohalides of Se" and SeV are known, SeOF2 and SeOCl2 are colourless, fuming, volatile liquids, whereas SeOBr2 is a rather less-stable orange solid which decomposes in air above 50°C (Table 16.7). The compounds can be conveniently made by reacting SeO2 with the appropriate tetrahalide and their molecular structure is probably pyramidal (like SOX2, p. 694). SeOF2 is an aggressive reagent which attacks glass, reacts violently with red phosphorus and with powdered SiO2 and slowly with Si. In the solid state, X-ray studies have revealed that the pyramidal SeOF2 units are linked by O and F bridges into layers thereby building a distorted octahedral environment around each Se with 3 close contacts (to O and 2F) and 3 (longer) bridging contacts grouped around the lone-pair to neighbouring units. This contrasts with the discrete molecular structure of SOF2 and affords yet another example of the influence of preferred coordination number on the structure and physical properties of isovalent compounds, e.g. molecular BF3 and 6-coordinate AlF3, molecular GeF4 and the 6-coordinate layer lattice of SnF4 and, to a less extent, molecular AsF3 and F-bridged SbF3. (See also the Group 14 dioxides, etc.)

SeOCl2 (Table 16.7) is a useful solvent: it has a high dielectric constant (46.2 at 20°C), a high dipole moment (2.62 D in benzene) and an appreciable electrical conductivity (2 x 10^-5 ohm^-1 cm^-1 at 25°C). This last has been ascribed to self-ionic dissociation resulting from chloride-ion transfer: 2SeOCl2 ----> SeOCl^+ + SeOCl^-.

Oxohalides of SeV are known only for fluorine (Table 16.7). SeO2F2 is a readily hydrolysable colourless gas which can be made by fluorinating SeO3 with SeF4 (or KBF4 at 70°C) or by reacting BaSeO4 with HSOF4 under reflux at 50°C. Its vibrational spectra imply a tetrahedral structure with C2v symmetry as expected. By contrast, SeOF4 is a dimer [F4Se(p-O)2SeF4] in which each Se achieves octahedral coordination via the 2 bridging O atoms: the planar central SeO2 ring has Se-O 178 pm and angle Se-O-Se 97.5°, and Se-Feq and Se-Fax are 167 and 170 pm respectively. Two further oxofluorides of SeV can be prepared by reaction of SeO2 with a mixture of F2/N2: at 80°C the main product is the "hypofluorite" F5SeOF whereas at 120°C the peroxide F5SeOOSF5 predominates. The compounds (Table 16.7) can be purified by

---

16.2.4 Oxohalides and pseudohalides

Numerous oxohalides of SeIV and SeVI are known, SeOF2 and SeOCl2 are colourless, fuming, volatile liquids, whereas SeOBr2 is a rather less-stable orange solid which decomposes in air above 50°C (Table 16.7). The compounds can be conveniently made by reacting SeO2 with the appropriate tetrahalide and their molecular structure is probably pyramidal (like SOCl2, p. 694). SeOF2 is an aggressive reagent which attacks glass, reacts violently with red phosphorus and with powdered SiO2 and slowly with Si. In the solid state, X-ray studies have revealed that the pyramidal SeOF2 units are linked by O and F bridges into layers thereby building a distorted octahedral environment around each Se with 3 close contacts (to O and 2F) and 3 (longer) bridging contacts grouped around the lone-pair to neighbouring units. This contrasts with the discrete molecular structure of SOF2 and affords yet another example of the influence of preferred coordination number on the structure and physical properties of isovalent compounds, e.g. molecular BF3 and 6-coordinate AlF3, molecular GeF4 and the 6-coordinate layer lattice of SnF4 and, to a less extent, molecular AsF3 and F-bridged SbF3. (See also the Group 14 dioxides, etc.)

SeOCl2 (Table 16.7) is a useful solvent: it has a high dielectric constant (46.2 at 20°C), a high dipole moment (2.62 D in benzene) and an appreciable electrical conductivity (2 x 10⁻⁵ ohm⁻¹ cm⁻¹ at 25°C). This last has been ascribed to self-ionic dissociation resulting from chloride-ion transfer: 2SeOCl2 ⇌ SeOCl⁺ + SeOCl⁻.

Oxohalides of SeVI are known only for fluorine (Table 16.7). SeO2F2 is a readily hydrolysable colourless gas which can be made by fluorinating SeO3 with SeF4 (or KBF4 at 70°C) or by reacting BaSeO4 with HSOF3 under reflux at 50°C. Its vibrational spectra imply a tetrahedral structure with C2v symmetry as expected. By contrast, SeOF4 is a dimer [F₄Se(p-O)₂SeF₄] in which each Se achieves octahedral coordination via the 2 bridging O atoms: the planar central Se₂O₂ ring has Se–O 178 pm and angle Se–O–Se 97.5°, and Se–Fₑq and Se–Fₐₓ are 167 and 170 pm respectively.²

Two further oxofluorides of SeVI can be prepared by reaction of SeO2 with a mixture of F₂/N₂: at 80°C the main product is the “hypofluorite” F₅SeOF whereas at 120°C the peroxide F₅SeOOSF₅ predominates. The compounds (Table 16.7) can be purified by

Footnotes:

fractional sublimation and are reactive, volatile, colourless solids. The analogous sulfur compounds were discussed on p. 688. The colourless liquid $F_5$Se$O$Se$F_5$ (mp $-85^\circ$, bp $53^\circ$) is made by a somewhat more esoteric route as follows: 

$$Xe(OSeF_5)_2 \rightarrow Xe + \frac{1}{2}O_2 + F_5SeOSeF_5$$

The corresponding tellurium analogue, $F_5$Te$O$Te$F_5$, is made by fluorinating $TeO_2$ in a copper vessel at $60^\circ$ using a stream of $F_2/N_2$ (1:10); it is a colourless, mobile, unreactive liquid, mp $-36.6^\circ$, bp $59.8^\circ$. 

The Se–O–Se angle in $F_5$Se$O$Se$F_5$ is $142.4^\circ$ (±1.9°) as in the sulfur analogue, and the Te–O–Te angle is very similar ($145.5^\circ$ ± 2.1°). The fluorination of $Te$ in the presence of oxygen yields (in addition to $TeF_5O$, p. 767) the dense colourless liquids $Te_2O_2F_14$ and $Te_2O_5F_26$. More purposeful synthetic routes have also been devised, leading to the isolation and structural characterization of the 6-coordinate $Te^V$ oxofluorides cis- and trans-$F_4$Te$(OTeF_5)_2$, cis- and trans-$F_2$Te$(OTeF_5)_3$, $FTe(OTeF_5)_5$ and even $Te(OTeF_5)_6$.

Similarly, thermolysis of $B(OTeF_5)_3$ at $600^\circ$ in a flow system yields the oxygen-bridged dimer $Te_2O_2F_8$ analogous to $Se_2O_2F_8$ above. $Te_2O_2F_8$ is a colourless liquid with a garlic-like smell, mp 28°, bp 77.5°. The planar central $Te_2O_2$ ring has $Te$–O 192 pm and angle $Te$–O–$Te$ 99.5°, and again the equatorial $Te$–F distances (180 pm) are shorter than the axial ones (185 pm).

The $-O$Te$F_5$ group (like the $-O$Se$F_5$ group) has a very high electronegativity as can be seen, for example, by the reactions of the ligand transfer reagent $[B(OTeF_5)_3]$; the $IF_3 + B(OTeF_5)_3 \rightarrow FI(OTeF_5)_4$

$$XeF_4 + B(OTeF_5)_3 \rightarrow Xe(OTeF_5)_4$$

(see also p. 899)

Direct fluorination of $B(OTeF_5)_3$ at $115^\circ$ gives a 95% yield of the hypofluorite, $F_5TeOF$, as a colourless gas which condenses to a colourless liquid below $0^\circ$ and finally to a glass at about $-80^\circ$; the extrapolated bp is 0.6°. The chlorine derivative, Cl$TeOF_5$, the so-called tellic acid, $HOTeF_5$, and the teflate anion, $F_5TeO^-$ (as caesium or tetraalkylammonium salts) are also useful synthons for a variety of metal derivatives, e.g. $[Fe(OTeF_5)_3]$, $[Nb(OTeF_5)_6]^-$, and $[Ta(OTeF_5)_6]$$. Other examples are $[Mn(CO)_5(OTeF_5)]$ and $[Pt(norbornadiene)(OTeF_5)]$. The $-O$Te$F_5$ group can also act as a bridging ligand, as in the dimeric $Ag^I$ and $Ti^I$ complexes, $[(\eta^5-tol)Ag]_2(\mu-O(OTeF_5)_2)$ and $[(\eta^6-mes)Ti]_2(\mu(OTeF_5)_2)_2$, which both feature a central planar $M_2O_2$ core (tol = toluene, $C_8H_8Me$; mes = mesitylene, 1,3,5-$C_6H_3Me_3$). The H-bonded anion $[H(OTeF_5)_2]^-$. 

Pseudohalides of $Se$ in which the role of halogen is played by cyanide, thiocyanate or selenocyanate are known and, in the case of $Se$II, are much more stable with respect to disproportionation than are the halides themselves. Examples are $Se(CN)_2$, $Se_2(CN)_2$, $Se(SeCN)_2$, $Se(SCN)_2$, $Se_2(SCN)_2$. The selenocyanate ion SeCN$^-$ is ambidentate like the thiocyanate ion, etc., being capable of ligating to metal centres via either N or Se, as in the osmium(IV) complexes $[OsCl_5(NCSe)]^{2-}$, $[OsCl_5(SeCN)]^{2-}$, and trans-$[OsCl_4(SeCN)(SeCN)]^{2-}$.

Tellurium and polonium pseudohalogen analogues include $Te(CN)_2$ and $Po(CN)_4$ but have been much

less studied than their Se counterparts. The long-sought tellurocyanate ion TeCN\(^-\) has finally been made, and isolated in crystalline form by the use of large counter-cations;\(^{(121)}\) as expected, the anion is essentially linear (angle Te\(-C\)-N 175\(^\circ\)), and the distances Te\(-C\) and C\(-N\) are 202 and 107 pm respectively.

The selenohalides and tellurohalides of both main-group elements and transition metals have been compared with the corresponding thiohalides in two extensive reviews.\(^{(122)}\) Other inorganic compounds of Se and Te, with bonds to N, P etc are described on pp. 783–6.

### 16.2.5 Oxides

The monoxides SeO and TeO have transient existence in flames but can not be isolated as stable solids. PoO has been obtained as a black, easily oxidized solid by the spontaneous radiolytic decomposition of the sulfoxide PoSO\(_3\). The dioxides of all 3 elements are well established and can be obtained by direct combination of the elements. SeO\(_2\) is a white solid which melts in a sealed tube to a yellow liquid at 340\(^\circ\) (sublimes at 315\(^\circ\)/760 mmHg). It is very soluble in water to give selenous acid H\(_2\)SeO\(_3\) from which it can be recovered by dehydration. It is also very soluble (as a trimer) in SeOCl\(_2\) and in H\(_2\)SO\(_4\) in which it behaves as a weak base. SeO\(_2\) is thermodynamically less stable than either SO\(_2\) or TeO\(_2\) and is readily reduced to the elements by NH\(_3\), N\(_2\)H\(_4\) or aqueous SO\(_2\) (but not gaseous SO\(_2\)). It also finds use as an oxidizing agent in organic chemistry. In the solid state SeO\(_2\) has a polymeric structure of corner-linked flattened \{SeO\(_3\)\} pyramids each carrying a pendant terminal O atom:

![Figure 16.16](image_url)

TeO\(_2\) is dimorphic: the yellow, orthorhombic mineral tellurite (\(\beta\)-TeO\(_2\)) has a layer structure in which pseudo-trigonal bipyramidal \{TeO\(_4\)\} groups form edge-sharing pairs (Fig. 16.16a) which then further aggregate into layers (Fig. 16.16b) by sharing the remaining vertices. By contrast, synthetic \(\alpha\)-TeO\(_2\) ("paratellurite")

forms colourless tetragonal crystals in which very similar \{TeO$_4$\} units (Fig. 16.16c) share all vertices (angle Te–O–Te 140°) to form a rutile-like (p. 961) three-dimensional structure. TeO$_2$ melts to a red liquid at 733° and is much less volatile than SeO$_2$. It can be prepared by the action of O$_2$ on Te, by dehydrating H$_2$TeO$_3$ or by thermal decomposition of the basic nitrate above 400°. TeO$_2$ is not very soluble in water; it is amphoteric and shows a minimum in solubility (at pH ~ 4.0). It is, however, very soluble in SeOCl$_2$.

PoO$_2$ is obtained by direct combination of the elements at 250° or by thermal decomposition of polonium(IV) hydroxide, nitrate, sulfate or selenate. The yellow (low-temperature) fcc form has a fluorite lattice; it becomes brown when heated and can be sublimed in a stream of O$_2$ at 885°. However, under reduced pressure it decomposes into the elements at almost 500°. There is also a high-temperature, red, tetragonal form. PoO$_2$ is amphoteric, though appreciably more basic than TeO$_2$: e.g. it forms the disulfate Po(SO$_4$)$_2$ for which no Te analogue is known.

It is instructive to note the progressive trend to higher coordination numbers in the Group 16 dioxides, and the consequent influence on structure:

The difficulty of oxidizing Se to the +6 state has already been mentioned (p. 755). Indeed, unlike SO$_3$ and TeO$_3$, SeO$_3$ is thermodynamically unstable with respect to the dioxide:

\[
\text{SeO}_3 \longrightarrow \text{SeO}_2 + \frac{1}{2}\text{O}_2; \quad \Delta H^\circ = -46 \text{ kJ mol}^{-1}
\]

Some comparative figures for the standard heats of formation $-\Delta H^\circ_f$ are in Table 16.8. Accordingly, SeO$_3$ can not be made by direct oxidation of Se or SeO$_2$ and is even hard to make by the dehydration of H$_2$SeO$_4$ with P$_2$O$_5$; a better route is to treat anhydrous K$_2$SeO$_4$ with SO$_3$ under reflux, followed by vacuum sublimation at 120°. SeO$_3$ is a white, hygroscopic solid which melts at 118°, sublimes readily above 100° (40 mmHg) and decomposes above 165°. The crystal structure is built up from cyclic tetramers, Se$_4$O$_{12}$, which have a configuration very similar to that of (PNC$_2$)$_4$ (p. 538). In the vapour phase, however, there is some dissociation into the monomer. In the molten state SeO$_3$ is probably polymeric like the isoelectronic polymetaphosphate ions (p. 528).

TeO$_3$ exists in two modifications. The yellow-orange $\alpha$-form and the more stable, less reactive, grey $\beta$-form. The $\alpha$-TeO$_3$ is made by dehydrating Te(OH)$_6$ (p. 782) at 300–360°; the $\beta$-TeO$_3$ is made by heating $\alpha$-TeO$_3$ or Te(OH)$_6$ in a sealed tube in the presence of H$_2$SO$_4$ and O$_2$ for 12 h at 350°. $\alpha$-TeO$_3$ has a structure like that of FeF$_3$, in which TeO$_6$ octahedra share all vertices to give a 3D lattice. It is unattacked by water, but is a powerful oxidizing agent when heated with a variety of metals or non-metals. It is also soluble in hot concentrated alkalis to form tellurates (p. 782). The $\beta$-form is even less reactive but can be cleaved with fused KOH.

PoO$_3$ may have been detected on a tracer scale but has not been characterized with weighable amounts of the element.
16.2.6 Hydroxides and oxoacids

The rich oxoacid chemistry of sulfur (pp. 705-21) is not paralleled by the heavier elements of the group. The redox relationships have already been summarized (p. 755). Apart from the dark-brown hydrated monoxide “Po(OH)₂”, which precipitates when alkali is added to a freshly prepared solution of Po(II), only compounds in the +4 and +6 oxidation states are known.

Selenous acid, O=Se(OH)₂, i.e. H₂SeO₃, and tellurous acid, H₂TeO₃, are white solids which can readily be dehydrated to the dioxide (e.g. in a stream of dry air). H₂SeO₃ is best prepared by slow crystallization of an aqueous solution of SeO₂ or by oxidation of powdered Se with dilute nitric acid:

3Se + 4HNO₃ + H₂O → 3H₂SeO₃ + 4NO

The less-stable H₂TeO₃ is obtained by hydrolysis of a tetrahalide or acidification of a cooled aqueous solution of a telluride. Crystalline H₂SeO₃ is built up of pyramidal SeO₃ groups (Se–O 174 pm) which are hydrogen-bonded to give an orthorhombic layer lattice. The detailed structure of H₂TeO₃ is unknown. Both acids form acid salts M₄HSeO₄ and M₄HTeO₄ by reaction of the appropriate aqueous alkali. The neutral salts M₂SeO₃ and M₂TeO₃ can be obtained similarly or by heating the metal oxide with the appropriate dioxide. Dissociation constants have not been precisely determined but approximate values are:

H₂SeO₃:  \[ K_1 \sim 3.5 \times 10^{-3} \quad K_2 \sim 5 \times 10^{-8} \]

H₂TeO₃:  \[ K_1 \sim 3 \times 10^{-3} \quad K_2 \sim 2 \times 10^{-8} \]

Alkali diselenites M₂Se₂O₅ are also known and appear (on the basis of vibrational spectroscopy) to contain the ion [O₂Se–O–SeO₂]²⁻, with \( C_{2v} \) symmetry and a nonlinear Se–O–Se bridge (cf. disulfite \( O₃S–SO₂²⁻ \), p. 720). Selenous acid, in contrast to H₂TeO₃, can readily be oxidized to H₂SeO₄ by ozone in strongly acid solution; it is reduced to elementary selenium by H₂S, SO₂ or aqueous iodide solution.

Hydrated polonium dioxide, PoO(OH)₂, is obtained as a pale-yellow flocculent precipitate by addition of dilute aqueous alkali to a solution containing Po(IV). It is appreciably acidic, e.g.:

\[
\text{PoO(OH)₂} + 2\text{KOH} \rightleftharpoons K_2\text{PoO}_3 + 2\text{H₂O};
\]

\[
K_a = \frac{[\text{PoO}_3^{2-}]}{[\text{OH}^-]^2} = 8.2 \times 10^{-5}
\]

In the +6 oxidation state the oxoacids of Se and Te show little resemblance to each other. H₂SeO₄ resembles H₂SO₄ (p. 710) whereas orthotelluric acid Te(OH)₆ and polytelluric acid (H₂TeO₄)n are quite different.

Anhydrous H₂SeO₄ is a viscous liquid which crystallizes to a white deliquescent solid (mp 62°). It loses water on being heated and combines readily with SeO₃ to give “pyroseleinic acid”, H₂Se₂O₇ (mp 19°), and triselenic acid, H₂Se₃O₁₁ (mp 25°). It also resembles H₂SO₄ in forming several hydrates: H₂SeO₄.H₂O (mp 26°) and H₂SeO₄.4H₂O (52°). Crystalline H₂SeO₄ (d 2.961 g cm⁻³) comprises tetrahedral SeO₄ groups strongly H-bonded into layers through all 4 O atoms (Se–O 161 pm, O–H…O 261–268 pm). H₂SeO₄ can be prepared by several routes:

(i) Oxidation of H₂SeO₃ with H₂O₂, KMnO₄ or HClO₃, which can be formally represented by the equations:

\[
\text{H₂SeO₃} + \text{H₂O₂} \rightarrow \text{H₂SeO₄} + \text{H₂O}
\]

\[
8\text{H₂SeO₃} + 2\text{KMnO₄} \rightarrow 5\text{H₂SeO₄} + \text{K₂SeO₃} + 2\text{MnSeO₃} + 3\text{H₂O}
\]

\[
5\text{H₂SeO₃} + 2\text{HClO₃} \rightarrow 5\text{H₂SeO₄} + \text{Cl}_2 + \text{H₂O}
\]

(ii) Oxidation of Se with chlorine or bromine water, e.g.:

\[
\text{Se} + 3\text{Cl}_2 + 4\text{H}_2\text{O} \rightarrow \text{H₂SeO₄} + 6\text{HCl}
\]

(iii) Action of bromine water on a suspension of silver selenite:

\[
\text{Ag₂SeO₃} + \text{Br}_2 + \text{H}_2\text{O} \rightarrow \text{H₂SeO₄} + 2\text{AgBr}
\]

The acid dissociation constants of H₂SeO₄ are close to those of H₂SO₄, e.g. \( K_2 \) (H₂SeO₄)
1.2 \times 10^{-2}. Selenium, tellurium and polonium Ch. 16

1.2

Selenates resemble sulfates and both acids form a series of alums (p. 76). Selenic acid differs from H₂SO₄, however, in being a strong oxidizing agent: this is perhaps most dramatically shown by its ability to dissolve not only Ag (as does H₂SO₄) but also Au, Pd (and even Pt in the presence of Cl⁻):

\[ 2Au + 6H₂SeO₄ \rightarrow Au₂(SeO₄)_3 + 3H₂SeO₃ + 3H₂O \]

It oxidizes halide ions (except F⁻) to free halogen. Solutions of S, Se, Te and Po in H₂SeO₄ are brightly coloured (cf. p. 664).

By contrast, the two main forms of telluric acid do not resemble H₂SO₄ and H₂SeO₄ and tellurates are not isomorphous with sulfates and selenates. Orthotelluric acid is a white solid, mp 136°, whose crystal structure is built up of regular octahedral molecules, Te(OH)₆. This structure, which persists in solution (Raman spectrum), is also reflected in its chemistry; e.g. breaks occur in the neutralization curve at points corresponding to Na₅H₅TeO₆, Na₉H₄TeO₆, Na₄H₂TeO₅ and Na₆TeO₆. Similar salts include Ag₆TeO₆ and Hg₃TeO₆. Moreover diazomethane converts it to the hexamethyl ester Te(OMe)₆. In this respect Te resembles its horizontal neighbours in the periodic table Sn, Sb and I which form the isoelectronic species [Sn(OH)₆]²⁻, [Sb(OH)₆]⁻ and IO(OH)₅. Orthotelluric acid can be prepared by oxidation of powdered Te with chloric acid solution or oxidation of TeO₂ with permanganate:

\[ 5Te + 6HClO₃ + 12H₂O \rightarrow 5H₆TeO₆ + 3Cl₂ \]

5TeO₂ + 2KMnO₄ + 6HNO₃ + 12H₂O \rightarrow 5H₆TeO₆ + 2KNO₃ + 3Mn(NO₃)₂

Alternatively, Te or TeO₂ can be oxidized by CrO₃/HNO₃ or by 30% H₂O₂ under reflux. Acidification of a tellurite with an appropriate precipitating acid offers a further convenient route:

BaTeO₄ + H₂SO₄ + 2H₂O \rightarrow BaSO₄↓ + H₆TeO₆

Ag₂TeO₄ + 2HCl + 2H₂O \rightarrow 2AgCl↓ + H₆TeO₆

Crystallization from aqueous solutions below 10° gives the tetrahydrate H₆TeO₆·4H₂O. The anhydrous acid is stable in air at 100° but above 120° gradually loses water to give polymetatelluric acid and allotelluric acid (see below). Unlike H₂SO₄ and H₂SeO₄, H₆TeO₆ is a weak acid, approximate values of its successive dissociation constants being K₁ \approx 2 \times 10⁻⁸, K₂ \approx 2 \times 10⁻¹¹, K₃ \approx 3 \times 10⁻¹⁵. It is a fairly strong oxidant, being reduced to the element by SO₂ and to H₂TeO₃ in hot HCl:

H₆TeO₆ + 3SO₂ \rightarrow Te + 3H₂SO₄

H₆TeO₆ + 2HCl \rightarrow H₂TeO₃ + 3H₂O + Cl₂

Polymetatelluric acid (H₂TeO₄)ₙ₋₁₀ is a white, amorphous hygroscopic powder formed by incomplete dehydration of H₆TeO₆ in air at 160°. Alternatively, in aqueous solution the equilibrium \( nH₆TeO₆ \rightleftharpoons (H₂TeO₄)ₙ + 2nH₂O \) can be shifted to the right by increasing the temperature; rapid cooling then precipitates the sparingly soluble polymetatelluric acid. The structure is unknown but appears to contain 6-coordinate Te. Allotelluric acid “(H₂TeO₄)₃(H₂O)₄” is an acid syrup obtained by heating Te(OH)₆ in a sealed tube at 305°: the compound has not been obtained pure but tends to revert to H₆TeO₆ at room temperature or to (H₂TeO₄)ₙ when heated in air; indeed, it may well be a mixture of these two substances.

Tellurates are prepared by fusing a tellurite with a corresponding nitrate, by oxidizing a tellurite with chlorine, by neutralizing telluric acid with a hydroxide. An interesting variant is to heat intimate mixtures of TeO₃ with metal oxides. For example, with Rb₂O at 680° for several weeks, colourless crystals having the unusual stoichiometry Rb₆Te₁₈O₉ were formed which contained both tetrahedral TeO₄²⁻ and trigonal bipyramidal TeO₅⁴⁻ groups, i.e. Rb₆[TeO₅]₂[TeO₄].

Numerous peroxyacid or thioacid derivatives of Se and Te have been reported but these add little to the discussion of the reaction chemistry or the structure types already discussed.

---

123 Ref. 11, pp. 94-7.
described. Examples are peroxoselenous acid HOSeO(OH) (stable at $-10^\circ$) and potassium peroxy-orthotellurate $K_2H_4TeO_7$ which also loses oxygen at room temperature. Isomeric selenosulfates, $M_2$SO$_3$Se, and thioselenates, $M_2$SeO$_3$S, are known and can be made by the obvious routes of $[SO_3^{2-}(aq) + Se]$ and $[SeO_3^{2-}(aq) + S]$. Likewise, colourless or yellow-green crystalline selenopolythionates $M_2$Se$_x$S$_y$O$_{6x}$ ($x = 1, 2; y = 2, 4$) and orange-yellow telluropentathionates $M_2$Te$_x$S$_y$O$_{6y}$ are known. X-ray structure analysis reveals unbranched chains with various conformations as found for the polythionates themselves (p. 718). Typical examples are in Fig. 16.17. It will be seen that these compounds contain Se and Te bonded to S rather than O and they therefore form a natural link with the Group 16 sulfides to be described in the next section.

16.2.7 Other inorganic compounds

The red compound Se$_4$S$_4$, obtained by fusing equimolar amounts of the elements, is a covalent molecular species which can be crystalized from benzene. Similar procedures yield Se$_2$S$_6$, Se$_7$ and Te$_7$, all of which are structurally related to S$_8$ (p. 654; see also p. 763).

PoS forms as a black precipitate when H$_2$S is added to acidic solutions of polonium compounds. Its solubility product is $\sim 5 \times 10^{-29}$. The action of aqueous ammonium sulfide on polonium(IV) hydroxide gives the same compound. It decomposes to the elements when heated to 275$^\circ$ under reduced pressure and is of unknown structure.

The chemistry of compounds containing Se–N and Te–N bonds has been very activity developed during the past decade and many new and unusual species are emerging. Se$_4$N$_4$ is an orange, shock sensitive crystalline compound which decomposes violently at 160$^\circ$. It resembles its sulfur analogue (p. 722) in being thermochroic (yellow-orange at $-195^\circ$, red at $+100^\circ$) and in having the same $D_{4d}$ molecular structure. Se$_4$N$_4$ can be made by reacting anhydrous NH$_3$ with SeBr$_4$ (or with SeO$_2$ at 70$^\circ$ under pressure). A new red-brown crystalline modification, $\beta$-Se$_4$N$_4$, which has a very similar cluster structure but differs in the packing arrangement, has recently been prepared by reacting SeO$_2$ with the phosphane imine, Me$_2$SiNPMe$_3$. Tellurium nitride can be prepared similarly (TeBr$_4$–NH$_3$); it is a lemon-yellow, violently explosive compound with a formula that might be Te$_3$N$_4$ rather than Te$_4$N$_4$; its structure is unknown.

Se$_4$N$_4$ reacts with [PtCl$_2$(PMe$_2$Ph)$_2$] in liquid ammonia (50 atm.) to give a quantitative yield of [Pt($\eta^2$-Se$_2$N$_2$)(PMe$_2$Ph)$_2$] which features a

---

5-membered Pt–SeNSeN heterocycle at the planar Pt centre. A similar reaction with [Pt(PPh3)3] in CH2Cl2 gives the analogous PPh3 complex plus the related dark-green dimer, [(PPh3)Pt(μ-η2-Se2N2)2Pt(PPh3)], in which the chelating ligand also bridges the two Pt atoms via the ipso-N atoms so as to form a central planar Pt2N2 core which is also coplanar with the two planar 5-membered heterocycles. Innumerable other Se/N species have been synthesized and characterized by X-ray diffraction analysis, e.g. the 7π-electron radical cation Se3N2+ (1), the 6π-electron dication Se2N22+ (2), ClSe3N2 (3), [N(SeCl2)2]+ (4), Se(NO)2 (5), ClSe3N2S+ (6), Cl2Se2N2S (7), Cl2Se2N2S+ (8), etc. The original papers should be consulted for preparative procedures.

Metal complexes with Se/N ligands are also appearing in increasing numbers in the literature. Thus, cyclo-Se4N2 forms the red-brown donor–acceptor complexes [SnCl4(η1-N2Se4)] (9) and [TiCl4(η2-N2Se4)], whereas reaction of [Se2SN2]Cl2 with cis-[PtCl2(PMe2Ph)2] in liquid ammonia gives [Pt(η2-SeSN2)(PMe2Ph)2] which in turn can be protonated with HBF4 to give [Pt(η2-SeSN2H)(PMe2Ph)2]+ (10). The di-Se analogues with η2-Se2N22− and η2-Se2N2H− have also been characterized.

Heterocycles involving P=N include [1,5-(Ph2P)2N4(SeMe)2] (11), which has an 8-membered chair configuration with the two Se atoms displaced on either side of the P2N4 plane, and the related [1,5-(Ph2P)2N4Se2] (12). The reaction of (12) with [PtCl2(PPh3)2] gives the η1-complexes (13), (14) which, in turn, can be oxidatively added to [PtCl2(PPh3)2] to give the η2-Se,Se′ complexes (15) and (16).

---

Reaction of $P_4Se_4$ with soluble polyselenides afforded the first isolated $P/Se$ anion, the yellow $P_2Se_8^{2-}$ (17) which further reacts with $Fe(CO)_5$ to generate the novel brown cluster anion $[Fe_2(CO)_4(PSe_5)_2]$ (18). Numerous other examples are known; indeed, the whole field is still rapidly developing and many new types of compound are being synthesized and characterized each year.

Tellurium-chalcogen-nitrogen chemistry is also burgeoning. Typical examples include the red crystalline $Te(NSO)_2$, isomorphous with $Se(NSO)_2$ (5), and the cationic heterocycle $[FTeNSNSeNSN]^+[TeF_5]^-$, which is formed, together with $[[SeNSNSe^*]_2]^{2+}[TeF_5]^-_2$, when $Se(NSO)_2$ reacts with $TeF_4$ in $CH_2Cl_2$. The first stable tellurophosphorane complexes $[M(CO)_3(TE=PBU)]$ ($M = Cr, Mo, W$) were prepared as dark-red crystals by photolysis of the hexacarbonyls in the presence of $Bu_3P=Te$, and the expected bent coordination at $Te$ was confirmed by X-ray analysis (angle $W-Te-P 120.1^\circ$). By Contrast, reaction of $Et_3P=Te$ with $[Mn(CH_2Ph)(CO)]_3$ in refluxing toluene results in the insertion of $Te$ into

---

the Mn–CH₂ bond and the displacement of two CO ligands to yield the red crystalline solid \([\text{Mn(CO)}_3(\text{PET}_3)_2(\text{TeCH}_2\text{Ph})]\), in which the three carbynls are \textit{mer} and the two tertiary phospine ligands are \textit{trans} to each other.\(^{(144)}\)

The increasing basicity of the heavier members of Group 16 is reflected in the increasing incidence of oxoacid salts. Thus polonium forms \(\text{Po(NO}_3\text{)}_4.\text{xN}_2\text{O}_4\), \(\text{Po(SO}_4\text{)}_2.\text{xH}_2\text{O}\), and a basic sulfate and selenate \(2\text{PoO}_2.\text{SO}_3\) and \(2\text{PoO}_2.\text{SeO}_3\) all of which are white, and a hydrated yellow chromate \(\text{Po(CrO}_4\text{)}_2.\text{xH}_2\text{O}\). There is also fragmentary information on the precipitation of an insoluble polonium(IV) carbonate, iodate, phosphate and vanadate.\(^{(4)}\) Tellurium(IV) forms a white basic nitrate \(2\text{TeO}_2.\text{HNO}_3\) and a basic sulfate and selenate \(2\text{TeO}_2.\text{XO}_3\), and there are indications of a white, hygroscopic basic sulfite of selenium(IV), \(\text{SeO}_2.\text{SO}_3\) or \(\text{SeO}_2.\text{SeO}_4\). Most of these compounds have been prepared by evaporation of aqueous solutions of the oxide or hydrated oxide in the appropriate acid. There is no doubt that more imaginative nonaqueous synthetic routes could be devised, but the likely products seem rather uninteresting and the field has attracted little recent attention.

16.2.8 Organo-compounds\(^{(145–149)}\)

Organoselenium and organotellurium chemistry is a large and expanding field which parallels but is distinct from organosulfur chemistry. The biochemistry of organoselenium compounds has also been much studied (p. 759). Organopolonium chemistry is almost entirely restricted to trace-level experiments because of the charring and decomposition of the compounds by the intense \(\alpha\) activity of polonium (pp. 749ff.).

The principal classes of organoselenium compound are summarized in the scheme above which indicates the central synthetic role of

\[^{145}\text{K. J. Irgolic and M. V. Kudchadker, The organic chemistry of selenium, Chap. 8 in ref. 2, pp. 408–545.}\]
\[^{146}\text{H. E. GANTHER, Biochemistry of selenium, Chap. 9 in ref. 2, pp. 546–614.}\]
\[^{147}\text{W. C. Cooper and J. R. Glover, The toxicology of selenium and its compounds, Chap. 11 in ref. 2, pp. 654–74.}\]
§16.2.8 Organo-compounds

Figure 16.18 Some coordination environments of Se and Te in their organohalides.

the selenides $R_2Se$ and diselenides $R_2Se_2$\(^{(1)}\).
Detailed discussion of these and related tellurium compounds falls outside the scope of the present treatment. Other compounds such as the cyano derivatives (p. 778) and CSe$_2$, COSe, COTe and CSTe (p. 754) have already been briefly mentioned.

Tellurocarbonyl derivatives $R'C(=Te)OR_2$ and telluroamides, e.g. $PhC(=Te)NMe_2$ (mp 73°) have been prepared\(^{(150)}\) and shown to be similar to, though more reactive than, the corresponding seleno derivatives.

Reaction of $[Se_4]^{2+}[AsF_6]_2^-$ with $Ph_2Se_2$ in liquid SO$_2$ gives the bright orange compound $[Se_6Ph_2]^{2+}[AsF_6]_2^-$.SO$_2$ in which the Se$_6$ ring adopts the boat conformation with pendent Ph groups in the 1- and 4-positions.\(^{(151)}\) By contrast the reaction of $K_2CO_3$ with red-Se in acetone in the presence of $[(Ph_3P)_2N]Cl$ yields red crystals of $[(Ph_3P)_2N][Se_3C(Se)(C)(O)Me]^-$; the anion, which adopts the chair conformation, is the first example of an Se$_3C$ ring, and the C atom has exocyclic =Se and −C(O)Me groups attached.\(^{(152)}\)

Stoichiometry is frequently an inadequate guide to structure in organo-derivatives of Se and Te particularly when other elements (such as halogens) are also present. This arises from the incipient tendency of many of the compounds to undergo ionic dissociation or, conversely, to increase the coordination number of the central atom by dimerization or other oligomeric interactions. Thus $Me_3SeI$ features pyramidal ions $[SeMe_3]^+$ but these are each associated rather closely with 1 iodide which is colinear with 1 Me−Se bond to give a distorted pseudotrigonal bipyramidal configuration (Fig. 16.18a).\(^{(125)}\) A regular pyramidal cation can, however, be obtained by use of a large non-coordinating counterion, as in

[TeMe₃]⁺[BPh₄]⁻ (Fig. 16.18b). By contrast, Ph₃TeCl is a chloride-bridged dimer with 5-coordinate square-pyramidal Te (Fig. 16.13c).

The possibility of isomerism also exists: e.g. 4-coordinate, monomeric molecular Me₂TeI₂ and its ionic counterpart [TeMe₃]⁺[TeMeI₄]⁻ in which interionic interactions make both the cation and the anion pseudo-6-coordinate (Fig. 16.18d).

Further complications obtrude when the halogen itself is capable of forming polyhalide units in the crystal. Thus reaction of molecular Me₂TeI₂ with iodine readily affords Me₂TeI₄ but the chemical behaviour and spectra of the product give no evidence for oxidation to Te(VI), and X-ray analysis indicates the formation of an adduct Me₂TeI₂.I₂ in which the axially disposed iodine atoms of the pseudo-trigonal-bipyramidal Me₂TeI₂ are weakly bonded to molecules of iodine to form a network as shown in Fig. 16.18e (cf. TII₃, p. 239).

Among the range of homoleptic organotelurium compounds that have recently been synthesized are the perfluoroalkyl derivatives Te(C,Fₙ⁺,)₄, (n = 1-4). Of these, the yellow oily liquid Te(CF₃)₄ is the least stable, being both light- and temperature-sensitive. It reacts with fluorides to give the complex anion [Te(CF₃)₄F]⁻ and with fluoride-ion acceptors to form the cation [Te(CF₃)₃]⁺. Te(CF₃)₄ is made by reacting Te(CF₃)₂Cl₂ with Cd(CF₃)₂ in MeCN. The higher members can be made directly from TeCl₄ and Cd(CF₃)₂ are also viscous yellow liquids. The related TeMe₄ was first made in 1989 as a yellow pyrophoric liquid by treating TeCl₄ with LiMe in ether at −78°C, it can be oxidized by XeF₂ to the volatile white solid Me₄TeF₂ which, when treated with ZnMe₂, gave TeMe₆ as a white solid.

Organopolytellurides (and polyselenides) are also known, e.g. ArTeTeAr (Ar = 2, 4, 6-Ph₃C₆H₂-)(159) and RTeTeTeR (R = (Me₃Si)₃-C);(160) the stabilizing rôle of the bulky end groups is evident. [The related “isoelectronic” cation Bu₃PTeTeTeBu₃⁺ can also be noted; it is prepared by oxidizing the tellurophosphorane Bu₃P=Te (see p. 785) using ferricenium salts.] Related compounds are R₂Se₁ (x = 2-7) and (RSe)₂S₁ (y = 1-15). Other compounds of note are the first “telluroketone”, Te=CF₂,(163) a thermally unstable violet compound which readily dimerizes even below room temperature to the dark-red crystalline 1,3-ditelluretane (19). Conden- sation with its analogue, Se=CF₂ yields the corresponding volatile orange solid, 1-selena-3-telluretane, F₂C₅TeCF₂Se.

The Halogens: Fluorine, Chlorine, Bromine, Iodine and Astatine

17.1 The Elements

17.1.1 Introduction

Compounds of the halogens have been known from earliest times and the elements have played a particularly important role during the past two hundred years in the development of both experimental and theoretical chemistry.\(^1\) Some of this early history is summarized in Table 17.1. The name “halogen” was introduced by J. S. C. Schweigger in 1811 to describe the property of chlorine, at that time unique among the elements, of combining directly with metals to give salts (Greek \(\alpha \lambda \varsigma\), sea salt, plus the root \(-\gamma \varepsilon \nu\), produce). The name has since been extended to cover all five members of Group 17 of the periodic table.

Fluorine

Fluorine derives its name from the early use of fluorspar (CaF\(_2\)) as a flux (Latin \(fluor\), flowing). The name was suggested to Sir Humphry Davy by A.-M. Ampère in 1812. The corrosive nature of hydrofluoric acid and the curious property that fluorspar has of emitting light when heated (“fluorescence”) were discovered in the seventeenth century. However, all attempts to isolate the element either by chemical reactions or by electrolysis were foiled by the extreme reactivity of free fluorine. Success was finally achieved on 26 June 1886 by H. Moissan who electrolysed a cooled solution of KHF\(_2\) in anhydrous liquid HF, using Pt/Ir electrodes sealed into a platinum U-tube sealed with fluorspar caps: the gas evolved immediately caused crystalline silicon to burst into flames, and Moissan reported the results to the Academy two days later in the following cautious words: “One can indeed make various hypotheses on the nature of the liberated gas; the simplest would be that we are in the

</table>

Noteworthy events are the development of inert fluorinated oils, greases and polymers: Freon gases such as CCl₂F₂ (1928) were specifically developed for refrigeration engineering; others were used as propellants in pressurized dispensers and aerosols; and the non-stick plastic polytetrafluoroethylene (PTFE or Teflon) was made in 1938. Inorganic fluorides, especially for the aluminium industry (p. 219) have been increasingly exploited from about 1900, and from 1940 UF₆ has been used in gaseous diffusion plants for the separation of uranium isotopes for nuclear reactor technology. The great oxidizing strength of F₂ and many of its compounds with N and O have attracted the attention of rocket compounds, pp. 267–466; Organic fluorine compounds, pp. 467–729.

engineers and there have been growing large-scale industrial applications of anhydrous HF (p. 810).

The aggressive nature of HF fumes and solutions has been known since Schwanhard of Nürnberg used them for the decorative etching of glass. Hydrofluoric acid inflicts excruciatingly painful skin burns (p. 810) and any compound that might hydrolyse to form HF should be treated with great caution. Maximum allowable concentration for continuous exposure to HF gas is 2–3 ppm (cf. HCN 10 ppm). The free element itself is even more toxic, maximum allowable concentration for a daily 8-h exposure being 0.1 ppm. Low concentrations of fluoride ion in drinking water have been known to provide excellent protection against dental caries since the classical work of H. T. Dean and his colleagues in the early 1930s; as there are no deleterious effects, even over many years, providing the total fluoride ion concentration is kept at or below 1 ppm, fluoridation has been a recommended and adopted procedure in several countries for many years (p. 810). However, at 2–3 ppm a brown mottling of teeth can occur and at 50 ppm harmful toxic effects are noted. Ingestion of 150 mg of NaF can cause nausea, vomiting, diarrhoea and acute abdominal pains though complete recovery is rapid following intravenous or intramuscular injection of calcium ions. The deliberate fluoridation of domestic water supplies has been a controversial, even polemical subject for several decades, though it is important to separate out the biological and toxicological aspects from the moral and philosophical aspects concerning the “right” of individuals to drink untreated water if they wish.\(^\text{5–7}\)

**Chlorine**

Chlorine was the first of the halogens to be isolated and common salt (NaCl) has been known from earliest times (see Table 17.1). Its efficacy in human diet was well recognized in classical antiquity and there are numerous references to its importance in the Bible. On occasion salt was used as part payment for the services of Roman generals and military tribunes (salary) and, indeed, it is an essential ingredient in mammalian diets (p. 68). The alchemical use of *aqua regia* (HCl/HNO\(_3\)) to dissolve gold is also well documented from the thirteenth century onwards. Concentrated hydrochloric acid was prepared by J. L. Glauber in 1648 by heating hydrated ZnCl\(_2\) and sand in a retort and the pure gas, free of water, was collected over mercury by J. Priestley in 1772. This was closely followed by the isolation of gaseous chlorine by C. W. Scheele in 1774: he obtained the gas by oxidizing nascent HCl with MnO\(_2\) in a reaction which would now formally be written as:

\[
4\text{NaCl} + 2\text{H}_2\text{SO}_4 + \text{MnO}_2 \xrightarrow{\text{heat}} 2\text{Na}_2\text{SO}_4 + \text{MnCl}_2 + 2\text{H}_2\text{O} + \text{Cl}_2
\]

However, Scheele believed he had prepared a *compound* (dephlogisticated marine acid air) and the misconception was compounded by C.-L. Berthollet who showed in 1785 that the action of chlorine on water releases oxygen: \[\text{Cl}_2(\text{g}) + \text{H}_2\text{O} \rightarrow 2\text{HCl}(\text{soln}) + \frac{1}{2}\text{O}_2(\text{g})\]; he concluded that chlorine was a loose compound of HCl and oxygen and called it oxymuriatic acid.\(^\dagger\)

\(^\dagger\) *Muriatic* and *marine* acid were synonymous terms for what is now called hydrochloric acid, thus signifying its relation to the sodium chloride contained in brine (Latin *maria*) or sea water (Latin *mare*). Both names were strongly criticized by H. Davy in a scathing paper entitled “Some reflections on the nomenclature of oxymuriatic compounds” in *Phil. Trans. R. Soc.* for 1811: “To call a body which is not known to contain oxygen, and which cannot contain muriatic acid, oxymuriatic acid, is contrary to the principles of that nomenclature in which it is adopted; and an alteration of it seems necessary to assist the progress of the discussion, and to diffuse just ideas on the subject. If the great discoverer of this substance (i.e. Scheele) had signified it by any simple name it would have been proper to have referred to it; but
The two decades from 1790 to 1810 were characterized by two major advances in chemical theory: Lavoisier's demolition of the phlogiston theory of combustion, and Davy's refutation of Lavoisier's contention that oxygen is a necessary constituent of all acids. Only when both these transformations had been achieved could the elementary nature of chlorine and the true composition of hydrochloric acid be appreciated, though some further time was to elapse (Dalton, Avogadro, Cannizaro) before gaseous chlorine was universally recognized to consist of diatomic molecules, Cl₂, rather than single atoms, Cl. The name, proposed by Davy in 1811, refers to the colour of the gas (Greek χλωρός, chloros, yellowish or light green — cf. chlorophyll).

The bleaching power of Cl₂ was discovered by Scheele in his early work (1774) and was put to technical use by Berthollet in 1785. This was a major advance on the previous time-consuming, labour-intensive, weather-dependent method of solar bleaching, and numerous patents followed (see Table 17.1). Indeed, the use of chlorine as a bleach remains one of its principal industrial applications (bleaching powder, elemental chlorine, hypochlorite solutions, chlorine dioxide, chloramines, etc.). Another all-pervading use of chlorine, as a disinfectant and germicide, also dates from this period (1801), and the chlorination of domestic water supplies is now almost universal in developed countries. Again, as with fluoride, higher concentrations are toxic to humans: the gas is detectable by smell at 3 ppm, causes throat irritation at 15 ppm, coughing at 30 ppm, and rapid death at 1000 ppm. Prolonged exposure to concentrations above 1 ppm should be avoided.

Sodium chloride, by far the most abundant compound of chlorine, occurs in extensive evaporite deposits, saline lakes and brines, and in the ocean (p. 795). It has played a dominant role in the chemical industry since its inception in the late eighteenth century (p. 71). The now defunct Leblanc process for obtaining NaOH from NaCl signalled the beginnings of large-scale chemical manufacture, and NaCl remains virtually the sole source of chlorine and hydrochloric acid for the vast present-day chlorine-chemicals industry. This embraces not only the large-scale production and distribution of Cl₂ and HCl, but also the manufacture of chlorinated methanes and ethanes, vinyl chloride, aluminium trichloride catalysts and the chlorides of Mg, Ti, Zr, Hf, etc., for production of the metals. Details of many of these processes are to be found either in other chapters or in later sections of the present chapter. About 15 000 chlorinated compounds are currently used to varying degrees in commerce. Of these, the environmental and health hazards posed by certain polychlorinated hydrocarbons is now well established, though not all such compounds are dangerous: focused selective restrictions rather than a blanket banning of all organochlorine compounds is advocated. The rôle of chlorofluorocarbons in the depletion of stratospheric ozone above the polar regions has already been mentioned (p. 608).

Bromine

The magnificent purple pigment referred to in the Bible and known to the Romans as Tyrian purple after the Phoenician port of Tyre (Lebanon), was shown by P. Friedländer in 1909 to be 6,6'-dibromoindigo. This precious dye was extracted in the early days from the small purple snail Murex brandaris, as many as 12 000 snails being required to prepare 1.5 g of dye. The element itself was isolated by A.-J. Balard in 1826 from the mother liquors remaining after the crystallization of sodium chloride and sulfate from the waters of the Montpellier salt marshes; 

10 Holy Bible, Ezekiel 27:7, 16.
the liquor is rich in MgBr₂, and the young Balard, then 23 y of age, noticed the deep yellow coloration that developed on addition of chlorine water. Extraction with ether and KOH, followed by treatment of the resulting KBr with H₂SO₄/MnO₂, yielded the element as a red liquid. Astonishingly rapid progress was possible in establishing the chemistry of bromine and in recognizing its elemental nature because of its similarity to chlorine and iodine (which had been isolated 15 y earlier). Indeed, J. von Liebig had missed discovering the element several years previously by misidentifying a sample of it as iodine monochloride.(1) Balard had proposed the name muride, but this was not accepted by the French Academy, and the element was named bromine (Greek βρωμός, stink) because of its unpleasant, penetrating odour. It is perhaps ironic that the name fluorine had already been preempted for the element in CaF₂ and HF (p. 789) since bromine, as the only non-metallic element that is liquid at room temperature, would preeminently have deserved the name.

The first mineral found to contain bromine (bromyrite, AgBr) was discovered in Mexico in 1841, and industrial production of bromides followed the discovery of the giant Stassfurt potash deposits in 1858. The major use at that time was in photography and medicine: AgBr had been introduced as the light-sensitive agent in photography about 1840, and the use of KBr as a sedative and anti-convulsant in the treatment of epilepsy was begun in 1857. Other major uses of bromine-containing compounds include their application as flame retardants and as phase-transfer catalysts. The scale of the present-day production of bromine and bromine chemicals will become clear in later sections of this chapter.⁷

Iodine

The lustrous, purple-black metallic sheen of resublimed crystalline iodine was first observed by the industrial chemist B. Courtois in 1811, and the name, proposed by J. L. Gay Lussac in 1813, reflects this most characteristic property (Greek γαλάς, violet-coloured). Courtois obtained the element by treating the ash of seaweed (which had been calcined to extract saltpetre and potash) with concentrated sulfuric acid. Extracts of the brown kelps and seaweeds Fucus and Laminaria had long been known to be effective for the treatment of goitre and it was not long before J. F. Coindet and others introduced pure KI as a remedy in 1819. It is now known that the thyroid gland produces the growth-regulating hormone thyroxine, an iodinated aminoacid: p-(HO)-C₆H₄(Ο)₂-O-C₆H₄(Ο)₂-CH₂CH(NH₂)CO₂H. If the necessary iodine input is insufficient the thyroid gland enlarges in an attempt to garner more iodine: addition of 0.01% NaI to table salt (iodized salt) prevents this condition. Tincture of iodine is a useful antiseptic.

The first iodine-containing mineral (AgI) was discovered in Mexico in 1825 but the discovery of iodate as an impurity in Chilean saltpetre in 1840 proved to be more significant industrially. The Chilean nitrate deposits provided the largest proportion of the world’s iodine until overtaken in the late 1960s by Japanese production from natural brines (pp. 796, 799).

In addition to its uses in photography and medicine, iodine and its compounds have been much exploited in volumetric analysis (iodometry and iodimetry, p. 864). Organoiiodine compounds have also played a notable part in the development of synthetic organic chemistry, being the first compounds used in A. W. von Hofmann’s alkylation of amines (1850), A. W. Williamson’s synthesis of ethers (1851), A. Wurtz’s coupling reactions (1855) and V. Grignard’s reagents (1900).

Astatine

From its position in the periodic table, all isotopes of element 85 would be expected to

---

be radioactive. Those isotopes that occur in the natural radioactive series all have half-lives of less than 1 min and thus occur in negligible amounts in nature (p. 796). Astatine (Greek αστάτος, unstable) was first made and characterized by D. R. Corson, K. R. Mackenzie and E. Segré in 1940: they synthesized the isotope $^{211}\text{At}$ ($\tau = 7.21$ h) by bombarding $^{209}\text{Bi}$ with $\alpha$-particles in a large cyclotron:

$$^{209}\text{Bi} + 4^n\text{He} \rightarrow 211^{\text{At}} + 2_0^n\text{He}$$

In all, some 27 isotopes from $^{194}\text{At}$ to $^{220}\text{At}$ have now been prepared by various routes but all are short-lived. The only ones besides $^{211}\text{At}$ having half-lives longer than 1 h are $^{207}\text{At}$ (1.80 h), $^{208}\text{At}$ (1.63 h), $^{209}\text{At}$ (5.41 h), and $^{210}\text{At}$ (8.1 h): this means that weighable amounts of astatine or its compounds cannot be isolated, and nothing is known of the bulk physical properties of the element. For example, the least-unstable isotope ($^{210}\text{At}$) has a specific activity corresponding to 2 curies per $\mu$g, i.e. $7 \times 10^{10}$ disintegrations per second per $\mu$g. The largest preparations of astatine to date have involved about 0.05 pg and our knowledge of the chemistry of this element comes from extremely elegant tracer experiments, typically in the concentration range $10^{-13} \text{ to } 10^{-15}$ M. The most concentrated aqueous solutions of the element or its compounds ever investigated were only $\sim 10^{-8}$ M.

### §17.1.2 Abundance and distribution

Because of their reactivity, the halogens do not occur in the free elemental state but they are both widespread and abundant in the form of their ions, $X^-$. Iodine also occurs as iodate (see below). In addition to large halide mineral deposits, particularly of NaCl and KCl, there are vast quantities of chloride and bromide in ocean waters and brines.

Fluorine is the thirteenth element in order of abundance in crustal rocks of the earth, occurring to the extent of 544 ppm (cf. twelfth Mn, 1060 ppm; fourteenth Ba, 390 ppm; fifteenth Sr, 384 ppm). The three most important minerals are fluorspar $\text{CaF}_2$, cryolite $\text{Na}_3\text{AlF}_6$ and fluorapatite $\text{Ca}_5(\text{PO}_4)_3\text{F}$. Of these, however, only fluorite is extensively processed for recovery of fluorine and its compounds (p. 809). Cryolite is a rare mineral, the only commercial deposit being in Greenland, and most of the $\text{Na}_3\text{AlF}_6$ needed for the huge aluminium industry (p. 219) is now synthetic. By far the largest amount of fluorine in the earth’s crust is in the form of fluorapatite, but this contains only about 3.5% by weight of fluorine and the mineral is processed almost exclusively for its phosphate content. Despite this, about 7% of the domestic requirement for fluorine compounds in the USA was obtained from fluorsilicic acid recovered as a by-product of the huge phosphate industry (pp. 476, 520). Minor occurrences of fluorine are in the rare minerals topaz $\text{Al}_2\text{Si}_3\text{O}_9(\text{OH},\text{F})_2$, sellaite $\text{MgF}_2$, villiaumite $\text{NaF}$ and bastnaesite ($\text{Ce},\text{La})(\text{CO}_3)_2\text{F}$ (but see p. 1229). The insolubility of alkaline-earth and other fluorides precludes their occurrence at commercially useful concentrations in ocean water (1.2 ppm) and brines.

Chlorine is the twentieth most abundant element in crustal rocks where it occurs to the extent of 126 ppm (cf. nineteenth V, 136 ppm, and twenty-first Cr, 122 ppm). The vast evaporite deposits of NaCl and other chloride minerals have already been described (pp. 69, 73). Dwarfing these, however, are the inconceivably vast reserves in ocean waters (p. 69) where more than half the total average salinity of 3.4 wt% is due to chloride ions (1.9 wt%). Smaller quantities, though at higher concentrations, occur in certain inland seas and in subterranean brine wells, e.g. the Great Salt Lake, Utah (23% NaCl) and the Dead Sea, Israel (8.0% NaCl, 13.0% MgCl$_2$, 3.5% CaCl$_2$).

Bromine is substantially less abundant in crustal rocks than either fluorine or chlorine; at 2.5 ppm it is forty-sixth in order of abundance being similar to Hf 2.8, Cs 2.6, U 2.3, Eu 2.1 and Sn 2.1 ppm. Like chlorine, the largest natural source of bromine is the oceans, which contain $\sim 6.5 \times 10^{-3}$, i.e. 65 ppm or 65 mg/l. The mass ratio Cl:Br is $\sim 300:1$ in the oceans, corresponding to an atomic ratio
Salt lakes and brine wells are also rich sources of bromine, and these are usually proportionately richer in bromine than are the oceans: the atom ratio Cl:Br spans the range ~200–700. Typical bromide-ion concentrations in such waters are: Dead Sea 0.4% (4 g/l), Sakskoe Ozoro (Crimea) 0.28% and Searle’s Lake (California) 0.085%.

Iodine is considerably less abundant than the lighter halogens both in the earth’s crust and in the hydrosphere. It comprises 0.46 ppm of the crustal rocks and is sixty-sixth in order of abundance (cf. Tl 0.7, Tm 0.5, In 0.24, Sb 0.2). It occurs but rarely as iodide minerals, and commercial deposits are usually as iodates, e.g. lautarite, Ca(IO₃)₂ and dietzeite, 7Ca(IO₃)₂·8CaCrO₄. Thus the caliche nitrate beds of Chile contain iodine in this form (~0.02–1 wt% I). These mine workings soon replaced calcined seaweeds as the main source of iodine during the last century, but have recently been themselves overtaken by iodine recovered from brines. Brines associated with oil-well drillings in Louisiana and California were found to contain 30–40 ppm iodine in the 1920s, and independent subterranean brines were located at Midland, Michigan, in the 1960s, and in Oklahoma (1977), which is now the main US source. Natural brine wells in Japan (up to 100 ppm I) were discovered after the Second World War, and exploitation of these now ensures Japan first place among the world’s iodine producers. The concentration of iodine in ocean waters is only 0.05 ppm, too low for commercial recovery, though brown seaweeds of the Laminaria family (and to a lesser extent Fucus) can concentrate this up to 0.45% of their dry weight (see above).

The fugitive radioactive element astatine can hardly be said to exist in nature though the punctilious would rightly point to its temporary participation in the natural radioactive series. Thus ²¹⁹At (t₁/₂ 54 s) occurs as a rare and inconspicuous branch (4 × 10⁻³%) of another minor branch (1.2%) of the ²³⁵U (4n + 3) series (see scheme). Another branch (5 × 10⁻⁴%) at ²¹⁵Po yields ²¹⁵At by β emission before itself decaying by α emission (t₁/₂ 1.0 × 10⁻⁴ s); likewise ²¹⁸At (t₁/₂ 72 s) is a descendant of the ²³⁸U (4n + 2) series, and traces have been detected of ²¹⁷At (t₁/₂ 0.0323 s) and ²¹⁶At (t₁/₂ 3.0 × 10⁻⁴ s). Estimates suggest that the outermost kilometre of the earth’s crust contains no more than 44 mg of astatine compared with 15 g of francium (p. 69) or the relatively abundant polonium (2500 tonnes) and actinium (7000 tonnes). Astatine can therefore be regarded as the rarest naturally occurring terrestrial element.

### 17.1.3 Production and uses of the elements

The only practicable large-scale method of preparing F₂ gas is Moissan’s original procedure based on the electrolysis of KF dissolved in anhydrous HF; (see however p. 821). Moissan used a mole ratio KF:HF of about 1:13, but this has a high vapour pressure of HF and had to be operated at −24°C. Electrolyte systems having mole ratios of 1:2 and 1:1 melt at ~72° and ~240°C respectively and have much lower vapour pressures of HF; accordingly
these compositions were subsequently favoured. Nowadays, medium-temperature cells (80–100°C) are universally employed, being preferred over the high-temperature cells because (a) they have a lower pressure of HF gas above the cell, (b) there are fewer corrosion problems, (c) the anode has a longer life and (d) the composition of the electrolyte can vary within fairly wide limits without impairing the operating conditions or efficiency. The highly corrosive nature of the electrolyte, coupled with the aggressive oxidizing power of F₂, pose considerable problems of handling, and these are exacerbated by the explosive reaction of F₂ with its co-product H₂, so that accidental mixing of the gases must be prevented at all costs. Scrupulous absence of grease and other flammable contaminants must also be ensured since they can lead to spectacular fires which puncture the protective fluoride coating of the metal containers and cause the whole system to enflame. Another hazard in early generators was the formation of explosive graphite-fluorine compounds at the anode (p. 289). All these problems have now been overcome and F₂ can be routinely generated with safety both in the laboratory and on a large industrial scale.\(^{(2,13)}\)

A typical generator (Fig. 17.1) consists of a mild-steel pot (cathode) containing the electrolyte KF₂HF which is kept at 80–100°C either by a heating jacket when the cell is quiescent or by a cooling system when the cell is working. The anode consists of a central rod of compacted, ungraphitized carbon, and the product gases are kept separate by a skirt or diaphragm dipping below the electrolyte surface. The temperature is automatically controlled, as is the level of the electrolyte by controlled addition of make-up anhydrous HF. Laboratory generators usually operate at about 10–50 A whereas industrial production, employing banks of cells, may operate at 4000–6000 A and 8–12 V. An individual cell in such a bank might typically be 3.0 × 0.8 × 0.6 m and hold 1 tonne of electrolyte; it might have 12 anode assemblies each holding two anode blocks and produce 3–4 kg F₂ per hour. A large-scale plant can produce ca. 9 tonnes of liquefied F₂ per day. The total annual production in the USA and Canada exceeds 5000 tonnes, and similar though somewhat smaller amounts are produced in several European countries (UK, France, Germany, Italy, Russia). Production in Japan approaches 1000 tpa.

Cylinders of F₂ are now commercially available in various sizes from 230-g to 2.7-kg capacity; 1993 price ~$110–260 per kg depending on cylinder size. The gas pressure is 2.86 MPa (~28 atm.) at 21°C. Liquid F₂ is shipped in tank trucks of 2.27 tonnes capacity, the container being itself cooled by a jacket of liquid N₂ which boils 8° below F₂. Alternatively, it can be converted to CIF₃, bp 11.7°C (p. 828), which is easier to handle and transport than F₂. In fact, about 70–80% of the elemental F₂ produced is used captively for the manufacture of UF₆ for nuclear power generation (p. 1259). Another important use is in the production of SF₆ for dielectrics (p. 687). The captive use to manufacture the versatile fluorinating agents CIF₃, BrF₃ and IF₅ is a third important outlet. Fluorination of W and Re to

their hexafluorides is also industrially important since these volatile compounds are used in chemical vapour deposition of W and Re films on intricately shaped components. Most other fluorinations of inorganic and organic compounds avoid the direct use of F₂. The former demand for liquid F₂ as a rocket-fuel oxidizer has now ceased.

Chlorine is rarely generated on a laboratory scale since it is so readily available in cylinders of all sizes from 450 g (net) to 70 kg. When required it can also be generated by adding concentrated, air-free hydrochloric acid (d 1.16 g cm⁻³) dropwise on to precipitated hydrated manganese dioxide in a flask fitted with a dropping funnel and outlet tube: the gas formation can be regulated by moderate heating and the Cl₂ thus formed can be purified by passage through water (to remove HCl) and H₂SO₄ (to remove H₂O). The gas, whether generated in this way or obtained from a cylinder, can be further purified if necessary by passage through successive tubes containing CaO and P₂O₅, followed by condensation in a bath cooled by solid CO₂ and fractionation in a vacuum line.

Industrial production of Cl₂ and chlorine chemicals is on a vast scale and comprises a major section of the heavy chemical industry. Some aspects have already been discussed on p. 793, and further details are in the Panel.

Bromine is invariably made on an industrial scale by oxidation of bromide ion with Cl₂. The main sources of Br⁻ are Arkansas brines (4000–5000 ppm) which account for most of US production, various brines and bitterns in Europe, the Dead Sea (4000–6000 ppm), and ocean waters (65 ppm). Following the oxidation of Br⁻ the Br₂ is removed from the solution either by passage of steam ("steaming out") or air ("blowing out"), and then condensed and purified. Although apparently simple, these unit operations must deal with highly reactive and corrosive materials, and the industrial processes have been ingeniously developed and refined.

Industrial Production and Uses of Chlorine

The large-scale production of Cl₂ is invariably achieved by the electrolytic oxidation of the chloride ion. Natural brines or aqueous solutions of NaCl can be electrolysed in an asbestos diaphragm cell or a mercury cathode cell, though these latter are being phased out for environmental and other reasons (p. 1225). Electrolysis of molten NaCl is also carried out on a large scale: in this case the co-product is Na rather than NaOH. Electrolysis of by-product HCl is also used where this is cheaply available. World consumption of Cl₂ in 1987 exceeded 35 million tonnes. Production is dominated by the USA, but large tonnages are produced in all industrial countries: USA 30%, Western Europe 29%, Eastern Europe 15%, Japan 8.5%, Asia/Pacific 6.8%. Cl₂ was ranked eighth among the large-volume chemicals manufactured in the USA during 1996. Diaphragm cells predominated though there is a growing interest in membrane cells in which the anolyte and catholyte are separated by a porous Nafion membrane (Nafion is a copolymer of tetrafluoroethylene and a perfluorosulfonylethylene ether and the membrane is reinforced with a Teflon mesh). In addition to cylinders of varying capacity up to 70 kg, chlorine can be transported in drums (865 kg), tank wagons (road: 15 tonnes; rail 27–90 tonnes), or barges (600–1200 tonnes).

The three main categories of use for Cl₂ are:

(a) Production of organic compounds by chlorination and/or oxychlorination using a fluidized bed of copper chloride catalyst (pre-eminent amongst these are vinyl chloride monomer and propylene oxide which in the USA alone are produced on a scale of 9.0 and 2.0 million tonnes respectively). Production of chlorinated organic compounds accounts for about 63% of the Cl₂ produced.

(b) Bleaches (for paper, pulp and textiles) sanitation and disinfection of municipal water supplies and swimming pools, sewage treatment and control. These uses account for about 19% of the Cl₂ produced.

(c) Production of inorganic compounds, notably HCl, Cl₂O, HOCl, NaClO₂, chlorinated isocyanurates, AlCl₃, SiCl₄, SnCl₄, PCl₃, POCl₃, AsCl₅, SbCl₅, BiCl₅, S₂Cl₂, SCl₂, SCl₄, ClF₃, IF₃, ICl₃, IF₅, TiCl₃, TiCl₄, MoCl₅, FeCl₃, ZnCl₂, Hg₂Cl₂, HgCl₂, etc. (see index for page references to production and uses). About 18% of Cl₂ production is used to manufacture inorganic chemicals.

to give optimum yields at the lowest possible operating costs.\(^{16,17}\)

World production of Br\(_2\) in 1990 was about 438 000 tonnes pa, i.e. about one-hundredth of the scale of the chlorine industry. The main producing countries are (tonnes): USA 177 000, Israel 135 000, Russia 60 000, UK 28 000, France 18 000 and Japan 15 000. The production capacity of Israel has recently increased almost threefold because of expanded facilities on the Dead Sea. Historically, bromine was shipped in individual 3-kg (net) bottles to minimize damage due to breakage, but during the 1960s bulk transport in monel metal drums (100-kg capacity) or lead-lined tanks (24 or 48 tonnes) was developed and these are now used for transport by road, rail and ship. The price of Br\(_2\) in tank-car lots was $975/kg in 1990.

The industrial usage of bromine has been dominated by the single compound ethylene dibromide which has been (with ethylene dichloride) a valuable gasoline (petrol) additive where it acts as a scavenger for lead from the anti-knock additive PbEt\(_4\). Environmental legislation has dramatically reduced the amount of leaded petrol produced and, accordingly, ethylene dibromide, which accounted for 90% of US bromine production in 1955, declined to 75% a decade later and now represents a mere 16% of the total bromine consumption in the USA (1990). Fortunately this decline has been matched by a steady increase in other applications and the industry worldwide has shown a modest growth.

Most of these large-volume applications involve organic compounds, notably MeBr, which is one of the most effective nematocides known (i.e. kills worms) and is also used as a general pesticide (herbicide, fungicide and insecticide). Ethylene dibromide and dibromochloropropane are also used as pesticides. Bromine compounds are extensively used as fire retardants, especially for fibres, carpets, rugs and plastics; they are about 3–4 times as effective (weight for weight) as chloro compounds which gives them a substantial cost advantage.

Other uses of bromo-organics include high-density drilling fluids, dyestuffs and pharmaceuticals. Bromine is also used in water sanitation and to synthesize a wide range of inorganic compounds, e.g. AgBr for photography, HBr, alkali metal bromides, bromates, etc. (see later sections). An indication of the overall pattern of use (USA, 1990) is as follows: flame retardants 29%, ethylene dibromide 16%, agrochemicals 16% drilling fluids 11% inorganic bromides 5.5%, water treatment chemicals 5.5%, other 17%.

The commercial recovery of iodine on an industrial scale depends on the particular source of the element.\(^{18}\) From natural brines, such as those at Midland (Michigan) or in Russia or Japan, chlorine oxidation followed by air blow-out as for bromine (above) is much used, the final purification being by resublimation. Alternatively the brine, after clarification, can be treated with just sufficient AgNO\(_3\) to precipitate the AgI which is then treated with clean scrap iron or steel to form metallic Ag and a solution of FeI\(_2\); the Ag is redissolved in HNO\(_3\) for recycling and the solution is treated with Cl\(_2\) to liberate the I\(_2\):

\[
\begin{align*}
\text{I}^- \text{(brine)} &\xrightarrow{\text{AgNO}_3} \text{AgI} \xrightarrow{\text{Fe}} \text{Ag} \uparrow + \text{FeI}_2 \ (\text{soln}) \\
\text{HNO}_3 &\downarrow \\
\text{FeCl}_2 \ (\text{soln}) &\uparrow \\
\text{Cl}_2 &\downarrow \\
&\text{I}_2
\end{align*}
\]

The newest process to be developed oxidizes the brine with Cl\(_2\) and then treats the solution with an ion-exchange resin: the iodine is adsorbed in the form of polyiodide which can be eluted with alkali followed by NaCl to regenerate the column. About 65% of the iodine consumed in the world comes from brines.

Recovery of iodine from Chilean saltpetre differs entirely from its recovery from brine since it is present as iodate. NaIO\(_3\) is extracted from the caliche and is allowed to accumulate in the mother liquors from the crystallization of NaNO\(_3\).

\(^{16}\) R. B. MCDONALD and W. R. MERRIMAN, pp. 168–82 of ref. 13.
\(^{17}\) Ref. 2, Vol. 4 (1992), Bromine, pp. 536–60; Bromine compounds, pp. 560–89.
until its concentration is about 6 g/l. Part is then drawn off and treated with the stoichiometric amount of sodium hydrogen sulfite required to reduce it to iodide:

$$\text{IO}_3^- + 3\text{HSO}_3^- \rightarrow \text{I}^- + 3\text{SO}_4^{2-} + 3\text{H}^+$$

The resulting acidic mixture is treated with just sufficient fresh mother liquor to liberate all the contained iodine:

$$5\text{I}^- + \text{IO}_3^- + 6\text{H}^+ \rightarrow 3\text{I}_2 \downarrow + 3\text{H}_2\text{O}$$

The precipitated $\text{I}_2$ is filtered off and the iodine-free filtrate returned to the nitrate-leaching cycle after neutralization of any excess acid with $\text{Na}_2\text{CO}_3$.

World production of $\text{I}_2$ in 1992 approached 15,000 tonnes, the dominant producers being Japan 41%, Chile 40%, USA 10% and the former Soviet Union 9%. Crude iodine is packed in double polythene-lined fibre drums of 10–50 kg capacity. Resublimed iodine is transported in lined fibre drums (11.3 kg) or in bottles containing 0.11, 0.45 or 2.26 kg. The price of $\text{I}_2$ has traditionally fluctuated wildly. Thus, because of acute over-supply in 1990 the price for $\text{I}_2$ peaked at $22/kg in 1988, falling to $12/kg in 1990 and $9.50/kg in 1992. Unlike $\text{Cl}_2$ and $\text{Br}_2$, iodine has no predominant commercial outlet. About 50% is incorporated into a wide variety of organic compounds and about 15% each is accounted for as resublimed iodine, $\text{KI}$, and other inorganics. The end uses include catalysts for synthetic rubber manufacture, animal- and fowl-feed supplements, stabilizers, dyestuffs, colourants and pigments for inks, pharmaceuticals, sanitary uses (tincture of iodine, etc.) and photographic chemicals for high-speed negatives. Uses of iodine compounds as smog inhibitors and cloud-seeding agents are small. In analytical chemistry $\text{KHgI}_3$ forms the basis for Nessler’s reagent for the detection of $\text{NH}_3$, and $\text{Cu}_2\text{HgI}_4$ was used in Mayer’s reagent for alkaloids. Iodides and iodates are standard reagents in quantitative volumetric analysis (p. 864). $\text{Ag}_2\text{HgI}_4$ has the highest ionic electrical conductivity of any known solid at room temperature but this has not yet been exploited on a large scale in any solid-state device.

### 17.1.4 Atomic and physical properties

The halogens are volatile, diatomic elements whose colour increases steadily with increase in atomic number. Fluorine is a pale yellow gas which condenses to a canary yellow liquid, bp $-188.1^\circ\text{C}$ (intermediate between $\text{N}_2$, bp $-195.8^\circ\text{C}$, and $\text{O}_2$, bp $-183.0^\circ\text{C}$). Chlorine is a greenish-yellow gas, bp $-34.0^\circ\text{C}$, and bromine a dark-red mobile liquid, bp $59.5^\circ\text{C}$: interestingly the colour of both elements diminishes with decrease in temperature and at $-195^\circ\text{C}$ $\text{Cl}_2$ is almost colourless and $\text{Br}_2$ pale yellow. Iodine is a lustrous, black, crystalline solid, mp $113.6^\circ\text{C}$, which sublimes readily and boils at $185.2^\circ\text{C}$.

Atomic properties are summarized in Table 17.3 and some physical properties are in Table 17.4.

</table>
As befits their odd atomic numbers, the halogens have few naturally occurring isotopes (p. 3). Only one isotope each of F and I occurs in nature and the atomic weights of these elements are therefore known very accurately indeed (p. 17). Chlorine has two naturally occurring isotopes (35Cl 75.77%, 37Cl 24.23%) as also does bromine (79Br 50.69%, 81Br 49.31%). All isotopes of At are radioactive (p. 795). The ionization energies of the halogen atoms show the expected trend to lower values with increase in atomic number. The electronic configuration of each atom (ns²np⁵) is one p electron less than that of the next succeeding noble gas, and energy is evolved in the reaction X(g) + e⁻ → X⁻(g). The electron affinity, which traditionally (though misleadingly) is given a positive sign despite the negative enthalpy change in the above reaction, is maximum for Cl, the value for F being intermediate between those for Cl and Br. Even more noticeable is the small enthalpy of dissociation for F₂ which is similar to that of I₂ and less than two-thirds of the value for Cl₂. In this connection it can be noted that N–N single bonds in hydrazines are weaker than the corresponding P–P bonds and that O–O single bonds in peroxides are weaker than the corresponding S–S bonds. This was explained (R. S. Mulliken and others, 1955) by postulating that partial pd hybridization imparts some double-bond character to the formal P–P, S–S and Cl–Cl single bonds thereby making them stronger than their first-row counterparts. However, following C. A. Coulson and others (1962), it seems unnecessary to invoke substantial d-orbital participation and the weakness of the F–F single bond is then ascribed to decreased overlap of bonding orbitals, appreciable internuclear repulsion and the relatively large electron–electron repulsions of the lone-pairs which are much closer together in F₂ than in Cl₂. The rapid diminution of bond-dissociation energies in the sequence N₂ ≫ O₂ ≫ F₂ is, of course, due to successive filling of the antibonding orbitals (p. 606), thus reducing the formal bond order from triple in N≡N to double and single in O=O and F–F respectively.

Radioactive isotopes of the halogens have found use in the study of isotope-exchange reactions and the mechanisms of various other reactions. The properties of some of the most used isotopes are in Table 17.5. Many of these isotopes are available commercially. A fuller treatment with detailed references

of the use of radioactive isotopes of the halogens, including exchange reactions, tracer studies of other reactions, studies of diffusion phenomena, radiochemical methods of analysis, physiological and biochemical applications, and uses in technology and industry is available.\textsuperscript{(23)} Excited states of $^{127}$I and $^{129}$I have also been used extensively in Mössbauer spectroscopy.\textsuperscript{(24)}

The nuclear spin of the stable isotopes of the halogens has been exploited in nmr spectroscopy. The use of $^{19}$F in particular, with its 100% abundance, convenient spin of $\frac{1}{2}$ and excellent sensitivity, has resulted in a vast and continually expanding literature since $^{19}$F chemical shifts were first observed in 1950.\textsuperscript{(25)} The resonances for $^{35}$Cl and $^{37}$Cl were also first observed in 1950.\textsuperscript{(26)} Appropriate nuclear parameters are in Table 17.6. From this it is clear that the $^{19}$F resonance can be observed with high receptivity at a frequency fairly close to that for $^1$H. Furthermore, since $I < 1$ there is no nuclear quadrupole moment and hence no quadrupolar broadening of the resonance. The observed range of $^{19}$F chemical shifts is more than an order of magnitude greater than for $^1$H and spans more than 800 ppm of the resonance frequency.\textsuperscript{(27,28)} The signal moves to higher frequency with increasing electronegativity and oxidation state of the attached atom thus following the usual trends. Results are regularly reviewed.\textsuperscript{(29)} For other halogens, as seen from Table 17.6, the nuclear spin $I$ is greater than $\frac{1}{2}$ which means that the nuclear charge distribution is non-spherical; this results in a nuclear quadrupole moment, and resonance broadening due to quadrupolar relaxation severely restricts the use of the technique except for the halide ions $X^-$ or for tetrahedral species such as $\text{ClO}_4^-$ which have zero electric field gradient at the halogen nucleus. The receptivity is also much less

than for $^1$H or $^{19}$F which accordingly renders observation difficult. Despite these technical problems, much useful information has been obtained, especially in physicochemical and biological investigations. The quadrupole moments of Cl, Br and I have also been exploited successfully in nuclear quadrupole resonance studies of halogen-containing compounds in the solid state.

The molecular and bulk properties of the halogens, as distinct from their atomic and nuclear properties, were summarized in Table 17.4 and have to some extent already been briefly discussed. The high volatility and relatively low enthalpy of vaporization reflect the diatomic molecular structure of these elements. In the solid state the molecules align to give a layer lattice: $F_2$ has two modifications (a low-temperature, $\alpha$-form and a higher-temperature, $\beta$-form) neither of which resembles the orthorhombic layer lattice of the isostructural Cl$_2$, Br$_2$ and I$_2$. The layer lattice is illustrated below for I$_2$ the layer distance of 271.5 pm is appreciably longer than in gaseous I$_2$ (266.6 pm) and the closest interatomic approach between the molecules is 350 pm within the layer and 427 pm between layers (cf the van der Waals radius of 215 pm). These values are
compared with similar data for the other halogens in Table 17.7 from which two further features of interest emerge: (a) the intralayer intermolecular distances Cl⋯Cl and Br⋯Br are almost identical, and (b) the differences between intra- and inter-layer X⋯X distances decreases with increase in atomic number. (Fluorine is not directly comparable because of its differing structure.)

As expected from their structures, the elements are poor conductors of electricity: solid F₂ and Cl₂ have negligible conductivity and Br₂ has a value of \( \sim 5 \times 10^{-13} \text{ ohm}^{-1} \text{ cm}^{-1} \) just below the mp. Iodine single crystals at room temperature have a conductivity of \( 5 \times 10^{-12} \text{ ohm}^{-1} \text{ cm}^{-1} \) perpendicular to the bc plane layer but this increases to \( 1.7 \times 10^{-8} \text{ ohm}^{-1} \text{ cm}^{-1} \) within this plane; indeed, the element is a two-dimensional semiconductor with a band gap \( E_g \sim 1.3 \text{ eV} \) (125 kJ mol⁻¹). Even more remarkably, when crystals of iodine are compressed they become metallic, and at 350 kbar have a conductivity of \( \sim 10^4 \text{ ohm}^{-1} \text{ cm}^{-1} \). (33) The metallic nature of the conductivity is confirmed by its negative temperature coefficient.

The ease of dissociation of the X₂ molecules follows closely the values of the enthalpy of dissociation since the entropy change for the reaction is almost independent of X. Thus F₂ at 1 atm pressure is 1% dissociated into atoms at 765°C but a temperature of 975°C is required to achieve the same degree of dissociation for Cl₂; thereafter, the required temperature drops to 775°C for Br₂ and 575°C for I₂ (see also next section for atomic halogens).

### 17.1.5 Chemical reactivity and trends

#### General reactivity and stereochemistry

Fluorine is the most reactive of all elements. It forms compounds, under appropriate conditions, with every other element in the periodic table except He, Ar and Ne, frequently combining directly and with such vigour that the reaction becomes explosive. Some elements such as O₂ and N₂ react less readily with fluorine (pp. 639, 438) and some bulk metals (e.g. Al, Fe, Ni, Cu) acquire a protective fluoride coating, though all metals react exothermically when powdered and/or heated. For example, powdered Fe (0.84 mm size, 20 mesh) is not attacked by liquid F₂ whereas at 0.14 mm size (100 mesh) it ignites and burns violently. Perhaps the most striking example of the reactivity of F₂ is the ease with which it reacts directly with Xe under mild conditions to produce crystalline xenon fluorides (p. 894). This great reactivity of F₂ can be related to its small dissociation energy (p. 801) (which leads to low activation energies of reaction), and to the great strength of the bonds that fluorine forms with other elements. Both factors in turn can be related to the small size of the F atom and ensure that enthalpies of fluorination are much greater than those of other halogenations. Some typical average bond energies (kJ mol⁻¹) illustrating these points are:

The tendency for F₂ to give F⁻ ions in solution is also much greater than for the other halogens as indicated by the steady decrease in oxidation potential \( (E^0) \) for the reaction \( X_2(\text{soln}) + 2e^- \rightarrow 2X^- (\text{aq}) \):

</tbody>
</table>

The corresponding free energy changes can be calculated from the relation \( \Delta G = -nE^0F \) where \( n = 2 \) and \( F = 96.485 \text{ kJ mol}^{-1} \). Note that \( E^0(F_2/2F^-) \) is greater than the decomposition potential for water (p. 629). Note also the different sequence of values for \( E^0(X_2/2X^-) \) and for the electron affinities of X(g) (p. 800). A similar "anomaly" was observed (p. 75) for \( E^0 \) (Li⁺/Li) and the ionization energy of Li(g), and

---

in both cases the reason is the same, namely the enhanced enthalpy of hydration of the smaller ions. Other redox properties of the halogens are compared on pp. 853–6.

It follows from the preceding paragraph that F₂ is an extremely strong oxidizing element that can engender unusually high oxidation states in the elements with which it reacts, e.g. IF₇, PtF₆, PuF₆, BiF₅, Tbf₄, CmF₄, KAg₃F₄ and AgF₂. Indeed, fluorine (like the other first-row elements Li, Be, B, C, N and O) is atypical of the elements in its group and for the same reasons. For all 7 elements deviations from extrapolated trends can be explained in terms of three factors:

1. Their atoms are small;
2. Their electrons are tightly held and not so readily ionized or distorted (polarized) as in later members of the group;
3. They have no low-lying d orbitals available for bonding.

Thus the ionization energy \( Z_{\text{F}} \) is much greater for F than for the other halogens, thereby making formal positive oxidation states virtually impossible to attain. Accordingly, fluorine is exclusively univalent and its compounds are formed either by gain of 1 electron to give \( F^- \) (2s²2p⁶) or by sharing 1 electron in a covalent single bond. Note, however, that the presence of lone-pairs permits both the fluoride ion itself and also certain molecular fluorides to act as Lewis bases in which the coordination number of F is greater than 1, e.g. it is 2 for the bridging F atoms in \( \text{AsF}_{11}^-, \text{SbF}_{16}^-, \text{Nbf}_{20}, (\text{Hf})_n \) and \( (\text{BeF}_2)_{oo} \). The coordination number of \( F^- \) can rise to 3 (planar) in compounds with the rutile structure (e.g. \( \text{MgF}_2, \text{MnF}_2, \text{CoF}_2, \text{NiF}_2, \text{ZnF}_2 \) and \( \text{PdF}_2 \)). Likewise, fourfold coordination (tetrahedral) is found in the zinc-blende-type structure of CuF and in the fluorite structure of \( \text{CaF}_2, \text{SrF}_2, \text{BaF}_2, \text{RaF}_2, \text{CdF}_2, \text{HgF}_2 \) and \( \text{PbF}_2 \). A coordination number of 6 occurs in the alkali metal fluorides MF (NaCl type). In many of these compounds \( F^- \) resembles \( O^2- \) stereochemically rather than the other halides, and the radii of the 2 ions are very similar (\( F^- \) 133, \( O^2- \) 140 pm, cf. \( \text{Cl}^- \) 184, \( \text{Br}^- \) 196 pm).

The heavier halogens, though markedly less reactive than fluorine, are still amongst the most reactive of the elements. Their reactivity diminishes in the sequence \( \text{Cl}_2 > \text{Br}_2 > I_2 \). For example, \( \text{Cl}_2 \) reacts with CO, NO and SO₂ to give \( \text{COCl}_2, \text{NOCI} \) and \( \text{SO}_2\text{Cl}_2 \), whereas iodine does not react with these compounds. Again, in the direct halogenation of metals, \( \text{Cl}_2 \) and \( \text{Br}_2 \) sometimes produce a higher metal oxidation state than does \( I_2 \), e.g. \( \text{Re} \) yields \( \text{ReCl}_6, \text{ReBr}_5 \) and \( \text{ReI}_4 \) respectively. Conversely, the decreasing ionization energies and increasing ease of oxidation of the elements results in the readier formation of iodine cations (p. 842) and compounds in which iodine has a higher stable oxidation state than the other halogens (e.g. IF₇). The general reactivity of the individual halogens with other elements (both metals and non-metals) is treated under the particular element concerned. Reaction between the halogens themselves is discussed on p. 824. In general, reaction of \( X_2 \) with compounds containing \( M-M, M-H \) or \( M-C \) bonds results in the formation of \( M-X \) bonds (\( M = \text{metal or non-metal} \)). Reaction with metal oxides sometimes requires the presence of C and the use of elevated temperatures.

The stereochemistry of the halogens in their various compounds is summarized in Table 17.8 and will be elucidated in more detail in subsequent sections.

Reactivity is enhanced in conditions which promote the generation of halogen atoms, though this does not imply that all reactions proceed via the intermediacy of \( X \) atoms. The reversible thermal dissociation of gaseous \( I_2 \) was first demonstrated by Victor Meyer in 1880 and has since been observed for the other halogens as well (p. 804). Atomic Cl and Br are more conveniently produced by electric discharge though, curiously, this particular method is not successful for I. Microwave and radiofrequency discharges have also been used as well as optical dissociation by ultraviolet light. At room temperature and at pressures below 1 mmHg, up to 40% atomization can be achieved, the mean lives of the Cl and Br atoms in glass apparatus being of the order of a few milliseconds. The

reason for the slow and relatively inefficient reversion to X2 is the need for a 3-body collision in order to dissipate the energy of combination: X* + X* + M → X2 + M*. A fuller account of the production, detection and chemical reactions of atomic Cl, Br and I is on pages 1141–8 and 1165–72 of reference 23.

Solutions and charge-transfer complexes (34)

The halogens are soluble to varying extents in numerous solvents though their great reactivity sometimes results in solvolysis or in halogenation of the solvent. Reactions with water are discussed on pp. 855ff. Iodine is only slightly soluble in water (0.340 g/kg at 25°, 4.48 g/kg at 100°). It is more soluble in aqueous iodide solutions due to the formation of polyiodides (p. 835) and these can achieve astonishing concentrations; e.g. the solution in equilibrium with solid iodine and KI7H2O at 25° contains 67.8 wt% of iodine, 25.6% KI and 6.6% H2O. Iodine is also readily soluble in many organic solvents, typical values of its solubility at 25°C being (g/Vkg solvent): Et2O 337.3, EtOH 271.7, mesitylene 253.1, p-xylene 198.3, CS2 197.0, toluene 182.5, benzene 164.0, ethyl acetate 157, EtBr 146, EtCN 141.

34 Ref. 23, pp. 1196–220.
The most notable feature of such solutions is the dramatic dependence of their colour on the nature of the solvent chosen. Thus, solutions in aliphatic hydrocarbons or CCl₄ are bright violet (λ_max 520–540 nm), those in aromatic hydrocarbons are pink or reddish brown, and those in stronger donors such as alcohols, ethers or amines are deep brown (λ_max 460–480 nm). This variation can be understood in terms of a weak donor–acceptor interaction leading to complex formation between the solvent (donor) and I₂ (acceptor) which alters the optical transition energy. Thus, referring to the conventional molecular orbital energy diagram for I₂ (or other X₂) as shown in Fig. 17.2, the violet colour of I₂ vapour can be seen to arise as a result of the excitation of an electron from the highest occupied MO (the antibonding π_u level) into the lowest unoccupied MO (the antibonding σ_u level). In non-coordinating solvents such as aliphatic hydrocarbons or their fluoro- or chloro-derivatives the transition energy (and hence the colour) remains essentially unmodified.

However, in electron-donor solvents, L, the vacant antibonding σ_u orbital of I₂ acts as an electron acceptor thus weakening the I–I bond and altering the energy of the electronic transitions:

\[ \sigma_u^2 \pi_u^2 \pi_g^2 \sigma_u^1 (^3 \Pi_u \text{ and } ^1 \Pi_u) \rightarrow \sigma_u^2 \pi_u^4 \pi_g^4 (^1 \Sigma_g^+) \]

Consistent with this: (a) the solubility of iodine in the donor solvents tends to be greater than in the non-donor solvents (see list of solubilities), (b) brown solutions frequently turn violet on being heated, and brown again on cooling, due to the ready dissociation and reformation of the complex, and (c) addition of a small amount of a donor solvent to a violet solution turns the colour brown. Such donor solvents can be classified as (i) weak π donors (e.g. the aromatic hydrocarbons and alkenes), (ii) stronger σ donors such as nitrogen bases (amines, pyridines, nitriles), oxygen bases (alcohols, ethers, carbonyls), and organic sulfides and selenides.

The most direct evidence for the formation of a complex L→I₂ in solution comes from the appearance of an intense new charge-transfer band in the near ultraviolet spectrum. Such a band occurs in the region 230–330 nm with a molar extinction coefficient ε of the order of 5 x 10³ – 5 x 10⁴ 1mol⁻¹ cm⁻¹ and a half-width typically of 4000–8000 cm⁻¹. Detailed physicochemical studies further establish that the formation constants of such complexes span the range 10⁻¹ – 10⁴ 1mol⁻¹ with enthalpies of formation 5–50 kJ mol⁻¹. Some typical examples are in Table 17.9. The donor strength of the various solvents (ligands) is rather independent of the particular halogen (or interhalogen) solute and follows the approximate sequence benzene < alkenes < polyalkylbenzenes ≈ alkyl iodides ≈ alcohols ≈ ethers ≈ ketones < organic sulfides < organic selenides < amines. Conversely, for a given solvent the relative acceptor strength of the halogens increases in the sequence Cl₂ < Br₂ < I₂ < IBr < ICl, i.e. they are class b or “soft” acceptors (p. 909). Further interactions may also occur in polar solvents leading to ionic dissociation which
renders the solutions electrically conducting, e.g.:

\[ 2\text{pyI}_2 \rightleftharpoons [\text{py}_2\text{I}]^+ + \text{I}_3^- \]

Numerous solid complexes have been crystallized from brown solutions of iodine and extensive X-ray structural data are available. Complexes of the type \( \text{L} \rightarrow \text{I} \rightarrow \text{X} \) and \( \text{L} \rightarrow \text{I} \rightarrow \text{X} \leftrightarrow \text{L} \) feature a linear configuration as expected from the involvement of the \( \sigma_0 \) antibonding orbital of IX (Fig. 17.3a, b, c). When the ligand has two donor atoms (as in dioxan) or the donor atom has more than one lone-pair of electrons (as in acetone) the complexes can associate

Figure 17.3 Structures of some molecular complexes of the halogens.
§17.2.1 Hydrogen halides, HX

into infinite chains (Fig. 17.3d, e), whereas with methanol, the additional possibility of hydrogen bonding permits further association into layers (Fig. 17.3f). The structure of C₆H₆·Br₂ is also included in Fig. 17.3(g). In all these examples, the lengthening of the X–X bond from that in the free halogen molecule is notable.

The intense blue colour of starch-iodine was mentioned on p. 790.

17.2 Compounds of Fluorine, Chlorine, Bromine and Iodine

17.2.1 Hydrogen halides, HX

It is common practice to refer to the molecular species HX and also the pure (anhydrous) compounds as hydrogen halides, and to call their aqueous solutions hydrohalic acids. Both the anhydrous compounds and their aqueous solutions will be considered in this section. HCl and hydrochloric acid are major industrial chemicals and there is also a substantial production of HF and hydrofluoric acid. HBr and hydrobromic acid are made on a much smaller scale and there seems to be little industrial demand for HI and hydriodic acid. It will be convenient to discuss first the preparation and industrial uses of the compounds and then to consider their molecular and bulk physical properties. The chemical reactivity of the anhydrous compounds and their acidic aqueous solutions will then be reviewed, and the section concludes with a discussion of the anhydrous compounds as nonaqueous solvents.

Preparation and uses

Anhydrous HF is almost invariably made by the action of conc H₂SO₄ (≥95%) on “acid grade” fluorspar (≥98% CaF₂):

\[
\text{CaF}_2(s) + \text{H}_2\text{SO}_4(l) \rightarrow \text{CaSO}_4(s) + 2\text{HF} (g)
\]

As the reaction is endothermic heat must be supplied to obtain good yields in reasonable time (e.g. 30–60 min at 200–250°C). Silica is a particularly undesirable impurity in the fluorspar since it consumes up to 6 moles of HF per mole of SiO₂ by reacting to form SiF₄ and then H₂SiF₆.

A typical unit, producing up to 20 000 tonnes of HF pa, consists of an externally heated, horizontal steel kiln about 30 m long rotating at 1 revolution per minute. The product gas emerges at 100–150°C and, after appropriate treatment to remove solid, liquid and gaseous impurities, is condensed to give a 99% pure product which is then redistilled to give a final product of 99.9% purity. The technical requirements to enable the safe manufacture and handling of so corrosive a product are considerable.²¹³ In principle, HF could also be obtained from the wet-processing of fluorapatite to give phosphoric acid (p. 521) but the presence of SiO₂ preferentially yields SiF₄ and H₂SiF₆ from which HF can only be recovered uneconomically.

\[
\text{Ca}_5(\text{PO}_4)_3\text{F} + 5\text{H}_2\text{SO}_4 \rightarrow 5\text{CaSO}_4 + 3\text{H}_3\text{PO}_4 + \text{HF}
\]

Some of the H₂SiF₆ so produced finds commercial outlets (p. 810), but it has been estimated that ~500 000 tonnes of H₂SiF₆ is discarded annually by the US phosphoric acid industry, equivalent to ~1 million tonnes of fluorspar — enough to supply that nation’s entire requirements for HF. Production figures and major uses are in the Panel.

Hydrogen chloride is a major industrial chemical and is manufactured on a huge scale. It is also a familiar laboratory reagent both as a gas and as an aqueous acid. The industrial production and uses of HCl are summarized in the Panel on p. 811. One important method for synthesis on a large scale is the burning of H₂ in Cl₂: no catalyst is needed but economic sources of the two elements are obviously required. Another major source of HCl is as a by-product of the chlorination of hydrocarbons (p. 798). The traditional “salt-cake” process of treating NaCl with conc H₂SO₄ also remains an important industrial source of the acid. On a small laboratory scale, gaseous HCl can be made by treating concentrated aqueous hydrochloric acid
into infinite chains (Fig. 17.3d, e), whereas with methanol, the additional possibility of hydrogen bonding permits further association into layers (Fig. 17.3f). The structure of C₆H₆Br₂ is also included in Fig. 17.3(g). In all these examples, the lengthening of the X–X bond from that in the free halogen molecule is notable.

The intense blue colour of starch-iodine was mentioned on p. 790.

### 17.2 Compounds of Fluorine, Chlorine, Bromine and Iodine

The chemical reactivity of the anhydrous compounds and their acidic aqueous solutions will then be reviewed, and the section concludes with a discussion of the anhydrous compounds as nonaqueous solvents.

**Preparation and uses**

Anhydrous HF is almost invariably made by the action of conc H₂SO₄ (≥95%) on “acid grade” fluorspar (≥98% CaF₂):

\[
\text{CaF}_2(s) + \text{H}_2\text{SO}_4(l) \longrightarrow \text{CaSO}_4(s) + 2\text{HF(g)}
\]

As the reaction is endothermic, heat must be supplied to obtain good yields in reasonable time (e.g. 30–60 min at 200–250°C). Silica is a particularly undesirable impurity in the fluorspar since it consumes up to 6 moles of HF per mole of SiO₂ by reacting to form SiF₄ and then H₂SiF₆. A typical unit, producing up to 20,000 tonnes of HF pa, consists of an externally heated, horizontal steel kiln about 30 m long rotating at 1 revolution per minute. The product gas emerges at 100–150°C and, after appropriate treatment to remove solid, liquid and gaseous impurities, is condensed to give a 99% pure product which is then redistilled to give a final product of 99.9% purity. The technical requirements to enable the safe manufacture and handling of so corrosive a product are considerable. In principle, HF could also be obtained from the wet-processing of fluorapatite to give phosphoric acid (p. 521) but the presence of SiO₂ preferentially yields SiF₄ and H₂SiF₆ from which HF can only be recovered uneconomically.

\[
\text{Ca}_5(\text{PO}_4)_3\text{F} + 5\text{H}_2\text{SO}_4 \longrightarrow 5\text{CaSO}_4 + 3\text{H}_3\text{PO}_4 + \text{HF}
\]

\[
\text{SiO}_2 + 4\text{HF} \longrightarrow \text{SiF}_4 + 2\text{H}_2\text{O} \longrightarrow \text{aq HF} \longrightarrow \text{aq H}_2\text{SiF}_6
\]

Some of the H₂SiF₆ so produced finds commercial outlets (p. 810), but it has been estimated that ~500,000 tonnes of H₂SiF₆ is discarded annually by the US phosphoric acid industry, equivalent to ~1 million tonnes of fluorspar — enough to supply that nation’s entire requirements for HF. Production figures and major uses are in the Panel.

Hydrogen chloride is a major industrial chemical and is manufactured on a huge scale. It is also a familiar laboratory reagent both as a gas and as an aqueous acid. The industrial production and uses of HCl are summarized in the Panel on p. 811. One important method for synthesis on a large scale is the burning of H₂ in Cl₂: no catalyst is needed but economic sources of the two elements are obviously required. Another major source of HCl is as a by-product of the chlorination of hydrocarbons (p. 798). The traditional “salt-cake” process of treating NaCl with conc H₂SO₄ also remains an important industrial source of the acid. On a small laboratory scale, gaseous HCl can be made by treating concentrated aqueous hydrochloric acid
Production and Uses of Hydrogen Fluoride

Anhydrous HF was first produced commercially in the USA in 1931 and in the UK from about 1942. By 1992 some eighteen countries were each producing at least 3000 tonnes pa with North America accounting for some 330 000 tonnes of the estimated annual world production of about 875 000 tonnes. A further 205 000 tonnes was used captively for production of AlF₃. Price in 1990 was about $150/kg for the anhydrous acid and somewhat less for 70% acid. The primary suppliers ship HF in tank-cars of 20–91-tonne capacity and the product is also repackaged in steel cylinders holding 8.0–900 kg (2.7–635 kg in the UK). Lecture bottles contain 340 g HF. The 70% acid is shipped in tank-cars of 32–80-tonne capacity, tank trucks of 20-tonne capacity, and in polyethylene-lined drums holding 114 or 208 l.

The early need for HF was in the production of chlorofluorocarbons for refrigeration units and pressurizing gases. The large increase in aluminium production in 1935–40 brought an equivalent requirement for HF (for synthetic cryolite, p. 219) and these two uses still account for the bulk of HF produced in North America (comprising the single market of USA, Canada and Mexico), namely 53.0% and 24.3%, respectively. Other outlets are petroleum alkylation catalysts and steel pickling (3.8% each) and the nuclear industry (3.0%). The remaining 12.1% is distributed amongst traditional uses (such as glass etching and the frosting of light bulbs and television tubes, and the manufacture of fluoride salts), and newer applications such as rocket-propellant stabilizers, preparation of microelectronic circuits, laundry soaps and stain removers.

Probably about 50 000 tonnes of HF are used worldwide annually to make inorganic compounds other than UF₄/UF₆ for the nuclear industry. Prominent amongst these products are:

- NaF: for water fluoridation, wood preservatives, the formulation of insecticides and fungicides, and as a fluxing agent. It is also used to remove HF from gaseous F₂ in the manufacture and purification of F₂.
- SnF₂: in toothpastes to prevent dental caries.
- HBF₄ (aq) and metal fluoroborates: electroplating of metals, catalysts, fluxing in metal processing and surface treatment.

The highly corrosive nature of HF and aqueous hydrofluoric acid solutions have already been alluded to (pp. 792, 797) and great caution must be exercised in their handling. The salient feature of HF burns is the delayed onset of discomfort and the development of a characteristic white lesion that is excruciatingly painful. The progressive action of HF on skin is due to dehydration, low pH and the specific toxic effect of high concentrations of fluoride ions: these remove Ca²⁺ from tissues as insoluble CaF₂ and thereby delay healing; in addition the immobilization of Ca²⁺ results in a relative excess of K⁺ within the tissue, so that nerve stimulation ensues. Treatment of HF burns involves copious sluicing with water for at least 15 min followed either by (a) immersion in (or application of wet packs of) cold MgSO₄, or (b) subcutaneous injection of a 10% solution of calcium gluconate (which gives rapid relief from pain), or (c) surgical excision of the burn lesion. Medical attention is essential, even if the initial effects appear slight, because of the slow onset of the more serious symptoms.

with conc H₂SO₄. Preparation of DCl is best effected by the action of D₂O on PhCOCl or a similar organic acid chloride; PCl₃, PCl₅, SiCl₄, AlCl₃, etc., have also been used.

Similar routes are available for the production of HBr and HI. The catalysed combination of H₂ and Br₂ at elevated temperatures (200–400°C in the presence of Pt/asbestos, etc.) is the principal industrial route for HBr, and is also used, though on a relatively small scale, for the energetically less-favoured combination of H₂ and I₂ (Pt catalyst above 300°C). Commercially HI is more often prepared by the reaction of I₂ with H₂S or hydrazine, e.g.:

\[ 2I₂ + N₂H₄ \xrightarrow{H₂O} 4HI + N₂ \text{ (quantitative)} \]

Reduction of the parent halogen with red phosphorus and water provides a convenient laboratory preparation of both HBr and HI:

\[ 2P + 6H₂O + 3X₂ \rightarrow 6HX + 2H₃PO₃ \]

\[ H₃PO₃ + H₂O + Br₂ \rightarrow 2HBr + H₃PO₄ \]

The rapid reaction of 1,2,3,4-tetrahydroxyphthalene (tetralin) with Br₂ at 20° affords an alternative small-scale preparation though only half the Br₂ is converted, the other half being lost in brominating the tetralin:

\[ C_{10}H_{12} + 4Br₂ \rightarrow 4HBr + C_{10}H₈Br₄ \]

The action of conc H₂SO₄ on metal bromides or iodides (analogous to the "salt-cake" process of HCl) causes considerable oxidation of the product HX but conc H₃PO₄ is satisfactory. Dehydration of the aqueous acids with P₂O₅ is a viable alternative. DBr and DI are obtained by reaction of D₂O on PBr₃ and PΙ₃ respectively.
§17.2.1 Hydrogen halides, HX

Industrial Production and Uses of Hydrogen Chloride (35)

World production of HCl is of the order of 10 million tonnes pa, thus making it one of the largest volume chemicals to be manufactured. Four major processes account for the bulk of HCl produced, the choice of method invariably being dictated by the ready availability of the particular starting materials, the need for the co-products, or simply the availability of by-product HCl which can be recovered as part of an integrated process.

1. The classic salt-cake method was introduced with the Leblanc process towards the end of the eighteenth century and is still used to produce HCl where rock-salt mineral is cheaply available (as in the UK Cheshire deposits). The process is endothermic and takes place in two stages:

\[ \text{NaCl} + \text{H}_2\text{SO}_4 \xrightarrow{\sim 150^\circ} \text{NaHSO}_4 + \text{HCl}; \text{ and NaCl} + \text{NaHSO}_4 \xrightarrow{540-600^\circ} \text{Na}_2\text{SO}_4 + \text{HCl} \]

2. The Hargreaves process (late 19th C) is a variant of the salt-cake process in which NaCl is reacted with a gaseous mixture of SO\(_2\), air and H\(_2\)O (i.e. "H\(_2\)SO\(_4\)") in a self-sustaining exothermic reaction:

\[ 2\text{NaCl} + \text{SO}_2 + \frac{1}{2}\text{O}_2 + \text{H}_2\text{O} \xrightarrow{430-450^\circ} \text{Na}_2\text{SO}_4 + 2\text{HCl} \]

Again the economic operation of the process depends on abundant rock-salt or the need for the by-product Na\(_2\)SO\(_4\) for the paper and glass industries.

3. Direct synthesis of HCl by the burning of hydrogen in chlorine is the favoured process when high-purity HCl is required. The reaction is highly exothermic (~92 kJ/mol HCl) and requires specially designed burners and absorption systems.

4. By-product HCl from the heavy organic-chemicals industry (p. 798) now accounts for over 90% of the HCl produced in the USA. Where such petrochemical industries are less extensive this source of HCl becomes correspondingly smaller. The crude HCl so produced may be contaminated with unreacted Cl\(_2\), organics, chloro-organics or entrained solids (catalyst supports, etc.), all of which must be removed.

Most of the byproduct HCl is used captively, primarily in oxyhydrochlorination processes for making vinyl chloride and chlorinated solvents or for Mg processing (p. 110). The scale of the industry is enormous; for example, 5.2 million tonnes of HCl per annum in the US alone (1993). HCl gas for industrial use can be transmitted without difficult over moderate distances in mild-steel piping or in tank cars or trailers. It is also available in cylinders of varying size down to laboratory scale lecture bottles containing 225 g. Aqueous hydrochloric acid consumption (1993) was 1.57 Mt (100% basis). Price for anhydrous HCl is ~$330/tonne and for 31.4% aqueous acid ~$73/tonne (1993) depending on plant location and amount required.

Industrial use of HCl gas for the manufacture of inorganic chemicals includes the preparation of anhydrous NH\(_4\)Cl by direct reaction with NH\(_3\) and the synthesis of anhydrous metal chlorides by reaction with appropriate carbides, nitrides, oxides or even the free metals themselves, e.g.:

\[
\begin{align*}
\text{SiC} & \xrightarrow{\text{HCl/700}^\circ} \text{SiCl}_4 \\
& \quad \text{(NiCl}_2\text{ catal)} \\
\text{MN}_y & \xrightarrow{\text{HCl/heat}} \text{MC}_2\text{(pure)} \\
& \quad \text{(Ti, Zr, Hf; Nb, Ta; Cr, Mo, W, etc.)} \\
\text{MO} + 2\text{HCl} & \longrightarrow \text{MCl}_2 + \text{H}_2\text{O} \\
& \quad \text{(especially for removal of impurities or waste recovery)} \\
\text{Al} + 3\text{HCl} & \longrightarrow \text{AlCl}_3 + \frac{3}{2}\text{H}_2
\end{align*}
\]

HCl is also used in the industrial synthesis of ClO\(_2\) (p. 846):

\[ \text{NaClO}_3 + 2\text{HCl} \longrightarrow \text{ClO}_2 + \frac{1}{2}\text{Cl}_2 + \text{NaCl} + \text{H}_2\text{O} \]

The reaction is catalysed by various salts of Ti, Mn, Pd and Ag which promote the formation of ClO\(_2\) rather than the competing reaction which otherwise occurs:

\[ \text{NaClO}_3 + 6\text{HCl} \longrightarrow 3\text{Cl}_2 + \text{NaCl} + 3\text{H}_2\text{O} \]

Panel continues

HCl is also used in the production of Al₂O₃ (p. 242) and TiO₂ (p. 959), the isolation of Mg from sea water (p. 110), and in many extractive metallurgical processes for isolating or refining metals, e.g. Ge, Sn, V, Mn, Ta, W and Ra.

Aqueous HCl is also produced on a vast scale (e.g. 1.57 Mt/yr in the USA, 1993). Most of this is made and consumed captively at the site of production, predominantly for brine acidification prior to electrolysis in Cl₂/alkali cells. The largest merchant market use is for pickling steel and other metals to remove adhering oxide scale, and for the desulfurization of petroleum. It is also used in pH control (effluent neutralization, etc.), the deliming of hides and chrome tanning, ore beneficiation, the coagulation of latex and the production of aniline from PhN₃ for dyestuffs intermediates. The manufacture of gelatine requires large quantities of hydrochloric acid to decompose the bones used as raw materials — high purity acid must be used since much of the gelatine is used in foodstuffs for human consumption. Another food-related application is the hydrolysis of starch to glucose under pressure: this process is catalysed by small concentrations of HCl and is extensively used to produce "maple syrup" from maize (corn) starch. At higher concentrations of HCl, wood (lignin) can be converted to glucose.

Other uses of HCl are legion and range from the purification of fine silica for the ceramics industry, and the refining of oils, fats and waxes, to the manufacture of chloroprene rubbers, PVC plastics, industrial solvents and organic intermediates, the production of viscose rayon yarn and staple fibre, and the wet processing of textiles (where hydrochloric acid is used as a sour to neutralize residual alkali and remove metallic and other impurities).

Anhydrous HBr is available in cylinders (6.8-kg and 68-kg capacity) under its own vapour pressure (24 atm at 25°C) and in lecture bottles (450-g capacity). Its main industrial use is in the manufacture of inorganic bromides and the synthesis of alkyl bromides either from alcohols or by direct addition to alkenes. HBr also catalyses numerous organic reactions. Aqueous HBr (48% and 62%) is available as a corrosive pale-yellow liquid in drums or in large tank trailers (15 000 l and 38 000 l).

There seem to be no large-scale uses for HI outside the laboratory, where it is used in various iodination reactions (lecture bottles containing 400 g HI are available). Commercial solutions contain 40–55 wt% of HI (cf. azeotrope at 56.9% HI, p. 815) and these solutions are thermodynamically much more stable than pure HI as indicated by the large negative free energy of solution.

**Physical properties of the hydrogen halides**

HF is a colourless volatile liquid and an oligomeric H-bonded gas (HF)_n, whereas the heavier HX are colourless diatomic gases at room temperature. Some molecular and bulk physical properties are summarized in Table 17.10. The influence of H bonding on the (low) vapour pressure, (long) liquid range and (high) dielectric constant of HF have already been discussed (pp. 53–5). Note also that the viscosity of liquid HF is lower than that of water (or indeed of the other HX) and this has been taken to imply the absence of a three-dimensional network of H bonds such as occurs in H₂O, H₂SO₄, H₃PO₄, etc. However, it should be remembered that the viscosity of HF is quoted for 0°C, i.e. some 80° above its mp and only 20° below its bp; a more relevant comparison might be its value of 0.772 centipoise at −62.5° (i.e. 19° above its mp) compared with a value of 1.00 centipoise for water at 20°. Hydrogen bonding is also responsible for the association of HF molecules in the vapour phase: the vapour density of the gas over liquid HF reaches a maximum value of ~86 at −34°. At atmospheric pressure the value drops from 58 at 25° to 20.6 at 80° (the limiting vapour density of monomeric HF is ~9.924). These results, together with infrared and electron diffraction studies, indicate that gaseous HF comprises an equilibrium mixture of monomers and cyclic hexamers, though chain dimers may also occur under some conditions of temperature and pressure:

\[
6\text{HF} \leftrightharpoons (\text{HF})_6; \quad 2\text{HF} \leftrightharpoons (\text{HF})_2
\]

The crystal structure of HF shows it to consist of planar zigzag chain polymers with an \( \text{F} - \text{H} \cdots \text{F} \) distance of 249 pm and an angle at F of 120.1°.

The other HX are not associated in the gaseous or liquid phases but the low-temperature forms of crystalline HCl and HBr both feature weakly
H-bonded zigzag chains similar to those in solid HF. At higher temperatures substantial disorder sets in. The standard heats of formation $\Delta H_f^\circ$ of gaseous HX diminish rapidly with increase in molecular weight and HI is endothermic. The very small (and positive) value for the standard free energy of formation $\Delta G_f^\circ$ of HI indicates that (under equilibrium conditions) this species is substantially dissociated at room temperature and pressure. However, dissociation is slow in the absence of a catalyst. The bond dissociation energies of HX show a similar trend from the very large value of 574 kJ mol$^{-1}$ for HF to little more than half this (295 kJ mol$^{-1}$) for HI.

**Chemical reactivity of the hydrogen halides**

Anhydrous HX are versatile and vigorous reagents for the halogenation of metals, nonmetals, hydrides, oxides and many other classes of compound, though reactions that are thermodynamically permissible do not always occur in the absence of catalysts, thermal initiation or photolytic encouragement, because of kinetic factors. For example, reaction of HX(g) with elements (M) can thermodynamically proceed according to the equation

$$M + nHX \rightarrow MX_n + \frac{1}{2}nH_2$$

providing that $\Delta G$ for the reaction [i.e. $\Delta G_f^\circ(MX_n) - n\Delta G_f^\circ(HX, g)$] is negative. From the data in Table 17.10 this means that M could be oxidized to the $n$-valent halide MX$_n$ if:

- for the fluoride $\Delta G_f^\circ(MF_n) < -274n$ kJ mol$^{-1}$
- for the chloride $\Delta G_f^\circ(MCl_n) < -96n$ kJ mol$^{-1}$
- for the bromide $\Delta G_f^\circ(MBr_n) < -54n$ kJ mol$^{-1}$
- for the iodide $\Delta G_f^\circ(MI_n) < -0$ kJ mol$^{-1}$

Using tables of free energies of formation it is clear that most metals will react with most HX. Moreover, in many cases, e.g. with the alkali metals, alkaline earth metals, Zn, Al and the lanthanide elements, such reactions are extremely exothermic. It is also clear that Ag should react with HCl, HBr and HI but not with HF, and

---

Cu should form CuF₂ with HF but not CuX₂ with the other HX. Iron should give FeCl₃ but in practice the reaction only proceeds to FeCl₂. TiX₄ can be made, but only at high temperatures. Reactions of Si to form SiX₄ are very favourable for X = F, Cl, Br, but only HF reacts at room temperature. With As, reaction with HF to give AsF₃ is thermodynamically favourable but reactions with the other HX are not. Similar, though more complicated, schemes can be worked out for the reactions of HX with oxides, other halides, hydrides, etc.

HF is miscible with water in all proportions and the phase diagram (Fig. 17.4a) shows the presence of three compounds: H₂O.HF (mp −35.5°), H₂O.2HF (mp −75.5°) and H₂O.4HF (mp −100.4°, i.e. 17° below the mp of pure HF). Recent X-ray studies have confirmed earlier conjectures that these compounds are best formulated as H-bonded oxonium salts [H₃O]F, [H₃O][HF₂], and [H₃O][H₃F₄] with three very strong H bonds per oxonium ion and average O⋯F distances of 246.7, 250.2 and 253.6 pm respectively.(37) More recently, the low-temperature crystal structure of Me₄NF.5HF (decomp. −76°C) has revealed the presence of H₃F₅⁻, i.e. [(FH)₂FHF(HF)₂]¹⁻, with four terminal F―H⋯F of 248.4 pm and a very strong central F―H⋯F of 226.6 pm. Me₄NF.7HF was also identified (decomp. −110°C).(38) Another significant crystal structure, that of tris(ethylenediamine)zinc(II) fluoride dihydrate reveals the strongly H-bonded difluoride cluster [F₂(H₂O)₂]²⁻ which adopts a diamond-shaped cyclic structure F⋯HOH⋯F⋯HOH⋯²⁻ with O―H⋯F distances of 258.6 and 267.9 pm and non-bonded distances across the lozenge of O⋯O 335 pm and F⋯F 406 pm.(39) Such H bonds are very relevant to the otherwise surprising observation that, unlike

![LIVE GRAPH](image-url)

**Figure 17.4** The phase diagrams of the systems (a) HF/H₂O and (b) HCl/H₂O. Note that for hydrofluoric acid all the solvates contain ≥1HF per H₂O, whereas for hydrochloric acid they contain ≤1HCl per H₂O. This is because the H bonds F―H⋯F and F―H⋯O are stronger than O―H⋯O, whereas Cl―H⋯Cl and Cl―H⋯O are weaker than O―H⋯O. Accordingly the solvates in the former system have the crystal structures [H₂O]⁺F−, [H₂O]⁺[HF₂]⁻ and [H₂O]⁺[H₂F₂]⁻, whereas the latter are [H₂O]⁺Cl⁻, [H₂O₂]⁺Cl⁻ and [H₃O₂]⁺Cl⁻. H₂O. The structures of HCl.6H₂O and the metastable HCl.4H₂O are not known.

§17.2.1  Hydrogen halides, HX

the other aqueous hydrohalic acids which are extremely strong, hydrofluoric acid is a very weak acid in aqueous solution. Indeed, the behaviour of such solutions is remarkable in showing a dissociation constant (as calculated from electrical conductivity measurements) that diminishes continuously on dilution. Detailed studies reveal the presence of two predominant equilibria:(40)

\[
\text{H}_2\text{O} + \text{HF} \rightleftharpoons [(\text{H}_3\text{O})^+\text{F}^-] \rightleftharpoons [\text{H}_3\text{O}]^+(\text{aq}) + \text{F}^-(\text{aq}); \quad pK_a = 2.95
\]

The dissociation constant for the first process is only \(1.1 \times 10^{-3}\) mol\(^{-1}\) at 25°C; this corresponds to \(pK_a = 2.95\) and indicates a rather small free hydrogen-ion concentration (cf. ClCH\(_2\text{CO}_2\text{H}, pK_a = 2.85\)) as a result of the strongly H-bonded, undissociated ion-pair \([(\text{H}_3\text{O})^+\text{F}^-]\). By contrast, \(K_2 = 2.6 \times 10^{-11}\) mol\(^{-1}\) \((pK_2 = 0.58)\), indicating that an appreciable number of the fluoride ions in the solution are coordinated by HF to give \(\text{HF}_2^-\) rather than by \(\text{H}_2\text{O}\) despite the very much higher concentration of \(\text{H}_2\text{O}\) molecules.

Numerous hydrates also occur in the HCl/H\(_2\text{O}\) system (Fig. 17.4b), e.g. HCl.H\(_2\text{O}\) (mp -15.4°), HCl.2H\(_2\text{O}\) (mp -17.7°), HCl.3H\(_2\text{O}\) (mp -24.9°), HCl.4H\(_2\text{O}\) and HCl.6H\(_2\text{O}\) (mp -70°). The system differs from HF/H\(_2\text{O}\) not only in the stoichiometry of the hydrates but also in separating into two liquid phases at HCl concentrations higher than 1:1. The weakness of the O–H⋯Cl hydrogen bond also ensures that there is very little impediment to complete ionic dissociation, and aqueous solutions of HCl (and also of HBr and HI) are strong acids; approximate values of \(pK_a\) are HCl -7, HBr -9, HI -10. The systems HBr/H\(_2\text{O}\) and HI/H\(_2\text{O}\) also show a miscibility gap at high concentrations of HX and also numerous hydrates which feature hydrated oxonium ions:

\[
\text{HBr.}_2\text{O}: \text{stable under pressure between } -3.3°\text{ and } -15.5°; \quad \text{[H}_3\text{O}]^+\text{Br}^-
\]

\[
\text{HBr.2H}_2\text{O}: \text{mp } -11.3°; \quad \text{presumably } [\text{H}_5\text{O}_2]^+\text{Br}^-, \text{i.e. } [(\text{H}_2\text{O})_2\text{H}]^+\text{Br}^-
\]

\[
\text{HBr.3H}_2\text{O}: \text{decomp } -47.9°; \text{structure unknown}
\]

\[
\text{HBr.4H}_2\text{O}: \text{mp } -55.8°; \quad [[(\text{H}_2\text{O})_3\text{H}]^+ - [(\text{H}_2\text{O})_4\text{H}]^+\text{Br}^-]_2\text{.H}_2\text{O} \quad (p. 630)
\]

\[
\text{HBr.6H}_2\text{O}: \text{decomposes at } -88.2°.
\]

The compound HI.H\(_2\text{O}\) does not appear as a stable hydrate in the phase diagram, but the vibrational spectra of frozen solutions of this composition indicate the formulation \([\text{H}_3\text{O}]^+\text{I}^-\). Higher hydrates appear at HI.2H\(_2\text{O}\) (mp ~ -43°), HI.3H\(_2\text{O}\) (mp ~ -48°), and HI.4H\(_2\text{O}\) (mp -36.5°C).

Just as the solid/liquid phase equilibria in the systems HX/H\(_2\text{O}\) show several points of interest, so too do the liquid/vapour phase equilibria. When dilute aqueous solutions of HX are heated to boiling the concentration of HX in the vapour is less than that in the liquid phase, so that the liquid becomes progressively more concentrated and the bp progressively rises until a point is reached at which the liquid has the same composition as the gas phase so that it boils without change in composition and at constant temperature. This mixture is called an azeotrope (Greek \(\alpha\), without; \(\zeta\epsilon\iota\eta\), zein, to boil; \(\tau\rho\omicron\omicron\omicron\iota\eta\), trope, change). The phenomenon is illustrated for HF and HCl in Fig. 17.5. Conversely, when more concentrated aqueous solutions are boiled, the concentration of HX in the vapour is greater than that in the liquid phase which thereby becomes progressively diluted by distillation until the azeotropic mixture is again reached, whereupon distillation continues without change of composition and at constant temperature. The bps and azeotropic compositions at atmospheric pressure are listed below, together with the densities of the azeotropic acids at 25°C:

The Halogens: Fluorine, Chlorine, Bromine, Iodine and Astatine Ch. 17

but the pure acid can now be safely handled without contamination using fluorinated plastics such as polytetrafluoroethylene. The self-ionic dissociation of the solvent, as evidenced by the residual electrical conductivity of highly purified HF, can be represented as $\text{HF} \rightleftharpoons \text{H}^+ + \text{F}^-;$. However, since both ions will be solvated it is more usual to represent the equilibrium as $3\text{HF} \rightleftharpoons \text{H}_2\text{F}^+ + \text{HF}_2^-$. The fluoride ion has an anomalously high conductance, $\lambda_\infty$, as shown by the following values obtained at 0°C:

As the specific conductivity of pure HF is $\sim 10^{-6}$ ohm$^{-1}$ cm$^2$ at 0°C, these values imply concentrations of H$_2$F$^+ = \text{HF}_2^- \approx 2.9 \times 10^{-8}$ mol l$^{-1}$ and an ionic product for the liquid of $\sim 8 \times 10^{-12}$ mol$^2$ l$^{-2}$ (cf. values of $\sim 10^{-33}$ for NH$_3$ and $\sim 10^{-14}$ for H$_2$O).

The high dielectric constant, low viscosity and long liquid range of HF make it an excellent solvent for a wide variety of compounds. Whilst most inorganic fluorides give fluoride ions when dissolved (see next paragraph), a few solutes dissolve without ionization, e.g. XeF$_2$, SO$_2$, HSO$_3$F, SF$_6$ and MF$_6$ (M = Mo, W, U, Re and Os). It is also probable that VF$_5$ and ReF$_7$ dissolve without ionizing. Perhaps more surprisingly liquid HF is now extensively used in biochemical research: carbohydrates, amino acids and proteins dissolve readily, frequently with only minor chemical consequences. In particular, complex organic compounds that are potentially

---

capable of eliminating the elements of water (e.g. cellulose, sugar esters, etc.) often dissolve without dehydration. Likewise globular proteins and many fibrous proteins that are insoluble in water, such as silk fibroin. These solutions are remarkably stable: e.g. the hormones insulin and ACTH were recovered after 2 h in HF at 0° with their biological activity substantially intact.

Many of the ionic fluorides of M\textsuperscript{I}, M\textsuperscript{II} and M\textsuperscript{III} dissolve to give highly conducting solutions due to ready dissociation. Some typical values of the solubility of fluorides in HF are in Table 17.11: the data show the expected trend towards greater solubility with increase in ionic radius within the alkali metals and alkaline earth metals, and the expected decrease in solubility with increase in ionic charge so that MF > MF\textsubscript{2} > MF\textsubscript{3}. This is dramatically illustrated by AgF which is 155 times more soluble than AgF\textsubscript{2} and TIF which is over 7000 times more soluble than TIF\textsubscript{3}.

With inorganic solutes other than fluorides, solvolysis usually occurs. Thus chlorides, bromides and iodides give the corresponding fluorides with evolution of HX, and fluorides are also formed from oxides, hydroxides, carbonates and sulfites. Indeed, this is an excellent synthetic route for the preparation of anhydrous metal fluorides and has been used with good effect for TiF\textsubscript{4}, ZrF\textsubscript{4}, UF\textsubscript{4}, SnF\textsubscript{4}, VO\textsubscript{2}F\textsubscript{3}, VF\textsubscript{3}, NbF\textsubscript{5}, TaF\textsubscript{5}, SbF\textsubscript{5}, MoO\textsubscript{2}F\textsubscript{2}, etc. (Note, however, that AgCl, PdCl\textsubscript{2}, PtCl\textsubscript{4}, Au\textsubscript{2}Cl\textsubscript{6} and ICl are apparently exceptions.)\textsuperscript{42} Less-extensive solvolysis occurs with sulfates, phosphates and certain other oxoanions. For example, a careful cryoscopic study of solutions of K\textsubscript{2}SO\textsubscript{4} in HF (at \(-84°C\)) gave a value of \(\nu = 5\) for the number of solute species in solution, but this increased to about 6 when determined by vapour-pressure depressions at 0°. These observations can be rationalized if unionized H\textsubscript{2}SO\textsubscript{4} is formed at the lower temperature and if solvolysis of this species to unionized HSO\textsubscript{3}F sets in at the higher temperatures:

\[
\begin{align*}
\text{K}_2\text{SO}_4 + 4\text{HF} & \rightarrow 2\text{K}^+ + 2\text{HF}_2^- + \text{H}_2\text{SO}_4 \\
\text{H}_2\text{SO}_4 + 3\text{HF} & \rightarrow \text{H}_3\text{O}^+ + \text{HSO}_3\text{F} + \text{HF}_2^- 
\end{align*}
\]

Consistent with this, the \(^{19}\text{F}\) nmr spectra of solutions at 0° showed the presence of HSO\textsubscript{3}F, and separate cryoscopic experiments with pure H\textsubscript{2}SO\textsubscript{4} as the sole solute gave a value of \(\nu\) close to unity.

Solvolysis of phosphoric acids in the system HF/P\textsubscript{2}O\textsubscript{5}/H\textsubscript{2}O gave successively H\textsubscript{3}PO\textsubscript{4}F, HPO\textsubscript{2}F\textsubscript{2} and H\textsubscript{2}O\textsuperscript{+}PF\textsubscript{6}\textsuperscript{−}, as shown by \(^{19}\text{F}\) and \(^{31}\text{P}\) nmr spectroscopy. Raman studies show that KNO\textsubscript{3} solvolyses according to the reaction

\[
\text{KNO}_3 + 6\text{HF} \rightarrow \text{K}^+ + \text{NO}_2^+ + \text{H}_3\text{O}^+ + 3\text{HF}_2^-
\]

Permanganates and chromates are solvolysed by HF to oxide fluorides such as MnO\textsubscript{2}F and CrO\textsubscript{2}F\textsubscript{2}.

Acid–base reactions in anhydrous HF are well documented. Within the Brønsted formalism, few if any acids would be expected to be sufficiently strong proton donors to be able to protonate the very strong proton-donor HF (p. 51), and this is borne out by observation. Conversely, HF can protonate many Brønsted bases, notably water,

\begin{table}[h]

\hline
\end{tabular}
\caption{Solubility of some metal fluorides in anhydrous HF (in g/100 g HF and at 12°C unless otherwise stated)}
\end{table}
alcohols, carboxylic acids and other organic compounds having one or more lone-pairs on O, N, etc.:

\[ \text{H}_2\text{O} + 2\text{HF} \rightleftharpoons \text{H}_3\text{O}^+ + \text{HF}_2^- \]
\[ \text{RCH}_2\text{OH} + 2\text{HF} \longrightarrow \text{RCH}_2\text{OH}_2^+ + \text{HF}_2^- \]
\[ \text{RCO}_2\text{H} + 2\text{HF} \longrightarrow \text{RC(OH)}_2^+ + \text{HF}_2^- \]

Alternatively, within the Lewis formalism, acids are fluoride-ion acceptors. The prime examples are AsF₅ and SbF₅ (which give MF₆⁻) and to a lesser extent BF₃ which yields BF₄⁻. A greater diversity is found amongst Lewis bases (fluoride-ion donors), typical examples being XeF₆, SF₄, ClF₃ and BrF₃:

\[ \text{MF}_n + \text{HF} \longrightarrow \text{MF}_{n+1}^+ + \text{HF}_2^- \]

Such solutions can frequently be “neutralized” by titration with an appropriate Lewis acid, e.g.:

\[ \text{BrF}_2^+\text{HF}_2^- + \text{H}_2\text{F}^+\text{SbF}_6^- \longrightarrow \text{BrF}_2^+\text{SbF}_6^- + 3\text{HF} \]

Oxidation-reduction reactions in HF form a particularly important group of reactions with considerable industrial application. The standard electrode potentials \( E^\circ (M^{\alpha+}/M) \) in HF follow the same sequence as for H₂O though individual values in the two series may differ by up to ±0.2 V. Early examples showed that CrF₂ and UF₄ reduced HF to H₂ whereas VCl₂ gave VF₃, 2HCl and H₂. Of more significance is the very high potential needed for the anodic oxidation of F⁻ in HF:

\[ \text{F}^- \longrightarrow \frac{1}{2}\text{F}_2 + \text{e}^-; \quad E^\circ (\text{F}_2/2\text{F}^-) = 2.71 \text{ V at } 0^\circ \text{C} \]

This enables a wide variety of inorganic and organic fluorinations to be effected by the electrochemical insertion of fluoride. For example, the production of NFH₂, NF₂H and NF₃ by electrolysis of NH₄F in liquid HF represents the only convenient route to these compounds. Again, CF₃CO₂H is most readily obtained by electrolysis of CH₃CO₂H in HF. Other examples of anodic oxidations in HF are as follows:

<table>

The other hydrogen halides are less tractable as solvents, as might be expected from their physical properties (p. 813), especially their low bps, short liquid ranges, low dielectric constants and negligible self-dissociation into ions. Nevertheless, they have received some attention, both for comparison with HF and as preparative media with their own special advantages.\(^{36,45,46}\) In particular, because of their low bp and consequent ease of removal, the liquid HX solvent systems have provided convenient routes to BX₄⁻, BF₃Cl⁻, B₂Cl₆⁻, NO₂Cl, Al₂Cl₇⁻, R₂SCl⁺, RSCl₂⁺, PCl₃Br⁺, Ni₂Cl₄(CO)₃ (from nickel tetracarbonyl and Cl₂) and Ni(NO)₂Cl₂ (from nickel tetracarbonyl and NOCl). Solubilities in liquid HX are generally much smaller than in HF and tend to be restricted to molecular compounds (e.g. NOCl, PhOH, etc.) or salts with small lattice energies, e.g. the tetraalkylammonium halides. Concentrations rarely attain 0.5 mol L⁻¹ (i.e. 0.05 mol/100 g HF). Ready protonation of compounds containing lone-pairs or \( \pi \) bonds is observed, e.g. amines, phosphines, ethers, sulfides, aromatic olefins, and compounds containing \( \text{C} = \text{N}, \text{N} = \text{N}, \text{N} = \text{O}, \text{C} = \text{O} > \text{C} = \text{O} \) etc. Of particular interest is the protonation of phosphine in the presence of BX₃ to give PH₄⁺BCl₄⁻, PH₄⁺BF₃Cl⁻, and PH₄⁺BBF₄⁻. Fe(CO)₅ affords [Fe(CO)₃H]⁺ and [Fe(η⁵-C₅H₅)(CO)₂]⁺ and yields [Fe(η⁵-C₅H₅)(CO)₂]⁺H⁺. Solvolysis is also well established:

\[ \text{Ph}_3\text{SnCl} + \text{HCl} \longrightarrow \text{Ph}_3\text{SnCl}_2 + \text{PhH} \]
\[ \text{Ph}_3\text{COH} + 3\text{HCl} \longrightarrow \text{Ph}_3\text{C}^+\text{HCl}_2^- + \text{H}_3\text{O}^+\text{Cl}^- \]

Likewise ligand replacement reactions and oxidations, e.g.:  
\[ \text{Me}_4\text{N}^+\text{HCl}_2^- + \text{BCl}_3 \rightarrow \text{Me}_4\text{N}^+\text{BCl}_4^- + \text{HCl} \]  
\[ \text{PCl}_3 + \text{Cl}_2 + \text{HCl} \rightarrow \text{PCl}_4^+\text{HCl}_2^- \]

The preparation and structural characterization of the ions HX$_2^-$ has been an important feature of such work.\(^{(36)}\) As expected, these H-bonded ions are much less stable than HF$_2^-$ though crystalline salts of all three anions and of the mixed anions HXY$^-$ (except HBrI$^-$) have been isolated by use of large counter cations, typically Cs$^+$ and NR$_4^+$ (R = Me, Et, Bu$^+$) — see pp. 1313–21, of ref. 23 for further details. Neutron and X-ray diffraction studies suggest that [Cl$^-$H...Cl$^-$] can be either centrosymmetric or non-centrosymmetric depending on the crystalline environment. An example of the latter mode involves interatomic distances of 145 and 178 pm respectively and a bond angle of \(\sim 168^\circ\) (Cl...Cl 321.2 pm).\(^{(47)}\)

### 17.2.2 Halides of the elements

The binary halides of the elements span a wide range of stoichiometries, structure types and properties which defy any but the most grossly oversimplified attempt at a unified classification. Indeed, interest in the halides as a class of compound derives in no small measure from this very diversity and from the fact that, being so numerous, there are many examples of well-developed and well-graded trends between the limiting cases. Thus the fluorides alone include OF$_2$, one of the most volatile molecular compounds known (bp \(-145^\circ\)), and CaF$_2$, which is one of the least-volatile “ionic” compounds (bp 2513°C). Between these extremes of discrete molecules on the one hand, and 3D lattices on the other, is a continuous sequence of oligomers, polymers and extended layer lattices which may be either predominantly covalent [e.g. CIF, (MoF$_3$)$_4$, (CF$_2$)$_\infty$, (CF)$_\infty$, p. 289] or substantially ionic [e.g. Na$^+$F$^-$(g), (SnF$_2$)$_4$, (BeF$_2$)$_\infty$ (quartz type), SnF$_4$, NaF (cryst)], or intermediate in bond type with secondary interactions also complicating the picture. The problems of classifying binary compounds according to presumed bond types or limiting structural characteristics have already been alluded to for the hydrides (p. 64), borides (p. 145), oxides, sulfides, etc. Such diversity and gradations are further compounded by the existence of four different halogens (F, Cl, Br, I) and by the possibility of numerous oxidation states of the element being considered, e.g. CrF$_2$, Cr$_2$F$_5$, CrF$_3$, CrF$_4$, CrF$_5$ and CrF$_6$, or S$_2$F$_2$, SF$_2$, SF$_4$, S$_2$F$_{10}$ and SF$_6$.

A detailed discussion of individual halides is given under the chemistry of each particular element. This section deals with more general aspects of the halides as a class of compound and will consider, in turn, general preparative routes, structure and bonding. For reasons outlined on p. 805, fluorides tend to differ from the other halides either in their method of synthesis, their structure or their bond-type. For example, the fluoride ion is the smallest and least polarizable of all anions and fluorides frequently adopt 3D “ionic” structures typical of oxides. By contrast, chlorides, bromides and iodides are larger and more polarizable and frequently adopt mutually similar layer-lattices or chain structures (cf. sulfides). Numerous examples of this dichotomy can be found in other chapters and in several general references.\(^{(48–52)}\) Because of this it is convenient to discuss fluorides as a group first, and then the other halides.

---

Fluorides

Binary fluorides are known with stoichiometries that span the range from $C_4F$ to $IF_7$ (or even, possibly, $XeF_8$). Methods of synthesis turn on the properties of the desired products. If hydrolysis poses no problem, fluorides can be prepared by halide metathesis in aqueous solution or by the reactions of aqueous hydrofluoric acid with an appropriate oxide, hydroxide, carbonate, or the metal itself. The following non-hydrated fluorides precipitate as easily filterable solids: $LiF, NaF, NH_4F; MgF_2, CaF_2, SrF_2, BaF_2; SnF_2, PbF_2; SbF_3$. Gaseous $SiF_4$ and $GeF_4$ can also be prepared from aqueous HF. Furthermore, the following fluorides separate as hydrates that can readily be dehydrated thermally, though an atmosphere of HF is required to suppress hydrolysis except in the case of the univalent metal fluorides:

- $RbF.3H_2O$
- $ZnF_2.4H_2O$
- $GaF_3.3H_2O$
- $HgF_2.2HF.1H_2O$
- $HgF_2.2H_2O$
- $InF_3.3H_2O$
- $HgF_2.4H_2O$
- $CsF.3H_2O$
- $InF_3.3H_2O$
- $NaF.2H_2O$
- $AgF.4H_2O$

By contrast $BeF_2.xH_2O$, $TiF_4.2H_2O$ and $ThF_4.4H_2O$ cannot be dehydrated without hydrolysis.

When hydrolysis is a problem then the action of anhydrous HF on the metal (or chloride) may prove successful (e.g. the difluorides of $Zn, Cd, Ge, Sn, Mn, Fe, Co, Ni$; the trifluorides of $Ga, In, Ti$ and the lanthanides; the tetrafluorides of $Sn, Pb, Kr, Xe, Mo, Mn, Ce, Am, Cm$; the pentafluorides of $As, Sb, Bi, Br, I, V, Nb, Ta, Mo$; the hexafluorides of $S, Se, Te, Xe, Mo, W, Te, Ru, Os, Rh, Ir, Pt, U, Np, Pu$; the heptafluorides of $I, Re$; the octafluorides of $Xe(?)$).

Wherever possible the use of elementary $F_2$ is avoided because of its cost and the difficulty of handling it; instead one of a graded series of halogen fluorides can often be used, the fluorinating power steadily diminishing in the sequence: $ClF_3 > BrF_3 > IF_7 > ClF > BrF_3 > IF_5$. Other “hard” oxidizing fluorinating agents are $AgF_2, CoF_3, MnF_3, PbF_4, CeF_4, BiF_5$ and $UF_6$. When selective fluorination of certain groups in organic compounds is required, then “moderate” fluorinating agents are employed, e.g. $HgF_2, SbF_5, SbF_5/SbCl_5, AsF_3, CaF_2$ or $KSO_2F$. Such nucleophilic reagents may replace other halogens in halohydrocarbons by F but rarely substitute F for H. An electrophilic variant is $ClO_3F$. Most recently $XeF_2$, which is available commercially, has been used to effect fluorinations via radical cations: it can oxidatively fluorinate CC double bonds and can replace either aliphatic or aromatic H atoms with F. Even gentler are the “soft” fluorinating agents which do not cause fragmentation of functional groups, do not saturate double bonds, and do not oxidize metals to their highest oxidation states; typical of such mild fluorinating agents are the monofluorides of $H, Li, Na, K, Rb, Cs, Ag$ and $TI$ and compounds such as $SF_4, SeF_4, COF_2, SiF_4$ and $Na_2SiF_6$.

The fluorination reactions considered so far can be categorized as metathesis, oxidation or substitution. Occasionally reductive fluorination is the preferred route to a lower fluoride. Examples are:

$$2PdF_3 + SeF_4 \rightarrow 2PdF_2 + SeF_6$$
$$6ReF_6 + W(CO)_6 \rightarrow 6ReF_5 + WF_6 + 6CO$$
5.2.2 Halides of the elements

The preparation of NF3H3 (x = 1, 2, 3) has already been described (p. 818). Likewise a reliable route to OF2 is the electrolysis of 80% HF in the presence of dissolved MF (p. 638). Perchloryl fluoride has been made by electrolyzing NaClO4 in HF but a simpler route (p. 879) is the direct reaction of a perchlorate with fluorosulfuric acid:

\[
\text{KCIO}_4 + \text{HSO}_3\text{F} \rightarrow \text{KHSO}_4 + \text{ClO}_3\text{F}
\]

Electrolysis of organic sulfides in HF affords a variety of fluorocarbon derivatives:

\[
\begin{align*}
\text{Me}_2\text{S} \quad &\rightarrow \quad \text{CF}_3\text{SF}_5 \quad \text{and} \quad (\text{CF}_3)_2\text{SF}_4 \\
(-\text{CH}_2\text{S}-)_3 \quad &\rightarrow \quad (-\text{CF}_2\text{SF}_4-)_3, \text{CF}_5\text{SF}_5 \\
\text{R}_2\text{S} \quad &\rightarrow \quad \text{R}_1\text{SF}_5 \quad \text{and} \quad (\text{R}_1)_2\text{SF}_4
\end{align*}
\]

where \( \text{R}_f \) is a perfluoroalkyl group.

The application of the foregoing routes has led to the preparation and characterization of fluorides of virtually every element in the periodic table except the three lightest noble gases, He, Ne and Ar. The structures, bonding, reactivity, and industrial applications of these compounds will be found in the treatment of the individual elements and it is an instructive exercise to gather this information together in the form of comparative tables.\(^{(2,50,53-62)}\)

One important postscript can be added — the achievement by K. O. Christe in 1986 of synthesizing fluorine itself by chemical means alone, a goal that had eluded chemists for at least 173 years.\(^{(63)}\) In this context, the term chemical synthesis excludes techniques such as electrolysis, photolysis, discharge, etc., or the use of F2 in the synthesis of any of the starting materials. It is well known that high oxidation states can often be stabilized by complex-ion formation. Christe’s ingenious strategy was to treat just such a complex fluoride with a strong fluoride-ion acceptor, thus liberating the unstable metal fluoride which then spontaneously decomposed to a lower oxidation state with the liberation of F2. He chose to use K2MnF6 and SbF5, both of which can be readily prepared from HF solutions without the use of F2 itself:

\[
\text{K}_2\text{MnF}_6 + 2\text{SbF}_5 \rightarrow 2\text{K}\text{SbF}_6 + [\text{MnF}_4]
\]

The reaction was carried out in a passivated Teflon-stainless steel reactor at 150°C for 1 hour, and the yield was >40%. Fluorine pressures of more than 1 atm were generated in this way.

\section*{Chlorides, bromides and iodides}

A similar set of preparative routes is available as were outlined above for the fluorides, though the range of applicability of each method and the products obtained sometimes vary from halogen to halogen. When hydrolysis is not a problem
or when hydrated halides are sought, then wet methods are available, e.g. dissolution of a metal or its oxide, hydroxide or carbonate in aqueous hydrohalic acid followed by evaporative crystallization:

Fe + 2HCl (aq) $\rightarrow$ [Fe(H$_2$O)$_6$]Cl$_2$ + H$_2$

CoCO$_3$ + 2HI (aq) $\rightarrow$ [Co(H$_2$O)$_6$]I$_2$ + H$_2$O + CO$_2$

Dehydration can sometimes be effected by controlled removal of water using a judicious combination of gentle warming and either reduced pressure or the presence of anhydrous HX:

\[
[M(H_2O)_6]Br_3 \xrightarrow{70-170^\circ \text{ reduced press}} MBr_3 + 6H_2O
\]

\[
\text{(M = Ln or actinide)}
\]

CuCl$_2$.2H$_2$O $\xrightarrow{\text{HCl(g)/150}^\circ}$ CuCl$_2$ + 2H$_2$O

Hydrated chlorides that are susceptible to hydrolysis above room temperature can often be dehydrated by treating them with SOCl$_2$ under reflux:

\[
[\text{Cr(H}_2\text{O)}_6]\text{Cl}_3 + 6\text{SOCl}_2 \xrightarrow{79^\circ} \text{CrCl}_3 + 12\text{HCl} + 6\text{SO}_2
\]

Alternative wet routes to hydrolytically stable halides are metathetical precipitation and reductive precipitation reactions, e.g.:

\[
\text{Ag}^+\text{(aq)} + \text{Cl}^-\text{(aq)} \xrightarrow{} \text{AgCl}
\]

\[
\text{Cu}^{2+}\text{(aq)} + 2\text{I}^-\text{(aq)} \xrightarrow{} \text{CuI} + \frac{1}{2}\text{I}_2
\]

More complex is the hydrolytic disproportionation of the molecular halogens themselves in aqueous alkali which is a commercial route to several alkali-metal halides:

\[
3\text{X}_2 + 6\text{OH}^- \xrightarrow{} 5\text{X}^- + \text{XO}_3^- + 3\text{H}_2\text{O}
\]

When the desired halide is hydrolytically unstable then dry methods must be used, often at elevated temperatures. Pre-eminent amongst these methods is the oxidative halogenation of metals (or non-metals) with X$_2$ or HX; when more than one oxidation state is available X$_2$ sometimes gives the higher and HX the lower, e.g.:

\[
\text{Cr} + \frac{3}{2}\text{Cl}_2 \xrightarrow{600^\circ} \text{CrCl}_3
\]

\[
\text{Cr} + 2\text{HCl(g)} \xrightarrow{\text{red heat}} \text{CrCl}_2 + \text{H}_2
\]

Similarly, Cl$_2$ sometimes yields a higher and Br$_2$ a lower oxidation state, e.g. MoCl$_5$ and MoBr$_3$.

Other routes include the high-temperature halogenation of metal oxides, sometimes in the presence of carbon, to assist removal of oxygen; the source of halogen can be X$_2$, a volatile metal halide CX$_4$ or another organic halide. A few examples of the many reactions that have been used industrially or for laboratory scale preparations are:

\[
\text{ZrO}_2 \xrightarrow{\text{Cl}_2} \text{ZrCl}_4
\]

\[
\text{Ta}_2\text{O}_5 \xrightarrow{\text{C + Br}_2} \text{TaBr}_5 >460^\circ
\]

\[
\text{Nb}_2\text{O}_5 \xrightarrow{370^\circ} \text{NbBr}_5
\]

\[
\text{UO}_3 \xrightarrow{\text{CCI}_2 = \text{CCICCl}_3 \text{ reflux}} \text{UCl}_4
\]

\[
\text{MoO}_2 \xrightarrow{\text{Al}_3 \text{ 230}^\circ} \text{MoI}_2
\]

The last two of these reactions also feature a reduction in oxidation state. A closely related route is halogen exchange usually in the presence of an excess of the "halogenating reagent", e.g.:

\[
\text{FeCl}_3 + \text{BBr}_3\text{(excess)} \rightarrow \text{FeBr}_3 + \text{BCl}_3
\]

\[
\text{MCl}_3 + 3\text{HBr}\text{ (excess)} \xrightarrow{400°-600°} \text{MBr}_3 + 3\text{HCl}
\]

\[
\text{(M = Ln or Pu)}
\]

\[
3\text{TaCl}_5 + 5\text{AlI}_3\text{(excess)} \xrightarrow{400°} 3\text{TaI}_5 + 5\text{AlCl}_3
\]

Reductive halogenation can be achieved by reducing a higher halide with the parent metal, another metal or hydrogen:

\[
\text{TaI}_5 + \text{Ta} \xrightarrow{630° \rightarrow 575°} \text{Ta}_6\text{I}_{14}
\]

\[
3\text{WBr}_5 + \text{Al} \xrightarrow{475° \rightarrow 240°} 3\text{WBr}_4 + \text{AlBr}_3
\]
MX₃ + ½H₂ $\rightarrow$ MX₂ + HX
(M = Sm, Eu, Yb, etc., X = Cl, Br, I)

Alternatively, thermal decomposition or disproportionation can yield the lower halide:

- at "bp" $\text{ReCl}_5 \rightarrow \text{ReCl}_3 + \text{Cl}_2$
- $\text{MoI}_3 \rightarrow \text{MoI}_2 + \frac{3}{2}\text{I}_2$ at 100°
- $\text{AuCl}_3 \rightarrow \text{AuCl} + \text{Cl}_2$ at 160°
- $2\text{TaBr}_4 \rightarrow \text{TaBr}_3 + \text{TaBr}_5$ at 500°

Many significant trends are apparent in the structures of the halides and in their physical and chemical properties. The nature of the element concerned, its position in the periodic table, the particular oxidation state, and, of course, the particular halogen involved, all play a role. The majority of pre-transition metals (Groups 1, 2) together with Group 3, the lanthanides and the actinides in the +2 and +3 oxidation states form halides that are predominantly ionic in character, whereas the non-metals and metals in higher oxidation states (≥ +3) tend to form covalent molecular halides. The "ionic-covalent transition" in the halides of Group 15 (P, As, Sb, Bi) and 16 (S, Se, Te, Po) has already been discussed at length (pp. 498, 558, 772) as has the tendency of the refractory transition metals to form cluster halides (pp. 991, 1021, etc.). The problems associated with the ionic bond model and its range of validity were considered in Chapter 4 (p. 79). Presumed bond types tend to show gradual rather than abrupt changes within series in which the central element, the oxidation state or the halogen are systematically varied. For example, in a sequence of chlorides of isoelectronic metals such as KCl, CaCl₂, ScCl₃ and TiCl₄ the first member is predominantly ionic with a 3D lattice of octahedrally coordinated potassium ions; CaCl₂ has a framework structure (distorted rutile) in which Ca is surrounded by a distorted octahedron of 6Cl; ScCl₃ has a layer structure and TiCl₄ is a covalent molecular liquid.

The sudden discontinuity in physical properties at TiCl₄ is more a function of stoichiometry and coordination number than a sign of any discontinuous or catastrophic change in bond type. Numerous other examples can be found amongst the transition metal halides and the halides of the post-transition elements. In general, the greater the difference in electronegativity between the element and the halogen the greater will be the tendency to charge separation and the more satisfactory will be the ionic bond model. With increasing formal charge on the central atom or with decreasing electronegativity difference the more satisfactory will be the various covalent bond models. The complexities of the situation can be illustrated by reference to the bp (and mp) of the halides: for the more ionic halides these generally follow the sequence MFₙ > MClₙ > MBrₙ > MIₙ, being dominated by coulombic interactions which are greatest for the small F⁻ and least for the large I⁻, whereas for molecular halides the sequence is usually the reverse, viz. MIₙ > MBrₙ > MClₙ > MFₙ being dictated rather by polarizability and London dispersion forces which are greatest for I and least for F. As expected, intermediate halides are less regular as the first sequence yields to the reverse, and no general pattern can be discerned. Physical techniques such as $^{35,37}$Cl nmr spectroscopy and nuclear quadrupole resonance spectroscopy are being increasingly used to probe such trends.⁶⁴

Similar observations hold for solubility. Predominantly ionic halides tend to dissolve in polar, coordinating solvents of high dielectric constant, the precise solubility being dictated by the balance between lattice energies and solvation energies of the ions, on the one hand, and on entropy changes involved in dissolution of the crystal lattice, solvation of the ions and modification of the solvent structure, on the other: $\Delta G(\text{cryst} \rightarrow \text{saturated soln}) = 0 = \Delta H - T\Delta S$. For a given cation (e.g. K⁺, Ca²⁺) solubility in water typically follows the sequence

The Halogens: Fluorine, Chlorine, Bromine, Iodine and Astatine

MFₙ < MClₙ < MBrₙ < MIₙ. By contrast for less-ionic halides with significant non-coulombic lattice forces (e.g. Ag) solubility in water follows the reverse sequence MIₙ < MBrₙ < MClₙ < MFₙ. For molecular halides solubility is determined principally by weak intermolecular van der Waals' and dipolar forces, and dissolution is commonly favoured by less-polar solvents such as benzene, CCl₄ or CS₂.

Trends in chemical reactivity are also apparent, e.g. ease of hydrolysis tends to increase from the non-hydrolysing predominantly ionic halides, through the intermediate halides to the readily hydrolysable molecular halides. Reactivity depends both on the relative energies of M–X and M–O bonds and also, frequently, on kinetic factors which may hinder or even prevent the occurrence of thermodynamically favourable reactions. Further trends become apparent within the various groups of halides and are discussed at appropriate points throughout the text.

17.2.3 Interhalogen compounds

The halogens combine exothermically with each other to form interhalogen compounds of four stoichiometries: XY, XY₃, XY₅ and XY₇ where X is the heavier halogen. A few ternary compounds are also known, e.g. IFCl₂ and IF₂Cl. For the hexatomic series, only the fluorides are known (ClF₅, BrF₅, IF₅), and IF₇ is the sole example of the octatomic series. All the interhalogen compounds are diamagnetic and contain an even number of halogen atoms. Similarly, the closely related polyhalide anions XY₂⁻ and polyhalonium cations XY₂⁺ (n = 1, 2, 3) each have an odd number of halogen atoms: these ions will be considered in subsequent sections (pp. 835, 839).

Related to the interhalogens chemically, are compounds formed between a halogen atom and a pseudohalogen group such as CN, SCN, N₃. Examples are the linear molecules CICN, BrCN, ICN and the corresponding compounds XSCN and XN₃. Some of these compounds have already been discussed (p. 319) and need not be considered further. A microwave study shows that chlorine thiocyanate is CICN (angle Cl–S–C 99.8°) rather than CINCS, in contrast to the cyanate which is CINCO. The corresponding fluoro compound, FNCO, can be synthesized by several low-temperature routes but is not stable at room temperature and rapidly dimerizes to F₂NC(O)NCO. The chemistry of iodine azide has been reviewed — it is obtained as volatile, golden yellow, shock-sensitive needles by reaction of I₂ with AgN₃ in non-oxygen-containing solvents such as CH₂Cl₂, CCl₄ or benzene: the structure in the gas phase (as with FN₃, ClN₃ and BrN₃ also) comprises a linear N₃ group joined at an obtuse angle to the pendant X atom, thereby giving a molecule of C₃ symmetry.

Diatomic interhalogens, XY

All six possible diatomic compounds between F, Cl, Br and I are known. Indeed, ICI was first made (independently) by J. L. Gay Lussac and H. Davy in 1813–4 soon after the isolation of the parent halogens themselves, and its existence led J. von Liebig to miss the discovery of the new element bromine, which has similar properties (p. 794). The compounds vary considerably in thermal stability: CIF is extremely robust; ICI and IBr are moderately stable and can be obtained in very pure crystalline form at room temperature; BrCl readily dissociates reversibly into its...

Interhalogen compounds

elements; BrF and IF disproportionate rapidly and irreversibly to a higher fluoride and Br₂ (or I₂). Thus, although all six compounds can be formed by direct, controlled reaction of the appropriate elements, not all can be obtained in pure form by this route. Typical preparative routes (with comments) are as follows:

$$\text{Cl}_2 + \text{F}_2 \xrightarrow{225^\circ} 2\text{ClF};$$

must be purified from ClF₃ and reactants

$$\text{Cl}_2 + \text{ClF}_3 \xrightarrow{300^\circ} 3\text{ClF};$$

must be purified from excess ClF₃

$$\text{Br}_2 + \text{F}_2 \xrightarrow{\text{gas phase}} 2\text{BrF};$$

disproportionates to Br₂ + BrF₃ (and BrF₅) at room temp

$$\text{Br}_2 + \text{BrF}_3 \xrightarrow{} 3\text{BrF};$$

BrF favoured at high temp

$$\text{I}_2 + \text{F}_2 \xrightarrow{\text{in CCl}_3\text{F}} 2\text{IF};$$

disproportionates rapidly to I₂ + IF₅ at room temp

(a) Substantial disproportionation or dissociation prevents meaningful determination of mp and bp; the figures merely indicate the approximate temperature range over which the (impure) compound is liquid at atmospheric pressure.

(b) Fused ICl and IBr both dissociate into the free halogens to some extent: ICl 0.4% at 25° (supercooled) and 1.1% at 100°C; IBr 8.8% at 25° (supercooled) and 13.4% at 100°C.
diatomic interhalogens. The most volatile compound, ClF, is a colourless gas which condenses to a very pale yellow liquid below $-100^\circ$. The least volatile is IBr; it forms black crystals in which the IBr molecules pack in a herringbone pattern similar to that in I$_2$ (p. 803) and in which the internuclear distance $r$(l-Br) is 252 pm, i.e. slightly longer than in the gas phase (248.5 pm). ICl is unusual in forming two crystalline modifications: the stable ($\alpha$) form crystallizes as large, transparent ruby-red needles from the melt and features zigzag chains of molecules (Fig. 17.6) with two different ICl units and appreciable interchain intermolecular bonding. The packing is somewhat different in the yellow, metastable ($\beta$) form (Fig. 17.6) which can be obtained as brownish-red crystals from strongly supercooled melts.

The chemical reactions of XY can be conveniently classified as (a) halogenation reactions, (b) donor-acceptor interactions and (c) use as solvent systems. Reactions frequently parallel those of the parent halogens but with subtle and revealing differences. CIF is an effective fluorinating agent (p. 820) and will react with many metals and non-metals either at room temperature or above, converting them to fluorides and liberating chlorine, e.g.:

$$W + 6\text{ClF} \rightarrow W\text{F}_6 + 3\text{Cl}_2$$
$$\text{Se} + 4\text{ClF} \rightarrow \text{SeF}_4 + 2\text{Cl}_2$$

It can also act as a chlorofluorinating agent by addition across a multiple bond and/or by oxidation, e.g.:

$$(\text{CF}_3)_2\text{CO} + \text{ClF} \rightarrow (\text{CF}_3)_2\text{CFOCl}$$

$$\text{CO} + \text{ClF} \rightarrow \text{COCl}$$
$$\text{RCN} + 2\text{ClF} \rightarrow \text{RCF}_2\text{NCl}_2$$
$$\text{SO}_3 + \text{ClF} \rightarrow \text{ClOSO}_2\text{F}$$
$$\text{SO}_2 + \text{ClF} \rightarrow \text{ClSO}_2\text{F}$$
$$\text{SF}_4 + \text{ClF} \rightarrow \text{SF}_3\text{Cl}$$
$$\text{N}≡\text{SF}_3 + 2\text{ClF} \rightarrow \text{Cl}_2\text{NSF}_3$$

Reaction with OH groups or NH groups results in the exothermic elimination of HF and the (often violent) chlorination of the substrate, e.g.:

$$\text{HOH} + 2\text{ClF} \rightarrow 2\text{HF} + \text{Cl}_2\text{O}$$
$$\text{HONO}_2 + \text{ClF} \rightarrow \text{HF} + \text{ClONO}_2$$
$$\text{HNF}_2 + \text{ClF} \rightarrow \text{HF} + \text{NF}_2\text{Cl}$$

Lewis acid (fluoride-ion acceptor) behaviour is exemplified by reactions with NOF and MF to give $[\text{NO}]^+\text{[ClF}_2]^-$ and $\text{M}^+\text{[ClF}_2]^-$ respectively ($\text{M} =$ alkali metal or $\text{NH}_4$). Lewis base (fluoride ion donor) activity includes reactions with $\text{BF}_3$ and $\text{AsF}_5$:

$$\text{BF}_3 + 2\text{ClF} \rightarrow [\text{Cl}_2\text{F}]^+[\text{BF}_4]^-$$

Figure 17.6 Structures of $\alpha$- and $\beta$-forms of crystalline ICl.
AsF₅ + 2ClF $\rightarrow$ [Cl₂F]⁺[AsF₆]⁻

The linear polyhalide anion [F⁻Cl⁻F⁻] and the angular polyhalonium cation [F⁻⁺Cl⁺⁻] are members of a more extensive set of ions to be treated on pp. 835ff. CIF is commercially available in steel lecture bottles of 500-g capacity but must be handled with extreme circumspection in scrupulously dried and degreased apparatus constructed in steel, copper, Monel metal or nickel; fluorocarbon polymers such as Teflon can also be used, but not at elevated temperatures.

The reactivity of ICl and IBr, though milder than that of CIF is nevertheless still extremely vigorous and the compounds react with most metals including Pt and Au, but not with B, C, Cd, Pb, Zr, Nb, Mo or W. With ICl, phosphorus yields PCl₅ and V conveniently yields VCl₃ (rather than VCl₄). Reaction with organic substrates depends subtly on the conditions chosen. For example, phenol and salicylic acid are chlorinated by ICl vapour, since homolytic dissociation of the ICl molecule leads to chlorination by Cl₂ rather than iodination by the less-reactive I₂. By contrast, in CCl₄ solution (low dielectric constant) iodination predominates, accompanied to a small extent by chlorination: this implies heterolytic fission and rapid electrophilic iodination by I⁺ plus some residual chlorination by Cl₂ (or ICl). In a solvent of high dielectric constant, e.g. PhNO₂, iodination occurs exclusively.¹

Likewise BrF₅, in the presence of EtOH, rapidly and essentially quantitatively monobrominates aromatics such as PhX; when X = Me, Bu', OMe or Br, substitution is mainly or exclusively para, whereas with deactivating substituents (X = -CO₂Et, -CHO, -NO₂) exclusively meta-bromination occurs.² A similar interpretation explains why IBr almost invariably brominates rather than iodinates aromatic compounds due to its appreciable dissociation into Br₂ and I₂ in solution and the much greater rate of reaction of bromination by Br₂ compared with iodination by iodine.

Both ICl and IBr are partly dissociated into ions in the fused state, and this gives rise to an appreciable electrical conductivity (Table 17.12). The ions formed by this heterolytic dissociation of IX are undoubtedly solvated in the melt and the equilibria can be formally represented as

$$3IX \rightleftharpoons I₂X^+ + IX_2^- (X = \text{Cl, Br})$$

The compounds can therefore be used as nonaqueous ionizing solvent systems (p. 424). For example the conductivity of ICl is greatly enhanced by addition of alkali metal halides or aluminium halides which may be considered as halide-ion donors and acceptors respectively:

$$\text{ICl} + \text{MCl} \rightarrow M^+ [\text{ICl}_2]^–$$

$$2\text{ICl} + \text{AlCl}_3 \rightarrow [\text{I}_2\text{Cl}]^+ [\text{AlCl}_4]^–$$

Similarly pyridine gives [pyI]⁺[ICl]₂⁻ and SbCl₅ forms a 2:1 adduct which can be reasonably formulated as [I₂Cl]⁺[SbCl₆]⁻. By contrast, the 1:1 adduct with PCl₅ has been shown by X-ray studies to be [PCL₄]⁺[ICl]₂⁻. Solvoacid–solvobase reactions have been monitored by conductimetric titration; e.g. titration of solutions of RbCl and SbCl₅ in ICl (or of KCl and NbCl₅) shows a break at 1:1 molar proportions, whereas titration of NH₄Cl with SnCl₄ shows a break at the 2:1 mole ratio:

$$\text{Rb}^+ [\text{ICl}_2]^– + [\text{I}_2\text{Cl}]^+[\text{SbCl}_6]^– \rightarrow$$

$$\text{Rb}^+[\text{SbCl}_6]^– + 3\text{ICl}$$

$$\text{K}^+ [\text{ICl}_2]^– + [\text{I}_2\text{Cl}]^+[\text{NbCl}_6]^– \rightarrow$$

$$\text{K}^+[\text{NbCl}_6]^– + 3\text{ICl}$$

$$2\text{NH}_4^+ [\text{ICl}_2]^– + [\text{I}_2\text{Cl}]_2^+[\text{SnCl}_6]^2– \rightarrow$$

$$[\text{NH}_4]^+ [2\text{SnCl}_6]^2– + 6\text{ICl}$$

The preparative utility of such reactions is, however, rather limited, and neither ICl or IBr has been much used except to form various mixed polyhalide species. Compounds must frequently

---

be isolated by extraction rather than by precipitation, and solvolysis is a further complicating factor.

**Tetra-atomic interhalogens, XY₃**

The compounds to be considered are ClF₃, BrF₃, IF₃ and ICl₃ (I₂Cl₆). All can be prepared by direct reaction of the elements, but conditions must be chosen so as to avoid formation of mixtures of interhalogens of different stoichiometries. ClF₃ is best formed by direct fluorination of Cl₂ or CIF in the gas phase at 200–300° in Cu, Ni or Monel metal apparatus. BrF₃ is formed similarly at or near room temperature and can be purified by distillation to give a pale straw-coloured liquid. With IF₃, which is only stable below −30° the problem is to avoid the more facile formation of IFS; this can be achieved either by the action of F₂ on I₂ suspended in CC₁₃F at −45° or more elegantly by the low-temperature fluorination of I₂ with XeF₂:

\[
I₂ + 3XeF₂ \rightarrow 2IF₃ + 3Xe
\]

I₂Cl₆ is readily made as a bright-yellow solid by reaction of I₂ with an excess of liquid chlorine at −80° followed by the low-temperature evaporation of the Cl₂; care must be taken with this latter operation, however, because of the very ready dissociation of I₂Cl₆ into ICl and Cl₂.

Physical properties are summarized in Table 17.13. Little is known of the unstable IF₃ but ClF₃ and BrF₃ are well-characterized volatile molecular liquids. Both have an unusual T-shaped structure of C₂ᵥ symmetry, consistent with the presence of 10 electrons in the valency shell of the central atom (Fig. 17.7a,b). A notable feature of both structures is the slight deviation from collinearity of the apical F–X–F bonds, the angle being 175.0° for ClF₃ and 172.4° for BrF₃; this reflects the greater electrostatic repulsion of the nonbonding pair of electrons in the equatorial plane of the molecule. For each molecule the X–F apical distance is some 5–6% greater than the X–F equatorial distance but the mean X–F distance is very similar to that in the corresponding monofluoride. The structure of crystalline ICl₃ is quite different, being built up of planar I₂Cl₆ molecules separated by normal van der Waals’ distances between the Cl atoms (Fig. 17.7c). The terminal I–Cl distances are similar to those in ICl but the bridging I–Cl distances are appreciably longer.

ClF₃ is one of the most reactive chemical compounds known and reacts violently with many substances generally thought of as inert. Thus it spontaneously ignites asbestos, wood, and other building materials and was used in incendiary bomb attacks on UK cities during the Second World War. It reacts explosively with water and with most organic substances, though

reaction can sometimes be moderated by dilution of ClF$_3$ with an inert gas, by dissolution of the organic compound in an inert fluorocarbon solvent or by the use of low temperatures. Spontaneous ignition occurs with H$_2$, K, P, As, Sb, S, Se, Te, and powdered Mo, W, Rh, Ir and Fe. Likewise, Br$_2$ and I$_2$ enflame and produce higher fluorides. Some metals (e.g. Na, Mg, Al, Zn, Sn, Ag) react at room temperature until a fluoride coating is established; when heated they continue to react vigorously. Palladium, Pt and Au are also attacked at elevated temperatures and even Xe and Rn are fluorinated. Mild steel can be used as a container at room temperature and Cu is only slightly attacked below 300° but the most resistant are Ni and Monel metal. Very pure ClF$_3$ has no effect on Pyrex or quartz but traces of HF, which are normally present, cause slow etching.

ClF$_3$ converts most chlorides to fluorides and reacts even with refractory oxides such as MgO, CaO, Al$_2$O$_3$, MnO$_2$, Ta$_2$O$_5$ and MoO$_3$ to form higher fluorides, e.g.:

$$\text{AgCl} + \text{ClF}_3 \rightarrow \text{AgF}_2 + \frac{1}{2} \text{Cl}_2 + \text{ClF}$$

$$\text{NiO} + \frac{3}{2} \text{ClF}_3 \rightarrow \text{NiF}_2 + \frac{1}{2} \text{Cl}_2 + \frac{1}{2} \text{O}_2$$

$$\text{Co}_3\text{O}_4 + 3\text{ClF}_3 \rightarrow 3\text{CoF}_3 + \frac{3}{2} \text{Cl}_2 + 2\text{O}_2$$

With suitable dilution to moderate the otherwise violent reactions, NH$_3$ gas and N$_2$H$_4$ yield HF and the elements:

$$\text{NH}_3 + \text{ClF}_3 \rightarrow 3\text{HF} + \frac{1}{2} \text{N}_2 + \frac{1}{2} \text{Cl}_2$$

$$\text{N}_2\text{H}_4 + \frac{4}{3} \text{ClF}_3 \rightarrow 4\text{HF} + \text{N}_2 + \frac{2}{3} \text{Cl}_2$$

At one time this latter reaction was used in experimental rocket motors, the ClF$_3$ oxidizer reacting spontaneously with the fuel (N$_2$H$_4$ or Me$_2$N$_2$H$_2$). At low temperatures NH$_4$F and NH$_4$HF$_2$ react with liquid ClF$_3$ when allowed to warm from −196 to −5° but the reaction is hazardous and may explode above −5°:

$$\text{NH}_4\text{F} + \frac{5}{3} \text{ClF}_3 \rightarrow \text{NF}_2\text{Cl} + 4\text{HF} + \frac{1}{3} \text{Cl}_2$$

The same products are obtained more safely by reacting gaseous ClF$_3$ with a suspension of NH$_4$F or NH$_4$HF$_2$ in a fluorocarbon oil.

ClF$_3$ is manufactured on a moderately large scale, considering its extraordinarily aggressive properties which necessitate major precautions during handling and transport. Production plant in Germany had a capacity of ~5 tonnes/day in 1940 (~1500 tonnes/yr). It is now used in the USA, the UK, France and Russia primarily for nuclear fuel processing. ClF$_3$ is used to produce UF$_6$(g):

$$\text{U}(s) + 3\text{ClF}_3(l) \xrightarrow{50-90°} \text{UF}_6(l) + 3\text{ClF}(g)$$

It is also invaluable in separating U from Pu and other fission products during nuclear fuel reprocessing, since Pu reacts only to give the (involatile) PuF$_4$ and most fission products...
The Halogens: Fluorine, Chlorine, Bromine, Iodine and Astatine

(except Te, I and Mo) also yield involatile fluorides from which the UF₆ can readily be separated. ClF₃ is available in steel cylinders of up to 82 kg capacity and the price in 1992 was $100 per kg.

Liquid ClF₃ can act both as a fluoride ion donor (Lewis base) or fluoride ion acceptor (Lewis acid) to give difluorochloronium compounds and tetrafluorochlorides respectively, e.g.:

\[
\text{MF}_5 + \text{ClF}_3 \rightarrow [\text{ClF}_2]^+ [\text{MF}_6]^-
\]

colourless solids: \( M = \text{As, Sb} \)

\[
\text{PtF}_5 + \text{ClF}_3 \rightarrow [\text{ClF}_2]^+ [\text{PtF}_6]^-
\]

orange, paramagnetic solid, mp 171°

\[
\text{BF}_3 + \text{ClF}_3 \rightarrow [\text{ClF}_2]^+ [\text{BF}_4]^-
\]

colourless solid, mp 30°

\[
\text{MF} + \text{ClF}_3 \rightarrow M^+ [\text{ClF}_4]^-
\]

white or pink solids, decomp \( \sim 350° \): \( M = \text{K, Rb, Cs} \)

\[
\text{NOF} + \text{ClF}_3 \rightarrow [\text{NO}]^+ [\text{ClF}_4]^-
\]

white solid, dissociates below 25°

Despite these reaction products there is little evidence for an ionic self-dissociation equilibrium in liquid ClF₃ such as may be formally represented by 2ClF₃ \( \rightarrow \) ClF₂⁺ + ClF₄⁻, and the electrical conductivity of the pure liquid (p. 828) is only of the order of \( 10^{-9} \text{ohm}^{-1} \text{cm}^{-1} \). The structures of these ions are discussed more fully in subsequent sections.

Bromine trifluoride, though it reacts explosively with water and hydrocarbon tap greases, is somewhat less violent and vigorous a fluorinating agent than is ClF₃. The sequence of reactivity usually quoted for the halogen fluorides is:

\[
\text{ClF}_3 > \text{BrF}_5 > \text{IF}_7 > \text{ClF} > \text{BrF}_3 > \text{IF}_5 > \text{BrF} > \text{IF}_3 > \text{IF}
\]

It can be seen that, for a given stoichiometry of XFₙ, the sequence follows the order Cl > Br > I and for a given halogen the reactivity of XFₙ diminishes with decrease in \( n \), i.e. XF₅ > XF₃ > XF. (A possible exception is ClF₅; this is not included in the above sequence but, from the fragmentary data available, it seems likely that it should be placed near the beginning — perhaps between ClF₃ and BrF₅.) BrF₃ reacts vigorously with B, C, Si, As, Sb, I and S to form fluorides. It has also been used to prepare simple fluorides from metals, oxides and other compounds: volatile fluorides such as MoF₆, WF₆ and UF₆ distil readily from solutions in which they are formed whereas less-volatile fluorides such as AuF₃, PdF₄, PtF₄ and BiF₅ are obtained as residues on removal of BrF₃ under reduced pressure. Reaction with oxides often evolves O₂ quantitatively (e.g. B₂O₃, Ti₂O₃, SiO₂, GeO₂, As₂O₃, Sb₂O₃, ScO₃, I₂O₅, CuO, TiO₂, UO₃):

\[
\text{B}_2\text{O}_3 + 2\text{BrF}_3 \rightarrow 2\text{BF}_3 + \text{Br}_2 + \frac{3}{2}\text{O}_2
\]

\[
\text{SiO}_2 + \frac{4}{3}\text{BrF}_3 \rightarrow \text{SiF}_4 + \frac{2}{3}\text{Br}_2 + \text{O}_2
\]

The reaction can be used as a method of analysis and also as a procedure for determining small amounts of O (or N) in metals and alloys of Li, Ti, U, etc. In cases when BrF₃ itself only partially fluorinates the refractory oxides, the related reagents KBrF₄ and BrF₂SbF₆ have been found to be effective (e.g. for MgO, CaO, Al₂O₃, MnO₂, Fe₂O₃, NiO, CeO₂, Nd₂O₃, ZrO₂, ThO₂). Oxygen in carbonates and phosphates can also be determined by reaction with BrF₃. Sometimes partial fluorination yields new compounds, e.g. perrhenates afford tetrafluoroperrhenates:

\[
\text{MReO}_4 + \frac{4}{3}\text{BrF}_3 \rightarrow \text{MReO}_2\text{F}_4 + \frac{2}{3}\text{Br}_2 + \text{O}_2
\]

\( M = \text{K, Rb, Cs, Ag, } \frac{1}{2}\text{Ca, } \frac{1}{2}\text{Sr, } \frac{1}{2}\text{Ba} \)

Likewise, K₂Cr₂O₇ and Ag₂Cr₂O₇ yield the corresponding MCrOF₄ (i.e. reduction from CrV to CrV'). Other similar reactions, which nevertheless differ slightly in their overall stoichiometry, are:

\[
\text{KClO}_3 + \frac{3}{2}\text{BrF}_3 \rightarrow \text{KBrF}_4 + \frac{3}{2}\text{Br}_2
\]

\[
+ \frac{3}{2}\text{O}_2 + \text{ClO}_2\text{F}
\]

\[
\text{ClO}_2 + \frac{1}{2}\text{BrF}_3 \rightarrow \text{ClO}_2\text{F} + \frac{1}{6}\text{Br}_2
\]
\[ N_2O_5 + \frac{1}{3}BrF_3 \rightarrow \frac{1}{2}Br(NO_3)_3 + NO_2F \]

\[ IO_2F + \frac{1}{3}BrF_3 \rightarrow IF_5 + \frac{2}{3}Br_2 + O_2 \]

As with ClF₃, BrF₃ is used to fluorinate U to UF₆ in the processing and reprocessing of nuclear fuel. It is manufactured commercially on a multitonne scale and is available as a liquid in steel cylinders of varying size up to 91 kg capacity. The US price in 1992 was \$80 per kg.

In addition to its use as a straight fluorinating agent, BrF₃ has been extensively investigated and exploited as a preparative nonaqueous ionizing solvent. The appreciable electrical conductivity of the pure liquid (p. 828) can be interpreted in terms of the dissociative equilibrium

\[ 2BrF_3 \rightleftharpoons BrF_2^+ + BrF_4^- \]

Electrolysis gives a brown coloration at the cathode but no visible change at the anode:

\[ 2BrF_2^+ + 2e^- \rightarrow BrF_3 + BrF \text{ (brown)} \]

\[ 2BrF_4^- \rightarrow BrF_3 + BrF_5 + 2e^- \text{ (colourless)} \]

The specific conductivity decreases from \(8.1 \times 10^{-3} \text{ ohm}^{-1} \text{ cm}^{-1}\) at 10°C to \(7.1 \times 10^{-3} \text{ ohm}^{-1} \text{ cm}^{-1}\) at 55°C and this unusual behaviour has been attributed to the thermal instability of the BrF₂⁺ and BrF⁻ ions at higher temperatures. Consistent with the above scheme KF, BaF₂ and numerous other fluorides (such as NaF, RbF, AgF, NOF) dissolve in BrF₃ with enhancement of the electrical conductivity due to the formation of the solvobases KBrF₄, Ba(BrF₄)₂, etc. Likewise, Sb and Sn give solutions of the solvoacids BrF₂SbF₆ and (BrF₂)₂SnF₆. Conductimetric titrations between these various species can be carried out, the end point being indicated by a sharp minimum in the conductivity:

\[ \text{BrF}_2^+ \text{SbF}_6^- + \text{Ag}^+ \text{BrF}_4^- \rightarrow \text{Ag}^+ \text{SbF}_6^- + 2\text{BrF}_3 \]

\[ (\text{BrF}_2^+)_2\text{SnF}_6^{2-} + 2\text{Ag}^+ \text{BrF}_4^- \rightarrow (\text{Ag}^+)_2\text{SnF}_6^{2-} + 4\text{BrF}_3 \]

Other solvoacids that have been isolated include the BrF₂⁺ compounds of AuF₄⁻, BiF₆⁻, NbF₆⁻, TaF₆⁻, RuF₆⁻ and PdF₆²⁻ and reactions of BrF₃ solutions have led to the isolation of large numbers of such anhydrous complex fluorides with a variety of cations.(73) Solvolysis sometimes complicates the isolation of a complex by evaporation of BrF₃ and solvates are also known, e.g. K₂TiF₆·BrF₃ and K₂PtF₆·BrF₃. It is frequently unnecessary to isolate the presumed reaction intermediates and the required complex can be obtained by the action of BrF₃ on an appropriate mixture of starting materials:

\[ \text{Ag} + \text{Au} \rightarrow \{\text{AgBrF}_4 + \text{BrF}_2\text{AuF}_4\} \]

\[ \text{Ag} \rightarrow 2\text{BrF}_3 \rightarrow \text{Ag[AuF}_4\} \]

\[ \text{N}_2\text{O}_4 + \text{Sb}_2\text{O}_3 \rightarrow [\text{NO}_2][\text{SbF}_6] \]

\[ \text{Ru} + \text{KCl} \rightarrow \text{K[RuF}_6\} \]

In these reactions BrF₃ serves both as a fluorinating agent and as a nonaqueous solvent reaction medium.

Molten I₂Cl₆ has been much less studied as an ionizing solvent because of the high dissociation pressure of Cl₂ above the melt. The appreciable electrical conductivity may well indicate an ionic self-dissociation equilibrium such as

\[ \text{I}_2\text{Cl}_6 \rightleftharpoons \text{ICl}_2^+ + \text{ICl}_4^- \]

Such ions are known from various crystal-structure determinations, e.g. K[ICl₂][H₂O], [ICl₂][AlCl₄] and [ICl₂][SbCl₆] (p. 839). I₂Cl₆ is a vigorous chlorinating agent, no doubt due at least in part to its ready dissociation into Cl⁻ and Cl₂. Aromatic compounds, including thiophen, C₄H₄S, give chlorosubstituted products with very little if any iodination. By contrast, reaction of I₂Cl₆ with aryl–tin or aryl–mercury compounds yield the corresponding diarylidoonium derivatives, e.g.:

\[ 2\text{PhSnCl}_3 + \text{ICl} \rightarrow \text{Ph}_2\text{ICl} + 2\text{SnCl}_4 \]
The three fluorides ClF₅, BrF₅ and IF₅ are the only known hexa-atomic interhalogens, and IF₇ is the sole representative of the octa-atomic class. The first to be made (1871) was IF₅ which is the most readily formed of the iodine fluorides, whereas the more vigorous conditions required for the others delayed the synthesis of BrF₅ and IF₇ until 1930/1 and ClF₅ until 1962. The preferred method of preparing all four compounds on a large scale is by direct fluorination of the element or a lower fluoride:

\[
\begin{align*}
\text{Cl}_2 + 5F_2 &\xrightarrow{\text{excess } F_2, 350{}^\circ\text{C}, 250 \text{ atm}} 2\text{ClF}_5 \\
\text{ClF}_3 + F_2 &\xrightarrow{h, \text{room temp.}, 1 \text{ atm}} \text{ClF}_5 \\
\text{Br}_2 + 5F_2 &\xrightarrow{\text{excess } F_2, \text{above } 150{}^\circ} \text{BrF}_5 \\
I_2(s) + 5F_2 &\xrightarrow{\text{room temp}} \text{IF}_5 \\
I_2(g) + 7F_2 &\xrightarrow{250-300{}^\circ} \text{IF}_7
\end{align*}
\]

Small-scale preparations can be conveniently effected as follows:

\[
\begin{align*}
\text{MCl}(s) + 3F_2 &\xrightarrow{100-300{}^\circ} \text{MF}(s) + \text{ClF}_5 \\
\text{KBr} + 3F_2 &\xrightarrow{25{}^\circ} \text{KF}(s) + \text{BrF}_5 \\
\text{AgF, ClF}_3 \text{ or BrF}_3 &\xrightarrow{I_2} \text{IF}_5 \\
\end{align*}
\]

⁽ᵃ⁾For liquid BrF₅: \(\Delta H_f\) (298 K) = 458.6 kJ mol⁻¹, \(\Delta G_f\) (298 K) = 351.9 kJ mol⁻¹.

⁽ᵇ⁾For liquid IF₅: \(\Delta H_f\) (298 K) = 885 kJ mol⁻¹, \(\Delta G_f\) (298 K) = 784 kJ mol⁻¹.
difference in electronegativity between X and F. ClF is an exception. As expected, for a given halogen, the mean bond energy decreases as \( n \) increases in \( \text{XF}_n \), the effect being most marked for Cl and least for I. Note that high bond energy (as in BrF and IF) does not necessarily confer stability on a compound (why?).

The molecular structure of \( \text{XF}_5 \) has been shown to be square pyramidal (C\(_{4v}\)) with the central atom slightly below the plane of the four basal \( \text{F} \) atoms (Fig. 17.10). The structure is essentially the same in the gaseous, liquid and crystalline phases and has been established by some (or all) of the following techniques: electron diffraction, microwave spectroscopy, infrared and Raman spectroscopy, \(^{19}\text{F} \) nmr spectroscopy and X-ray diffraction analysis. This structure immediately explains the existence of a small permanent dipole moment, which would be absent if the structure were trigonal bipyramidal (C\(_{3v}\)), and is consistent with the presence of 12 valence-shell electrons on the central atom \( X \). Electrostatic effects account for the slight displacement of the four \( \text{F}_b \) away from the lone-pair of electrons and also the fact that \( X-\text{F}_b > X-\text{F}_a \). The \(^{19}\text{F} \) nmr spectra of both \( \text{BrF}_5 \) and \( \text{IF}_5 \) consist of a highfield doublet (integrated relative area 4) and a 1:4:6:4:1 quintet of integrated area 1; these multiplets can immediately be assigned on the basis of \(^{19}\text{F}–^{19}\text{F} \) coupling and relative area to the 4 basal and the unique apical \( \text{F} \) atom respectively. The molecules are fluxional at higher temperatures: e.g. spin–spin coupling disappears in \( \text{IF}_5 \) at 115° and further heating leads to broadening and coalescence of the two signals, but a sharp singlet could not be attained at still

higher temperatures because of accelerated attack of IF₅ on the quartz tube.

The structure of IF₇ is generally taken to be pentagonal bipyramidal (D₅h symmetry) as originally suggested on the basis of infrared and Raman spectra (Fig. 17.11). Electron diffraction data have been interpreted in terms of slightly differing axial and equatorial distances and a slight deformation from D₅h symmetry due to a 7.5° puckering displacement and a 4.5° axial bending displacement. An assessment of the diffraction data permits the Delphic pronouncement(74) that, on the evidence available, it is not possible to demonstrate that the molecular symmetry is different from D₅h.

The very great chemical reactivity of ClF₅ is well established but few specific stoichiometric reactions have been reported. Water reacts vigorously to liberate HF and form FCIO₂ (ClF₅ + 2H₂O → FCIO₂ + 4HF). AsF₅ and SbF₅ form 1:1 adducts which may well be ionic: [ClF₄]⁺-[MF₆]-. A similar reaction with BrF₅ yields a 1:2 adduct which has been shown by X-ray crystallography to be [BrF₄][Sb₂F₁₁]⁻ (p. 841). Fluoride ion transfer probably also occurs with SO₃ to give [BrF₄][SO₃F]⁻, but adducts with BF₃, PF₅ or TiF₄ could not be formed. Conversely, BrF₅ can act as a fluoride ion acceptor (from CsF) to give CsBrF₆ as a white, crystalline solid stable to about 300°, and this solvobase can be titrated with the solvobase [BrF₄][Sb₂F₁₁]⁻ according to the following stoichiometry:

\[ [\text{BrF}_4]^+\text{[Sb}_2\text{F}_{11}]^- + 2\text{Cs}^+\text{[BrF}_6]^- \rightarrow 3\text{BrF}_5 + 2\text{CsSbF}_6 \]

BrF₅ reacts explosively with water but when moderated by dilution with MeCN gives boric and hydrofluoric acids:

\[ \text{BrF}_5 + 3\text{H}_2\text{O} \rightarrow \text{HBrO}_3 + 5\text{HF} \]

The vigorous fluorinating activity of BrF₅ is demonstrated by its reaction with silicates, e.g.:

\[ \text{KAlSi}_3\text{O}_8 + 8\text{BrF}_5 \overset{450^\circ\text{C}}{\rightarrow} \text{KF} + \text{AlF}_3 + 3\text{SiF}_4 + 4\text{O}_2 + 8\text{BrF}_3 \]

The chemical reactions of IF₅ have been more extensively and systematically studied because the compound can be handled in glass apparatus and is much less vigorous a reagent than the other pentafluorides. The (very low) electrical conductivity of the pure liquid has been ascribed to slight ionic dissociation according to the equilibrium

\[ 2\text{IF}_5 \rightleftharpoons \text{IF}_4^+ + \text{IF}_6^- \]

Consistent with this, dissolution of KF increases the conductivity and KIF₆ can be isolated on removal of the solvent. Likewise NOF affords [NO]⁺[IF₆]⁻. Antimony compounds yield ISbF₁₀, i.e. [IF₄]⁺[SbF₆]⁻, which can be titrated with KSbF₆. However, the milder fluorinating power of IF₅ frequently enables partially fluorinated adducts to be isolated and in some of these the iodine is partly oxygenated. Complete structural identification of the products has not yet been established in all cases but typical stoichiometries are as follows:

\[ \begin{align*}
\text{CrO}_3 & \rightarrow \text{CrO}_2\text{F}_2 \\
\text{V}_2\text{O}_5 & \rightarrow 2\text{VO}_2\text{.}_3\text{OF}_3 \\
\text{MoO}_3 & \rightarrow 2\text{MoO}_2\text{.}_3\text{IF}_5 \\
\text{Sb}_2\text{O}_5 & \rightarrow \text{SbF}_5\text{.}_3\text{IO}_2\text{F} \\
\text{WO}_3 & \rightarrow \text{WO}_2\text{.}_2\text{IF}_5 \\
\text{KMnO}_4 & \rightarrow \text{MnO}_3 + 1\text{OF}_3 + \text{KF}
\end{align*} \]

Potassium perrhenate reacts similarly to KMnO₄ to give ReO₃F. Similarly, the mild fluorinating

---

Figure 17.11 Approximate structure of IF₇ (see text).

action of IF$_5$ enables substituted iodine fluorides to be synthesized, e.g.:

$$\text{Me}_3\text{SiOMe} + \text{IF}_5 \rightarrow \text{IF}_4\text{OMe} + \text{Me}_3\text{SiF}$$

IF$_5$ is unusual as an interhalogen in forming adducts with both XeF$_2$ and XeF$_4$:

$$\text{XeF}_2 + 2\text{IF}_5 \rightarrow \text{XeF}_2\cdot 2\text{IF}_5$$
$$\text{XeF}_4 + \text{IF}_5 \rightarrow \text{XeF}_4\cdot \text{IF}_5 \quad (>92^\circ)$$

It should be emphasized that the reactivity of IF$_5$ is mild only in comparison with the other halogen fluorides (p. 830). Reaction with water is extremely vigorous but the iodine is not reduced and oxygen is not evolved:

$$\text{IF}_5 + 3\text{H}_2\text{O} \rightarrow \text{HIO}_3 + 5\text{HF}; \quad \Delta H = -92.3 \text{ kJ mol}^{-1}$$
$$\text{IF}_5 + 6\text{KOH(aq)} \rightarrow 5\text{KF(aq)} + \text{KIO}_3 + 3\text{H}_2\text{O}; \quad \Delta H = -497.5 \text{ kJ mol}^{-1}$$

Boron enflames in contact with IF$_5$; so do P, As and Sb. Molybdenum and W enflame when heated and the alkali metals react violently. KH and CaC$_2$ become incandescent in hot IF$_5$. However, reaction is more sedate with many other metals and non-metals, and compounds such as CaCO$_3$ and Ca$_3$(PO$_4$)$_2$ appear not to react with the liquid.

IF$_7$ is a stronger fluorinating agent than IF$_5$ and reacts with most elements either in the cold or on warming. CO enflames in IF$_7$ vapour but NO reacts smoothly and SO$_2$ only when warmed. IF$_7$ vapour hydrolyses without violence to HIO$_4$ and HF; with small amounts of water at room temperature the oxyfluoride can be isolated:

$$\text{IF}_7 + \text{H}_2\text{O} \rightarrow \text{IOF}_5 + 2\text{HF}$$

The same compound is formed by action of IF$_7$ on silica (at 100°) and Pyrex glass:

$$2\text{IF}_7 + \text{SiO}_2 \rightarrow 2\text{IOF}_5 + \text{SiF}_4$$

IF$_7$ acts as a fluoride ion donor towards AsF$_5$ and SbF$_5$ and the compounds [IF$_6$]$^+$$[\text{MF}_6]^- \quad (n = 1, 2, 3, 4)$ have been isolated. Few complexes with alkali metal fluorides have been isolated but CsF and NOF form adducts which have been characterized by X-ray powder data, and formulated on the basis of Raman spectroscopy as Cs$^+$$[\text{IF}_8]$ and [NO]$^+$$[\text{IF}_8]^-$.\(^{75}\)

### 17.2.4 Polyhalide anions

Polyhalide anions of general formula XY$_{2n}$ (n = 1, 2, 3, 4) have been mentioned several times in the preceding section. They can be made by addition of a halide ion to an interhalogen compound, or by reactions which result in halide-ion transfer between molecular species. Ternary polyhalide anions X$_m$Y$_n$Z$_p$ (m + n + p odd) are also known as are numerous polyiodides I$_n^-$. Stability is often enhanced by use of a large counter-cation, e.g. Rb$^+$, Cs$^+$, NR$_4^+$, PCl$_4^+$, etc.; likewise, for a given cation, thermal stability is enhanced the more symmetrical the polyhalide ion and the larger the central atom (i.e. stability decreases in the sequence I$^- >$ IBr$^- >$ ICl$^- >$ I$_2$Br$^- >$ Br$_3^- >$ BrCl$_2^- >$ Br$_2$Cl$^-$. The structures of many of these polyhalide anions have been established by X-ray diffraction analysis or inferred from vibrational spectroscopic data and in all cases the gross stereochemistry is consistent with the expectations of simple bond theories (p. 897); however, subtle deviations from the highest expected symmetry sometimes occur, probably due to crystal-packing forces and residual interactions between the various ions in the condensed phase.

Typical examples of linear (or nearly linear) triatomic polyhalides are in Table 17.15;\(^{67,76}\) the structures are characterized by considerable variability of interatomic distances and these distances are individually always substantially greater than for the corresponding diatomic interhalogen (p. 825). Note also that for

(a) In the compound \([\text{Me}_3\text{NH}]^+\text{Br}^-\text{Br}_3^-\); same dimensions for Br\(_3^-\) in Ph\(_2\text{Br}_3\) and in \([\text{C}_6\text{H}_7\text{NH}]_2[\text{SbBr}_6]\)[Br\(_3\)]. Other known values summarized in ref. 77

(b) Piperazinium, \([\text{H}_2\text{NC}_4\text{H}_8\text{NH}_2]^2^+\).

(c) Triethylenediammonium, \([\text{HN}(\text{C}_2\text{H}_5\text{NH})]^+\): compound contains 2 non-equivalent ICl\(_2^-\) ions.

[Cl\text{–I}^\text{–Br}]^– the I–Cl distance is greater than the I–Br distance, and in [Br–I–I]– I–Br is greater than I–I. On dissociation, the polyhalide yields the solid monohalide corresponding to the smaller of the halogens present, e.g. CsICl\(_2\) gives CsCl and ICl rather than CsI and ICl\(_2\). Likewise for CsIBrCl the favoured products are CsCl(s) + IBr(g) rather than CsBr(s) + ICl(g) or CsI(s) + BrCl(g). Thermochemical cycles have been developed to interpret these results.(76)

Penta-atomic polyhalide anions \([\text{XY}_4]^–\) favour the square-planar geometry (\(D_{4h}\)) as expected for species with 12 valence-shell electrons on the central atom. Examples are the Rb\(^+\) and Cs\(^+\) salts of \([\text{ClF}_4]^–\), and KBrF\(_4\) (in which Br–F is 189 pm and adjacent angles F–Br–F are 90° \((\pm 2^\circ)\). The symmetry of the anion is slightly lowered in CsIF\(_4\)(C\(_{2v}\)) and also in KICl\(_4\)H\(_2\O\) (in which I–Cl is 242, 247, 253, and 260 pm and the adjacent angles Cl–I–Cl are 90.6°, 90.7°, 89.2° and 89.5°. Other penta-atomic polyhalide anions for which the structure has not yet been determined are \([\text{ICl}_3F]^–\), \([\text{IBrCl}_3]^–\), \([\text{I}_2\text{Cl}_3]^–\), \([\text{I}_2\text{BrCl}_2]^–\), \([\text{I}_2\text{Br}_2\text{Cl}]^–\), \([\text{I}_2\text{Br}_3]^–\), \([\text{I}_4\text{Br}^-]\) and \([\text{I}_2\text{Cl}^-]\). Some of these may be “square planar” but the polyiodo species might well be more closely related to \(15^–\): the tetramethylammonium salt of this anion features a planar V-shaped array in which two \(15^–\) units are bonded to a single iodide ion, i.e. \([\text{I}(\text{I}_2^-)]^–\) as in Fig. 17.12. The V-shaped ions are arranged in a planar array which bear an interesting relation to a (hypothetical) array of planar IX\(_4^-\) ions.

Hepta-atomic polyhalide anions are exemplified by BrF\(_6^-\) (K\(^+\), Rb\(^+\) and Cs\(^+\) salts) and IF\(_6^-\) (K\(^+\), Cs\(^+\), NMe\(_4^+\) and NEt\(_4^+\) salts). The

---

Figure 17.12 Structure of some polyiodides.

anions have 14 valence-shell electrons on the central atom and spectroscopic studies indicate non-octahedral geometry ($D_{3d}$ for BrF$_6^-$). Other possible examples are Br$_2$Cl$^-$ and I$_5$Br$^-$ but these have not been shown to contain discrete hepta-atomic species and may be extended anionic networks such as that found in Et$_4$Ni$_7$ (Fig. 17.12).

IF$_7$ has been shown to act as a weak Lewis acid towards CsF and NOF, and the compounds CsIF$_8$ and NOIF$_8$ have been characterized by X-ray powder patterns and by Raman spectroscopy; they are believed to contain the IF$_8^-$ anion.\(^{(75)}\) A rather different structure motif occurs in the polyiodide Me$_4$Ni$_9$; this consists of discrete units with a "twisted h" configuration (Fig. 17.12). Interatomic distances within these units vary from 267 to 343 pm implying varying strengths of bonding, and the anions can be thought of as being built up either from I$^- + 4$I$_2$ or from a central unsymmetrical I$_3^-$ and 3I$_2$. (The rather arbitrary recognition of discrete I$_9^-$ anions is emphasized by the fact that the closest interionic I..I contact is 349 pm which is only slightly greater than the 343 pm separating one I$_2$ from the remaining I$_7^-$ in the structure.)

The propensity for iodine to catenate is well illustrated by the numerous polyiodides which crystallize from solutions containing iodide ions and iodine. The symmetrical and unsymmetrical I$_3^-$ ions (Table 17.15) have already been mentioned as have the I$_5^-$ and I$_9^-$ anions and the extended networks of stoichiometry I$_7^-$(Fig. 17.12). The stoichiometry of the crystals and the detailed geometry of the polyhalide depend sensitively on the relative concentrations of the components and the nature of the cation. For example, the linear I$_4^{2-}$ ion may have the following dimensions:

\[
\begin{align*}
&334 \text{ pm} \quad 280 \text{ pm} \\
[I \quad \quad \quad \quad \quad I - - - - - I]^{2-} \\
\end{align*}
\]

in [Cu(NH$_3$)$_4$I$_4$]$_{80}$\(^{(80)}\)

\[
\begin{align*}
&318 \text{ pm} \quad 314 \text{ pm} \quad 318 \text{ pm} \\
[I \quad \quad \quad \quad \quad I - - - - - I]^{2-} \\
\end{align*}
\]

in Tl$_6$PbI$_{10}$\(^{(81)}\) (Note, however, that the overall length of the two I$_4^{2-}$ ions is virtually identical.) Again, the I$_8^{2-}$ anion is found with an acute-angled planar Z configuration in its Cs$^+$ salt but with an outstretched configuration in the black methyltetraazaadamantanium salt (Fig. 17.12). The largest discrete polyiodide ion so far encountered is the planar centro-symmetric I$_{16}^{4-}$ anion; this was shown by X-ray diffraction$^{(79)}$ to be present in the dark-blue needle-shaped crystals of (theobromine)$_2$H$_2$I$_8$ which had first been prepared over a century earlier by S. M. Jorgensen in 1869.

The bonding in these various polyiodides as in the other polyhalides and neutral interhalogens has been the subject of much speculation, computation and alteration. The detailed nature of the bonds probably depends on whether F is one of the terminal atoms or whether only the heavier halogens are involved. There is now less tendency than formerly to invoke much d-orbital participation (because of the large promotion energies required) and Mössbauer spectroscopic studies in iodine-containing species$^{(82)}$ also suggest rather scant s-orbital participation. The bonding appears predominantly to involve p orbitals only, and multicentred (partially delocalized) bonds such as are invoked in discussions of the isoelectronic xenon halides (p. 897) are currently favoured. However, no bonding model yet comes close to reproducing the range of interatomic distances and angles observed in the crystalline polyhalides.$^{(76)}$ There has also been much interest in the bis(ethylenedithio)tetrathiafulvalene layer-like compounds with polyhalide anions. For example, [(BEDT-TTF)(ICl)$_2$] is a one-dimensional metal down to ~22 K at which temperature it transforms to an insulator. The [BrICl]$^-$ salt is similar, whereas with the larger

17.2.5 Polyhalonium cations $XY_{2n}^+$

Numerous polyhalonium cations have already been mentioned in Section 17.2.3 during the discussion of the self-ionization of interhalogen compounds and their ability to act as halide-ion donors. The known species are summarized in Table 17.16. Preparations are usually by addition of the appropriate interhalogen and halide-ion acceptor, or by straightforward modification of this general procedure in which the interhalogen or halogen is also used as an oxidant. For example Au dissolves in BrF$_3$ to give [BrF$_2$][AuF$_4$], BrF$_3$ fluorinates and oxidizes PdCl$_2$ and PdBr$_2$ to [BrF$_2$][PdF$_4$]; ClF$_3$ converts AsCl$_3$ to [ClF$_2$][AsF$_6$]; stoichiometric amounts of I$_2$, Cl$_2$ and 2SbCl$_5$ yield [ICl$_2$][SbCl$_6$]. The fluorocations tend to be colourless or pale yellow but the colour deepens with increasing atomic weight so that compounds of ICl$_2^+$ are wine-red or bright orange whilst I$_2$Cl$_2^+$ compounds are dark brown or purplish black.

Structures are as expected from simple valency theory and the isoelectronic principle (20 valency electrons). Thus the triatomic species are bent, rather than linear, as illustrated in Fig. 17.13 for ClF$_2^+$, BrF$_2^+$ and ICl$_2^+$; there is frequently some residual interionic interaction due to close approach of the cation and anion and this sometimes complicates the interpretation of vibrational spectroscopic data. In the case of [ICl$_2$][SbF$_6$] (Fig. 17.13c) the very short I⋯F distance implies one of the strongest secondary interactions known between these two elements and the Sb–F⋯I angle deviates appreciably from linearity. The ion [ClF$_2$]$^+$ was originally thought to have the symmetrical

(a) The date given refers to the first isolation of a compound containing the cation, or the characterization of the cation in solution.
bent $C_{2v}$ structure $[\text{Cl} \cdots \text{F} \cdots \text{Cl}]^+$ but later Raman spectroscopic studies were interpreted on the basis of the unsymmetrical bent structure $[\text{Cl} \cdots \text{Cl} \cdots \text{F}]^+$. Calculations\(^{87}\) suggest that the symmetrical $C_{2v}$ structure is indeed the more stable form at least for the isolated cation and the question must be regarded as still open:

$$2\text{Cl}_2\text{F}^+ \rightarrow \text{ClF}_2^+ + \text{Cl}_3^+$$

The pentaatomic cations $\text{ClF}_4^+$, $\text{BrF}_4^+$ and $\text{IF}_4^+$ are precisely isoelectronic with $\text{SF}_4$, $\text{SeF}_4$ and $\text{TeF}_4$ and adopt the same T-shaped ($C_{2v}$) configuration. This is illustrated in Fig. 17.14.

---

for the case of [BrF₄][Sb₂F₁₁]: again there are strong subsidiary interactions, the coordination about Br being pseudo-octahedral with four short Br–F distances and two longer Br⋯F distances which are no doubt influenced by the presence of the stereochemically active nonbonding pair of electrons on the Br atom. In addition, the mean Sb–F distance in the central SbF₆ unit is substantially longer than the mean of the five “terminal” Sb–F distances in the second unit and the structure can be described approximately as [BrF₄⋯SbF₆⋯SbF₅]. The structure of the final pentaatomic cation, I₃Cl₂⁺ (1), is different and resembles that of I₅⁺ (p. 844) in being a planar centrosymmetric species with C₂ᵥ symmetry: ¹⁺

\[ \text{ClF}_5(\text{excess}) + \text{PtF}_6(\text{red gas}) \xrightarrow{\text{sapphire reactor, room temp}} \text{ClF}_6^+ \text{PtF}_6^- + \text{ClF}_4^+ \text{PtF}_6^- \]

(bright yellow solids)

\[ \text{BrF}_5(\text{excess}) + \text{KrF}^+ \text{AsF}_6^- \rightarrow \text{Kr} + \text{BrF}_6^+ \text{AsF}_6^- \]

Vibrational spectra and ¹⁹F nmr studies on all three cations XF₆⁺ and the ¹²⁹¹ Mössbauer spectrum of [IF₆][AsF₆] establish octahedral (O₆) symmetry as expected for species isoelectronic with SF₆, SeF₆ and TeF₆ respectively.

Attempts to prepare ClF₇ and BrF₇ by reacting the appropriate cation with NOF failed; instead the following reactions occurred:

\[ \text{ClF}_6^+ \text{PtF}_6^- + \text{NOF} \rightarrow \text{NO}^+ \text{PtF}_6^- + \text{ClF}_5 + \text{F}_2 \]

\[ \text{BrF}_6^+ \text{AsF}_6^- + 2\text{NOF} \rightarrow \text{NO}^+ \text{AsF}_6^- + \text{NO}^+ \text{BrF}_6^- + \text{F}_2 \]
As expected, the cations are extremely powerful oxidants, e.g.:

\[
\begin{align*}
O_2 + BrF_5^+AsF_6^- & \rightarrow O_2^+AsF_6^- + BrF_5 + \frac{1}{2}F_2 \\
Xe + BrF_5^+AsF_6^- & \rightarrow XeF^+AsF_6^- + BrF_5 \\
Rn + IF_6^+SbF_6^- & \rightarrow RnF^+SbF_6^- + IF_5
\end{align*}
\]

### 17.2.6 Halogen cations

It has been known for many years that iodine dissolves in strongly oxidizing solvents such as oleum to give bright blue paramagnetic solutions, but only in 1966 was this behaviour unambiguously shown to be due to the formation of the diiodine cation I\(_2^+\). (The production of similar brightly coloured solutions of S, Se and Te has already been discussed on pp. 664, 759.) The ionization energies of Br\(_2\) and Cl\(_2\), whilst greater than that for I\(_2\) (Table 17.17), are nevertheless smaller than for O\(_2\), which can likewise be oxidized to O\(_2^+\) (p. 616). Accordingly, compounds of the bright-red cationic species Br\(_2^+\) are now well established, but Cl\(_2^+\) is known only from its electronic band spectrum obtained in a low-pressure discharge tube. Some properties of the three diatomic cations X\(_2^+\) are compared with those of the parent halogen molecules X\(_2\) in Table 17.17; as expected, ionization reduces the interatomic distance and increases the vibration frequency (\(\nu \text{ cm}^{-1}\)) and force constant (\(k \text{ N m}^{-1}\)). The principal synthetic routes to crystalline compounds of Br\(_2^+\) and I\(_2^+\) have been either (a) the comproportionation of BrF\(_3\), BrF\(_5\) or IF\(_5\) with the stoichiometric amount of halogen in the presence of SbF\(_5\), or (b) the direct oxidation of the halogen by an excess of SbF\(_5\) or by SbF\(_5\) dissolved in SO\(_2\), e.g.:

\[
2I_2 + 5SbF_5 \xrightarrow{SO_2/20^\circ} 2[I_2]^+[Sb_2F_{11}]^- + SbF_3
\]

More recently, a simpler route has been devised which involves oxidation of Br\(_2\) or I\(_2\) with the peroxide S\(_2\)O\(_6\)F\(_2\) (p. 640) followed by solvolysis using an excess of SbF\(_5\), e.g.:

\[
Br_2 + \frac{1}{2}S_2O_6F_2 \xrightarrow{rt} \left(\frac{1}{2}Br_2 \text{ dissolved in BrSO}_3F\right) \xrightarrow{3SbF_5} [Br_2]^+[Sb_3F_{16}]^-
\]

The bright-red crystals of [Br\(_2\)]\(^+[Sb_3F_{16}]^-\) melt at 85.5°C to a cherry-red liquid. Dark-blue crystals of [I\(_2\)]\(^+[Sb_2F_{11}]^-\) melt sharply at 127°C and the corresponding blue solid [I\(_2\)]\(^+[Ta_2F_{11}]^-\) melts at 120°C. When solutions of I\(_2^+\) in HSO\(_3\)F are cooled below -60°C there is a dramatic colour change from deep blue to red as the cation dimerizes: 2I\(_2^+\) \(\rightleftharpoons\) I\(_4^{2+}\). There is a simultaneous drop in the paramagnetic susceptibility of the solution and in its electrical conductivity. The changes are rapid and reversible, the blue colour appearing again on warming.

During the past 20 y numerous other highly coloured halogen cations have been characterized by Raman spectroscopy, X-ray crystallography, and other techniques, as summarized in Table 17.18. Typical preparative routes involve direct oxidation of the halogen (a) in the absence of solvent, (b) in a solvent which is itself the oxidant (e.g. AsF\(_3\)) or (c) in a non-reactive solvent (e.g. SO\(_2\)). Some examples are listed below:

\[
\begin{align*}
\text{Cl}_2 + \text{ClF} + \text{AsF}_5 & \xrightarrow{-78^\circ} \text{Cl}_3^+\text{AsF}_6^- \\
\frac{3}{2}\text{Br}_2 + \text{O}_2^+\text{AsF}_6^- & \xrightarrow{} \text{Br}_3^+\text{AsF}_6^- + \text{O}_2
\end{align*}
\]

(a)[I₃][AlCl₄] is described as greenish-black needles, dark brown-red in thin sections.

\[4\text{Br}_2 + \text{BrF}_3 + 3\text{AsF}_5 \rightarrow 3\text{Br}_3^+\text{AsF}_6^- (\text{subl } 50\, ^\circ \text{C}, \text{decomp } 70\, ^\circ \text{C}) \]

\[3\text{I}_2 + 3\text{AsF}_5 \rightarrow 2\text{I}_3^+\text{AsF}_6^- + \text{AsF}_3 \]

\[3\text{I}_2 + \text{S}_2\text{O}_6\text{F}_2 \rightarrow 2\text{I}_3^+\text{SO}_3\text{F}^- (\text{mp } 101.5\, ^\circ \text{C}) \]

\[\text{I}_2 + \text{ICl} + \text{AlCl}_3 \rightarrow \text{I}_3^+\text{AlCl}_4^- (\text{mp } 45\, ^\circ \text{C}) \]

\[2\text{I}_2 + \text{ICl} + \text{AlCl}_3 \rightarrow \text{I}_5^+\text{AlCl}_4^- (\text{mp } 50\, ^\circ \text{C}) \]

\[7\text{I}_2 + \text{S}_2\text{O}_6\text{F}_2 \rightarrow 2\text{I}_7\text{SO}_3\text{F} (\text{mp } 90.5\, ^\circ \text{C}) \]

Other compounds that have been prepared⁹¹ include the dark-brown gold(III) complexes \[\text{Br}_3[\text{Au(SO}_3\text{F})_4] \] (decomp \( \sim 150\, ^\circ \text{C} \)) and \[\text{Br}_5[\text{Au(SO}_3\text{F})_4] \] (mp 65\, ^\circ \text{C}).

The triatomic cations \(X_3^+\) are nonlinear and thus isostructural with other 20-electron species such as \(XY_2^+\) (p. 839) and \(S\text{Cl}_2\) (p. 689). The contrast in bond lengths and angles between \(I_3^+\) (Fig. 17.15)⁹² and the linear 22-electron anion \(I_3^-\) (p. 836) is notable, as is its similarity with the isolectronic \(\text{Te}_3^{2^-}\) anion (p. 764). Likewise, \(\text{Br}_3\text{AsF}_6\) is isomorphous with \(I_3\text{AsF}_6\) and the non-linear cation has \(\text{Br-Br } 227.0\, \text{pm}\) and an angle of \(102.5\, ^\circ\) (⁹³) (cf. \(\text{Br}_3^-\), Table 17.15). The structures of the penta-atomic cations \(\text{Br}_5^+\) (²)⁹⁴ and \(\text{I}_5^+\) (³)⁹⁵ have been determined by X-ray analysis of their \(\text{AsF}_6^-\) salts and shown to have centrosymmetric \(C_{2h}\) symmetry like the

Figure 17.15  The structure of (a) the nonlinear \(I_3^+\) cation in \(I_3\text{AsF}_6\) and (b) the weaker cation–anion interactions along the chain (cf. Fig. 17.13). For comparison, the dimensions of (c) the linear 22-electron cation \(I_3^-\) and (d) the non-linear 20-electron cation \(\text{Te}_3^{2^-}\) are given. The data for this latter species refer to the compound \([\text{K(crypt)}]_2\text{Te}_3\cdot\text{en};\) in \(\text{K}_2\text{Te}_3\) itself, where there are stronger cation–anion interactions, the dimensions are \(r = 280\, \text{pm}\) and angle = 104.4°).
analogous cation $I_3Cl_2^+$ (1) (p. 841). The figures in parenthesis in (2) refer to the SbF$_6^-$ salt.

The black compound $I_7$SO$_3$F (mp 90.5°) was established as a local mp maximum in the phase diagram of the system $I_2$/S$_2$O$_6$F$_2$, together with the known compounds $I_5$SO$_3$F (mp 101.5°), ISO$_3$F (mp 50.2°), and I(SO$_3$F)$_3$ (mp 33.7°), but its structure has not been determined and there is at present no evidence for the presence of the discrete heptaatomic cation $I_7^+$ in the crystals.

17.2.7 Oxides of chlorine, bromine and iodine

Perhaps nowhere else are the chemical differences between the halogens so pronounced as in their binary compounds with oxygen. This stems partly from the factors that distinguish F from its heavier congenors (p. 804) and partly from the fact that oxygen is less electronegative than F but more electronegative than Cl, Br and I. The varying relative strengths of O–X bonds and the detailed redox properties of the halogens also ensure considerable diversity in stoichiometry, structure, thermal stability and chemical reactivity of the various species. The binary compounds between O and F have already been described (p. 638). About 25 further binary halogen oxide species are known, which vary from shock-sensitive liquids and short-lived free radicals to rather stable solids. It will be convenient to treat the 3 halogens separately though intercomparison of corresponding species is instructive and the chemistry is also, at times, related to that of the oxoacids (p. 853) and the halogen oxide fluorides (p. 875).

Oxides of chlorine

Despite their instability (or perhaps because of it) the oxides of chlorine have been much studied and some (such as Cl$_2$O and particularly ClO$_2$) find extensive industrial use. They have also assumed considerable importance in studies of the upper atmosphere because of the vulnerability of ozone in the stratosphere to destruction by the photolysis products of chlorofluorocarbons (p. 848). The compounds to be discussed are:

Cl$_2$O: a brownish-yellow gas at room temperature (or red-brown liquid and solid at lower temperatures) discovered in 1834; it explodes when heated or sparked.

Cl$_2$O$_3$: a dark-brown solid (1967) which explodes even below 0°.

ClO$_2$: a yellow paramagnetic gas (deep-red paramagnetic liquid and solid) discovered in 1811 by H. Davy; the liquid explodes above –40° and the gas at room temperature may explode at pressures greater than 50 mmHg (6.7 kPa); despite this more than half a million tonnes are made for industrial use each year in North America alone.

Cl$_2$O$_4$: a pale-yellow liquid (1970), ClOClO$_2$, which readily decomposes at room temperature into Cl$_2$, O$_2$, ClO$_2$ and Cl$_2$O$_6$.

---

97 Ref. 23, pp. 1361–86. The oxides of the halogens.

Cl₂O₆: a dark-red liquid (1843) which is in equilibrium with its monomer ClO₃ in the gas phase; it decomposes to ClO₂ and O₂.

Cl₂O₇: a colourless oily liquid (1900) which can be distilled under reduced pressure.

In addition, there are the short-lived radical ClO, the chlorine peroxide radical ClO(O (cf. OCIO above), and the tetroxide radical ClO₄ (p. 850).

Some physical and molecular properties are summarized in Table 17.19. All the compounds are endothermic, having large positive enthalpies and free energies of formation. Structural data are in Fig. 17.16. Cl₂O has $C_2v$ symmetry, as expected for a molecule with 20 valency-shell electrons; the dimensions indicate normal single bonds, and the bond angle can be compared with those for similar molecules such as OF₂, H₂O, SC₁₂, etc.

Chlorine dioxide, ClO₂, also has $C_2v$ symmetry but there are only 19 valency-shell electrons and this is reflected in the considerable shortening of the Cl–O bonds and the increase in the bond angle, which is only 1.7° less than in the 18-electron species SO₂ (p. 700). ClO₂ is an interesting example of an odd-electron molecule which is stable towards dimerization (cf. NO, p. 445); calculations suggest that the odd electron is delocalized throughout the molecule and this probably explains the reluctance to dimerize. Indeed, there is no evidence of dimerization even in the liquid or solid phases, or in solution. This contrasts with the precisely isoelectronic thionite ion SO₃⁻ which exists as dithionite, S₂O₄²⁻, albeit with a rather long S–S bond (p. 721). The trioxide ClO₃ is also predominantly dimeric in the condensed phase (see below) as probably is BrO₂ (p. 850).

The gaseous molecule of Cl₂O₇ has $C_2$ symmetry (Fig. 17.16) the ClO₃ groups being twisted 15° from the staggered ($C_{2v}$) configuration; the Cl–Oₐ bonds are also inclined...
at an angle of 4.7° to the three-fold axis of the ClO₃ groups and there is a substantial decrease from the (single-bonded) Cl–O₄ to the (multiple-bonded) Cl–O distance. A recent X-ray crystal structure analysis at −160° revealed a mixed-valence ionic compound [ClVIO₂]⁺[ClVIIIO₄]⁻ in which the angular ClO₂⁺ and tetrahedral ClO₄⁻ ions were arranged in a distorted CsCl-type structure.\(^{(100)}\) By contrast an X-ray examination of crystalline Cl₂O₆ at −70° revealed the \(\text{C}_2\) symmetry of Cl₂O₇ and found Cl–O₄ (av.) 141.6 pm.\(^{(99)}\) Much of the Cl₂O manufactured industrially is used to make hypochlorites, particularly Ca(OCl)₂, and it is an effective bleach for wood-pulp and textiles. Cl₂O is also used to prepare chloroisocyanurates (p. 324) and chlorinated solvents (via mixed chain reactions in which Cl and OCl are the chain-propagating species).\(^{(101)}\) Its reactions with inorganic reagents are summarized in the scheme opposite.

Gaseous mixtures of Cl₂O and NH₃ explode violently: the overall stoichiometry of the reaction can be represented as

\[
3\text{Cl}_2\text{O} + 10\text{NH}_3 \rightarrow 2\text{N}_2 + 6\text{NH}_4\text{Cl} + 3\text{H}_2\text{O}
\]

Chlorine dioxide, ClO₂, was the first oxide of chlorine to be discovered and is now manufactured on a massive scale for the bleaching of wood-pulp and for water treatment;\(^{(98,102)}\) however, because of its explosive character as a liquid or concentrated gas, it must be made at low concentrations where it is to be used. For this reason, production statistics can only be estimated, but it is known that its use in the US wood-pulp and paper industry increased tenfold from 7800 tonnes in 1955 to 78 800 tonnes in 1970; thereafter captive production for this purpose increased less rapidly but the total US production of this gas for all purposes reached 361 000 tonnes in 1990. Production in Canada paralleled this growth and was 200 000 tonnes in 1990. Prices in 1992 were in the range $1100–1800/tonne. Usually ClO₂ is prepared by reducing NaClO₃ with NaCl, HCl, SO₂ or MeOH in strongly acid solution; other reducing agents that have been used on a laboratory scale include oxalic acid, N₂O, EtOH and sugar. With Cl⁻ as reducing agent the formal reaction can be written:

\[
\text{ClO}_3^- + \text{Cl}^- + 2\text{H}^+ \rightarrow \text{ClO}_2 + \frac{1}{2}\text{Cl}_2 + \text{H}_2\text{O}
\]

\[\text{ClO}_3^- + \text{Cl}^- + 2\text{H}^+ \rightarrow \text{ClO}_2 + \frac{1}{2}\text{Cl}_2 + \text{H}_2\text{O}\]

\[\text{ClO}_3^- + \text{Cl}^- + 2\text{H}^+ \rightarrow \text{ClO}_2 + \frac{1}{2}\text{Cl}_2 + \text{H}_2\text{O}\]

\[\text{ClO}_3^- + \text{Cl}^- + 2\text{H}^+ \rightarrow \text{ClO}_2 + \frac{1}{2}\text{Cl}_2 + \text{H}_2\text{O}\]

\[\text{ClO}_3^- + \text{Cl}^- + 2\text{H}^+ \rightarrow \text{ClO}_2 + \frac{1}{2}\text{Cl}_2 + \text{H}_2\text{O}\]

\[\text{ClO}_3^- + \text{Cl}^- + 2\text{H}^+ \rightarrow \text{ClO}_2 + \frac{1}{2}\text{Cl}_2 + \text{H}_2\text{O}\]
Oxides of chlorine, bromine and iodine

Scheme  Some reactions of dichlorine monoxide. * [In addition AsCl3 → AsO2Cl; SbCl5 → SbO2Cl; VOCl3 → VO2Cl; TiCl4 → TiOCl2.]  

Contamination of the product with Cl₂ gas is not always undesirable but can be avoided by using SO₂:

\[ 2\text{ClO}_3^- + \text{SO}_2 \xrightarrow{\text{acid solution}} 2\text{ClO}_2 + \text{SO}_4^{2-} \]

On a laboratory scale reduction of KClO₃ with moist oxalic acid generates the gas suitably diluted with oxides of carbon:

\[ \text{ClO}_3^- + \frac{1}{2}\text{C}_2\text{O}_4^{2-} + 2\text{H}^+ \xrightarrow{} \text{ClO}_2 + \text{CO}_2 + \text{H}_2\text{O} \]

Samples of pure ClO₂ for measurement of physical properties can be obtained by chlorine reduction of silver chlorate at 90°C:

\[ 2\text{AgClO}_3 + \text{Cl}_2 \xrightarrow{} 2\text{ClO}_2 + \text{O}_2 + 2\text{AgCl} \]

Chlorine oxidation of sodium chlorite has also been used on both an industrial scale (by mixing concentrated aqueous solutions) or on a laboratory scale (by passing Cl₂/air through a column packed with the solid chlorite):

\[ 2\text{NaClO}_2 + \text{Cl}_2 \xrightarrow{} 2\text{ClO}_2 + 2\text{NaCl} \]

The production of ClO₂ obviously hinges on the redox properties of oxochlorine species (p. 853) and, indeed, the gas was originally obtained simply by the (extremely hazardous) disproportionation of chloric acid liberated by the action of concentrated sulfuric acid on a solid chlorate:

\[ 3\text{HClO}_3 \xrightarrow{} 2\text{ClO}_2 + \text{HClO}_4 + \text{H}_2\text{O} \]

ClO₂ is a strong oxidizing agent towards both organic and inorganic materials and it reacts readily with S, P, PX₃ and KBH₄. Some further reactions are in the scheme overleaf:

\[ \text{ClO}_2 \xrightarrow{hv} \text{ClO} + \text{O} \]

\[ \text{ClO} + \text{H}_2\text{O} \xrightarrow{} \text{H}_2\text{ClO}_2 \xrightarrow{\text{ClO}} \text{HCl} + \text{HClO}_3 \]

By contrast, alkaline solutions hydrolyse vigorously to a mixture of chlorite and chlorate (see scheme overleaf).
The photochemical and thermal decomposition of ClO₂ both begin by homolytic scission of a Cl–O bond:

\[ \text{ClO}_2 \xrightarrow{\Delta \text{ or } h\nu} \text{ClO} + \text{O}; \quad \Delta H_{298}^{\circ} = 278 \text{ kJ mol}^{-1} \]

Subsequent reactions depend on conditions. Ultraviolet photolysis of isolated molecules in an inert matrix yields the radicals ClO and ClOO. At room temperature, photolysis of dry gaseous ClO₂ yields Cl₂, O₂, and some ClO₃ which either dimerizes or is further photolysed to Cl₂ and O₂:

\[ \text{ClO}_2 + \text{O} \rightarrow \text{ClO}_3 \]
\[ \text{ClO} + \text{ClO} \rightarrow \text{Cl}_2 + \text{O}_2 \]
\[ 2\text{ClO}_3 \rightarrow \text{Cl}_2\text{O}_6 \]
\[ 2\text{ClO}_3 \rightarrow \text{Cl}_2 + 3\text{O}_2 \]

By contrast, photolysis of solid ClO₂ at -78°C produces some Cl₂O₃ as well as Cl₂O₆:

\[ \text{ClO}_2 + \text{ClO} \leftrightarrow \text{O} - \text{Cl} \cdots \text{Cl} - \text{O} \]

The ClO radical in particular is implicated in environmentally sensitive reactions which lead to depletion of ozone and oxygen atoms in the stratosphere.¹⁰³ Thus (as was first pointed out by M. J. Molina and F. S. Rowland in 1974¹⁰⁴) chlorofluorocarbons such as CFCl₃ and CF₂Cl₂, which have been increasingly used as aerosol spray propellants, refrigerants, solvents and plastic foaming agents (p. 304), have penetrated the stratosphere (10–50 km above the earth’s surface) where they are photolysed or react with electronically excited O(¹D) atoms to yield Cl atoms and chlorine oxides; this leads to the continuous removal of O₃ and O atoms via such reactions as:

\[ \text{Cl} + \text{O}_3 \rightarrow \text{ClO} + \text{O}_2 \]
\[ \text{ClO} + \text{O} \rightarrow \text{Cl} + \text{O}_2 \]

i.e. \[ \text{O} + \text{O}_3 \rightarrow 2\text{O}_2 \] plus regeneration of Cl

Depletion of O₃ results in an increased penetration of ultraviolet light with wavelengths in the range 290–320 nm which may in time effect changes in climate and perhaps lead also to an increased incidence of skin cancer in

humans. Because of these concerns, the alarming increase in global sales of chlorofluorocarbons, which grew 15-fold between 1948 and 1973, has since been drastically reduced as shown by the following illustrative figures for CFC-11 and CFC-12 (tonnes):

<table>
<thead>
<tr>
<th></th>
<th>1948</th>
<th>1973</th>
<th>1983</th>
</tr>
</thead>
<tbody>
<tr>
<td>CFC13 (CFC-11)</td>
<td>2,270</td>
<td>302,000</td>
<td>93,000</td>
</tr>
<tr>
<td>CF2Cl2 (CFC-12)</td>
<td>2,220</td>
<td>383,000</td>
<td>120,000</td>
</tr>
</tbody>
</table>

The decrease is continuing due to global adherence to the provisions of the Montreal (1989) and London (1990) Protocols, and it is hoped that the most deleterious CFCs will eventually be phased out completely. As a result of their work, Rowland and Molina were awarded the Nobel Prize for Chemistry for 1995 (together with P. Crutzen, who showed how NO and NO2 could similarly act as catalysts for the depletion of stratospheric ozone).

Several excellent accounts giving more details of the chemistry and meteorology involved are available.\(^{105-108}\)

The great importance of the short-lived C10 radical has stimulated numerous investigations of its synthesis and molecular properties. Several routes are now available to this species (some of which have already been indicated above):

(a) thermal decomposition of ClO2 or ClO3;
(b) decomposition of FCIO3 in an electric discharge;
(c) passage of a microwave or radio-frequency discharge through mixtures of Cl2 and O2;
(d) reactions of Cl atoms with ClO or O3 at 300 K;
(e) gas-phase photolysis of Cl2O, ClO2 or mixtures of Cl2 and O2.

It is an endothermic species with \(\Delta H^\circ_r(298 \text{ K}) = 101.8 \text{ kJ mol}^{-1}\), \(\Delta G^\circ_r(298 \text{ K}) = 98.1 \text{ kJ mol}^{-1}\), \(S^\circ(298 \text{ K}) = 226.5 \text{ J K}^{-1} \text{ mol}^{-1}\). The interatomic distance Cl–O is 156.9 pm, its dipole moment is 1.24 D, and the bond dissociation energy \(D_0\) is 264.9 kJ mol\(^{-1}\) (cf. BrO p. 851, IO p. 853).

Chlorine perchlorate ClOClO3 is made by the following low-temperature reaction:

\[
\text{MCIO}_4 + \text{ClO}_3\text{OSO}_2\text{F} \rightarrow \text{MSO}_3\text{F} + \text{ClOClO}_3
\]

(M = Cs, NO2)

Little is known of its structure and properties; it is even less stable than ClO2 and decomposes at room temperature to Cl2, O2 and Cl2O6.

Dichlorine hexoxide, Cl2O6, is best made by ozonolysis of ClO2:

\[
2\text{ClO}_2 + 2\text{O}_3 \rightarrow \text{Cl}_2\text{O}_6 + 2\text{O}_2
\]

The dark-red liquid freezes to a solid which is yellow at \(-180^\circ\text{C}\). The structure in the liquid phase is not known but two possibilities have been considered. The Cl–Cl linked structure is superficially attractive as the product of dimerization of the paramagnetic gaseous species ClO3, but magnetic susceptibility studies of the equilibrium Cl2O6 \(\rightleftharpoons 2\text{ClO}_3\) in the liquid phase were flawed by the subsequent finding that there was no esr signal from ClO3 and that ClO2 (as an impurity) was the sole paramagnetic species present. Accordingly, the much-quoted value of 7.24 kJ mol\(^{-1}\) for the derived heat of dimerization is without foundation. The alternative oxygen-bridged dimer, though requiring more electronic and geometric rearrangement of the presumed pyramidal \(\text{ClO}_3\) monomers, is rather closer to the ionic structure \([\text{ClO}_2]^+\text{ClO}_4^-\) which has been established by X-ray analysis (p. 846) of the solid. Cl2O6 does, in fact, frequently behave as chloryl perchlorate in its reactions though experience with N2O4 as “nitrosyl nitrate” (p. 455) engenders caution in attempting to deduce a geometrical structure from chemical reactions (cf. however, diborane, p. 165).

---

Hydrolysis of Cl₂O₆ gives a mixture of chloric and perchloric acids, whereas anhydrous HF sets up an equilibrium:

\[
\begin{align*}
\text{Cl}_2\text{O}_6 + \text{H}_2\text{O} & \rightarrow \text{HOCIO}_2 + \text{HClO}_4 \\
\text{Cl}_2\text{O}_6 + \text{HF} & \rightleftharpoons \text{FCIO}_2 + \text{HClO}_4
\end{align*}
\]

Nitrogen oxides and their derivatives displace ClO₂ to form nitrosyl and nitril perchlorates. These and other reactions are summarized in the scheme below.

Dichlorine heptoxide, Cl₂O₇, is the anhydride of perchloric acid (p. 865) and is conveniently obtained by careful dehydration of HClO₄ with H₃PO₄ at -10°C followed by cautious low-pressure distillation at -35°C and 1 mmHg. The compound is a shock-sensitive oily liquid with physical properties and structure as already described (p. 845). Cl₂O₇ is less reactive than the lower oxides of chlorine and does not ignite organic materials at room temperature. Dissolution in water or aqueous alkalis regenerates perchloric acid and perchlorates respectively. Thermal decomposition (which can be explosive) is initiated by rupture of a Cl–O₂⁺ bond, the activation energy being \(\sim 135 \text{ kJ mol}^{-1}\):

\[
\text{Cl}_2\text{O}_7 \xrightarrow{\Delta} \text{ClO}_3 + \text{ClO}_4
\]

**Oxides of bromine**

The oxides of Br are less numerous, far less studied, and much less well characterized than the ten oxide species of chlorine discussed in the preceding section. The reasonably well established compounds are listed below.

Br₂O: a dark-brown solid moderately stable at -60°C (mp -17.5°C with decomposition), prepared by reaction of Br₂ vapour on HgO (cf. Cl₂O p. 846) or better, by low-temperature vacuum decomposition of BrO₂. The molecule has \(C_{2v}\) symmetry in both the solid and vapour phase with Br–O 185 ± 1 pm and angle BrOBr 112 ± 2° as determined by EXAFS (extended X-ray absorption fine structure).\(^{109}\) It oxidizes I₂ to I₂O₅, benzene to 1,4-quinone, and yields OBr⁻ in alkaline solution.

“BrO₂”^+: a pale yellow crystalline solid formed quantitatively by low-temperature ozonolysis of Br₂O.

\(^{1}\) Ozonolysis of Br₂ at 0°C yields white, poorly characterized solids which, depending on the conditions used, have compositions close to Br₂O₅, Br₃O₈, and BrO₃; no structural data are available.
Oxides of chlorine, bromine and iodine

\[
\text{Br}_2 + 4 \text{O}_3 \xrightarrow{\text{CF}_3\text{Cl}^{-78^\circ\text{C}}\text{Br}_2 + 4 \text{O}_2}
\]

The structure has recently been shown by EXAFS to be bromine perbromate \(\text{BrOBrO}_3\) with \(\text{Br}^-\text{O} 186.2\text{ pm}, \text{Br}^{\text{VII}}\text{O} 160.5\text{ pm}\) and angle \(\text{BrOBr} 110^\circ\text{3}\text{'}\);\(^{(110)}\) (cf. \(\text{ClOClO}_3\) and \(\text{BrOC}_1\text{O}_3\)). \(\text{BrOBrO}_3\) is thermally unstable above \(-40^\circ\text{C}\) and decomposes violently to the elements at \(0^\circ\text{C}\); slower warming yields \(\text{BrO}_2\) (see above). Alkaline hydrolysis leads to disproportionation:

\[
6\text{BrO}_2 + 6\text{OH}^- \rightarrow 5\text{BrO}_3^- + \text{Br}^- + 3\text{H}_2\text{O}
\]

Reaction with \(\text{F}_2\) yields \(\text{FBrO}_2\) and with \(\text{N}_2\text{O}_4\) yields \(\text{NO}_2^-\text{[Br(NO}_3\text{)]}^\text{2}^-\).

\(\text{Br}_2\text{O}_3\): an orange crystalline solid very recently isolated at \(-90^\circ\) from \(\text{CH}_2\text{Cl}_2\) solution after ozonization of \(\text{Br}_2\) in \(\text{CFCl}_3\). It decomposes above \(-40^\circ\), detonates if warmed rapidly to \(0^\circ\), and was shown by X-ray analysis to be \(\text{syn-BrOBrO}_2\) with \(\text{Br}^\text{I}\text{O} 184.5\text{ pm}, \text{Br}^{\text{V}}\text{O} 161.3\text{ pm}\) and angle \(\text{BrOBr} 111.6^\circ\);\(^{(111)}\) It is thus, formally, the anhydride of hypobromous and bromic acids.

In addition to these compounds the unstable monomeric radicals \(\text{BrO}, \text{BrO}_2\) and \(\text{BrO}_3\) have been made by \(\gamma\)-radiolysis or flash photolysis of the anions \(\text{OB}^-, \text{BrO}^-\) and \(\text{BrO}_3^-\). For \(\text{BrO}\) the interatomic distance is 172.1 pm, the dipole moment 1.55 D, and the thermodynamic properties \(\Delta H^\circ_\text{f}(298 K) 125.8\text{ kJ mol}^{-1}, \Delta G^\circ_\text{f}(298 K) 108.2\text{ kJ mol}^{-1}\) and \(\Delta S^\circ(298 K) 237.4\text{ J K}^{-1}\text{ mol}^{-1}\). Most recently\(^{(112)}\) it has been shown that flash pyrolysis at \(800\text{–}1000^\circ\text{C}\) of a mixture containing \(\text{Br}_2/\text{O}_2/\text{Ar}\) yields bromine superoxide, \([\text{BrOO}]^\text{+}\), which can be trapped at \(12\text{K}\) and shown by ir-and uv-spectroscopy to be non-linear. Irradiation of this species at 254 nm results in isomerization to bromine dioxide, \([\text{OBrO}]^\text{+}\), which is also non-linear (angle \(~110^\circ\)) and which can be reconverted to the superoxide by irradiating the matrix at wavelengths greater than 360 nm.

Oxides of iodine

Iodine forms the most stable oxides of the halogens and \(\text{I}_2\text{O}_3\) was made (independently) by J. L. Gay Lussac and H. Davy in 1813. However, despite this venerable history the structure of the compound was not determined unambiguously until 1970. It is most conveniently prepared by dehydrating iodic acid (p. 863) at \(200^\circ\text{C}\) in a stream of dry air but it also results from the direct oxidation of \(\text{I}_2\) with oxygen in a glow discharge. The structure (Fig. 17.17) features molecular units of \(\text{O}_3\text{IOIO}_2\) formed by joining two pyramidal \(\text{IO}_3\) groups at a common oxygen. The bridging \(1\text{-O}\) distances correspond to single bonds, whereas the terminal \(1\text{-O}\) distances are substantially shorter.\(^{(113)}\) There are also appreciable intermolecular interactions which join the molecular units into cross-linked chains; this gives each iodine pseudo-fivefold coordination, the sixth position of the distorted

---

octahedron presumably being occupied by the lone-pair of electrons on the iodine atom.

$I_2O_5$ forms white, hygroscopic, thermodynamically stable crystals: $\Delta H^\circ = -158.1$ kJ mol$^{-1}$, $d$ 4.980 g cm$^{-3}$. The compound is very soluble in water, reforming the parent acid $HIO_3$. So great is the affinity for water that commercial "$I_2O_5$" consists almost entirely of $H_3O_8$, i.e. $I_2O_5.HIO_3$. The interrelations between these compounds and the rather less stable oxides $I_4O_9$ and $I_2O_4$ are shown in the scheme below. $I_4O_9$ is a hygroscopic yellow powder which decomposes to $I_2O_5$ when heated above 75°C; $I_2O_4$ forms diamagnetic lemon-yellow crystals ($d$ 4.2 g cm$^{-3}$) which start to decompose above 85°C and which rapidly yield $I_2O_5$ at 135°C:

$$2I_4O_9 \xrightarrow{75^\circ} 3I_2O_5 + I_2 + \frac{3}{2}O_2$$
$$5I_2O_4 \xrightarrow{135^\circ} 4I_2O_5 + I_2$$

The structure of these oxides are unknown but $I_4O_9$ has been formulated as $I^{7+}(I[V^O_3])_3$ and $I_2O_4$ as $[IO]^+[IO_3]^-$. $I_2O_5$ is notable in being one of the few chemicals that will oxidize CO rapidly and completely at room temperature:

$$5CO + I_2O_5 \rightarrow I_2 + 5CO_2$$

The reaction forms the basis of a useful analytical method for determining the concentration of CO in the atmosphere or in other gaseous mixtures. $I_2O_5$ also oxidizes NO, $C_2H_4$ and $H_2S$. $SO_3$ and $S_2O_8F_2$ yield iodyl salts, $[IO_2]^+$, whereas concentrated $H_2SO_4$ and related acids reduce $I_2O_5$ to iodosyl derivatives, $[IO]^+$. Fluorination of $I_2O_5$ with $F_2$, $BrF_3$, $SF_4$ or $FClO_2$ yields $IF_5$ which itself reacts with the oxide to give $OIF_3$. It is also convenient to note here other related compounds which have recently been characterized: $I(O_{TeF_5})_3$, $O=I(O_{TeF_5})_3$, $I(O_{TeF_5})_5$, $[I(O_{TeF_5})_4]^-$ and $[O=I(O_{TeF_5})_4]^-$(114) all have the expected structures (cf. pp. 688, 777, 899, 904).

**Scheme:** Preparation of reactions of iodine oxides.
§17.2.8 Oxoacids and oxoacid salts

In addition to the stable I$_2$O$_5$ and moderately stable I$_2$O$_3$ and I$_2$O$_4$, several short-lived radicals have been detected and characterized during γ-radiolysis and flash photolysis of iodates in aqueous alkali:

$$\text{IO}_3^- \xrightarrow{\text{hv}} \text{IO}_2 + \text{O}^-$$
$$\text{IO}_3^- + \text{O}^- \xrightarrow{\text{H}_2\text{O}} \text{IO}_3 + 2\text{OH}^-$$
$$\text{IO}_3^- + \text{IO}_2 \longrightarrow \text{IO} + \text{IO}_4^-$$

The endothermic radical IO has also been studied in the gas phase: the interatomic distance is 186.7 pm and the bond dissociation energy $\sim 175 \pm 20 \text{kJ mol}^{-1}$. It thus appears that, although the higher oxides of iodine are much more stable than any oxide of Cl or Br, nevertheless, IO is much less stable than ClO (p. 849) or BrO (p. 851). Its enthalpy of formation and other thermodynamic properties are: $\Delta H_f^{\circ}(298 \text{ K}) = 175.1 \text{kJ mol}^{-1}$, $\Delta G_f^{\circ}(298 \text{ K}) = 149.8 \text{kJ mol}^{-1}$, $S^{\circ}(298 \text{ K}) = 245.5 \text{J K}^{-1}\text{mol}^{-1}$.

17.2.8 Oxoacids and oxoacid salts

General considerations

The preparative chemistry and technical applications of the halogen oxoacids and their salts have been actively pursued and developed for over two centuries (p. 790) and can now be very satisfactorily systematized in terms of general thermodynamic principles. The thermodynamic data are codified in the form of reduction potentials and equilibrium constants and these, coupled with the relative rates of competing reactions, allow a vast range of aqueous solution chemistry of the halogens to be interrelated. Thus, although all the halogens are to some extent soluble in water, extensive disproportionation reactions and/or mutual redox reactions with the solvent can occur to an extent that depends crucially on conditions such as pH and concentration (which influence the thermodynamic variables) and the presence of catalysts or light quanta (which can overcome kinetic activation barriers). Fluorine is again exceptional and, because of its very high standard reduction potential, $E^\circ(\frac{1}{2} \text{F}_2/\text{F}^-) + 2.866 \text{V}$, reacts very strongly with water at all values of pH (p. 629). Its inability to achieve formal oxidation states higher than +1 also limits the available oxoacids to hypofluorous acid HOF (p. 856). Numerous other oxoacids are known for the heavier halogens (Table 17.20) though most cannot be isolated pure and are stable only in aqueous solution or in the form of their salts. Anhydrous perchloric acid (HClO$_4$), iodic acid (HIO$_3$), paraperiodic acid (H$_5$IO$_6$) and metaperiodic acid (HIO$_4$) have been isolated as pure compounds.

The standard reduction potentials for Cl, Br and I species in acid and in alkaline aqueous solutions are summarized in Fig. 17.18. The couples $\frac{1}{2}X_2/X^-$ are independent of pH and, together with the value for F$_2$, indicate a steadily decreasing oxidizing power of the halogens in the sequence F$_2$(+2.866 V) > Cl$_2$(+1.358 V) > Br$_2$(+1.066 V) > I$_2$(+0.536V). $^{(a)}$Stable only in aqueous solution.
$^{(b)}$HOF also known (p. 856).
Figure 17.18  Standard reduction potentials for Cl, Br and I species in acid and alkaline solutions. For At see p. 886.
that $E^\circ\left(\frac{1}{2}\text{O}_2/\text{H}_2\text{O}\right) = 1.229$ V these values indicate that the potentials for the reaction:

$$\text{X}_2 + \text{H}_2\text{O} \rightarrow \frac{1}{2}\text{O}_2 + 2\text{H}^+ + 2\text{X}^-$$

decrease in the sequence $\text{F}_2(+1.637 \text{ V}) > \text{Cl}_2(+0.129 \text{ V}) > \text{Br}_2(-0.163 \text{ V}) > \text{I}_2(-0.693 \text{ V})$. As already mentioned, this implies that $\text{F}_2$ will oxidize water to $\text{O}_2$ and the same should happen with chlorine in the absence of sluggish kinetic factors. In fact, were it not for the further fortunate circumstance of an appreciably higher overvoltage for oxygen, chlorine would not be evolved during the electrolysis of aqueous chloride solutions at low current densities: the phenomenon is clearly of great technical importance for the industrial preparation of chlorine by electrolysis of brines (p. 798).

For all other couples in Fig. 17.18 (i.e. for all couples involving oxygenated species) an increase in pH causes a dramatic reduction in $E^\circ$ as expected (p. 435). For example, in acid solution the couple $\text{BrO}_3^-/\frac{1}{2}\text{Br}_2(1)$ refers to the equilibrium reaction

$$\text{BrO}_3^- + 6\text{H}^+ + 5\text{e}^- \rightleftharpoons \frac{1}{2}\text{Br}_2 + 3\text{H}_2\text{O}; \quad (E^\circ 1.478 \text{ V})$$

The equilibrium constant clearly depends on the sixth power of the hydrogen-ion concentration and, when this is reduced (say to $10^{-14}$ in 1 M alkali), the potential is likewise diminished by an amount $\sim (RT/nF)\log[H^+]^6$, i.e. by $ca. (0.0592/5) \times 14 \times 6 \approx 0.99$ V. In agreement with this (Fig. 17.18) the potential at pH 14 is 0.485 V (calc $\sim 0.49$ V) for the reaction

$$\text{BrO}_3^- + 3\text{H}_2\text{O} + 5\text{e}^- \rightleftharpoons \frac{1}{2}\text{Br}_2(1) + 6\text{OH}^-$$

The data in Fig. 17.18 are presented in graphical form in Fig. 17.19 which shows the volt-equivalent diagrams (p. 436) for acid and alkaline solutions. It is clear from these that $\text{Cl}_2$ and $\text{Br}_2$ are much more stable towards disproportionation in acid solution (concave angle at $\text{X}_2$) than in alkaline solutions (convex angle). In terms of

**Figure 17.19** Volt-equivalent diagrams for Cl, Br and I.
equilibrium constants:

**acid solution**:

\[ X_2 + H_2O \rightleftharpoons HOX + H^+ + X^-; \]

\[ K_{ac} = \frac{[HOX][H^+][X^-]}{[X_2]} \]

**alkaline solution**:

\[ X_2 + 2OH^- \rightleftharpoons OX^- + H_2O + X^-; \]

\[ K_{alk} = \frac{[OX^-][X^-]}{[X_2][OH^-]^2} \]

For Cl₂, Br₂ and I₂, \( K_{ac} \) is \( 4.2 \times 10^{-4}, 7.2 \times 10^{-9} \) and \( 2.0 \times 10^{-13} \) mol² l⁻¹ respectively, thereby favouring the free halogens, whereas \( K_{alk} \) is \( 7.5 \times 10^{13}, 2.0 \times 10^8 \) and 30 mol⁻¹ l⁻¹ respectively, indicating a tendency to disproportionation which is overwhelming for Cl₂ but progressively less pronounced for Br₂ and I₂. In actuality the situation is somewhat more complicated because of the tendency of the hypohalite ions themselves to disproportionate further to produce the corresponding halite ions:

\[ 3XO^- \rightleftharpoons 2X^- + XO_3^- \]

The equilibrium constant for this reaction is very favourable in each case: \( 10^{27} \) for ClO⁻, \( 10^{15} \) for BrO⁻, and \( 10^{20} \) for IO⁻. However, particularly in the case of ClO⁻, the rate of disproportionation is slow at room temperature and only becomes appreciable above 70°. Similarly, the disproportionation

\[ 4ClO_3^- \rightleftharpoons Cl^- + 3ClO_4^- \]

has an equilibrium constant of \( 10^{20} \) but the reaction is very slow even at 100°. By contrast, as indicated by the concavity of the volt-equivalent curve at BrO₃⁻ and IO₃⁻ (Fig. 17.19), the bromate and iodate ions are stable with respect to disproportionation (in both acid and alkaline solutions), e.g.:

\[ 7IO_3^- + 9H_2O + 7H^+ \rightleftharpoons I_2 + 5H_3IO_6; \]

\[ K = 10^{-85} \text{ mol}^{-8} \text{ l}^8 \]

\[ 4IO_3^- + 3OH^- + 3H_2O \rightleftharpoons I^- + 3H_3IO_6^{2-}; \]

\[ K = 10^{-44} \text{ mol}^{-3} \text{ l}^3 \]

More detailed consideration of these various equilibria and other redox reactions of the halogen oxoacids will be found under the separate headings below. As expected, the rates of redox reactions of the halogen oxanions will depend, sometimes crucially, on the precise conditions used. However, as a very broad generalization, they tend to become progressively faster as the oxidation state of the halogen decreases, i.e.:

\[ ClO_4^- < ClO_3^- < ClO_2^- \ll ClO^- \approx Cl_2; \]

\[ BrO_4^- < BrO_3^- < BrO^- \approx Br_2; \]

\[ IO_4^- < IO_3^- < I_2; \text{ and } ClO_4^- < BrO_4^- < IO_4^- . \]

The strengths of the monobasic acids increase rapidly with increase in oxidation state of the halogen in accordance with Pauling’s rules (p. 50). For example, approximate values of \( pK_a \) are: HOCI 7.52, HOClO 1.94, HOClO₂ 3, HOClO₃ 10. The \( pK_a \) values of related acids increase in the sequence Cl < Br < I.

**Hypohalous acids, HOX, and hypohalites, XO⁻**

Hypofluorous acid is the most recent of the halogen oxoacids to be prepared. Traces were obtained in 1968 by photolysis of a mixture of F₂ and H₂O in a matrix of solid N₂ at 14–20 K but weighable amounts of the compound were first obtained by M. H. Studier and E. H. Appelman in 1971 by the fluorination of ice:

\[ F_2 + H_2O \xrightarrow{-40°C} HOF + HF \]

The isolation of HOF depends on removing it rapidly from the reaction zone so that it is prevented from reacting further with HF, F₂ or H₂O (see below). The method used was to recirculate F₂ at \( \sim 100 \) mmHg through a Kel-F U-tube filled with moistened Räschig rings cut from Teflon “spaghetti” tubing (Kel-F is polymerized chlorotrifluoroethene; Teflon is polymerized tetrafluoroethene). The U-tube was held at about \(-40°C\) and the effluent was passed through U-tubes cooled to \(-50°\) and \(-79°\) to

---

remove water and HF, and, finally, through a U-tube at −183° to trap the HOF. The use of the −50° trap was found to be critical because without it all of the HOF was caught in the −79° with the \( \text{H}_2\text{O} \), from which it could not be isolated because of subsequent reaction.

HOF is a white solid which melts at −117° to a pale-yellow liquid. Its bp (extrap) is somewhat below room temperature and its volatility is thus comparable to that of HF with which it is always slightly contaminated. Spectroscopic data establish a nonlinear structure with \( \text{H} - \text{O} \) 96.4 pm, \( \text{O} - \text{F} \) 144.2 pm, and bond angle \( \text{H} - \text{O} - \text{F} \) 97.2°: this is the smallest known bond angle at an unrestricted O atom (cf. \( \text{H} - \text{O} - \text{H} \) 104.7°, \( \text{F} - \text{O} - \text{F} \) 103.2°). It has been suggested that this arises in part from electrostatic attraction of the 2 terminal atoms, since nmr data lead to a charge of \( -0.5e \) on H and \( -0.5e \) on F. The negative charge on F is intermediate between those estimated for F in HF and OF\(_2\), and this emphasizes the strictly formal nature of the +1 oxidation state for F in HOF. Subsequently, the crystal structure of HOF was determined at −160° in an experimental tour de force. The dimensions were similar to those found for the gaseous molecule except for the expected artefact of a slightly shorter \( \text{H} - \text{O} \) distance due to the X-ray method (\( \text{H} - \text{O} \) 0.78 pm, \( \text{O} - \text{F} \) 144.2 pm, angle HOF 101°). The molecules are arranged in chains along a screw axis parallel to the \( b \) axis of the crystal as a result of almost linear O−H⋯O bonds (angle 163°, O⋯O 289.5 pm).

The most prominent chemical property of HOF is its instability. It decomposes spontaneously (sometimes explosively) to HF and \( \text{O}_2 \) with a half-life of ca. 30 min in a Teflon apparatus at room temperature and 100 mmHg. It reacts rapidly with water to produce HF, \( \text{H}_2\text{O}_2 \) and \( \text{O}_2 \); in dilute aqueous acid \( \text{H}_2\text{O}_2 \) is the predominant product whereas in alkaline solution \( \text{O}_2 \) is the principal O-containing product. The kinetics of these processes have been studied and, by use of \(^{18}\text{O}\)-enriched \( \text{H}_2\text{O}_2 \), it has been shown, uniquely, that the \( \text{O}_2 \) formed in the reaction, \([\text{HOF} + \text{H}_2\text{O}_2 \rightarrow \text{O}_2 + \text{HF} + \text{H}_2\text{O}]\), contains a substantial amount of oxygen from the HOF.

HOF reacts with HF to reverse the equilibrium used in its preparation. It does not dehydrate to its formal anhydride OF\(_2\) but in the presence of \( \text{H}_2\text{O} \) it reacts with F\(_2\) to form this species.

\[
\text{F}_2 + \text{HOF} \rightarrow \text{OF}_2 + \text{HF}
\]

This reaction does not occur in the gas phase, however, in the absence of \( \text{H}_2\text{O} \).

By contrast with the elusive though isolable HOF, the history of HOCl goes back over two centuries to the earliest experiments of C. W. Scheele with Cl\(_2\) in 1774 (p. 792), and the bleaching and sterilizing action of hypochlorites have long been used both industrially and domestically. HOCl, HOBr and HOI are all highly reactive, relatively unstable compounds that are known primarily in aqueous solutions. The most convenient preparation of such solutions is by perturbing the hydrolytic disproportionation equilibrium (p. 856):

\[
\text{X}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}^+ + \text{X}^- + \text{HOX}
\]

by addition of HgO or Ag\(_2\)O so as to remove the halide ions. On an industrial scale, aqueous solutions of HOCl (containing Cl\(^-\)) are readily prepared by reacting Cl\(_2\) with aqueous alkali. With strong bases \([\text{NaOH, Ca(OH)}_2]\) the reaction proceeds via the intermediate formation of hypochlorite, but this intermediate product is not formed with weaker bases such as NaHCO\(_3\) or CaCO\(_3\):

\[
\text{Cl}_2 + 2\text{OH}^- \rightarrow \text{aq} \left[ \text{ClO}^- + \text{Cl}^- + \text{H}_2\text{O} \right]
\]

\[
\text{Cl}_2 \rightarrow 2\text{HOCl} + 2\text{Cl}^-
\]

Chloride-free solutions (up to 5 M concentration) can be made by treating Cl\(_2\)O with water at 0° or industrially by passing Cl\(_2\)O gas into water. In fact, concentrated solutions of HOCl also contain appreciable amounts of Cl\(_2\)O which can form a

\[\text{Cl}_2 \]
The Halogens: Fluorine, Chlorine, Bromine, Iodine and Astatine

Separate layer and which is probably the source of the yellow colour of such solutions:

$$2\text{HOCl(aq)} \rightleftharpoons \text{Cl}_2\text{O(aq)} + \text{H}_2\text{O(l)};$$

$$K(0^\circ\text{C}) = 3.55 \times 10^{-3}\text{mol}^{-1}\text{l}$$

Organic solutions can be obtained in high yield by extracting HOCl from Cl$^-$-containing aqueous solutions into polar solvents such as ketones, nitriles or esters. Electrodialysis using semipermeable membranes affords an alternative route.

Solutions of the corresponding hypohalites can be made by the rapid disproportionation of the individual halogens in cold alkaline solutions (p. 856):

$$\text{X}_2 + 2\text{OH}^- \rightleftharpoons \text{X}^- + \text{OX}^- + \text{H}_2\text{O}$$

Such solutions are necessarily contaminated with halide ions and with the products of any subsequent decomposition of the hypohalite anions themselves. Alternative routes are the electrochemical oxidation of halides in cold dilute solutions or the chemical oxidation of bromides and iodides:

$$\text{X}^- + \text{OCl}^- \rightarrow \text{OX}^- + \text{Cl}^- \quad (\text{X} = \text{Br, I})$$

$$\text{I}^- + \text{OBr}^- \rightarrow \text{OI}^- + \text{Br}^-$$

Hypochlorites can also be made by careful neutralization of aqueous solutions of hypochlorous acid or Cl$_2$O.

The most stable solid hypochlorites are those of Li, Ca, Sr and Ba (see below). NaOCl has only poor stability and cannot be isolated pure; KOC1 is known only in solution, Mg yields a basic hypochlorite and impure Ag and Zn hypochlorites have been reported. Hydrated salts are also known. Solid, yellow, hydrated hypobromites NaOBr$_x$H$_2$O ($x = 5, 7$) and KOB$_r$3H$_2$O can be crystallized from solutions obtained by adding Br$_2$ to cold conc solutions of MOH but the compounds decompose above 0°C. No solid metal hypoiodites have yet been isolated.

HOCI is more stable than HOBr and HO1 and its microwave spectrum in the gas phase confirms the expected nonlinear geometry with H–O 97 pm, O–Cl 169.3 pm, and angle H–O–Cl $103 \pm 3^\circ$ (cf. HOF, p. 857). All three hypohalous acids are weak and solutions of their salts are therefore alkaline since the equilibrium

$$\text{OX}^- + \text{H}_2\text{O} \rightleftharpoons \text{HOX} + \text{OH}^-$$

lies well to the right. Except at high pH, hypohalite solutions contain significant amounts of the undissociated acid. Approximate values for the acid dissociation constants $K_a$ at room temperature are HOCl $2.9 \times 10^{-8}$, HOBr $5 \times 10^{-9}$, HOI $\sim 10^{-11}$: these values are close to those of many $\alpha$-aminoacids and may also be compared with carbonic acid $K_a 4.3 \times 10^{-7}$, which is some 10 times stronger than HOCl, and phenol, which has $K_a 1.3 \times 10^{-10}$.

The manner and rate of decomposition of hypohalous acids (and hypohalite ions) in solution are much influenced by the concentration, pH and temperature of the solutions, by the presence or absence of salts which can act as catalysts, promotors or activators, and by light quanta. The main competing modes of decomposition are:

$$2\text{HOX} \rightarrow 2\text{H}^+ + 2\text{X}^- + \text{O}_2$$

(or $2\text{OX}^- \rightarrow 2\text{X}^- + \text{O}_2$)

and

$$3\text{HOX} \rightarrow 3\text{H}^+ + 2\text{X}^- + \text{XO}_3^-$$

(or $3\text{OX}^- \rightarrow 2\text{X}^- + \text{XO}_3^-$)

The acids decompose more readily than the anions so hypohalites are stabilized in basic solutions. The stability of the anions diminishes in the sequence ClO$^-$ > BrO$^-$ > IO$^-$. Hypochlorites are amongst the strongest of the more common oxidizing agents and they react with inorganic species, usually by the net transfer of an O atom. Kinetic studies suggest that the oxidizing agent can be either HOCI or OCl$^-$ in a given reaction, but rarely both simultaneously. Some typical examples are in Table 17.21. Hypochlorites react with ammonia and organic amino compounds to form chloramines. The characteristic “chlorine” odour of water that has been sterilized with hypochlorite is, in fact, due to chloramines produced from attack on bacteria. By contrast, hypobromites
oxidize amines quantitatively to $N_2$, a reaction that is exploited in the analysis of urea:

$$(NH_2)_2CO + 3OB^- + 2OH^- \rightarrow N_2 + CO_3^{2-} + 3Br^- + 3H_2O$$

Other uses of hypohalous acids and hypohalites are described in the Panel.

This section concludes with a reminder that, in addition to the hypohalous acids HOX and metal hypohalites $M(OX)_n$, various covalent (molecular) hypohalites are known. Hypochlorites are summarized in Table 17.22. All are volatile liquids or gases at room temperature and are discussed elsewhere (see Index). Organic hypohalites are unstable and rapidly expel $HX$ or $RX$ to form the corresponding aldehyde or ketone:

$$ROH + HOX \rightarrow ROX + H_2O$$

$$RCH_2OX \rightarrow RCHO +HX$$

$$RR'CHOX \rightarrow RR'C=O + HX$$

$$RR'R''COX \rightarrow RR'C=O + R''X \quad \text{hv}$$

Some Uses of Hypohalous Acids and Hypohalites

In addition to the applications indicated on p. 858, hypohalous acids are useful halogenating agents for both aromatic and aliphatic compounds. HOBr and HOI are usually generated in situ. The ease of aromatic halogenation increases in the sequence \( \text{OCI}^- < \text{OBr}^- < \text{OI}^- \) and is facilitated by salts of Pb or Ag. Another well-known reaction of hypohalites is their cleavage of methyl ketones to form carboxylates and haloform:

\[
\text{RCOCH}_3 + 3\text{OX}^- \longrightarrow \text{RCO}_2^- + 2\text{OH}^- + \text{CH}_3\text{X}
\]

This is the basis of the iodoform test for the CH\(_3\)CO group. In addition to these reactions there is considerable industrial use for HOCI and hypochlorites in the manufacture of hydrazine (p. 427), chlorhydrins and \(\alpha\)-glycols:

\[
\begin{align*}
\text{Cl}_2 + \text{H}_2\text{O} & \rightleftharpoons \text{HCl} + \text{HOCl} \\
\text{C} & \text{C} \quad \text{H} \quad \text{OH} \\
\text{Cl} & \text{HCl} \\
\text{HO} & \text{OH} \\
\text{C} & \text{C} \\
\text{HO} & \text{OH} \\
\text{Cl} & \\
\text{Cl} & \text{C} \\
\text{OH} \quad \text{Cl} & \text{OH} \\
\text{HCl} & \text{HCl} \\
\end{align*}
\]

Chlorhydrin \(\alpha\)-glycol

By far the largest tonnage of hypochlorites is used for bleaching and sterilizing. “Liquid bleach” is an alkaline solution of NaOCl (pH > 11); domestic bleaches have about 5% “available chlorine” content whereas small-scale commercial installations such as laundries use ∼12% concentration. Chlorinated trisodium phosphate, which is a crystalline efflorescent product of approximate empirical composition \(\text{Na}_3\text{PO}_4.11\text{H}_2\text{O}_2\text{NaOCl} \), has 3.5–4.5% available Cl and is used in automatic dishwasher detergents, scouring powders, and acid metal cleaners for dairy equipment. Paper and pulp bleaching is effected by “bleach liquor”, a solution of Ca(OCl)\(_2\) and CaCl\(_2\), yielding ∼85 g l\(^{-1}\) of “available chlorine”. Powdered calcium hypochlorite, Ca(OCl)\(_2\) 2H\(_2\)O (70% available Cl), is used for swimming-pool sanitation whereas “bleaching powder”, Ca(OCl)\(_2\) 2CaCl\(_2\) 2Ca(OH)\(_2\) 2H\(_2\)O (obtained by the action of Cl\(_2\) gas on slaked lime) contains 35% available Cl and is used for general bleaching and sanitizing:

\[
3\text{Ca(OH)}_2 + 2\text{Cl}_2 \longrightarrow \text{Ca(OCl)}_2 \cdot \text{CaCl}_2 \cdot \text{Ca(OH)}_2 \cdot 2\text{H}_2\text{O}
\]

The specialty chemical LiOCl (40% “Cl”) is used when calcium is contra-indicated, such as in the sanitation of hard water and in some dairy applications. Some idea of the scale of these applications can be gained from the following production figures which relate to the USA:

<table>
<thead>
<tr>
<th>Chemical</th>
<th>annual production (USA)</th>
<th>Price (US)</th>
</tr>
</thead>
<tbody>
<tr>
<td>LiOCl</td>
<td>~2500 tonnes pa.</td>
<td>~$2.80/kg</td>
</tr>
<tr>
<td>NaOCl</td>
<td>~250000 tpa (dry basis)</td>
<td>~$0.70/kg</td>
</tr>
<tr>
<td>NaOCl (Na(_3)PO(_4).11H(_2)O)(_2)NaOCl</td>
<td>commercialized in 1930 and demand rose to 81 000 tonnes in 1973. Use has dropped sharply since about 1980 (37000 tonnes in 1988, price $0.70/kg).</td>
<td></td>
</tr>
<tr>
<td>Ca(OCl)(_2)</td>
<td>~85 000 tpa plus production facilities in numerous other countries (e.g. the USSR, Japan, South Africa and Canada).</td>
<td></td>
</tr>
</tbody>
</table>

Bleaching power is now much less used than formerly in highly industrialized countries but is still manufactured on a large scale in less-developed regions. In the USA its production peaked at 133 000 tonnes in 1923 but had fallen to 23 600 tonnes by 1955 and has not been reported since, though ~1160 tonnes per annum were imported during the 1980s.

*"Available chlorine" content is defined as the weight of Cl\(_2\) which liberates the same amount of I\(_2\) from HI as does a given weight of the compound; it is often expressed as a percentage. For example, from the two (possibly hypothetical) stoichiometric equations Cl\(_2\) + 2HI → I\(_2\) + 2HCl and LiOCl + 2HI → I\(_2\) + LiCl + H\(_2\)O it can be seen that 1 mol of I\(_2\) is liberated by 70.92 g Cl\(_2\) or by 58.4 g LiOCl. Whence the “available chlorine” content of pure LiOCl is (70.92/58.4) × 100 = 121%. The commercial product is usually diluted by sulfates to about one-third of this strength (see below).
dilute sulfuric acid:

\[ \text{Ba(OH)}_2(\text{aq}) + \text{H}_2\text{O}_2 + \text{ClO}_2 \rightarrow \text{Ba(ClO)}_2\text{H}_2 + 2\text{H}_2\text{O} + \text{O}_2 \]

\[ \text{Ba(ClO)}_2\text{H}_2(\text{suspension}) + \text{dil} \ \text{H}_2\text{SO}_4 \rightarrow \text{BaSO}_4 \downarrow + 2\text{HClO}_2 \]

Evidence for the undissociated acid comes from spectroscopic data but the solutions cannot be concentrated without decomposition. HClO₂ is a moderately strong acid \( K_a(25^\circ\text{C}) = 1.1 \times 10^{-2} \) (cf \( \text{H}_2\text{SeO}_4 K_a 1.2 \times 10^{-2}, \text{H}_4\text{P}_2\text{O}_7 K_a 2.6 \times 10^{-2} \)).

The decomposition of chlorous acid depends sensitively on its concentration, pH and the presence of catalytically active ions such as \( \text{Cl}^- \) which is itself produced during the decomposition. The main mode of decomposition (particularly if \( \text{Cl}^- \) is present) is to form ClO₂:

\[ 5\text{HClO}_2 \rightarrow 4\text{ClO}_2 + \text{Cl}^- + \text{H}^+ + 2\text{H}_2\text{O}; \quad \Delta G^\circ = -144 \text{kJ mol}^{-1} \]

Competing modes produce ClO₃⁻ or evolve O₂:

\[ 3\text{HClO}_2 \rightarrow 2\text{ClO}_3^- + \text{Cl}^- + 3\text{H}^+; \quad \Delta G^\circ = -139 \text{kJ mol}^{-1} \]

\[ \text{HClO}_2 \rightarrow \text{Cl}^- + \text{O}_2 + \text{H}^+; \quad \Delta G^\circ = -123 \text{kJ mol}^{-1} \]

Metal chlorites are normally made by reduction of aqueous solutions of ClO₂ in the presence of the metal hydroxide or carbonate. As with the preparation of Ba(ClO₂)₂ above, the reducing agent is usually a peroxide since this adds no contaminant to the resulting chlorite solution:

\[ 2\text{ClO}_2 + \text{O}_2^{2-} \rightarrow 2\text{ClO}_2^- + \text{O}_2 \]

The ClO₂⁻ ion is nonlinear, as expected, and X-ray studies of NH₄ClO₂ (at −35°C) and of AgClO₂ lead to the dimensions Cl—O 156 pm, angle O—Cl—O 111°. The chlorites of the alkali metals and alkaline earth metals are colourless or pale yellow. Heavy metal chlorites tend to explode or detonate when heated or struck (e.g. those of \( \text{Ag}^+, \text{Hg}^+, \text{TI}^+, \text{Pb}^{2+} \) and also those of \( \text{Cu}^{2+} \) and NH₄⁺). Sodium chlorite is the only one to have sufficient stability and to be sufficiently inexpensive to be a major article of commerce (see below).

Anhydrous NaClO₂ crystallizes from aqueous solutions above 37.4°C but below this temperature the trihydrate is obtained. The commercial product contains about 80% NaClO₂. The anhydrous salt forms colourless deliquescent crystals which decompose when heated to 175—200°C: the reaction is predominantly a disproportionation to ClO₃⁻ and Cl⁻ but about 5% of molecular O₂ is also released (based on the ClO₂⁻ consumed). Neutral and alkaline aqueous solutions of NaClO₂ are stable at room temperature (despite their thermodynamic instability towards disproportionation as evidenced by the reduction potentials on p. 854). This is a kinetic activation-energy effect and, when the solutions are heated near to boiling, slow disproportionation occurs:

\[ 3\text{ClO}_2^- \rightarrow 2\text{ClO}_3^- + \text{Cl}^- \]

Photochemical decomposition is rapid and the products obtained depend on the pH of the solution;

at pH 8.4: \( 6\text{ClO}_2^- \xrightarrow{hv} 2\text{ClO}_3^- + 4\text{Cl}^- + 3\text{O}_2 \)

at pH 4.0: \( 10\text{ClO}_2^- \xrightarrow{hv} 2\text{ClO}_3^- + 6\text{Cl}^- \quad + 2\text{ClO}_4^- + 3\text{O}_2 \)

The stoichiometry in acid solution implies that, in addition to the more usual disproportionation into ClO₃⁻ and Cl⁻, the following disproportionation also occurs:

\[ 2\text{ClO}_2^- \rightarrow \text{Cl}^- + \text{ClO}_4^- \]

The mechanisms of these various reactions have been the subject of many studies.\(^{98,115,119}\)

The main commercial applications of NaClO₂ are in the bleaching and stripping of textiles, and as a source of ClO₂ where required volumes are comparatively small. It is also used as an oxidant for removal of nitrogen oxide pollutants from industrial off-gases. The specific oxidizing properties of NaClO₂ towards certain malodorous or toxic compounds such as unsaturated aldehydes, mercaptans, thioethers,
H₂S and HCN have likewise led to its use for scrubbing the off-gases of processes where these noxious pollutants are formed. Production statistics are rather sparse but the main production plants are in Europe, which produced some 11 000 tonnes pa in 1990 and the USA, where production is expected to exceed 10 000 tonnes in 1995. Other major producers are in Japan (~5000 tpa) and Canada (2700 tpa in 1990). The 1991 price for technical grade NaClO₂ in the USA was $2.65/kg.

Crystalline barium bromite Ba(BrO₂)₂·H₂O was first isolated in 1959; it can be made by treating the hypobromite with Br₂ at pH 11.2 and 0°C, followed by slow evaporation. Sr(BrO₂)₂·2H₂O was obtained similarly.

Halic acids, HOXO₂, and halates, XO₃⁻(121,122)

Disproportionation of X₂ in hot alkaline solution has long been used to synthesize chlorates and bromates (see oxidation state diagrams, p. 855):

\[ 3X_2 + 6OH^- \rightarrow XO_3^- + 5X^- + 3H_2O \]

For example, J. von Liebig developed the technical preparation of KClO₃ by passing Cl₂ into a warm suspension of Ca(OH)₂ and then adding KCl to enable the less-soluble chlorate to crystallize on cooling:

\[ 6Ca(OH)_2 + 6Cl_2 \rightarrow Ca(ClO_3)_2 + 5CaCl_2 + 6H_2O \]

\[ Ca(ClO_3)_2 + 2KCl \rightarrow 2KClO_3 + CaCl_2 \]

However, only one-sixth of the halogen present is oxidized and alternative routes are more generally preferred for large-scale manufacture. Thus, the most important halate, NaClO₃, is manufactured on a huge scale† by the electrolysis of brine in a diaphragmless cell which promotes efficient mixing. Under these conditions, the Cl₂ produced by anodic oxidation of Cl⁻ reacts with cathodic OH⁻ to give hypochlorite which then either disproportionates or is itself further anodically oxidized to ClO₃⁻:

**anode:** Cl⁻ → ½Cl₂ + e⁻;

**cathode:** H₂O + e⁻ → ½H₂ + OH⁻

**mixing:** Cl₂ + 2OH⁻ → Cl⁻ + OCl⁻ + H₂O

**further disproportionation:**

\[ 3OCl^- \rightarrow ClO_3^- + 2Cl^- \]

**further anodic oxidation:**

\[ OCl^- + 2H_2O \rightarrow ClO_3^- + 2H_2 \]

Modern cells employ arrays of anodes (TiO₂ coated with a noble metal) and cathodes (mild steel) spaced 3 mm apart and carrying current at 2700 A mp² into brine (80–100 g l⁻¹) at 60–80°C. Under these conditions current efficiency can reach 93% and 1 tonne of NaClO₃ can be obtained from 565 kg NaCl and 4535 kWh of electricity. The off-gas H₂ is also collected.

Bromates and iodates are prepared on a much smaller scale, usually by chemical oxidation. For example, Br⁻ is oxidized to BrO₃⁻ by aqueous hypochlorite (conveniently effected by passing

† World production of NaClO₃ (1989–91) exceeds 2 billion tonnes pa, Canada alone producing some 872 000 tpa, USA 630 000 tpa and Europe 421 000 tpa. Consumption in the USA exceeds production by some 50%, the rest being imported. The 1991 price (~$480/tonne) was similar in both North America and Europe where, interestingly, the main consumers are Finland (156 800 tpa) and Sweden (109 700 tpa). The overwhelming use of NaClO₃ (95% in the USA) is in the manufacture of ClO₂, mainly for bleaching paper pulp (p. 846). Other uses are to make perchlorates and other chlorates (3%), in uranium production (1% but declining sharply) and for agricultural uses (0.7%) such as herbicides, cotton defoliants and soya-bean desiccants. The use of NaClO₃ in pyrotechnic formulations is hampered by its hygroscopicity. KClO₃ does not suffer this disadvantage and is unexcelled as an oxidizer in fireworks and flares, the colours being obtained by admixture with salts of Sr (red), Ba (green), Cu (blue), etc. In addition KClO₃ is a crucial component in the head of "safety matches" (KClO₃, S, Sb₂S₃, powdered glass and dextrin paste). Its price in very similar to that of NaClO₃.
Cl₂ into alkaline solutions of Br⁻). Iodates can be prepared either by direct high-pressure oxidation of alkali metal iodides with oxygen at 600° or by oxidation of I₂ with chlorates:

\[
I₂ + NaClO₃ \rightarrow 2NaIO₃ + Cl₂
\]

Salts of other metals are obtained by metathesis, and aqueous solutions of the corresponding acids are obtained by controlled addition of sulfuric acid to the barium salts:

\[
Ba(\text{XO}_3)_2 + H₂SO₄ \rightarrow 2H\text{XO}_3 + BaSO₄
\]

Chloric acid, HClO₃, is fairly stable in cold water up to about 30% concentration but, on being warmed, such solutions evolve Cl₂ and ClO₂. Evaporation under reduced pressure can increase the concentration up to about 40% (~HClO₃.7H₂O) but thereafter it is accompanied by decomposition to HClO₄ and the evolution of Cl₂, O₂ and ClO₂:

\[
8HClO₃ \rightarrow 4HClO₄ + 2H₂O + 2Cl₂ + 3O₂
\]

\[
3HClO₃ \rightarrow HClO₄ + H₂O + 2ClO₂
\]

Likewise, aqueous HBrO₃ can be concentrated under reduced pressure to about 50% concentration (~HBrO₃.7H₂O) before decomposition obtrudes:

\[
4HBrO₃ \rightarrow 2H₂O + 2Br₂ + 5O₂
\]

Both chloric and bromic acids are strong acids in aqueous solution (pKₐ ≤ 0) whereas iodic acid is slightly weaker, with pKₐ 0.804, i.e. Kₐ 0.157.

Iodic acid is more conveniently synthesized by oxidation of an aqueous suspension of I₂ either electrolytically or with fuming HNO₃. Crystallization from acid solution yields colourless, orthorhombic crystals of α-HIO₃ which feature H-bonded pyramidal molecules of HOIO₂:

\[ r(1-O) 181 \text{ pm}, \ r(1-OH) 189 \text{ pm}, \ \text{angle} \ O-1-O 101.4°, \ \text{angle} \ O-1-(OH) 97°. \]

When heated to ~100°C iodic acid partly dehydrates to HI₃O₈ (p. 852); this comprises an H-bonded array of composition HOIO₂.I₂O₅ in which the HIO₃ has almost identical dimensions to those in α-HIO₃. Further heating to 200° results in complete dehydration to I₂O₅. In concentrated aqueous solutions of HIO₃, the iodate ions formed by deprotonation react with undissociated acid according to the equilibrium

\[
IO₃⁻ + HIO₃ \Leftrightarrow [H(\text{IO}_3)_2]⁻; \ K \approx 4 \text{ mol}^{-1}
\]

Accordingly, crystallization of iodates from solutions containing an excess of HIO₃ sometimes results in the formation of hydrogen iodates, M⁺H(IO₃)₂, or even dihydrogen triiodates, M⁺H₂(IO₃)₃.

Chlorates and bromates feature the expected pyramidal ions XO₃⁻ with angles close to the tetrahedral (106–107°). With iodates the interatomic angles at iodine are rather less (97–105°) and there are three short I–O distances (177–190 pm) and three somewhat longer distances (251–300 pm) leading to distorted perovskite structures (p. 963) with pseudo-sixfold coordination of iodine and piezoelectric properties (p. 58). In Sr(IO₃)₂.H₂O the coordination number of iodine rises to 7 and this increases still further to 8 (square antiprism) in Ce(IO₃)₄ and Zr(IO₃)₄.

The modes of thermal decomposition of the halates and their complex oxidation-reduction chemistry reflect the interplay of both thermodynamic and kinetic factors. On the one hand, thermodynamically feasible reactions may be sluggish, whilst, on the other, traces of catalyst may radically alter the course of the reaction. In general, for a given cation, thermal stability decreases in the sequence iodate > chlorate > bromate, but the mode and ease of decomposition can be substantially modified. For example, alkali metal chlorates decompose by disproportionation when fused:

\[
4ClO₃⁻ \rightarrow Cl⁻ + 3ClO₄⁻
\]

e.g. LiClO₃, mp 125° (d 270°); NaClO₃, mp 248° (d 265°); KClO₃, mp 368° (d 400°). However, in

\[ \text{Note, however, that thermal decomposition of } NH₄ClO₃ \text{ begins at 50°C and the compound explodes on further heating; this much lower decomposition temperature may result from prior proton transfer to give the less-stable acid: } [NH₄]^+ + ClO₃⁻ \rightarrow NH₃ + HClO₃. \]

A similar thermal instability afflicts NH₄BrO₃ (d −5°) and NH₄IO₃ (d ~ 100°).
the presence of a transition-metal catalyst such as MnO₂ decomposition of KClO₃ to KCl and oxygen begins at about 70° and is vigorous at 100°

\[ 2\text{ClO}_3^- \rightarrow 2\text{Cl}^- + 3\text{O}_2 \]

This is, indeed, a classic laboratory method for preparing small amounts of oxygen (p. 603). For bromates and iodates, disproportionation to halide and perhalate is not thermodynamically feasible and decomposition occurs either with formation of halide and liberation of O₂ (as in the catalysed decomposition of ClO₃⁻ just considered), or by formation of the oxide:

\[ 4\text{OXO}_3^- \rightarrow 2\text{O}^{2-} + 2\text{X}_2 + 5\text{O}_2 \]

For all three halates (in the absence of disproportionation) the preferred mode of decomposition depends, again, on both thermodynamic and kinetic considerations. Oxide formation tends to be favoured by the presence of a strongly polarizing cation (e.g. magnesium, transition-metal and lanthanide halates), whereas halide formation is observed for alkali-metal, alkaline-earth and silver halates.

The oxidizing power of the halate ions in aqueous solution, as measured by their standard reduction potentials (p. 854), decreases in the sequence bromate ≥ chlorate > iodate but the rates of reaction follow the sequence iodate > bromate > chlorate. In addition, both the thermodynamic oxidizing power and the rate of reaction depend markedly on the hydrogen-ion concentration of the solution, being substantially greater in acid than in alkaline conditions (p. 855).

An important series of reactions, which illustrates the diversity of behaviour to be expected, is the comproportionation of halates and halides. Bromides are oxidized quantitatively to bromine and iodides to iodine, this latter reaction being much used in volumetric analysis:

\[ \text{XO}_3^- + 5\text{X}^- + 6\text{H}^+ \rightarrow 3\text{X}_2 + 3\text{H}_2\text{O} \]

\( (\text{X} = \text{Cl, Br, I}) \)

Numerous variants are possible, e.g.:

\[ \text{ClO}_3^- + 6\text{Br}^- (\text{or I}^-) + 6\text{H}^+ \rightarrow 3\text{Br}_2 (\text{or I}_2) + 3\text{H}_2\text{O} \]

\[ \text{BrO}_3^- + 6\text{I}^- + 6\text{H}^+ \rightarrow \text{Br}^- + 3\text{I}_2 + 3\text{H}_2\text{O} \]

\[ \text{IO}_3^- + 5\text{Br}^- + 6\text{H}^+ \rightarrow 2\text{Br}_2 + \text{IBr} + 3\text{H}_2\text{O} \]

\[ 2\text{ClO}_3^- + 2\text{Cl}^- + 4\text{H}^+ \rightarrow \text{Cl}_2 + 2\text{ClO}_2 + 2\text{H}_2\text{O} \]

\( (\text{p. 846}) \)

\[ 2\text{BrO}_3^- + 2\text{Cl}^- + 12\text{H}^+ \rightarrow \text{Br}_2 + \text{Cl}_2 + 6\text{H}_2\text{O} \]

\[ \text{IO}_3^- + 3\text{Cl}^- + 6\text{H}^+ \rightarrow \text{ClI} + \text{Cl}_2 + 3\text{H}_2\text{O} \]

The greater thermodynamic stability of iodates enables iodine to displace Cl₂ and Br₂ from their halates:

\[ \text{I}_2 + 2\text{XO}_3^- \rightarrow \text{X}_2 + 2\text{IO}_3^- \quad (\text{X} = \text{Cl, Br}) \]

With bromate at pH 1.5–2.5 the reaction occurs in four stages:

(1) an induction period in which a catalyst (probably HOB₃) is produced;

(2) \[ \text{I}_2 + \text{BrO}_3^- \rightarrow \text{IBr} + \text{IO}_3^- ; \]

(3) \[ 3\text{IBr} + 2\text{BrO}_3^- + 3\text{H}_2\text{O} \rightarrow 5\text{Br}^- + 3\text{IO}_3^- + 6\text{H}^+ ; \]

(4) \[ 5\text{Br}^- + \text{BrO}_3^- + 6\text{H}^+ \rightarrow 3\text{Br}_2 + 3\text{H}_2\text{O} . \]

The dependence of reaction rates on pH and on the relative and absolute concentrations of reacting species, coupled with the possibility of autocatalysis and induction periods, has led to the discovery of some spectacular kinetic effects such as H. Landolt’s “chemical clock” (1885): an acidified solution of Na₂SO₃ is reacted with an excess of iodic acid solution in the presence of starch indicator — the induction period before the appearance of the deep-blue starch-iodine colour can be increased systematically from seconds to minutes by appropriate dilution of the solutions before mixing. With an excess of sulfite, free iodine may appear and then disappear as a single pulse due to the following sequence of reactions:

\[ \text{IO}_3^- + 3\text{SO}_3^{2-} \rightarrow \text{I}^- + 3\text{SO}_4^{2-} \]

\[ 5\text{I}^- + \text{IO}_3^- + 6\text{H}^+ \rightarrow 3\text{I}_2 + 3\text{H}_2\text{O} \]

\[ 3\text{I}_2 + 3\text{SO}_4^{2-} + 3\text{H}_2\text{O} \rightarrow 6\text{I}^- + 6\text{H}^+ + 3\text{SO}_4^{2-} \]
A true periodic reaction was discovered by W. C. Bray in 1921 and involves the reduction of iodic acid to I₂ by H₂O₂ followed by the reoxidation of I₂ to HIO₃:

$$2\text{HIO}_3 + 5\text{H}_2\text{O}_2 \rightarrow 5\text{O}_2 + \text{I}_2 + 6\text{H}_2\text{O}$$
$$\text{I}_2 + 5\text{H}_2\text{O}_2 \rightarrow 2\text{HIO}_3 + 4\text{H}_2\text{O}$$

The net reaction is the disproportionation of H₂O₂ to H₂O + ½O₂ and the starch indicator oscillates between deep blue and colourless as the iodine concentration pulsates.

Even more intriguing is the Belousov-Zhabotinskii class of oscillating reactions some of which can continue for hours. Such a reaction was first observed in 1959 by B. P. Belousov who noticed that, in stirred sulfuric acid solutions containing initially KBrO₃, cerium(IV) sulfate and malonic acid, CH₂(CO₂H)₂, the concentrations of Br⁻ and Ce⁴⁺ underwent repeated oscillations of major proportions (e.g. tenfold changes on a time-scale which was constant but which could be varied from a few seconds to a few minutes depending on concentrations and temperature). These observations were extended by A. M. Zhabotinskii in 1964 to the bromate oxidation of several other organic substrates containing a reactive methylene group catalysed either by Ce⁴⁺/Ce⁴⁺ or Mn⁵⁺/Mn⁴⁺. Not surprisingly these reactions have attracted considerable attention, but detailed studies of their mechanisms are beyond the scope of this chapter. (123–125)

The various reactions of bromates and iodates are summarized in the schemes on p. 866. (121)

The oxidation of halates to perhalates is considered further in the next section.

**Perhalic acid and perhalates**

Because of their differing structures, chemical reactions and applications, perchloric acid and the perchlorates are best considered separately from the various periodic acids and their salts; the curious history of perbromates also argues for their individual treatment.

**Perchloric acid and perchlorates** (126–128)

The most stable compounds of chlorine are those in which the element is in either its lowest oxidation state (−I) or its highest (VII); accordingly perchlorates are the most stable oxo-compounds of chlorine (see oxidation-state diagram, (p. 855) and most are extremely stable both as solids and as solutions at room temperature. When heated they tend to decompose by loss of O₂ (e.g. KClO₄ above 400°). Aqueous solutions of perchloric acid and perchlorates are not notable oxidizing agents at room temperature but when heated they become vigorous, even violent, oxidants. Considerable CAUTION should therefore be exercised when handling these materials, and it is crucial to avoid the presence of readily oxidizable organic (or inorganic) matter since this can initiate reactions of explosive intensity.

On an industrial scale, perchlorates are now invariably produced by the electrolytic oxidation of NaClO₃ (see Panel, p. 867). Alternative routes have historical importance but are now only rarely used, even for small-scale laboratory syntheses.

Perchloric acid is best made by treating anhydrous NaClO₄ or Ba(ClO₄)₂ with concentrated HCl, filtering off the precipitated chloride and concentrating the filtrate by distillation. The azeotrope (p. 815) boils at 203°C and contains 71.6% HClO₄ (i.e. HClO₄·2H₂O). The anhydrous acid is obtained by low-pressure distillation of the azeotrope (p < 1 mmHg = 0.13 kPa) in an all-glass apparatus in the presence of fuming sulfuric acid. Commercially available perchloric acid is usually 60–62% (~3.5H₂O) or 70–72%

---

126 Ref. 23, pp. 1435–60, Perhalic acids and perhalates.
Some reactions of aqueous bromates.

Some reactions of iodates.

Pure HClO₄ is a colourless mobile, shock-sensitive, liquid: $d(25^\circ) \, 1.761 \, \text{g cm}^{-3}$. At least 6 hydrates are known (Table 17.23). The structure of HClO₄, as determined by electron diffraction in the gas phase, is as shown in Fig. 17.20. This molecular structure persists in the liquid phase, with some H bonding, and also in the crystalline phase, where an X-ray study at $-160^\circ$ found three Cl–O distances of 142 pm and one of 161 pm (very close to the dimensions of the extremely stable "isoelectronic" molecule, FCLO₃ (140.4 and 161.9 pm, p. 879)). The (low) electrical conductivity and other physical properties of anhydrous HClO₄ have been interpreted on the
Production and Uses of Perchlorates

NaClO₄ is made by the electrolytic oxidation of aqueous NaClO₃ using smooth Pt or PbO₂ anodes and a steel cathode which also acts as the container. All other perchlorates, including HClO₄, are made either directly or indirectly from this NaClO₄. In a typical cell NaClO₃ (600 g/l pH 6.5) is oxidized at 30–50°C with 90% current efficiency at 5000 A and 6.0 V with an anode current density of 3100 A m⁻² and an electrode separation of ~5 mm. The process can be either batch or continuous and energy consumption is ~2.5 kWh/kg. A small concentration of Na₂Cr₂O₇ (1–5 g/l) is found to be extremely beneficial in inhibiting cathodic reduction of ClO₄⁻.

World production of perchlorates was less than 1800 tonnes p.a. until 1940 when wartime missile and rocket requirements boosted this tenfold. World production capacity peaked at around 40000 tonnes p.a. in 1963 but is now still above 30000 tonnes p.a. More than half of this is converted to NH₄ClO₄ for use as a propellant:

\[
\text{NaClO}_4 + \text{NH}_4\text{Cl} \rightarrow \text{NH}_4\text{ClO}_4 + \text{NaCl}
\]

US production was severely disrupted by a series of devastating explosions in May 1988 which killed 2 people and injured several hundred. Ultrapure NH₄ClO₄ for physical measurements and research purposes can be made by direct neutralization of aqueous solutions of NH₃ and HClO₄. One of the main current uses of NH₄ClO₄ is in the Space Shuttle Programme: the two booster rockets use a solid propellant containing 70% by weight of NH₄ClO₄, this being the oxidizer for the “fuel” (powdered Al metal) which comprises most of the rest of the weight. Each shuttle launch requires about 770 tonnes of NH₄ClO₄.

The annual consumption of 70% HClO₄ is about 450 tonnes mainly for making other perchlorates. Most of the NaClO₄ produced is used captively to make NH₄ClO₄ and HClO₄, but about 725 tonnes is used for explosives, particularly in slurry blasting formulations.

The two other perchlorates manufactured on a fairly large scale industrially are Mg(ClO₄)₂ and KClO₄. The former is used as the electrolyte in “dry cells” (batteries), whereas KClO₄ is a major constituent in pyrotechnic devices such as fireworks, flares, etc. Thus the white flash and thundering boom in fireworks displays are achieved by incorporating a compartment containing KClO₄/Si/Al, whereas the flash powder commonly used in rock concerts and theatricals comprises KClO₄/Mg. Vivid blues, perhaps the most difficult pyrotechnic colour to achieve, are best obtained from the low temperature (< 1200° C) flame emission of CuCl in the 420–460 nm region: because of the instability of copper chloride and perchlorate this colour is generated by ignition of a mixture containing 38% KClO₄, 29% NH₄ClO₄, and 14% CuCO₃ bound with red gum (14%) and dextrin (5%).

order and homogeneous, the rate-determining step being homolytic fission of the Cl–OH bond:

$$\text{HClO}_3 \longrightarrow \text{HO}^+ + \text{ClO}_4^−$$

The hydroxyl radical rapidly abstracts an H atom from a second molecule of HClO$_4$ to give H$_2$O plus ClO$_4^−$ and the 2 radicals ClO$_3^−$ and ClO$_4^−$ then decompose to the elements via the intermediate oxides. Above 450°C the Cl$_2$ produced reacts with H$_2$O to give 2HCl plus $\frac{1}{2}$O$_2$ whilst in the low-temperature range (150–310°C) the decomposition is heterogeneous and second order in HClO$_4$.

Aqueous perchloric acid solutions exhibit very little oxidizing power at room temperature, presumably because of kinetic activation barriers, though some strongly reducing species slowly react, e.g. Sn$^{II}$, Ti$^{III}$, V$^{II}$ and V$^{III}$, and dithionite. Others do not, e.g. H$_2$S, SO$_2$, HNO$_2$, HI and, surprisingly, Cr$^{II}$ and Eu$^{III}$. Electropositive metals dissolve with liberation of H$_2$ and oxides of less basic metals also yield perchlorates. e.g. with 72% acid:

Mg + 2HClO$_4$ → [Mg(H$_2$O)$_6$](ClO$_4$)$_2$ + H$_2$

Ag$_2$O + 2HClO$_4$ → 2AgClO$_4$ + H$_2$O

NO and NO$_2$ react to give NO$^+ClO_4^−$ and F$_2$ yields FOClO$_3$ (p. 639). P$_2$O$_5$ dehydrates the acid to Cl$_2$O$_7$ (p. 850).

Perchlorates are known for most metals in the periodic table. The alkali-metal perchlorates are thermally stable to several hundred degrees above room temperature but NH$_4$ClO$_4$ deflagrates with a yellow flame when heated to 200°C:

2NH$_4$ClO$_4$ → N$_2$ + Cl$_2$ + 2O$_2$ + 4H$_2$O

NH$_4$ClO$_4$ has a solubility in water of 20.2 g per 100 g solution at 25°C and 135 g per 100 g liquid NH$_3$ at the same temperature. Aqueous solubilities decrease in the sequence Na > Li > NH$_4$ > K > Rb > Cs; indeed, the low solubility of the last 3 perchlorates in this series has been used for separatory purposes and even for gravimetric analysis (e.g. KClO$_4$ 1.99 g per 100 g H$_2$O at 20°C). Many of these perchlorates and those of M$^{II}$ can also be obtained as hydrates. AgClO$_4$ has the astonishing solubility of 557 g per 100 g H$_2$O at 25°C and even in toluene its solubility is 101 g per 100 g PhMe at 25°C. This has great advantages in the metathetic preparation of other perchlorates, particularly organic perchlorates, e.g. RI yields ROCIO$_3$, Ph$_3$CCI yields Ph$_3$C$^+$ClO$_4^−$, and CCl$_4$ affords CCl$_3$OCIO$_3$.

Oxidation-reduction reactions involving perchlorates have been mentioned in several of the preceding sections and the reactivity of aqueous solutions is similar to that of aqueous solutions of perchloric acid.

The perchlorate ion was for long considered to be a non-coordinating ligand and has frequently been used to prepare “inert” ionic solutions of constant ionic strength for physicochemical measurements. Though it is true that ClO$_4^−$ is a weaker ligand than H$_2$O it is not entirely toothless and, as shown schematically in Fig. 17.21, examples are known in which the perchlorate acts as a monodentate ($\eta^1$), bidentate chelating ($\eta^2$) and bidentate bridging ($\mu,\eta^2$) ligand. The first unambiguous structural evidence for coordinated ClO$_4^−$ was obtained in 1965 for the 5 coordinate cobalt(II)
a p-block element (Sn$^{II}$ and Sn$^{IV}$),\(^{133}\) and an f-block element (Sm$^{III}$)\(^{134}\) as well as to the d-block elements Co$^{II}$, Ni$^{II}$, Cu$^{II}$ and Ag$^{I}$.\(^{131,135}\) It is also known to function as a bidentate ligand towards Na,\(^{132}\) Ba,\(^{132}\) Sn$^{IV}$,\(^{133}\) Sm$^{III}$,\(^{134}\) Ti$^{IV}$ in [Ti($\eta^2$-ClO$_4$)$_4$]\(^{137}\) and Ni$^{II}$ in [Ni($\eta^2$-ClO$_4$)L$_2$]$^+\) where L is a chiral bidentate organic ligand.\(^{138}\) Sometimes both $\eta^1$ and $\eta^2$ modes occur in the same compound. The bidentate bridging mode occurs in the silver complex $[\text{Ag}(\mu,\eta^2$-OC$_1$(O)$_2$O-$(m$-\text{xylene})$_2]$.\(^{139}\) The structure of appropriate segments of some of these compounds are in Fig. 17.23. The distinction between coordinated and non-coordinated (“ionic”) perchlorate is sometimes hard to make and there is an almost continuous

complex $[\text{Co(OAsMePh}_2)_4(\eta^1$-OCIO$_3$)$_2]^{130}$ and this was quickly followed by a second example, the red 6-coordinate trans complex $[\text{Co}(\eta^2$-MeSCH$_2$CH$_2$SMe)$_2(\eta^1$-OCIO$_3$)$_2]$.\(^{131}\) The two structures are shown in Fig. 17.22. The perchlorate ion has now been established as a monodentate ligand towards an s-block element (Ba),\(^{132}\)

Figure 17.23 Examples of monodentate, chelating and bridging perchlorate ligands.

gradation between the two extremes. Similarly it is sometimes difficult to distinguish unambiguously between $\eta^1$ and unsymmetrical $\eta^2$ and, in the colourless complex $[\text{Ag}(\text{cyclohexylbenzene})_2\text{(ClO}_4\text{)}_2]$, the $\eta^1$ bonding between Ag and ClO$_4$ (Ag–O 266 pm) is accompanied by a further weak symmetrical $\eta^2$ bonding from each ClO$_4$ to the neighbouring Ag (2Ag–O 284 pm) thereby generating a weakly-bridged chain-like structure involving pseudo-$\eta^3$ coordination of the perchlorate group.\(^{(135)}\)

Because of its generally rather weak coordinating ability quite small changes can determine whether
or not a perchlorate group coordinates and if so, in which mode. For example, the barium crown-ether dihydrate complex illustrated in Fig. 17.23 features 10-coordinate Ba with 6 oxygen atoms from the crown ring (Ba–O 280–285 pm), two H2O molecules (Ba–O 278 and 284 pm), and one of the perchlorates (Ba–O 294 pm) all on one side of the ring, and the other perchlorate (Ba–O 279 pm) below it. By contrast, the analogous strontium complex is a trihydrate with 9-coordinate Sr (six Sr–O from the crown ring at 266–272 pm, plus two H2O at 257, 259 pm, on one side of the ring, and one H2O on the other side at 255 pm); the ClO4− ions are uncoordinated though they are H-bonded to the water molecules.

An even more dramatic change occurs with nickel(II) perchlorate complexes. Thus, the complex with 4 molecules of 3,5-dimethylpyridine (Fig. 17.23a) is blue, paramagnetic, and 6-coordinate with trans-(η1-OClO3) ligands, whereas the corresponding complex with 3,4-dimethylpyridine is yellow and diamagnetic with square-planar NiII and uncoordinated ClO4− ions. There is no steric feature of the structure which prevents the four 3,4-ligands from adopting the propeller-like configuration of the four 3,5-ligands thereby enabling Ni to accept two η1-OClO3, or vice versa, and one must conclude that subtle differences in secondary valency forces and energies of packing are sufficient to dictate whether the complex that crystallizes is blue, paramagnetic and octahedral, or yellow, diamagnetic and square planar.

**Perbromic acid and perbromates**

The quest for perbromic acid and perbromates and the various reasons adduced for their apparent non-existence make fascinating and salutary reading. The esoteric radiochemical synthesis of BrO4− in 1968 using the β-decay of radioactive 83Se, whilst not providing a viable route to macroscopic quantities of perbromate, proved that this previously elusive species could exist:

\[
\begin{align*}
83\text{SeO}_4^{2−} & \xrightarrow{T1/2 \, 22.5 \text{ min}} 83\text{BrO}_4^{−} \\
& \xrightarrow{T1/2 \, 2.39 \text{ h}} ^{83}\text{Kr} + 2\text{O}_2
\end{align*}
\]

This stimulated the search for a chemical synthesis. Electrolytic oxidation of aqueous LiBrO3 produced a 1% yield of perbromate, but the first isolation of a solid perbromate salt (RbBrO4) was achieved by oxidation of BrO3− with aqueous XeF2:(141)

\[
\text{BrO}_3^{−} + \text{XeF}_2 + \text{H}_2\text{O} \xrightarrow{10\% \text{ yield}} \text{BrO}_4^{−} + \text{Xe} + 2\text{HF}
\]

The best synthesis is now by oxidation of alkaline solutions of BrO3− using F2 gas under rather specific conditions:(142)

\[
\text{BrO}_3^{−} + \text{F}_2 + 2\text{OH}^{−} \xrightarrow{20\% \text{ yield}} \text{BrO}_4^{−} + 2\text{F}^{−} + \text{H}_2\text{O}
\]

In practice, F2 is bubbled in until the solution is neutral, at which point excess bromate and fluoride are precipitated as AgBrO3 and CaF2; the solution is then passed through a cation exchange column to yield a dilute solution of HBrO4. Several hundred grams at a time can be made by this route. The acid can be concentrated up to 6 M (55%) without decomposition and such solutions are stable for prolonged periods even at 100°. More concentrated solutions of HBrO4 can be obtained but they are unstable; a white solid, possibly HBrO4·2H2O, can be crystallized.

Pure KBrO4 is isomorphous with KClO4 and contains tetrahedral BrO4− anions (Br–O 161 pm, cf. Cl–O 144 pm in ClO4− and I–O 179 pm in IO4−). Oxygen-18 exchange between 0.14 M KBrO4 and H2O proceeds to less than 7% completion during 19 days at 94° in either acid or basic solutions and there is no sign of any increase in coordination number of Br; in this BrO4− resembles ClO4− rather than IO4−. KBrO4 is stable to 275–280° at which

temperature it begins to dissociate into KBrO₃ and O₂. Even NH₄BrO₄ is stable to 170°. Dilute solutions of BrO₄⁻ show little oxidizing power at 25°; they slowly oxidize I⁻ and Br⁻ but not Cl⁻. More concentrated HBrO₄ (3 M) readily oxidizes stainless steel and 12 M acid rapidly oxidizes Cl⁻. The general inertness of BrO₄⁻ at room temperature stands in sharp contrast to its high thermodynamic oxidizing power, which is greater than that of any other oxohalogen ion that persists in aqueous solution. The oxidation potential is

\[
\text{BrO}_4^- + 2H^+ + 2e^- \rightarrow \text{BrO}_3^- + H_2O; \quad E^+ = +1.853 \text{ V}
\]

(cf. 1.201 V for ClO₄⁻ and 1.653 for IO₄⁻). Accordingly, only the strongest oxidants would be expected to convert bromates to perbromates. As seen above, F₂/H₂O (E° = 2.87 V) and XeF₂/H₂O (E° = 2.64 V) are effective, but ozone (E° = 2.07 V) and S₂O₅²⁻ (E° = 2.01 V) are not, presumably for kinetic reasons. Thermochemical measurements further show that KBrO₄ is thermodynamically stable with respect to its elements, but less so than the corresponding KClO₄ and KIO₄: this is not due to any significant difference in entropy effects or lattice energies and implies that the Br–O bond in BrO₄⁻ is substantially weaker than the X–O bond in the other perhalates. Some comparative data (298.15 K) are:

<table>

No entirely satisfactory explanation of these observations has been devised, though they are paralleled by the similar reluctance of other elements following the completion of the 3d subshell to achieve their highest oxidation states — see particularly Se (p. 755) and As (p. 552) immediately preceding Br in the periodic table. The detailed kinetics of several oxidation reactions involving aqueous solutions of BrO₄⁻ have been studied. In general, the reactivity of perbromates lies between that of the chlorates and perchlorates which means that, after the perchlorates, perbromates are the least reactive of the known oxohalogen compounds. It has even been suggested that earlier investigators may actually have made perbromates, but not realized this because they were expecting a highly reactive product rather than an inert one.

**Periodic acids and periodates**

At least four series of periodates are known, interconnected in aqueous solutions by a complex series of equilibria involving deprotonation, dehydration and aggregation of the parent acid H₅IO₆ — cf. telluric acids (p. 782) and antimonic acids (p. 577) in the immediately preceding groups. Nomenclature is summarized in Table 17.24, though not all of the fully protonated acids have been isolated in the free state. The structural relationship between these acids, obtained mainly from X-ray studies on their salts, are shown in Fig. 17.24. H₅IO₆ itself (mp 128.5° decom) consists of molecules of (HO)₅IO linked into a three-dimensional array by O–H...O bonds (10 for each molecule, 260–278 pm).

Periodates can be made by oxidation of I⁻, I₂ or IO₃⁻ in aqueous solution. Industrial processes involve oxidation of alkaline NaIO₃ either electrochemically (using a PbO₂ anode) or with Cl₂:

\[
\text{IO}_3^- + 6OH^- - 2e^- \rightarrow \text{IO}_6^{5-} + 3H_2O
\]

Figure 17.24 Structures of periodic acids and periodate anions.

$\text{IO}_3^- + 6\text{OH}^- + \text{Cl}_2 \rightarrow \text{IO}_6^{5-} + 2\text{Cl}^- + 3\text{H}_2\text{O}$

The product is the dihydrogen orthoperiodate $\text{Na}_3\text{H}_2\text{IO}_6$, which is a convenient starting point for many further preparations (see Scheme on next page). Paraperiodates of the alkaline earth metals can be made by the thermal disproportionation of the corresponding iodates, e.g.:

$$5\text{Ba}([\text{IO}_3]_2) \xrightarrow{\Delta} \text{Ba}_5([\text{IO}_6]_2) + 4\text{I}_2 + 9\text{O}_2$$

Aqueous solutions of periodic acid are best made by treating this barium salt with concentrated nitric acid. White crystals of $\text{H}_3\text{IO}_6$ can be obtained from these solutions. Dehydration of $\text{H}_3\text{IO}_6$ at 120° yields $\text{H}_3\text{I}_3\text{O}_{14}$, whereas heating to 100° under reduced pressure affords $\text{HIO}_4$. Attempts to dehydrate further do not yield the non-existent $\text{I}_2\text{O}_7$ (p. 852); oxygen is progressively evolved to form the mixed oxide $\text{I}_5\text{O}_4.\text{I}_2\text{O}_7$ and finally $\text{I}_3\text{O}_5$. Protonation of orthoperiodic acid with concentrated HClO$_4$ yields the cation $[\text{I(OH)}_6]^+$. Similarly, dissolution of crystalline $\text{H}_3\text{IO}_6$ in 95% H$_2$SO$_4$ (or H$_2$SeO$_4$) at 120° yields colourless crystals of $[\text{I(OH)}_6][\text{H}_2\text{SO}_4]$ on slow cooling to room temperature and prolonged digestion of these with trichloroacetic acid extracts $\text{H}_2\text{SO}_4$ to give the
white, hygroscopic powder $[\text{I(OH)}_6]_2\text{SO}_4$. These compounds thus complete the series of octahedral hexahydroxo species $[\text{Sn(OH)}_6]^{2-}$, $[\text{Sb(OH)}_6]^{-}$, $[\text{Te(OH)}_6]^{2-}$ and $[\text{I(OH)}_6]^{+}$.

In aqueous solution increase in pH results in progressive deprotonation, dehydration and dimerization, the principal species being $[(\text{HO})_3\text{IO}_2]^{-}$, $[(\text{HO})_2\text{IO}_3]^{2-}$, $[(\text{HO})_2\text{IO}_4]^{3-}$, $[\text{IO}_4]^{-}$ and $[(\text{HO})_2\text{I}_2\text{O}_8]^{4+}$. The various equilibrium constants are:

Periodates are both thermodynamically potent and kinetically facile oxidants. The oxidation potential is greatest in acid solution (p. 855) and can be progressively diminished by increasing the pH of the solution. In acid solution it is one of the few reagents that can rapidly and quantitatively convert Mn$^{II}$ to Mn$^{IV}$O$^4$$. In organic chemistry it specifically cleaves 1,2-diols (glycols) and related compounds such as α-diketones, α-ketols, α-aminoalcohols, and α-diamines, e.g.:

\[ \text{Me}_2\text{C} = \text{OH} + \text{O}^− \rightarrow \text{Me}_2\text{C} \cdot \text{O} \cdot \text{O} \cdot \text{OH} \]

\[ \text{Me}_2\text{CO} + \text{I}_2 + \text{H}_2\text{O} \rightarrow \text{Me}_2\text{CO} + \text{I}_2^− + 2\text{H}^+ \]

In rigid systems only cis-difunctional groups are oxidized, the specificity arising from the

---

Halogen oxide fluorides and related compounds

Formation of the cyclic intermediate. Such reactions have been widely used in carbohydrate and nucleic acid chemistry.

Periodates form numerous complexes with transition metals in which the octahedral IO$_6^{5-}$ unit acts as a bidentate chelate. Examples are:

$$[\text{Mn}^{IV}(\text{IO}_6)]^{-}, \ [\text{Ni}^{IV}(\text{IO}_6)]^{-}, \ [\text{Fe}^{III}(\text{IO}_6)]^{2-},$$
$$[\text{Co}^{III}(\text{IO}_6)]^{2-},$$
$$[\text{M}^{IV}(\text{IO}_6)_2]^{5-} \ (\text{M}^{IV} = \text{Pd, Pd, Ce});$$
$$[\text{M}^{III}(\text{IO}_6)_2]^{7-} \ (\text{M}^{III} = \text{Fe, Co, Cu, Ag, Au})$$
$$[\text{Mn}^{IV}(\text{IO}_6)_3]^{11-}, [\text{Fe}^{III}(\text{IO}_6)_3]^{1-},$$
$$[\text{Co}^{III}(\text{IO}_6)_3]^{3-}$$

The stabilization of Ni$^{IV}$, Cu$^{III}$ and Ag$^{III}$ is notable and many of the complexes have very high formation constants, e.g. $[\text{Cu}(\text{IO}_6)_2]^{7-} \approx 1 \times 10^{10}$, $[\text{Co}(\text{IO}_6)_2]^{5-} \approx 1 \times 10^{18}$. The high formal charge on the anion is frequently reduced by protonation of the $[\text{I}(\mu-\text{O})_2\text{O}_4]$ moiety, as in orthoperiodic acid itself. For example $\text{H}_4[\text{Mn}(\text{IO}_6)_3]$ is a heptabasic acid with $pK_1$ and $pK_2 < 0$, $pK_3 2.75$, $pK_4 4.35$, $pK_5 5.45$, $pK_6 9.55$, and $pK_7 10.45$. The crystal structure of $\text{Na}_7[\text{H}_4\text{Mn}(\text{IO}_6)_3]\cdot 17\text{H}_2\text{O}$ features a 6-coordinate paramagnetic Mn$^{IV}$ anion (Fig. 17.25a) whereas the diamagnetic compound $\text{Na}_3\text{K}[\text{H}_3\text{Cu}(\text{IO}_6)_2]\cdot 14\text{H}_2\text{O}$ has square-planar Cu$^{III}$ (Fig. 17.25b).

### 17.2.9 Halogen oxide fluorides and related compounds

This section considers compounds in which X (Cl, Br or I) is bonded to both O and F, i.e. $F_2XO_m$. Oxofluorides $-OF$ and peroxofluorides $-OOF$ have already been discussed (p. 638) and halogen derivatives of oxoacids, containing $-OX$ bonds are treated in the following section (p. 883).

**Chlorine oxide fluorides**

Of the 6 possible oxide fluorides of Cl, 5 have been characterized: they range in stability from the thermally unstable FCl$^{III}$O to the chemically rather inert perchloryl fluoride FCl$^{VII}$O$_3$. The others are FCl$^{V}$O$_2$, F$_3$Cl$^{V}$O and F$_3$Cl$^{VII}$O$_2$.

---

$^{146}$ Ref. 23, pp. 1386–96, The oxyfluorides of the halogens.

formation of the cyclic intermediate. Such reactions have been widely used in carbohydrate and nucleic acid chemistry.

Periodates form numerous complexes with transition metals in which the octahedral $\text{IO}_6^{5-}$ unit acts as a bidentate chelate. Examples are:

- $[\text{Mn}^{\text{IV}}(\text{IO}_6)]^{-}$, $[\text{Ni}^{\text{IV}}(\text{IO}_6)]^{-}$, $[\text{Fe}^{\text{III}}(\text{IO}_6)]^{2-}$
- $[\text{Co}^{\text{III}}(\text{IO}_6)]^{2-}$
- $[\text{M}^{\text{IV}}(\text{IO}_6)_2]^{6-}$ (M$^{\text{IV}}$ = Pd, Pd, Ce);
- $[\text{M}^{\text{III}}(\text{IO}_6)_2]^{7-}$ (M$^{\text{III}}$ = Fe, Co, Cu, Ag, Au)
- $[\text{Mn}^{\text{IV}}(\text{IO}_6)_3]^{11-}$, $[\text{Fe}^{\text{III}}(\text{IO}_6)_3]^{13-}$
- $[\text{Co}^{\text{III}}(\text{IO}_6)_3]^{13-}$

The stabilization of Ni$^{\text{IV}}$, Cu$^{\text{III}}$ and Ag$^{\text{III}}$ is notable and many of the complexes have very high formation constants, e.g. $[\text{Cu}(\text{IO}_6)_2]^{7-} \approx 10^{10}$, $[\text{Co}(\text{IO}_6)_2]^{7-} \approx 10^{18}$. The high formal charge on the anion is frequently reduced by protonation of the $\{\text{I(µ-O)}_2\text{O}_4\}$ moiety, as in orthoperiodic acid itself. For example $\text{H}_1[\text{Mn}(\text{IO}_6)_3]$ is a heptabasic acid with $pK_1$ and $pK_2 < 0$, $pK_3 2.75$, $pK_4 4.35$, $pK_5 5.45$, $pK_6 9.55$, and $pK_7 10.45$. The crystal structure of $\text{Na}_7[\text{H}_4\text{Mn}(\text{IO}_6)_3].17\text{H}_2\text{O}$ features a 6-coordinate paramagnetic Mn$^{\text{IV}}$ anion (Fig. 17.25a) whereas the diamagnetic compound $\text{Na}_3\text{K}[\text{H}_3\text{Cu}(\text{IO}_6)_2].14\text{H}_2\text{O}$ has square-planar Cu$^{\text{III}}$ (Fig. 17.25b).

**17.2.9 Halogen oxide fluorides and related compounds**

This section considers compounds in which X (Cl, Br or I) is bonded to both O and F, i.e. $\text{F}_n\text{XO}_m$. Oxofluorides $\text{OF}$ and peroxofluorides $\text{OF}$ have already been discussed (p. 638) and halogen derivatives of oxoacids, containing $\text{OX}$ bonds are treated in the following section (p. 883).

**Chlorine oxide fluorides**

Of the 6 possible oxide fluorides of Cl, 5 have been characterized: they range in stability from the thermally unstable $\text{FCI}^{\text{III}}\text{O}$ to the chemically rather inert perchloryl fluoride $\text{FCI}^{\text{VII}}\text{O}_3$. The others are $\text{FCI}^{\text{V}}\text{O}_2$, $\text{F}_2\text{Cl}^{\text{V}}\text{O}$ and $\text{F}_3\text{Cl}^{\text{VII}}\text{O}_2$.

---

146 Ref. 23, pp. 1380–96, The oxyfluorides of the halogens.
The remaining compound F$_5$Cl$^{VII}$O has been claimed but the report could not be confirmed. Fewer bromine oxide fluorides are known, only FBrO$_2$, F$_3$BrO and possibly FBrO$_3$ being characterized. The compounds of iodine include the I$^+$ derivatives FIO$_2$ and F$_3$I0 and the I$^{VII}$ derivatives FIO$_3$, F$_3$IO$_2$ and F$_3$IO. All the halogen oxide fluorides resemble the halogen fluorides (p. 824), to which they are closely related both structurally and chemically. Thus they tend to be very reactive oxidizing and fluorinating agents and several can act as Lewis acids or bases (or both) by gain or loss of fluoride ions, respectively.

The structures of the chlorine oxide fluorides are summarized in Fig. 17.26, together with those of related cationic and anionic species formed from the neutral molecules by gain or loss of F$^-$. The first conclusive evidence for free FClO in the gas phase came in 1972 during a study of the hydrolysis of ClF$_3$ with substoichiometric amounts of H$_2$O in a flow reactor:

\[ \text{ClF}_3 + \text{H}_2\text{O} \rightarrow \text{FCIO} + 2\text{HF} \]

The compound is thermally unstable, and decomposes with a half-life of about 25 s at room temperature:

\[ \text{ClF}_3 + \frac{1}{2} \text{O}_2 + \text{H}_2\text{O} \rightarrow \text{FCIO}_2 + \text{ClF} \]

The compound can also be made by photolysis of a mixture of ClF and O$_2$ in Ar at 4–15 K; evidence for the expected nonlinear by structure comes from vibration spectroscopy (Fig. 17.26a).

F$_3$ClO was discovered in 1965 but not published until 1972 because of US security classification. It has low kinetic stability and is an extremely powerful fluorinating and oxidizing agent. It can be made in yields of up to 80% by fluorination of Cl$_2$O in the presence of metal fluorides, e.g. NaF:

\[ \text{Cl}_2\text{O} + 2\text{F}_2 \rightarrow \text{F}_3\text{ClO} + \text{ClF} \]

However, the unpredictably explosive nature of Cl$_2$O in the liquid state renders this process somewhat hazardous and the best large-scale preparation is the low-temperature fluorination of ClONO$_2$ (p. 884):

\[ \text{ClONO}_2 + 2\text{F}_2 \rightarrow \text{F}_3\text{ClO} + \text{FNO}_2 \]

F$_3$ClO is a colourless gas or liquid: mp $-43^\circ$, bp $28^\circ$ $d(1, 20^\circ) 1.865$ g cm$^{-3}$. The compound
is stable at room temperature: \( \Delta H^\circ_e(g) = -148 \text{ kJ mol}^{-1}, \Delta H^\circ_i(l) = -179 \text{ kJ mol}^{-1}. \) Its \( C_s \) structure (Fig. 17.26d) has been established by gas electron diffraction which also led to the dimensions \( \text{Cl} = 140.5 \text{ pm}, \text{Cl} - F_{eq} = 160.3 \text{ pm}, \text{Cl} - F_{ax} = 171.3 \text{ pm}, \) and angle \( F_{ax} - \text{Cl} - F_{ax} = 171^\circ; \) other angles are \( F_{eq} - \text{Cl} - F_{eq} = 88^\circ, F_{ax} - \text{Cl} - F_{eq} = 95^\circ \) and \( F_{eq} - \text{Cl} - F_{ax} = 109^\circ. \) \( F_3ClO \) can be handled in well-passivated metal, Teflon or Kel-F but reacts rapidly with glass or quartz. Its thermal stability is intermediate between those of \( ClF_3 \) and \( ClF_5 \) (p. 832) and it decomposes above \( 300^\circ C \) according to

\[
F_3ClO \rightarrow ClF_3 + \frac{1}{2}O_2
\]

\( F_3ClO \) tends to react slowly at room temperature but rapidly on heating or under ultraviolet irradiation. Typical of its fluorinating reactions are:

\[
\begin{align*}
\text{Cl}_2 + F_3ClO & \rightarrow 3ClF + \frac{1}{2}O_2 \\
\text{Cl}_2O + F_3ClO & \rightarrow 2ClF + FCIO_2 \\
\text{ClISO}_2F + F_3ClO & \rightarrow SO_2F_2 + FCIO_2 + ClF \\
2\text{ClISO}_2F + F_3ClO & \rightarrow S_2O_5F_2 + FCIO_2 + 2ClF
\end{align*}
\]

Combined fluorinating and oxygenating capacity is exemplified by the following (some of the reactions being complicated by further reaction of the products with \( F_3ClO \)):

\[
\begin{align*}
\text{SF}_4 + F_3ClO & \rightarrow \text{SF}_6, FCIO_2, SF_5Cl, SF_4O \\
\text{MoF}_5 + F_3ClO & \rightarrow \text{MoF}_6, MF_3O \\
2\text{N}_2F_4 + F_3ClO & \rightarrow 3\text{NF}_3 + \text{FNO} + ClF \\
HNF_2 + F_3ClO & \rightarrow \text{NF}_3O, NF_2Cl, N_2F_4, FCIO_2, HF \\
F_2NC(O)F + F_3ClO & \rightarrow NF_5O, ClNF_2, N_2F_4
\end{align*}
\]

It reacts as a reducing agent towards the extremely strong oxidant \( PtF_6^- \):

\[
F_3ClO + PtF_6^- \rightarrow [F_2ClO]^+ [PtF_6]^- + \frac{1}{2}F_2
\]

Hydrolysis with small amounts of water yields HF but this can react further by fluoride ion abstraction:

\[
\begin{align*}
F_3ClO + H_2O & \rightarrow FCIO_2 + 2HF \\
F_3ClO + HF & \rightarrow [F_2ClO]^+ [HF_2]^- \\
\end{align*}
\]

This last reaction is typical of many in which \( F_3ClO \) can act as a Lewis base by fluoride ion donation to acceptors such as \( MF_5 \) (M = P, As, Sb, Bi, V, Nb, Ta, Pt, U), MoF_4O, SiF_4, BF_3, etc. These products are all white, stable, crystalline solids (except the canary yellow \( PtF_6^- \)) and contain the \([F_2ClO]^+ \) cation (see Fig. 17.26h) which is isostructural with the isoelectronic \( F_2SO \). Chlorine trifluoride oxide can also act as a Lewis acid (fluoride ion acceptor) and is therefore to be considered as amphoteric (p. 225). For example \( KF, RbF \) and \( CsF \) yield \( M^+ [F_2ClO]^- \) as white solids whose stabilities increase with increasing size of \( M^+ \). Vibration spectroscopy establishes the \( C_{4v} \) structure of the anion (Fig. 17.29b).

The other \( Cl^\prime \) oxide fluoride \( FCIO_2 \) (1942) can be made by the low-temperature fluorination of \( ClO_2 \) but is best prepared by the reaction:

\[
6NaClO_3 + 4ClF_3 \xrightarrow{\text{rt/1 day}} 6FCIO_2 + 6NaF + 2Cl_2 + 3O_2
\]

The \( C_s \) structure and dimensions (Fig. 17.26b) were established by microwave spectroscopy which also yielded a value for the molecular dipole moment \( \mu = 1.72 \text{ D}. \) Other physical properties of this colourless gas are mp \(-115^\circ \) (or \(-123^\circ \), \( bp \sim -6^\circ \), \( \Delta H^\circ_f(g, 298 \text{ K}) = -34 \pm 10 \text{ kJ mol}^{-1} \) [or \(-273 \text{ kJ mol}^{-1} \) when corrected for \( \Delta H^\circ_f(HF, g) \)]]. FCIO_2 is thermally stable at room temperature in dry passivated metal containers and quartz. Thermal decomposition of the gas (first-order kinetics) only becomes measurable above \( 300^\circ \) in quartz and above \( 200^\circ \) in Monel metal:

\[
\text{FCIO}_2(g) \rightarrow \text{ClF}(g) + O_2(g)
\]

It is far more chemically reactive than \( FCIO_3 \) (p. 879) despite the lower oxidation state of Cl.
Hydrolysis is slow at room temperature and the corresponding reaction with anhydrous HNO₃ results in dehydration to the parent N₂O₅:

\[
2\text{FCIO}_2 + \text{H}_2\text{O} \rightarrow 2\text{HF} + 2\text{ClO}_2 + \frac{1}{2}\text{O}_2
\]

\[
2\text{FCIO}_2 + 2\text{HONO}_2 \rightarrow 2\text{HF} + 2\text{ClO}_2 + \frac{1}{2}\text{O}_2 + \text{N}_2\text{O}_3
\]

Other reactions with protonic reagents are:

\[
2\text{OH}^- (\text{aq}) + \text{FCIO}_2 \rightarrow \text{ClO}_3^- + \text{F}^- + \text{H}_2\text{O}
\]

\[
\text{NH}_3(\text{l}) + \text{FCIO}_2 \rightarrow \text{NH}_4\text{Cl}, \text{NH}_4\text{F}
\]

\[
\text{HCl}(\text{l}) + \text{FCIO}_2 \rightarrow \text{HF} + \text{ClO}_2 + \frac{1}{2}\text{Cl}_2
\]

\[
\text{HOSO}_2\text{F} + \text{FCIO}_2 \rightarrow \text{HF} + \text{ClO}_2\text{OSO}_2\text{F}
\]

\[
\text{HOCIO}_3 (\text{anhydrous}) + \text{FCIO}_2 \rightarrow \text{HF} + \text{ClO}_2\text{OCIO}_3
\]

\[
\text{SO}_3 + \text{FCIO}_2 \rightarrow \text{ClO}_2\text{OSO}_2\text{F} (\text{insertion})
\]

FCIO₂ explodes with the strong reducing agent SO₂ even at -40° and HBr likewise explodes at -110°.

Chlorine dioxide fluoride is a good fluorinating agent and a moderately strong oxidant: SF₄ is oxidized to SF₆, SF₃O and SF₂O₂ above 50°, whereas N₂F₄ yields NF₃, FNO₂ and FNO at 30°. UF₄ is oxidized to UF₅ at room temperature and to UF₆ at 100°. Chlorides (and some oxides) are fluorinated and the products can react further to form fluoro complexes. Thus, whereas AlCl₃ yields AlF₃, B₂O₃ affords [ClO₂⁺BF₄⁻], and the Lewis acid chlorides SbCl₅, SnCl₄ and TiCl₄ yield [ClO₂⁺][SbF₆]⁻, [ClO₂⁺][Zn(SF₆)]²⁻ and [ClO₂⁺]₂[TiF₆]²⁻. Such complexes, and many others can, of course, be prepared directly from the corresponding fluorides either with or without concurrent oxidation, e.g.:

\[
\text{AsF}_3 + 3\text{FCIO}_2 \rightarrow [\text{ClO}_2]^+ [\text{AsF}_6]^- + 2\text{ClO}_2
\]

\[
\text{SbF}_5 + \text{FCIO}_2 \rightarrow [\text{ClO}_2]^+ [\text{SbF}_6]^- (\text{mp } 220°)
\]

\[
2\text{SbF}_5 + \text{FCIO}_2 \rightarrow [\text{ClO}_2]^+ [\text{Sb}_2\text{F}_{11}]^-
\]

An X-ray study on this last compound showed the chloryl cation to have the expected nonlinear structure, with angle OCIO 122° and Cl–O 131 pm. FCIO₂ can also act as a fluoride ion acceptor, though not so readily as F₃ClO₂ above. For example CsF reacts at room temperature to give the white solid Cs[FCIO₂]; this is stable at room temperature but dissociates reversibly into its components above 100°. The C₂₀ structure of [F₂ClO₂]⁻ (Fig. 17.26f) is deduced from its vibration spectrum.

The two remaining ClVII oxide fluorides are F₃ClO₂ and FCIO₃. At one time F₃ClO₂ was thought to exist in isomeric forms but the so-called violet form, previously thought to be the peroxo compound F₂ClOOF has now been discounted. The well-defined compound F₃ClO₂ was first made in 1972 as an extremely reactive colourless gas: mp -81.2°, bp -21.6°. It is a very strong oxidant and fluorinating agent and, because of its corrosive action, must be handled in Teflon or sapphire apparatus. It thus resembles the higher chlorine fluorides. The synthesis of F₃ClO₂ is complicated and depends on an ingenious sequence of fluorine-transfer reactions as outlined below:

\[
2\text{FCIO}_2 + 2\text{PtF}_6 \rightarrow \text{[F}_2\text{ClO}_2][\text{PtF}_6]^- + \text{[ClO}_2][\text{PtF}_6]^- + 2\text{FNO}_2
\]

\[
\text{F}_3\text{ClO}_2 + \text{FCIO}_2 + 2\text{[NO}_2][\text{PtF}_6]^- \rightarrow 2\text{FNO}_2
\]

Fractional condensation at -112° removes most of the FCIO₂, which is slightly less volatile than F₃ClO₂. The remaining FCIO₂ is removed by complexing with BF₃ and then relying on the greater stability of the F₃ClO₂ complex:

\[
[\text{ClO}_2]^+ [\text{BF}_4]^- (\text{dissoc press } 1 \text{ atm at } 44°C)
\]

\[
\text{FCIO}_2 (\text{mixture}) + 2\text{BF}_3 \rightarrow 2\text{F}_3\text{ClO}_2 \rightarrow [\text{F}_2\text{ClO}_2]^+ [\text{BF}_4]^- \text{ stable at room temperature}
\]

Pumping at 20° removes [ClO₂⁺][BF₄⁻] as its component gases, leaving [F₂ClO₂⁺][BF₄⁻] which, on treatment with FNO₂, releases the
desired product:

\[
[F_2ClO_2]^+ [BF_4]^- + FNO_2 \rightarrow [NO_2]^+ [BF_4]^- + F_3ClO_2
\]

The whole sequence of reactions represents a tour de force in the elegant manipulation of extremely reactive compounds. \(F_3ClO_2\) is a violent oxidizing reagent but forms stable adducts by fluoride ion transfer to Lewis acids such as \(BF_3\), \(AsF_5\) and \(PtF_6\). The structures of \(F_3ClO_2\) and \([F_2ClO_2]^+\) have \(C_{2v}\) symmetry as expected (Fig. 17.26e and i).

In dramatic contrast to \(F_3ClO_2\), perchloryl fluoride (\(FClO_3\)) is notably inert, particularly at room temperature. This colourless tetrahedral molecular gas (Fig. 17.26c) was first synthesized in 1951 by fluorination of \(KClO_3\) at \(-40^\circ\) and it can also be made (in 50% yield) by the action of \(F_2\) on an aqueous solution of \(NaClO_3\). Electrolysis of \(NaClO_4\) in anhydrous HF has also been used but the most convenient route for industrial scale manufacture is the fluorination of a perchlorate with \(SbF_5\), \(SbFS/HF\), \(HOSO_2F\) or perhaps best of all \(HOSO_2F/SbF_5\):

\[
\text{HOSO}_2\text{F/SbF}_5 \quad \xrightarrow{\text{rt (or above)}} \quad \text{FClO}_3 \quad (97\% \text{ yield})
\]

Because of its remarkably low reactivity at room temperature and its very high specific impulse, the gas has been much studied as a rocket propellant oxidizer (e.g. it compares favourably with \(N_2O_4\) and with \(ClF_3\) as an oxidizer for fuels such as \(N_2H_4\), \(Me_2NNH_2\) and \(LiH\)). \(FClO_3\) has \(mp\) \(-147.8^\circ\), \(bp\) \(-46.7^\circ\), \(d(I, -73^\circ\) C\) 1.782 g cm\(^{-3}\), viscosity \(\eta(-73^\circ)\) 0.55 centipoise. The extremely low dipole moment (\(\mu = 0.023\) D) is particularly noteworthy. \(FClO_3\) has high kinetic stability despite its modest thermodynamic instability: \(\Delta H_f^\circ(g, 298\ K) = -23.8\) kJ mol\(^{-1}\), \(\Delta G_f^\circ(g, 298\ K) +48.1\) kJ mol\(^{-1}\). \(FClO_3\) offers the highest known resistance to dielectric breakdown for any gas (30% greater than for \(SF_6\), p. 687) and has been used as an insulator in high-voltage systems.

Perchloryl fluoride is thermally stable up to about \(400^\circ\). Above \(465^\circ\) it undergoes decomposition with first-order kinetics and an activation energy of \(244\) kJ mol\(^{-1}\). Hydrolysis is slow even at \(250–300^\circ\) and quantitative reaction is only achieved with concentrated aqueous hydroxide in a sealed tube under high pressure at \(300^\circ\):

\[
FClO_3 + 2NaOH \rightarrow NaClO_4 + NaF + H_2O
\]

However, alcoholic KOH effects a similar quantitative reaction at \(25^\circ\). Reaction with liquid \(NH_3\) is also smooth particularly in the presence of a strong nucleophile such as \(NaNH_2\):

\[
FClO_3 + 3NH_3 \rightarrow [NH_4]^+ [HNClO_3]^- + NH_4F
\]

Metallic Na and K react only above \(300^\circ\). \(FClO_3\) shows no tendency to form adducts with either Lewis acids or bases. This is in sharp contrast to most of the other oxide fluorides of chlorine discussed above and has been related to the preferred tetrahedral \((C_{3v})\) geometry as compared with the planar \((D_{3h})\) and trigonal bipyramidal \((D_{3h})\) geometries expected for \([ClO_3]^+\) and \([F_2ClO_3]^-\) respectively. Conversely the pseudo-trigonal bipyramidal \(C_3\) structure \(F_3ClO\) gains stability when converted to the pseudo-tetrahedral \([F_2ClO]^+\) or pseudo-octahedral \([F_4ClO]^-\) (see Fig. 17.26).

In reactions with organic compounds \(FClO_3\) acts either as an oxidant or as a 1- or 2-centre electrophile which can therefore be used to introduce either F, a \(-ClO_3\) group, or both F and O into the molecule. As \(FClO_3\) is highly susceptible to nucleophilic attack at Cl it reacts readily with organic anions:

\[
FClO_3 + Li^+ Ph^- \rightarrow PhClO_3 + LiF
\]

\[
FClO_3 + Li^+ [C_4H_3 S]^- \rightarrow [\text{S-F-LiClO}_3]
\]

Compounds having a cyclic double bond conjugated to an aromatic ring (e.g. indene) undergo oxofluorination, with \(FClO_3\) acting as a 2-centre electrophile:
The Halogens: Fluorine, Chlorine, Bromine, Iodine and Astatine  Ch. 17

FC1O3 also acts as a mild fluorinating agent for compounds possessing a reactive methylene group, e.g.:

\[
\text{CH}_2(\text{CO}_2\text{R})_2 + \text{FCIO}_3 \rightarrow \text{CF}_2(\text{CO}_2\text{R})_2
\]

It is particularly useful for selective fluorination of steroids.

Bromine oxide fluorides\(^{(149)}\)

These compounds are less numerous and rather less studied than their chlorine analogues; indeed, until fairly recently only FBrO\(_2\) was well characterized. The known species are:

<table>
<thead>
<tr>

<td></td>
</tr>
</tbody>
</table>

Despite several attempts at synthesis, there is little or no evidence for the existence of FBrO, F\(_3\)BrO\(_2\) or F\(_5\)BrO. The bromine oxide fluorides are somewhat less thermally stable than their chlorine analogues and somewhat more reactive chemically. The structures are as already described for the chlorine oxide fluorides (Fig. 17.26).

Bromyl fluoride, FBrO\(_2\), is a colourless liquid, mp \(-9^\circ\), which attacks glass at room temperature and which undergoes rapid decomposition above \(55^\circ\):

\[
3\text{FBrO}_2 \xrightarrow{\Delta} \text{BrF}_3 + \text{Br}_2 + 3\text{O}_2
\]

It is best prepared by fluorine transfer reactions such as

\[
\text{K[F}_2\text{BrO}_2\] + \text{HF}(\text{aq}) \rightarrow \text{KHF}_2 + \text{FBrO}_2
\]

The \(\text{K[F}_2\text{BrO}_2\] can be prepared by fluorination of KBrO\(_3\) with BrF\(_5\) in the presence of a trace of HF:

\[
\text{KBrO}_3 + \text{BrF}_5 \rightarrow \text{FBrO}_2 + \text{K[F}_4\text{BrO}\]

However, the most convenient method of preparation of \(\text{K[F}_2\text{BrO}_2\] is by reaction of KBrO\(_3\) with KBrF\(_6\) in MeCN:

\[
\text{KBrO}_3 + \text{KBrF}_6 \rightarrow \text{K[F}_2\text{BrO}_2\] \downarrow
\]

+ K[F\(_4\)BrO] (sol)

Bromyl fluoride is also produced by fluorine-oxygen exchange between BrF\(_5\) and oxoiodine compounds (p. 881), e.g.:

\[
\text{FI}_2\text{O} + \text{BrF}_5 \rightarrow \text{FBrO}_2 + \text{IF}_5
\]

\[
2\text{F}_2\text{IO} + \text{BrF}_5 \rightarrow \text{FBrO}_2 + 2\text{IF}_5
\]

\[
2\text{I}_2\text{O}_5 + 5\text{BrF}_5 \rightarrow 5\text{FBrO}_2 + 4\text{IF}_5
\]

As with FCIO\(_3\) and FI\(_2\)O, hydrolysis regenerates the halate ion, the reaction with FBrO\(_2\) being of explosive violence. Hydrolysis in basic solution at \(0^\circ\) can be represented as

\[
\text{FBrO}_2 + 2\text{OH}^- \rightarrow \text{BrO}_3^- + \text{F}^- + \text{H}_2\text{O}
\]

Organic substances react vigorously, often enflaming. Co-condensation of FBrO\(_2\) with the Lewis acid AsF\(_5\) produced \([\text{BrO}_2]\)\(^+\)[AsF\(_6\)]\(^-\). Vibrational spectra establish the expected non-linear structure of the cation (3 bands active in both Raman and infrared). FBrO\(_2\) can also react as a fluoride ion acceptor (from KF).

Bromine oxide trifluoride, F\(_3\)BrO, is made by reaction of K[F\(_4\)BrO] with a weak Lewis acid:

\[
\text{K[F}_4\text{BrO}\] + [\text{O}_2]\)\(^+\)[AsF\(_6\)]\(^-\) \rightarrow \text{F}_3\text{BrO}
\]

+ KAsF\(_6\) + \text{O}_2 + \frac{1}{2}\text{F}_2

\[
\text{K[F}_4\text{BrO}\] + \text{HF(anhdyr)} \rightarrow \text{F}_3\text{BrO} + \text{KHF}_2
\]

The product is a white solid which melts to a clear liquid at about \(-5^\circ\); it is only marginally stable at room temperature and slowly decomposes with loss of oxygen:

\[
F_3\text{BrO} \rightarrow \text{BrF}_3 + \frac{1}{2}\text{O}_2
\]

The molecular symmetry is \(C_\text{s}\) (like \(F_3\text{ClO}\); Fig. 17.26d) and there is some evidence for weak intermolecular association via \(\text{F}_\text{ax}-\text{Br} \cdots \text{F}_\text{ax}\) bonding. Fluoride ion transfer reactions have been established and yield compounds such as \([F_2\text{BrO}]^+\text{[AsF}_6^-\), \([F_2\text{BrO}]^+\text{[BF}_4^-\) and \(K[F_4\text{BrO}]\), though this last compound is more conveniently made independently, e.g. by the reaction of \(K\text{BrO}_3\) with \(K\text{BrF}_6\) mentioned above, or by direct fluorination of \(K[F_2\text{BrO}_3]\):

\[
K[F_2\text{BrO}_3] + \text{F}_2 \rightarrow K[F_4\text{BrO}] + \frac{1}{2}\text{O}_2
\]

Perbromyl fluoride, \(\text{FBrO}_3\), is made by fluorinating the corresponding perbromate ion with \(\text{AsF}_5\), \(\text{SbF}_5\), \(\text{BrF}_5\) or \([\text{BrF}_6]^+\text{[AsF}_6^-\) in HF solutions. The reactions are smooth and quantitative at room temperature:

\[
\begin{align*}
K\text{BrO}_4 + 2\text{AsF}_5 + 3\text{HF} & \rightarrow \text{FBrO}_3 + [\text{H}_3\text{O}]^+\text{[AsF}_6^-]^- + K\text{AsF}_6 \\
2K\text{BrO}_4 + \text{BrF}_5 + 2\text{HF} & \rightarrow 2\text{FBrO}_3 + \text{FBrO}_2 + 2K\text{HF}_2 \\
K\text{BrO}_4 + [\text{BrF}_6]^+\text{[AsF}_6^-]^- & \rightarrow \text{FBrO}_3 + \text{BrF}_5 + \frac{1}{2}\text{O}_2 + K\text{AsF}_6
\end{align*}
\]

Perbromyl fluoride is a reactive gas which condenses to a colourless liquid (bp \(2.4^\circ\)) and then solidifies to a white solid (mp ca. \(\sim 110^\circ\)). It has the expected \(C_{3\nu}\) symmetry Fig. 17.27 and decomposes slowly at room temperature; it is more reactive than \(\text{FCIO}_2\) and, unlike that compound, it reacts rapidly with water, aqueous base and even glass:

\[
\begin{align*}
\text{FBrO}_3 + \text{H}_2\text{O} & \rightarrow \text{BrO}_4^- + \text{HF} + \text{H}^+ \\
\text{FBrO}_3 + 2\text{OH}^- & \rightarrow \text{BrO}_4^- + \text{F}^- + \text{H}_2\text{O}
\end{align*}
\]

Fluoride ion transfer reactions have not been established for \(\text{FBrO}_3\) and may be unlikely, (see p. 879).

\[\text{Figure 17.27}\] Structure of \(\text{FBrO}_3\) as determined by gas-phase electron diffraction.

### Iodine oxide fluorides

The compounds to be considered are the \(I^\text{V}\) derivatives \(\text{FIO}_2\) and \(\text{F}_3\text{IO}\) and the \(I^{\text{VI}}\) derivatives \(\text{FIO}_3\), \(\text{F}_3\text{IO}_2\) and \(\text{F}_3\text{IO}\). Note that, unlike Cl, no \(I^{\text{III}}\) compound \(\text{FIO}\) has been reported and that, conversely, \(\text{F}_5\text{IO}\) (but not \(\text{F}_5\text{ClO}\)) has been characterized.

\(\text{FIO}_2\) has been prepared both by direct fluorination of \(\text{I}_2\text{O}_5\) in anhydrous HF at room temperature and by thermal dismutation of \(\text{F}_3\text{IO}\):

\[
\begin{align*}
\text{I}_2\text{O}_5 + \text{F}_2 & \xrightarrow{\text{HF/20}^\circ} 2\text{FIO}_2 + \frac{1}{2}\text{O}_2 \\
2\text{F}_3\text{IO} & \xrightarrow{110^\circ} \text{FIO}_2 + \text{IF}_5
\end{align*}
\]

Unlike gaseous molecular \(\text{FCIO}_2\), it is a colourless polymeric solid which decomposes without melting when heated above \(200^\circ\). Like the other halyl fluorides it readily undergoes alkaline hydrolysis and also forms a complex with \(\text{F}^-\):

\[
\begin{align*}
\text{FIO}_2 + 2\text{OH}^- & \rightarrow \text{IO}_3^- + \text{F}^- + \text{H}_2\text{O} \\
\text{FIO}_2 + \text{KF} & \xrightarrow{\text{HF}} \text{K}^+\text{[F}_2\text{IO}_2^-]
\end{align*}
\]

An X-ray study of this latter complex reveals a \(C_{3\nu}\) anion as in the chlorine analogue (Fig. 17.28a). This is closely related to the \(C_\text{s}\) structure of the neutral molecule \(\text{F}_3\text{IO}\) (Fig. 17.28b).

\(\text{F}_3\text{IO}\) is prepared as colourless crystals by dissolving \(\text{I}_2\text{O}_5\) in boiling \(\text{IF}_5\) and then cooling the mixture:

\[
\text{I}_2\text{O}_5 + 3\text{IF}_5 \xrightarrow{105^\circ} 5\text{F}_3\text{IO}
\]
Above 110° it dismutates into FIO2 and IF3 as mentioned above.

Of the I"" oxide fluorides FIO3 has been prepared by the action of F2/liquid HF on HIO4. It is a white, crystalline solid, stable in glass but decomposing with loss of oxygen on being heated:

\[
\text{FIO}_3 \xrightarrow{100^\circ} \text{FIO}_2 + \frac{1}{2}\text{O}_2
\]

Unlike its analogue FClO3 it forms adducts with BF3 and AsF5, possibly by F\(^-\) donation to give [IO3]\(^+\)[BF4\(^-\)] and [IO3]\(^+\)[AsF6\(^-\)], though the structures have not yet been determined. Alternatively, the coordination number of the central I atom might be increased. SO3 reduces FIO3 to iodyl fluorosulfate:

\[
\text{FIO}_3 + \text{SO}_3 \rightarrow \text{IO}_2\text{SO}_2\text{F} + \text{O}_2
\]

Like FClO3 it reacts with NH3 but the products have not been fully characterized.

F3IO2, first made in 1969, has posed an interesting structural problem. The yellow solid, mp 41°, can be prepared by partial fluorination of a periodate with fluorosulfuric acid:

\[
\text{Ba}_3\text{H}_4(\text{IO}_6)_2 \xrightarrow{\text{HSO}_3\text{F}} [\text{HIO}_2\text{F}_4] \xrightarrow{\text{SO}_3} \text{F}_3\text{IO}_2
\]

Unlike monomeric F3ClO2 (p. 878) the structure is oligomeric not only in the solid state but also in the gaseous and solution phases. This arises from the familiar tendency of iodine to increase its coordination number to 6. Fluorine-19 nmr and Raman spectroscopy of F3IO2 dissolved in BrF3 at -48° have been interpreted in terms of a cis-oxygen-bridged trimer with axial terminal O atoms and a C3\(^v\) boat conformation (Fig. 17.28c).\(^{150}\) On warming the solution to 50° there is a fast interconversion between this and the C\(^s\) chair conformer. The vibration spectrum of the gas phase at room temperature has been interpreted in terms of a centrosymmetric dimer.

---

31.7.2.10 Halogen derivatives of oxoacids

(Fig. 17.28d). There is significant dissociation into monomers at 100° and this is almost complete at 185°. The centrosymmetric dimer has also been found in an X-ray study of the crystalline solid at −80° (Fig. 17.28d). Complexes of F$_3$IO$_2$ with AsF$_5$, SbF$_5$, NbF$_5$ and TaF$_5$ have been studied; they are oxygen-bridged polymers with alternating [F$_4$IO$_2$] and [O$_2$MF$_4$] groups. For example, the crystal structure of the complex with SbF$_5$ shows it to be dimeric (Fig. 17.29a). A similar structure motif is found in the adduct F$_3$IO:F$_3$IO$_2$ which features alternating 5- and 6-coordinate I atoms (Fig. 17.29b); the structure can be regarded as a cyclic dimer of the ion pair [F$_2$IO]$_2$+[F$_4$IO$_2$]$^-$. See also p. 885 for the mixed valence oxo-iodine polymeric cation in [(IO$_2$)$_3$]$^+$HSO$_4^-$.

Finally in this section we mention iodine oxide pentafluoride, F$_3$IO, obtained as a colourless liquid, mp 45°, when IF$_7$ is allowed to react with water, silica, glass or I$_2$O$_5$. As implied by its preparation from water, F$_5$IO is not readily hydrolysed. Vibrational spectroscopy and $^{19}$F nmr studies point to the 6-coordinate $C_{4v}$ geometry in Fig. 17.28c (i.e. $I^{VI}$) rather than the alternative 5-coordinate structure F$_4$I$^V$OF. Microwave spectroscopy yields a value of 1.08 D for the molecular dipole moment.

17.2.10 Halogen derivatives of oxoacids

Numerous compounds are known in which the H atom of an oxoacid has been replaced by a halogen atom. Examples are:

- halogen(I) perchlorates XOCIO$_3$ (X=F, Cl, Br, I)
- halogen(I) fluorsulfates XOSO$_2$F (X=F, Cl, Br, I)
- halogen(I) nitrates XONO$_2$ (X=F, Cl, Br, I)

In addition, halogen(III) derivatives such as Br(ONO$_2$)$_3$, I(ONO$_2$)$_3$, Br(OSO$_2$)F$_3$ and I(OSO$_2$F)$_3$ are known, as well as complexes M$^I$-[X$^I$(ONO$_2$)$_2$]$, \ M^I[\tau^I$(ONO$_2$)$_2$]$, \ M^I[X^III$(OSO$_2$F)$_4$] (X=Br, I). In general, thermal stability decreases with increase in atomic number of the halogen.

The properties of halogen(I) perchlorates are in Table 17.25. FOCIO$_3$ was originally prepared

by the action of F₂ on concentrated HOC103, but the product had a pronounced tendency to explode on freezing. More recently, extremely pure FOCI03 has been obtained by thermal decomposition of NF₄ClO₄ and such samples can be manipulated and repeatedly frozen without mishap. Thermal decomposition occurs via two routes:

ClF + 2O₂ → FOCI03 → FClO₂ + O₂

It readily oxidizes iodide ions: FOCI03 + 2I⁻ → ClO₄⁻ + F⁻ + I₂. FOCI03 also adds to C=C double bonds in fluorocarbons to give perfluoroalkyl perchlorates:

CF₂=CF₂ + FOCI03 → CF₃CF₂OCIO₃

CF₃CF = CF₂ + FOCI03 → CF₃CF₂CF₂OCIO₃

68%

+ CF₃CF(OCIO₃)CF₃ 32%

The formation of isomers in this last reaction implies a low bond polarity of FO⁻ in FOCI03.

Chlorine perchlorate, ClOClO₃, is made by low-temperature metathesis:

MClO₄ + ClO₄SO₂F → ClOClO₃ + MSO₃F

(M=Cs, NO₂)

The bromine analogue can be made similarly using BrOSO₂F at -20° or by direct bromination of ClOClO₃ with Br₂ at -45°. Both compounds are thermally unstable and shock sensitive; e.g. ClOClO₃ decomposes predominantly to Cl₂O₆ with smaller amounts of ClO₂, Cl₂ and O₂ on gentle warming. Direct iodination of ClOClO₃ at -50° yields the polymeric white solid I(ClOClO₃)₃ rather than IOClO₃; this latter compound has never been obtained pure but is among the products of the reaction of I₂ with AgClO₄ at -85°, the other products being I(ClOClO₃)₃, Ag[I(ClOClO₃)₂] and AgI.

Halogen nitrates are even less thermally stable than the perchlorates: they are made by the action of AgNO₃ on an alcoholic solution of the halogen at low temperature. With an excess of AgNO₃, bromine and iodine yield X(NO₃)₃. Numerous other routes are available; e.g., the reaction of CIF on HONO₂ gives a 90% yield of ClONO₂ and the best preparation of this compound is probably the reaction

Cl₂O + N₂O₅ → 2ClONO₂

Some physical properties are in Table 17.26. Both FONO₂ and ClONO₂ feature planar NO₃ groups with the halogen atom out of the plane. ClONO₂ has been used to convert metal chlorides to anhydrous metal nitrates, e.g. Ti(NO₃)₄. Likewise ICl₃ at -30° yields I(NO₃)₃. ClONO₂ and IONO₂ add across C=C double bonds, e.g.:

CH₂=CMe₂ + Cl−ONO₂ → CICH₂C(Me₂)ONO₂

Several other reactions have been studied but the overall picture is one of thermal instability,
hazardous explosions, and vigorous chemical reactivity leading to complex mixtures of products.

The halogen fluorosulfates are amongst the most stable of the oxoacid derivatives of the halogens. FOSO$_2$F is made by direct addition of F$_2$ to SO$_3$ and the others are made by direct combination of the halogen with an equimolar quantity of peroxodisulfuryl difluoride, S$_2$O$_6$F$_2$ (p. 640). With an excess of S$_2$O$_6$F$_2$, bromine and iodine yield X(OSO$_2$F)$_3$. An alternative route to ClOSO$_2$F is the direct addition of CIF to SO$_3$, whilst BrOSO$_2$F and IOSO$_2$F can be made by thermal decomposition of the corresponding X(OSO$_2$F)$_3$. The halogen fluorosulfates are thermally unstable, moisture sensitive, highly reactive compounds. Some physical properties are summarized in Table 17.27. The vibrational spectra of FOSO$_2$ and ClIOSO$_2$F are consistent with C$_4$ molecular symmetry as in HOSO$_2$F:

![Diagram]

Much of the chemistry of the halogen fluorosulfates resembles that of the interhalogens (p. 824) and in many respects the fluorosulfate group can be regarded as a pseudohalogen (p. 319). There is some evidence of ionic self-dissociation and reactions can be classified as exchange, addition, displacement and complexation. This is illustrated for the iodine fluorosulfates in the following scheme:($^{156}$)

\[
\begin{align*}
\text{IF}_3(\text{OSO}_2\text{F})_2 & \rightarrow \text{FOSO}_2\text{F} & \rightarrow & \text{I}_2 & \rightarrow & \text{S}_2\text{O}_6\text{F}_2 \\

\end{align*}
\]

BrOSO$_2$F has also been used to prepare new N-bromo sulfonimides such as (CF$_3$SO$_2$)$_2$NBr.$^{(157)}$ Other novel compounds include [I(OSO$_2$F)$_2$]$^{+}$-I$^{-}$.$^{(158)}$ and the mixed valent iodine (III,V) poly-cation in [(IO$_2$)$_3$]$^{+}$HSO$_4$$.^{(159)}$

156 Ref. 23, pp. 1466–75, Halogen derivatives of oxyacids.

conclusions. Nevertheless, a picture of the element is emerging, as outlined below. The synthesis of the element (p. 795), its natural occurrence in rare branches of the $^{235}$U decay series (p. 796), and its atomic properties (p. 800) have already been mentioned.

The chemistry of At is most conveniently studied using $^{211}$At ($t_{1/2}$ 7.21 h). This isotope is prepared by $\alpha$-particle bombardment of $^{209}$Bi using acceleration energies in the range 26–29 MeV. Higher energies result in the concurrent formation of $^{213}$At and $^{209}$At which complicate the subsequent radiochemical assays. The Bi is irradiated either as the metal or its oxide and the target must be cooled to avoid volatilization of the At produced. Astatine is then removed by heating the target to 300–600° (i.e. above the mp of Bi, 217°) in a stream of N$_2$ and depositing the sublimed element on a glass cold finger or cooled Pt disc. Aqueous solutions of the element can be prepared by washing the cold finger or disc with dilute HNO$_3$ or HCl. Alternatively, the irradiated target can be dissolved in perchloric acid containing a little iodine as carrier for the astatine; the Bi is precipitated as phosphate and the aqueous solution of AtI used as it is or the activity can be extracted into CCl$_4$ or CHCl$_3$.

Five oxidation states of At have been definitely established (−I, 0, +I, V, VII) and one other (III) has been postulated. The standard oxidation potentials connecting these states in 0.1 M acid solution are $E^\circ(iX^2/X^-)$:

\[
\begin{align*}
\text{At}^- & \quad +0.3 \quad \text{At}(0) \quad +1.0 \quad \text{HOAt} \quad +1.5 \quad \text{AtO}_3^- \\
& \quad > +1.6 \quad \text{AtO}_4^- \\
\end{align*}
\]

These values should be compared with those for the other halogens (in 1 M acid) (p. 854). Noteworthy features are that At is the only halogen with an oxidation state between 0 and V that is thermodynamically stable towards disproportionation, and that the smooth trends in the values of $E^\circ(\frac{1}{2}X_2/X^-)$ and $E^\circ(\text{HOX}/\frac{1}{2}X_2)$ continue to At.

The astatide ion At$^-$ (which coprecipitates with AgI, TlI, PtI$_2$ or PdI$_2$) can be obtained from At(0) or AtI using moderately powerful reducing agents, e.g. Zn/H, SO$_2$, SO$_3$/$\text{OH}^-$, [Fe(CN)$_6$]$^{3-}$ or As$^{\text{III}}$. Reoxidation to At(0) can be effected by the weak oxidants [Fe(CN)$_6$]$^{3-}$, As$^{\text{V}}$ or dilute HNO$_3$. Oxidants of intermediate power (e.g. Cl$_2$, Br$_2$, Fe$^{3+}$, Cr$_2$O$_7^{2-}$, VO$^{2+}$) convert astatine to an intermediate oxidation state which is most probably AtO$^-$ or At$^+$ and which does not extract into CCl$_4$. Powerful oxidants (Ce$^{IV}$, NaBiO$_3$, S$_2$O$_8^{2-}$, IO$_4^-$) convert At(0) directly to AtO$_3^-$ (carried by AgIO$_3$, Ba(IO$_3$)$_2$, etc., and not extractable into CCl$_4$). The perastatate ion, AtO$_4^-$, was first conclusively prepared by V. A. Khalkin’s group in the USSR in 1970 using solid XeF$_2$ in hot NaOH solution at pH ~ 10. It is unstable in acid solutions, being completely decomposed to AtO$_3^-$ within 5–10 minutes at pH 1 and 90°C, for example.

At(0) reacts with halogens X$_2$ to produce interhalogen species AtX, which can be extracted into CCl$_4$, whereas halide ions X$^-$ yield polyhalide ions AtX$_2^-$ which are not extracted by CCl$_4$ but can be extracted into Pr$_2$O. The equilibrium formation constants of the various trihalide ions are intercompared in Table 17.28.

A rudimentary chemistry of organic derivatives of astatine is emerging, but the problems of radiation damage, product separation and tracer

identification, already severe for inorganic compounds of astatine, are even worse with organic derivatives. Two reviews are available.\(^{162,163}\) Various compounds of the type RAt, RAtCl\(_2\), R\(_2\)AtCl and RAtO\(_2\) (R = phenyl or p-tolyl) have been synthesized using astatine-labelled iodine reagents, e.g.:

\[
\begin{align*}

\text{PhN}_2\text{Cl} & \xrightarrow{\text{At}^-} \text{PhAt}
\end{align*}
\]

In addition, demercuriation reactions have resulted in a wide variety of rather complex compounds including aromatic aminoacids, steroids, imidazols, etc. in good yields (at the tracer level). The driving force in these studies has been the hope of incorporating \(^{211}\)At into biologically active compounds for therapeutic use.

Astatine has been shown to be superior to radio-iodine for the destruction of abnormal thyroid tissue (p. 794) because of the localized action of the emitted \(\alpha\)-particles which dissipate 5.9 MeV within a range of 70 \(\mu\)m of tissue, whereas the much less energetic \(\beta\)-rays of radio-iodine have a maximum range of \(\text{ca. } 2000 \mu\)m. However, its general inaccessibility and high cost render its extensive application unlikely.

18.1 Introduction

In 1785 H. Cavendish in his classic work on the composition of air (p. 406) noted that, after repeatedly sparking a sample of air with an excess of O₂, there was a small residue of gas which he was unable to remove by chemical means and which he estimated with astonishing accuracy to be “not more than \( \frac{1}{120} \)th part of the whole”. He could not further characterize this component of air, and its identification as argon had to wait for more than a century. But first came the discovery of helium, which is unique in being the only element discovered extraterrestrially before being found on earth.

During the solar eclipse of 18 August 1868, a new yellow line was observed close to the sodium D lines in the spectrum of the sun’s chromosphere. This led J. N. Lockyer (founder in 1869 of the journal *Nature*) and E. Frankland to suggest the existence of a new element which, appropriately, they named helium (Greek \( \lambda \), the sun). The same line was observed by L. Palmieri in 1881 in the spectrum of volcanic gas from Mount Vesuvius, and the terrestrial existence of helium was finally confirmed by W. Ramsay\(^{(1)}\) in the course of his intensive study of atmospheric gases which led to the recognition of a new group in the periodic table. This work was initiated by the physicist, Lord Rayleigh, and was recognized in 1904 by the award of the Nobel Prizes for Chemistry and Physics to Ramsay and Rayleigh respectively.

In order to test Prout’s hypothesis (that the atomic weights of all elements are multiples of that of hydrogen) Rayleigh made accurate measurements of the densities of common gases and found, to his surprise, that the density of nitrogen obtained from air by the removal of O₂, CO₂ and H₂O was consistently about 0.5% higher than that of nitrogen obtained chemically from ammonia. Ramsay then treated “atmospheric nitrogen” with heated magnesium (\( 3\text{Mg} + \text{N}_2 \rightarrow \text{Mg}_3\text{N}_2 \)), and was left with a small amount of a much

denser, monatomic gas† which, in a joint paper [Proc. R. Soc. 57, 265 (1895)], was identified as a new element which was named argon (Greek ἀργόν, idle or lazy) because of its inert nature. Unfortunately there was no space for a new and unreactive, gaseous, element in the periodic table (p. 20), which led to Ramsay’s audacious suggestion that a whole new group might be accommodated. By 1898 Ramsay and M. W. Travers had isolated three further new elements by the low-temperature distillation of liquid air (which had only recently become available) and characterized them by spectroscopic analysis: krypton (Greek κρύπτων, hidden, concealed), neon (Greek νέον, new) and xenon (Greek ἕξεον, strange).

In 1895 Ramsay also identified helium as the gas previously found occluded in uranium minerals and mistakenly reported as nitrogen. Five years later he and Travers isolated helium from samples of atmospheric neon.

Element 86, the final member of the group, is a short-lived, radioactive element, formerly known as radium-emanation or niton or, depending on which radioactive series it originates in (i.e. which isotope) as radon, thoron, or actinon. It was first isolated and studied in 1902 by E. Rutherford and F. Soddy and is now universally known as radon (from radium and the termination-on adopted for the noble gases; Latin radius, ray).

Once the existence of the new group had been established it was apparent that it not only fitted into the periodic table but actually improved it by providing a bridge between the strongly electronegative halogens and strongly electropositive alkali metals. The elements became known as “inert gases” comprising Group 0, though A. von Antropoff suggested that a maximum valency of eight might be attainable and designated them as Group VIIIB. They have also been described as the “rare gases” but, since the lighter members are by no means rare and the heavier ones are not entirely inert, “noble” gases seems a more appropriate name and has come into general use during the past three decades as has their designation as Group 18 of the periodic table.

The apparent inertness of the noble gases gave them a key position in the electronic theories of valency as developed by G. N. Lewis (1916) and W. Kossel (1916) and the attainment of a “stable octet” was regarded as a prime criterion for bond formation between atoms (p. 21). Their monatomic, non-polar nature makes them the most nearly “perfect” gases known, and has led to continuous interest in their physical properties.

### 18.2 The Elements

#### 18.2.1 Distribution, production and uses

Helium is the second most abundant element in the universe (76% H, 23% He) as a result of its synthesis from hydrogen (p. 9) but, being too light to be retained by the earth’s gravitational field, all primordial helium has been lost and terrestrial helium, like argon, is the result of radioactive decay (4He from α-decay of heavier elements, 40Ar from electron capture by 40K (p. 18).

The noble gases make up about 1% of the earth’s atmosphere in which they are major constituent is Ar. Smaller concentrations are occluded in igneous rocks, but the atmosphere is the principal commercial source of Ne, Ar, Kr and Xe, which are obtained as by-products of the liquefaction and separation of air (p. 604). Some Ar is also obtained from synthetic ammonia plants in which it accumulates after entering as impurity in the N2 and H2 feeds. World production of

---

† The molecular weight (mean relative molecular mass) was obtained by determination of density but, in order to determine that the gas was monatomic and its atomic and molecular weights identical, it was necessary to measure the velocity of sound in the gas and to divide from this the ratio of its specific heats: kinetic theory predicts that \( C_P/C_v = 1.67 \) for a monatomic and 1.40 for a diatomic gas.

Ar in 1975 was 700,000 tonnes for use mainly as an inert atmosphere in high-temperature metallurgical processes and, in smaller amounts, for filling incandescent lamps. By 1993, production had increased considerably and 716,000 tonnes ($427 \times 10^6 \text{ m}^3$) were produced in the USA alone. The price was $0.76/\text{m}^3$ for bulk supplies and $2.6-8.5/\text{m}^3$ for laboratory quantities, depending on purity. Along with Ne, Kr and Xe, which are produced on a much smaller scale, Ar is also used in discharge tubes — the so-called neon lights for advertisements — (the colour produced depending on the particular mixture of gases used). They are also used in fluorescent tubes, though here the colour produced depends not on the gas but on the phosphor which is coated on the inside walls of the tube. Lasers are another important application, though the actual amount of gas required for this use is minute compared with the other uses.

Although the concentration of He in the atmosphere is five times that of Kr and sixty times that of Xe (see Table 18.1), its recovery from this source is uneconomical compared to that from natural gas if more than 0.4% He is present. This concentration is attained in a number of gases in the USA (concentrations as high as 7% are known) and in eastern Europe (mainly Poland). Some $99 \times 10^6 \text{ m}^3$ (16,800 tonnes) of He was produced in the USA in 1993, the bulk price being $1.77/\text{m}^3$ ($2.30/\text{m}^3$ for liquid He). Laboratory quantities were in the range $5.00-45.00/\text{m}^3$ depending on purity. The former use of He as a non-flammable gas (it has a lifting power of approximately 1 kg per m$^3$) in airships is no longer important, though it is still employed in meteorological balloons. The primary domestic use of He (30%) in as a cryogenic fluid for temperatures at or below 4.2 K; as much as two-thirds of this is for magnetic resonance imaging and other nmr instruments. Other major uses are in arc welding (21%), pressurizing and purging (11%). The choice between Ar and He for these purposes is determined by cost and, except in the USA, this generally favours Ar. Smaller, but important, uses for He are:

(a) as a substitute for N$_2$ in synthetic breathing gas for deep-sea diving (its low solubility in blood minimizes the degassing which occurs with N$_2$ when divers are depressurized and which produces the sometimes fatal "bends");
(b) as a leak detector;
(c) as a coolant in HTR nuclear reactors (p. 1258);
(d) as a flow-gas in gas-liquid chromatography;
(e) for deaeration of solutions and as a general inert diluent or inert atmosphere.

The price per m$^3$ of the other noble gases is considerably higher (Ne $70$, Kr $350$ and Xe $3,500$, and this tends to restrict their usage to specialist applications only. Radon has been used in the treatment of cancer and as a radioactive source in testing metal castings but, because of its short half-life (3.824 days) it has been superseded by more convenient materials. Such small quantities as are required are obtained as a decay product of $^{226}$Ra (1 g of which yields 0.64 cm$^3$ in 30 days).

### 18.2.2 Atomic and physical properties of the elements$^{(2-4)}$

Some of the important properties of the elements are given in Table 18.1. The imprecision of the atomic weights of Kr and Xe reflects the natural occurrence of several isotopes of these elements. For He, however, and to a lesser extent Ar, a single isotope predominates ($^4$He, 99.999 863%; $^{40}$Ar, 99.600%) and much greater precision is possible. The natural preponderance of $^{40}$Ar is indeed responsible for the well-known inversion of atomic weight order of Ar and K in the periodic table, and the position of Ar in front of K was only finally accepted when it was shown that the atomic weight of He placed it in front of Li. The second isotope of helium, $^3$He, has only been available in significant amounts since

(a) In the pioneering work of J. J. Thomson and F. W. Aston on mass-spectrometry, neon was the first non-radioactive element shown to exist in different isotopic forms.

(b) The relative atomic mass of this nuclide is 222.0176.

(c) Mean value ~6 x 10⁻¹⁴.

(d) Helium is the only liquid which cannot be frozen by the reduction of temperature alone. Pressure must also be applied. It is also the only substance lacking a “triple point”, i.e. a combination of temperature and pressure at which solid, liquid and gas coexist in equilibrium.

In the 1950s when it began to accumulate as a β-decay product of tritium stored for thermonuclear weapons.

All the elements have stable electronic configurations (1s² or ns²np⁶) and, under normal circumstances are colourless, odourless and tasteless monatomic gases. The non-polar, spherical nature of the atoms which this implies, leads to physical properties which vary regularly with atomic number. The only interatomic interactions are weak van der Waals forces. These increase in magnitude as the polarizabilities of the atoms increase and the ionization energies decrease, the effect of both factors therefore being to increase the interactions as the sizes of the atoms increase. This is shown most directly by the enthalpy of vaporization, which is a measure of the energy required to overcome the interactions, and increases from He to Rn by a factor of over 200. However, ΔH_vap is in all cases small and bps are correspondingly low, that of He being the lowest of any substance.

The stability of the electronic configuration is indicated by the fact that each element has the highest ionization energy in its period, though the value decreases down the group as a result of increasing size of the atoms. For the heavier elements it is actually smaller than for first-row elements such as O and F with consequences for the chemical reactivities of the noble gases which will be considered in the next section. Nuclear properties, particularly for xenon, have been exploited for nmr spectroscopy(5) and Mössbauer.

---

spectroscopy\(^6\) (p. 896). The environmental health hazard posed by the natural generation of radioactive radon gas should also be noted.\(^7\)

As the first member of this unusual group He has, of course, a number of unique properties. Among these is the astonishing transition from so-called HeI to HeII which occurs around 2.2 K (the \(\lambda\)-point temperature) when liquid He (\(^4\)He to be precise, since \(^3\)He does not behave in this way until 1–3 millikelvin) is cooled by continuous pumping. The transition is clearly seen as the sudden cessation of turbulent boiling, even though evaporation continues. HeI is a normal liquid but at the transition the specific heat increases abruptly by a factor of 10, the thermal conductivity by the order of \(10^6\), and the viscosity, as measured by its flow through a fine capillary, becomes effectively zero (hence its description as a “superfluid”). HeII also has the curious ability to cover, with a film a few hundred atoms thick, all solid surfaces which are connected to it and are below the \(\lambda\) point. This can be spectacularly demonstrated by dipping the bottom of a suitable container into a bath of HeII. Once the vessel has cooled, liquid He flows, apparently without friction, up and over the edge of the container until the levels inside and outside are equal. These phenomena are evidently the result of quantum effects on a macroscopic scale, and HeII is believed to consist of two components: a true superfluid with zero viscosity and entropy, together with a normal fluid, the fraction of the former increasing to 1 at absolute zero. No completely satisfactory explanation of these phenomena is yet available.

Finally, a property of practical importance which may be noted is the ability of noble gases, especially He, to diffuse through many materials commonly used in laboratories. Rubber and PVC are cases in point, and He will even diffuse through most glasses so that glass Dewar vessels cannot be used in cryoscopic work involving liquid He.

### 18.3 Chemistry of the Noble Gases\(^8\text{--}^{12}\)

The discovery of the noble gases was a direct result of their unreactive nature, and early unsuccessful attempts to induce chemical reactions reinforced the belief in their inertness. Nevertheless, attempts were made to make the heavier gases react, and in 1933 Linus Pauling, from a consideration of ionic radii, suggested that KrF\(_6\) and XeF\(_6\) should be preparable. D. M. Yost and A. L. Kaye attempted to prepare the latter by passing an electric discharge through a mixture of Xe and F\(_2\) but failed\(^7\) and, until “XePtF\(_6\)” was prepared in 1962, the only compounds of the noble gases which could be prepared were clathrates.

While investigating the chemistry of PtF\(_6\), N. Bartlett noticed that its accidental exposure to air produced a change in colour, and with D. H. Lohmann he later showed this to be O\(_2^+\)-[PtF\(_6\)]\(^-\).\(^{13}\) Recognizing that PtF\(_6\) must therefore be an oxidizing agent of unprecedented power, he noted that Rn and Xe should similarly be oxidizable by this reagent since the first ionization energy of Rn is less than, and that of

---

\(^12\)pp. 38–53 of ref. 2.

Xe is comparable to, that of molecular oxygen \((1175 \text{ kJ mol}^{-1} \text{ for } \text{O}_2 \rightarrow \text{O}_2^+ + e^-)\). He quickly proceeded to show that deep-red \(\text{PtF}_6\) vapour spontaneously oxidized Xe to produce an orange-yellow solid and announced this in a brief note.\(^{14}\) Within a few months \(\text{XeF}_4\) and \(\text{XeF}_2\) had been synthesized in other laboratories.\(^{15,16}\) Noble-gas chemistry had begun.

Isolable compounds are obtained only with the heavier noble gases Kr and Xe; radon also reacts with \(\text{F}_2\) but isolation and characterization of products is hampered by its intense radioactivity which is not only hazardous but also decomposes the reagents involved. The compounds usually involve bonds to \(\text{F}\) or \(\text{O}\), in most cases exclusively so. However, a growing number of compounds involving bonds to \(\text{Cl}\), \(\text{N}\) and even \(\text{C}\) are becoming known (p. 901). Chemical combinations involving the lighter noble gases have been observed but are very unstable, and frequently occur only as transient species (p. 903).

### 18.3.1 Clathrates

Probably the most familiar of all clathrates are those formed by \(\text{Ar}\), \(\text{Kr}\) and \(\text{Xe}\) with quinol, \(1,4-\text{C}_6\text{H}_4(\text{OH})_2\), and with water. The former are obtained by crystallizing quinol from aqueous or other convenient solution in the presence of the noble gas at a pressure of 10–40 atm. The quinol crystallizes in the less-common \(\beta\)-form, the lattice of which is held together by hydrogen bonds in such a way as to produce cavities in the ratio 1 cavity: 3 molecules of quinol. Molecules of gas (\(G\)) are physically trapped in these cavities, there being only weak van der Waals interactions between “guest” and “host” molecules. The clathrates are therefore nonstoichiometric but have an “ideal” or “limiting” composition of \([G(\text{C}_6\text{H}_4(\text{OH})_2)]_3\). Once formed they have considerable stability but the gas is released on dissolution or melting. Similar clathrates are obtained with numerous other gases of comparable size, such as \(\text{O}_2\), \(\text{N}_2\), \(\text{CO}\) and \(\text{SO}_2\) (the first clathrate to be fully characterized, by H. M. Powell in 1947) but not \(\text{He}\) or \(\text{Ne}\), which are too small or insufficiently polarizable to be retained.

Noble gas hydrates are formed similarly when water is frozen under a high pressure of gas (p. 626). They have the ideal composition, \([\text{G}(\text{H}_2\text{O})_{46}]\), and again are formed by \(\text{Ar}\), \(\text{Kr}\) and \(\text{Xe}\) but not by \(\text{He}\) or \(\text{Ne}\). A comparable phenomenon occurs when synthetic zeolites (molecular sieves) are cooled under a high pressure of gas, and \(\text{Ar}\) and \(\text{Kr}\) have been encapsulated in this way (p. 358). Samples containing up to 20% by weight of \(\text{Ar}\) have been obtained.

Clathrates provide a means of storing noble gases and of handling the various radioactive isotopes of \(\text{Kr}\) and \(\text{Xe}\) which are produced in nuclear reactors.

### 18.3.2 Compounds of xenon

The chemistry of Xe is much the most extensive in this group and the known oxidation states of Xe range from +2 to +8. Details of some of the more important compounds are given in Table 18.2. There is clearly a rich variety of stereochemistries, though the description of these depends on whether only nearest-neighbour atoms are considered or whether the supposed disposition of lone-pairs of electrons is also included. Weaker secondary interactions in crystalline compounds also tend to increase the number of atoms surrounding a central Xe atom. For example, \([\text{XeF}_5]^+[\text{AsF}_6]^−\) has 5 F at 179–182 pm and \(\text{three}\) further F at 265–281 pm, whereas \([\text{XeF}_5]^+[\text{RuF}_6]^−\) has 5 F at 179–184 pm and \(\text{four}\) further F at 255–292 pm. If only the most closely bonded atoms are counted, then Xe is known with all coordination numbers from 0 to 8 as shown schematically in Table 18.3.

The three fluorides of Xe can be obtained by direct reaction but conditions need to be carefully controlled if these are to be produced individually in pure form. XeF₂ can be prepared by heating F₂ with an excess of Xe to 400 °C in a sealed nickel vessel or by irradiating mixtures of Xe and F₂ with sunlight. The product is a white, crystalline solid consisting of parallel linear XeF₂ units (Fig. 18.1). It is sublimable and its infrared and Raman spectra show that the linear molecular structure is retained in the vapour. XeF₂ is a versatile mild fluorinating agent and will, for instance, difluorinate olefins (alkenes). Oxidative fluorination of MeI yields MeF₂, and similar reactions yield Me₂EF₂ (E = S, Se, Te) and Me₃EF₂ (E = P, As, Sb). A related reaction was used to prepare the organometallic(VI) compound mer-Ph₃TeF₃.

\[
\text{CHCl₃ + XeF₂} \rightarrow \text{Ph₃TeF³ + Xe}
\]

Reductive fluorination is exemplified by the high-yield synthesis of crystalline CrOF₃ at 275°C:¹⁹

\[
2\text{CrO₂F₂} + \text{XeF₂} \rightarrow 2\text{CrOF₃} + \text{Xe} + \text{O₂}
\]

XeF₂ sequentially fluorinates Ir₄(CO)₁₂ dissolved in anhydrous HF yielding, initially, the novel neutral complexes mer- and fac-[Ir(CO)₃F₃].²⁰

By contrast, reaction of XeF₂ with the iridium carbonyl complex cation [Ir(CO)₃(PÉt₃)₂]^+ in CH₂Cl₂ results in addition across one of the Ir–CO bonds to give the first example of a metal fluoroacyl complex:(21)

\[
\text{OC-}\text{Ir-}\text{CO} + \text{XeF}_2 \rightarrow \text{OC-}\text{Ir-}\text{C-O} + \text{XeF}_2 + \text{Xe}
\]

The product was isolated as white, air-sensitive crystals of the BF₄⁻ and PF₆⁻ salts.

XeF₂ dissolves in water to the extent of 25 g dm⁻³ at 0°C, the solution being fairly stable (half-life ~7 h at 0°C) unless base is present, in which case almost instantaneous decomposition takes place:

\[
2\text{XeF}_2 + 2\text{H}_2\text{O} \rightarrow 2\text{Xe} + 4\text{HF} + \text{O}_2
\]

The aqueous solutions are powerful oxidizing agents, converting 2Cl⁻ to Cl₂, Ce⁴⁺ to Ce⁴⁺, Cr³⁺ to Cr⁶⁺, Ag⁺ to Ag²⁺, and even BrO₃⁻ to BrO₄⁻ (p. 871).

---

XeF₄ is best prepared by heating a 1:5 volume mixture of Xe and F₂ to 400°C under 6 atm pressure in a nickel vessel. It also is a white, crystalline, easily sublimed solid; the molecular shape is square planar (Xe–F 195.2 pm) and is essentially the same in both the solid and gaseous phases. Its properties are similar to those of XeF₂ except that it is a rather stronger fluorinating agent, as shown by the reactions:

\[
\begin{align*}
2\text{Hg} + \text{XeF}_4 & \rightarrow \text{Xe} + 2\text{HgF}_2 \\
\text{Pt} + \text{XeF}_4 & \rightarrow \text{Xe} + \text{PtF}_4 \\
2\text{SF}_4 + \text{XeF}_4 & \rightarrow \text{Xe} + 2\text{SF}_6
\end{align*}
\]

It is also hydrolyzed instantly by water, yielding a variety of products which include XeO₃:

\[
\text{XeF}_4 + 2\text{H}_2\text{O} \rightarrow \frac{1}{2}\text{XeO}_3 + \frac{3}{2}\text{Xe} + \frac{3}{2}\text{O}_2 + 4\text{HF}
\]

This reaction is indeed a major hazard in Xe/F chemistry, since XeO₃ is highly explosive, and the complete exclusion of moisture is therefore essential (see p. 165 of ref. 10). Interestingly, the maximum yield of XeO₃ is 33% rather than the 50% that would be expected from a simple disproportionation of 2Xe⁴⁺ → Xe⁶⁺ + Xe²⁺, and the following reaction sequence has been suggested to explain this:

\[
3\text{Xe}^{IV}\text{F}_4 + 6\text{H}_2\text{O} \rightarrow \frac{1}{2}\text{XeO}_3 + \frac{3}{2}\text{Xe} + \frac{3}{2}\text{O}_2 + 4\text{HF}
\]

The stoichiometry of the reaction also depends sensitively on the precise conditions of hydrolysis.²²

XeF₆ is produced by the prolonged heating of 1:20 volume mixtures of Xe and F₂ at 250–300°C under 50–60 atm pressure in a nickel vessel. It is a crystalline solid, even more volatile than XeF₂ and XeF₄, and although colourless in the solid it is yellow in the liquid and gaseous phases. It is also more reactive than the other fluorides, being both a stronger oxidizing and a stronger fluorinating agent. Hydrolysis occurs with great vigour and the compound cannot be handled in glass or quartz apparatus because of a stepwise reaction which finally produces the dangerous XeO₃:

\[
\begin{align*}
2\text{XeF}_6 + \text{SiO}_2 & \rightarrow 2\text{XeOF}_4 + \text{SiF}_4 \\
2\text{XeOF}_4 + \text{SiO}_2 & \rightarrow 2\text{XeO}_2\text{F}_2 + \text{SiF}_4 \\
2\text{XeO}_2\text{F}_2 + \text{SiO}_2 & \rightarrow 2\text{Xe}_2\text{O}_3 + \text{SiF}_4
\end{align*}
\]

The structure of XeF₆ was the source of some controversy for more than a decade after its discovery in 1963. This was partly a result of the obvious problems associated with a substance which attacks most of the materials used to construct apparatus for structural determinations. It is now clear that in the gaseous phase this seemingly simple molecule is not a regular octahedron; it appears to be a non-rigid, distorted octahedron although, in spite of numerous theoretical studies, the precise nature of the distortion is uncertain (see, for instance, p. 299 of ref. 8). In the crystalline state at least four different forms of XeF₆ are known comprising square-pyramidal XeF₅⁺ ions bridged by F⁻ ions. Three of these forms are tetramers, [(XeF₅⁺)F⁻]₄, while in the fourth and best-characterized cubic form,²³ the unit cell comprises 24 tetramers and 8 hexamers, [(XeF₅⁺)F⁻]₆ (Fig. 18.2).

The nature of the bonding in these xenon fluorides is discussed in the Panel opposite.

Apart from XeF, which is the light-emitting species in certain Xe/F₂ lasers, there is no evidence for the existence of any odd-valent fluorides. Reports of XeF₈ have not been confirmed. Of the other halides, XeCl₂, XeBr₂ and XeCl₄ have been detected by Mössbauer spectroscopy as products of the β-decay of their ¹²⁹I³⁻

---

§18.3.2 Compounds of xenon

Bonding in Noble Gas Compounds

As it was widely believed, prior to 1962, that the noble gases were chemically inert because of the stability, if not inviolability, of their electronic configurations, the discovery that compounds could in fact be prepared, immediately necessitated a description of the bonding involved. A variety of approaches has been suggested,\(^\text{24}\) none of which is universally applicable. The simplest molecular-orbital description is that of the 3-centre, 4-electron \(\sigma\) bond in \(\text{XeF}_2\), which involves only valence shell \(p\) orbitals and eschews the use of higher energy \(d\) orbitals. The orbitals involved are the colinear set comprising the \(5p_z\) orbital of \(\text{Xe}\), which contains 2 electrons, and the \(2p_x\) orbitals from each of the \(\text{F}\) atoms, each containing 1 electron. The possible combinations of these orbitals are shown in Fig. A and yield 1 bonding, 1 nonbonding, and 1 antibonding orbital. A single bonding pair of electrons is responsible for binding all 3 atoms, and the occupation of the nonbonding orbital, situated largely on the \(\text{F}\) atoms, implies significant ionic character. The scheme should be compared with the 3-centre, 2-electron bonding proposed for boron hydrides (p. 158).

![Diagram of bonding in XeF2](image)

Fig. A. Molecular-orbital representation of the 3-centre F–Xe–F bond. (a) The possible combinations of colinear \(p\) atomic orbitals, and (b) the energies of the resulting MOs (schematic).

A similar treatment, involving two 3-centre bonds accounts satisfactorily for the planar structure of \(\text{XeF}_4\) but fails when applied to \(\text{XeF}_6\) since three 3-centre bonds would produce a regular octahedron instead of the distorted structure actually found. An improvement is possible if involvement of the \(\text{Xe} 5d\) orbitals is invoked,\(^\text{25}\) since this produces a triplet level which would be subject to a Jahn-Teller distortion (p. 1021). However, the approach which has most consistently rationalized the stereochemistries of noble-gas compounds (as distinct from their bonding) is the electron-pair repulsion theory of Gillespie and Nyholm.\(^\text{26}\) This assumes that stereochemistry is determined by the repulsions between valence-shell electron-pairs, both nonbonding and bonding, and that the former exert the stronger effect. Thus, in \(\text{XeF}_2\) the \(\text{Xe}\) is surrounded by 10 electrons (8 from \(\text{Xe}\) and 1 from each \(\text{F}\)) distributed in 5 pairs; 2 bonding and 3 nonbonding. The 5 pairs are directed to the corners of a trigonal bipyramid and, because of their greater mutual repulsions, the 3 nonbonding pairs are situated in the equatorial plane at 120° to each other, leaving the 2 bonding pairs perpendicular to the plane and so producing a linear \(\text{F}–\text{Xe}–\text{F}\) molecule.

In the same way \(\text{XeF}_4\), with 6 electron-pairs, is considered as pseudo-octahedral with its 2 nonbonding pairs trans to each other, leaving the 4 \(\text{F}\) atoms in a plane around the \(\text{Xe}\). More distinctively, the 7 electron-pairs of \(\text{XeF}_6\) suggest the possibility of a non-regular octahedral geometry and imply a distorted structure based on either a monocapped octahedral or a pentagonal pyramidal arrangement of electron-pairs, with the \(\text{Xe}–\text{F}\) bonds bending away from the projecting nonbonding pair.

It is an instructive exercise to devise similar rationalizations for the xenon oxides and oxofluorides listed in Table 18.3.

---

anallogues, for instance:

\[ ^{129}_{53}\text{ICl}_2^- \rightarrow ^{129}_{54}\text{XeCl}_2 \]

XeCl\(_2\) has also been trapped in a matrix of solid Xe after Xe/Cl\(_2\) mixtures had been passed through a microwave discharge, but these halides are too unstable to be chemically characterized.

It is from the binary fluorides that other compounds of xenon are invariably prepared, by reactions which fall mostly into four classes:

(a) with F\(^-\) acceptors, yielding fluorocations of xenon;
(b) with F\(^-\) donors, yielding fluoroanions of xenon;
(c) F/H metathesis between XeF\(_2\) and an anhydrous acid;
(d) hydrolysis, yielding oxofluorides, oxides and xenates.

(a) **Reactions with F\(^-\) acceptors.** XeF\(_2\) has a more extensive F\(^-\) donor chemistry than has XeF\(_4\); it reacts with the pentafluorides of P, As, Sb, I, as well as with metal pentafluorides, to form salts of the types [XeF]\(^+\)[MF\(_5\)]\(^-\), [XeF]\(^+\)[M\(_2\)F\(_{11}\)]\(^-\) and [Xe\(_2\)F\(_3\)]\(^+\)[MF\(_6\)]\(^-\). The [XeF]\(^+\) ions are apparently always weakly attached to the counter-anion forming linear F–Xe···F–M units with one short and one long Xe–F bond, while the [Xe\(_2\)F\(_3\)]\(^+\) ions are V-shaped (see p. 899; cf. isoelectronic I\(_5^-\) with central angle 95°, p. 837). With SbF\(_3\) the bright-green paramagnetic Xe\(_2\)\(^+\) cation has been identified as a further product.\(^{27}\) MOF\(_4\) (M = W, Mo) are also weak F\(^-\) acceptors and form [XeF]\(^+\)[MOF\(_5\)]\(^-\), which again contain linear F–Xe···F–M units.\(^{28}\) The XeF\(^+\) cation is an excellent Lewis acid and this property has been used to prepare a range of compounds featuring Xe–N bonds\(^{29}\) (see also p. 902).

---

Although the orange-yellow solid prepared by Bartlett (p. 892) was originally formulated as \( \text{Xe}^+\text{[PtF}_6^- \), it was subsequently found to have the variable composition \( \text{Xe}(\text{PtF}_6)_x \), \( x \) lying between 1 and 2. The material has still not been fully characterized but probably contains both \( [\text{XeF}]^+\text{[PtF}_6^- \) and \( [\text{XeF}]^+\text{[Pt}_2\text{F}_{11}^- \). \( \text{XeF}_4 \) forms comparable complexes only with the strongest \( \text{F}^- \) acceptors such as \( \text{SbF}_5 \) and \( \text{BiF}_5 \), but \( \text{XeF}_6 \) combines with a variety of pentafluorides to yield 1:1 adducts. In view of the structure of \( \text{XeF}_6 \) (see Fig. 18.2) it is not surprising that these adducts contain \( \text{XeF}_5^+ \) cations, as for instance in \( [\text{XeF}_5]^+\text{[AsF}_6^- \) and \( [\text{XeF}_5]^+\text{[PtF}_6^- \). In a similar manner, reactions with \( \text{FeF}_3 \) and \( \text{CoF}_3 \) yield \( [\text{XeF}_5][\text{MF}_4] \) in which layers of corner-sharing \( \text{FeF}_6 \) octahedra are separated by \( [\text{XeF}_5]^+ \) ions.\(^{30}\)

(b) Reactions with \( \text{F}^- \) donors. \( \text{F}^- \) acceptor behaviour of xenon fluorides is evidently confined to \( \text{XeF}_6 \) which reacts with alkali metal fluorides to form \( \text{MXeF}_7 \) (\( M=\text{Rb}, \text{Cs} \)) and \( \text{M}_2\text{XeF}_8 \) (\( M=\text{Na}, \text{K}, \text{Rb}, \text{Cs} \)). These compounds lose \( \text{XeF}_6 \) when heated:

\[
2\text{MXeF}_7 \longrightarrow \text{M}_2\text{XeF}_8 + \text{XeF}_6
\]

\[
\text{M}_2\text{XeF}_8 \longrightarrow 2\text{MF} + \text{XeF}_6
\]

Their thermal stability increases with molecular weight. Thus the Cs and Rb octafluoroxo complexes only decompose above 400°C, whereas the Na complex decomposes below 100°C. NaF can therefore conveniently be used to separate \( \text{XeF}_6 \) from \( \text{XeF}_2 \) and \( \text{XeF}_4 \), with which it does not react, the purified \( \text{XeF}_6 \) being regenerated on heating.

A similar product, \( [\text{NO}]^+2[\text{XeF}_8]^2^- \), is formed with NOF and its anion has been shown by X-ray crystallography to be a slightly distorted square antiprism\(^{31}\) (probably due to weak \( \text{F} \cdots \text{NO}^+ \) interactions). The absence of any clearly defined ninth coordination position for the lone-pair of valence electrons which is present, implies that this must be stereochemically inactive.

(c) \( \text{F}/\text{H} \) metathesis between \( \text{XeF}_2 \) and an anhydrous acid:

\[
\text{XeF}_2 + n\text{HL} \longrightarrow \text{F}_2\text{XeL}_n + n\text{HF} \quad (n=1,2)
\]

where \( L = \text{OTeF}_5, \text{OSeF}_5, \text{OSO}_2\text{F}, \text{OCIO}_3, \text{ONO}_2, \text{OC(O)Me}, \text{OC(O)CF}_3, \text{OSO}_2\text{Me} \) and \( \text{OSO}_2\text{CF}_3 \) (see also p. 902 for an analogous reaction with \( \text{HN(OSO}_2\text{F})_2 \)). The compounds are colourless or pale yellow and many are thermodynamically unstable. The perchlorate (mp 16.5°C) is dangerously explosive. The fluorosulfate (mp 36.6°C) can be stored for many weeks at 0°C but decomposes with a half-life of a few days at 20°C.

\[
2\text{FXeOSO}_2\text{F} \longrightarrow \text{XeF}_2 + \text{Xe} + 2\text{S}_2\text{O}_6\text{F}_2
\]

The molecular structure of \( \text{FXeOSO}_2\text{F} \) is in Fig. 18.3a. Many other such compounds have been made by similar routes e.g. \( \text{O}_2\text{Xe}(\text{F})(\text{OTeF}_5), \text{O}_2\text{Xe}(\text{OTeF}_5)_2, \text{OXeF}_{4-n^-}\) \( (\text{OTeF}_5)_n \) \( (n=1-4) \) and \( \text{XeF}_{4-n^-}(\text{OTeF}_5)_n \) \( (n=1-4) \);\(^{32}\) \( \text{FXeOI(O)F}_4 \) and \( \text{Xe}[\text{OI(O)F}_2]_2 \);\(^{33}\) \( \text{FXeOP(O)F}_2 \) and \( \text{Xe}[\text{OP(O)F}_2]_2 \) etc. Typical reactions are:

\[
3\text{O}_2\text{XeF}_2 + 2\text{B}(\text{OTeF}_5)_3 \longrightarrow 3\text{O}_2\text{Xe}(\text{OTeF}_5)_2 + 2\text{BF}_3
\]

\[
\text{OXe}(\text{OTeF}_5)_4 \longrightarrow \text{O}_2\text{Xe}(\text{OTeF}_5)_2 + 2\text{O}(\text{TeF}_5)_2
\]

\[
\text{XeF}_2 + (\text{IO}_2\text{O}_3)_2 \longrightarrow \text{FXeO}_3(\text{O})_4
\]

\[
+ \text{OIF}_3 + 1/2\text{O}_2
\]

Figure 18.3  (a) The molecular structure of FXeOSO₂F. Precision of bond lengths is ca. 1 pm (uncorrected for thermal motion). The angle F(1)-Xe-O(1) is 177.5 ± 0.4° and angle Xe-O(1)-S is 123.4 ± 0.6°.  (b) The molecular structure of Xe(O' TeF₅)₄ (see text)

FXeOỊ(O)F₄ + (IO₂F₃)₂ →
Xe[OỊ(O)F₄]₂ + OỊF₃ + ½O₂

Xe(O'TeF₅)₂ + 2HŌI(O)F₄ →
Xe[OỊ(O)F₄]₂ + 2HŌTeF₅

3XeF₂ + B(OSO₂CF₃)₃ →
3FXe(OSO₂CF₃) + BF₃

3XeF₂ + 2B(OCOCF₃)₃ →
3Xe(OCOCF₃)₂ + 2BF₃

The molecular structure of yellow crystalline Xe(O'TeF₅)₄ has been determined by X-ray analysis (see Fig. 18.3b);(34) the Xe atom is surrounded by a square-planar array of four O atoms, with the adjacent TeF₅ groups pointing, curiously, pair-wise up and down from this plane (Xe–O 203.9(5) and 202.6(5) pm, Te–O 188.5 pm).

(d) Hydrolysis and related reactions. Two XeVІ oxofluorides, XeOF₄ and XeO₂F₂, have been characterized, and the XeVІІ derivative XeO₃F₂ (mp. -54.1°C)(22) is also known (see below). XeOF₄ is a colourless volatile liquid with a square-pyramidal molecular structure, the O atom being at the apex. It can be prepared by the controlled hydrolysis of XeF₆:

XeF₆ + H₂O → XeOF₄ + 2HF

Its most pronounced chemical characteristic is its propensity to hydrolyse further to XeO₂F₂ and then XeO₃ (p. 901). This reaction is difficult to control, and the low-melting, colourless solid, XeO₂F₂, is more reliably obtained by the reaction:

XeO₃ + XeOF₄ → 2XeO₂F₂

An analogous reaction with XeO₄ (see p. 901) is:

XeO₄ + XeF₆ → XeO₃F₂ + XeOF₄

Indeed, many of the reactions of the xenon oxides, fluorides and oxofluorides can be systematized in terms of generalized acid-base theory in which any acid (here defined as an oxide acceptor) can react with any base (oxide donor) lying beneath it in the sequence of descending acidity: XeF₆ > XeO₂F₄ > XeO₃F₂ > XeO₄ > XeOF₄ > XeF₄ > XeO₂F₂ > XeO₃ ≈ XeF₂.(22)

In addition, oxofluoro anions may be produced by treating hydrolysis products with F⁻. Thus aqueous XeO₃ and MF (M = K, Cs) yield the stable white solids M[XeO₃F] in which the anion consists of chains of pseudo-octahedral Xe atoms (the lone-pair of valence electrons occupying one of the six positions) linked by angular F bridges.

Again, the reaction of XeOF₄ and dry CsF has been shown to yield the labile Cs[(XeOF₄)₃F] in which the anion consists of three equivalent XeOF₄ groups attached to a central F⁻ ion. The ready loss of 2XeOF₄ produces the more stable CsXeOF₅, the anion of which has a distorted octahedral geometry, the lone-pair of electrons again being stereochemically active and apparently occupying an octahedral face.

Complete hydrolysis of XeF₆ is the route to XeO₃. The most effective control of this potentially violent reaction is achieved by using a current of dry N₂ to sweep XeF₆ vapour into water:

\[
\text{XeF}_6 + 3\text{H}_2\text{O} \rightarrow \text{XeO}_3 + 6\text{HF}
\]

The HF may then be removed by adding MgO to precipitate MgF₂ and the colourless deliquescent solid XeO₃ obtained by evaporation. The aqueous solution known as “xenic acid” is quite stable if all oxidizable material is excluded, but the solid is a most dangerous explosive (reported to be comparable to TNT) which is easily detonated.

In aqueous solution XeO₃ is an extremely strong oxidizing agent (for \(\text{XeO}_3 + 6\text{H}^+ + 6\text{e}^- \rightarrow \text{Xe} + 3\text{H}_2\text{O}; E^\circ = 2.10 \text{ V}\)), but may be kinetically slow; the oxidation of Mn¹¹ takes hours to produce MnO₂ and days before MnO₄⁻ is obtained. Treatment of aqueous XeO₃ with alkali produces xenate ions:

\[
\text{XeO}_3 + \text{OH}^- \leftrightarrow \text{HXeO}_4^-; \quad K = 1.5 \times 10^3
\]

However, although some salts have been isolated, alkaline solutions are not stable and immediately, if slowly, begin to disproportionate into Xe⁸⁺ (perxenates) and Xe gas by routes such as:

\[
2\text{HXeO}_4^- + 2\text{OH}^- \rightarrow \text{XeO}_6^{4-} + \text{Xe} + \text{O}_2 + 2\text{H}_2\text{O}
\]

Similar results are obtained by the alkaline hydrolysis of XeF₆:

\[
2\text{XeF}_6 + 16\text{OH}^- \rightarrow \text{XeO}_6^{4-} + \text{Xe} + \text{O}_2
\]

\[+ 12\text{F}^- + 8\text{H}_2\text{O}\]

The most efficient production of perxenate is the treatment of XeO₃ in aqueous NaOH with ozone, when Na₄XeO₆·2\(\frac{1}{2}\)H₂O precipitates almost quantitatively. The crystal structures of Na₄XeO₆·6H₂O and Na₄XeO₆·8H₂O show them to contain octahedral XeO₆⁴⁻ units with Xe–O 184 pm and 186.4 pm respectively. Perxenates of other alkali metals (Li⁺, K⁺) and of several divalent and trivalent cations (e.g. (Ba²⁺, Am³⁺) have also been prepared. They are colourless solids, thermally stable to over 200°C, and contain octahedral XeO₆⁴⁻ ions. They are powerful oxidizing agents, the reduction of Xe⁸⁺ to Xe⁶⁺ in aqueous acid solution being very rapid. The oxidation of Mn¹¹ to MnO₄⁻ by perxenates, unlike that by XeO₃, is thus immediate and is accompanied by evolution of O₂:

\[
2\text{H}_2\text{XeO}_6^{2-} + 2\text{H}^+ \rightarrow 2\text{HXeO}_4^- + \text{O}_2 + 2\text{H}_2\text{O}
\]

The addition of solid Ba₂XeO₆ to cold conc H₂SO₄ produces the second known oxide of xenon, XeO₄. This is an explosively unstable gas which may be condensed in a liquid nitrogen trap. The solid tends to detonate when melted but small sublimed crystals have been shown to melt sharply at -35.9°C. XeO₄ has only been incompletely studied, but electron diffraction and infrared evidence show the molecule to be tetrahedral.

Whilst the great bulk of noble-gas chemistry concerns Xe–F or Xe–O bonds, attempts to bond Xe to certain other atoms have also been successful. Compounds containing Xe–N bonds have been produced by the replacement of F

---

atoms by \(-N(SO_2F)_2\) groups.\(^{(39)}\) The relevant reactions may be represented as:

\[
\begin{align*}
2\text{XeF}_2 + 2\text{HN}(SO_2F)_2 &\quad \text{in CF}_3\text{Cl}_2 \quad 0^\circ\text{C}, 4\text{ days} \quad 2\text{F}^–\text{Xe}–N(SO_2F)_2 \quad \text{white solid} \\
2[\text{FXe}(SO_2F)_2] \cdot \text{AsF}_3 &\quad \text{unstable, bright yellow solid} \\
[\text{F[Xe–N(SO_2F)_2]}_2]^+ \cdot \text{AsF}_6^- &\quad \text{pale yellow solid}
\end{align*}
\]

The first (white) product has been characterized by X-ray diffraction at \(-55^\circ\) and features a linear F–Xe–N group and a planar N atom (Fig. 18.4).\(^{(40)}\) On the basis of Raman and \(^{19}\)F nmr data, the cation of the final (pale yellow) product is believed to be essentially like the V-shaped \([\text{XeF}_3]^+\) cation but with the 2 terminal F atoms replaced by \(-N(SO_2F)_2\) groups.\(^{(40)}\) The related compound \([\text{Xe}[N(SO_2F)_2]_2]\) was the first to feature an Xe atom bonded to two N atoms.\(^{(41)}\) The cations \([\text{XeN}(SO_2F)_2]^+\) and \([\text{F[XeN(SO_2F)_2]}_2]^+\) have also been characterized and the X-ray structure of \([\text{XeN(SO_2F)_2}]^+[\text{SbF}_6]^-\) determined.\(^{(42)}\) An important new synthetic strategy was introduced by G. J. Schrobilgen who exploited the Lewis acid (electron-pair acceptor) properties of the XeF\(^{+}\) cation to prepare a wide range of stable nitrile adducts featuring Xe–N bonds, e.g. \([\text{RC}≡\text{NXeF}]^+\text{AsF}_6^-\) (R = H, Me, CH\(_3\)F, Et, C\(_2\)F\(_5\), C\(_3\)F\(_7\), C\(_5\)F\(_7\)).\(^{(43)}\)

Similarly, perfluoropyridine ligands have been used to prepare \([4-\text{RCF}_4\text{NXeF}]^+\) cations (R = F, CF\(_3\)) in HF or BrF\(_3\) solutions at temperatures below \(-30^\circ\).\(^{(44)}\) Other cationic species involving Xe–N bonds include \([\text{F}_3\text{S}≡\text{NXeF}]^+, [\text{F}_4\text{S}≡\text{NXe}]^+, [\text{F}_5\text{SN}(\text{H})\text{NXe}]^+, [\text{F}_5\text{TeN}(\text{H})\text{NXe}]^+, [\text{s-C}_3\text{F}_3\text{N}_2\text{NXeF}]^+, [\text{MeC}≡\text{NXeOTeF}_4]^+, [\text{C}_5\text{F}_{13}\text{NXeOTeF}_5]^+\) and \([\text{F}_3\text{S}≡\text{NXeOSeF}_3]^+\). Over three dozen such compounds are now known and the field has been recently reviewed.\(^{(29)}\)

Fewer compounds with Xe–C bonds have been characterized. The first to be claimed was synthesized by the plasma reaction of XeF\(_2\) with CF\(_3^+\) radicals; the volatile waxy white solid produced, Xe(CF\(_3\))\(_2\), decomposed at room temperature with a half-life of about 30 min.\(^{(45)}\)

\[
\begin{align*}
\text{XeF}_2 + \text{C}_2\text{F}_6 \quad \text{plasma} \quad &\rightarrow \quad \text{Xe(CF}_3)_2 + \text{F}_2 \\
\text{Xe(CF}_3)_2 \quad t_{\frac{1}{2}} = 30\text{ min} \quad &\rightarrow \quad \text{XeF}_2 + \text{C}_n\text{F}_m
\end{align*}
\]

---

However, the first compound to have a stable Xe–C bond was reported independently by two groups in 1989:(46) reaction of XeF₂ with an excess of B(C₆F₅)₃ in MeCN or CH₂Cl₂ yielded [XeC₆F₅]⁺[B(C₆F₅)₃]F⁻ which was characterized by its chemical reactions and by ¹²⁹Xe and ¹⁹F nmr spectroscopy. The compound can be isolated as a colourless solid. Several other similar compounds have since been synthesized at temperatures below -4°C, e.g. [XeC₆H₄R]⁺[B(C₆H₄R)ₙF₄₋ₙ⁻] (R = m-F, p-F, m-CF₃, p-CF₃), (n = 0, 1, 2).(47) An X-ray structure analysis of the adduct, [MeC＝N⁺Xe-C₆Fs]⁺[(CsFs)₂BF₂]⁻ at -123°C established the Xe-C distance as 209.2(8) pm and the coordinate link N⁺Xe as 268.1(8)pm (substantially longer than the Xe-N distance in Fig. 18.4; the angle C-Xe-N is 174.5(3)°).(48) The alkynyl xenonium compound [Bu'C≡C-Xe]⁺BF₄⁻ has also been characterized.(49)

The most recent extension of xenon chemistry is the formation of a compound containing a Xe–Xe bond.(49a) Thus, when the yellow compound XeF₇Sb₂F₁₁⁻ was reacted with Xe in "magic acid" (HF/SbFs), dark-green crystals of Xe₂+Sb₄F₁₆ were formed at -30°C. An X-ray structure analysis at -143°C revealed that the Xe–Xe+ bond length was 308.7(1) pm, making it the longest element-element bond yet known [cf. 304.1(1) pm for Re–Re in Re₂(CO)₁₀].

### 18.3.3 Compounds of other noble gases

No stable compounds of He, Ne or Ar are known. Radon apparently forms a difluoride and some complexes such as [RnF]⁺X⁻ (X⁻ = SbF₆⁻, TaF₆⁻, BiF₆⁻), but the evidence is based solely on radiochemical tracer techniques since Rn has no stable isotopes.(50) The remaining noble gas, Kr, has an emerging chemistry though this is less extensive than that of Xe.

Apart from the violet free radical KrF, which has been generated in minute amounts by γ-radiation of KrF₂ and exists only below -153°C, the chemistry of Kr was for some time confined to the difluoride and its derivatives. An early claim for KrF₄ remains unsubstantiated. The volatile, colourless solid, KrF₂, is produced when mixtures of Kr and F₂ are cooled to temperatures near -196°C and then subjected to electric discharge, or irradiated with high-energy electrons or X-rays. It is a thermally (and thermodynamically) unstable compound which slowly decomposes even at room temperature. It has the same linear molecular structure as XeF₂ (Kr-F 188.9pm) but, consistent with its lower stability, is a stronger fluorinating agent and is rapidly decomposed by water without requiring the addition of a base. KrF₂ has been used as a specialist reagent to prepare high oxidation state fluorides. Reaction with Ag or AgF in HF gave the new fluoride AgF₃;(51) high-purity MnF₄ was prepared from MnF₂/HF via the adducts 2KrF₂.MnF₄ and KrF₂.MnF₄;(52) the square-pyramidal CrF₄0 (mp. 55°C) was obtained by an improved route from CrO₂F₂/HF.(53) KrF₂ also affords an unusual and extremely useful room-temperature route to NpF₆ and PuF₆, thus avoiding the necessity of using F₂ at high temperatures, the compound O₂F₂ being the only other reagent known to do this.(54)

Complexes of KrF₂ are analogous to those of XeF₂ and are confined to cationic species

which can be generated by reaction with \( F^- \) acceptors. Thus, such compounds as 
\([\text{KrF}^+]\text{[MF}_6^- \), \([\text{Kr}_2\text{F}_3]^+\text{[MF}_6^+ \) \( (M = \text{As, Sb}) \) are known, and also \([\text{KrF}]^+\text{[MoOF}_5^- \) and 
\([\text{KrF}]^+\text{[WOOF}_5^- \) which have been prepared and characterized by \(^{19}\text{F} \) nmr and Raman spectroscopy.\(^{55}\) In addition, adducts of \( \text{KrF}^+ \) with nitrile donors have been synthesized, analogous to those of \( \text{XeF}^+ \) described in the preceding section, e.g. \([\text{RC}=\equiv\text{NKR}F]^+ \) \( (R = \text{Me, CF}_3, \text{C}_2\text{F}_5, n\text{.C}_3\text{F}_5) \).\(^{20,56}\)

The formation of the first compound having \( \text{Kr}^-\text{O} \) bonds has been documented by using \(^{19}\text{F} \) and \(^{17}\text{O} \) nmr spectroscopy of \(^{17}\text{O} \)-enriched samples to follow the synthesis and decomposition of the thermally unstable compound, \([\text{Kr(OTeF}_5)_2] \), according to the reactions:\(^{57}\)

\[
3\text{KrF}_2 + 2\text{B(OTeF}_5) \rightarrow 3\text{Kr(OTeF}_5)_2 + 2\text{BF}_3
\]

\[
\text{Kr(OTeF}_5)_2 \rightarrow \text{Kr} + \text{F}_3\text{TeOOF}_5
\]

19
Coordination and Organometallic Compounds

19.1 Introduction

The three series of elements arising from the filling of the 3d, 4d and 5d shells, and situated in the periodic table following the alkaline earth metals, are commonly described as ‘transition elements’, though this term is sometimes also extended to include the lanthanide and actinide (or inner transition) elements. They exhibit a number of characteristic properties which together distinguish them from other groups of elements:

(i) They are all metals and as such are lustrous and deformable and have high electrical and thermal conductivities. In addition, their melting and boiling points tend to be high and they are generally hard and strong.

(ii) Most of them display numerous oxidation states which vary by steps of 1 rather than 2 as is usually the case with those main-group elements which exhibit more than one oxidation state.

(iii) They have an unparalleled propensity for forming coordination compounds with Lewis bases.

(i) and (ii) will be dealt with more fully in later chapters but it is the purpose of the present chapter to expand the theme of (iii).

A coordination compound, or complex, is formed when a Lewis base (ligand) is attached to a Lewis acid (acceptor) by means of a ‘lone-pair’ of electrons. Where the ligand is composed of a number of atoms, the one which is directly attached to the acceptor is called the ‘donor atom’. This type of bonding has already been discussed (p. 198) and is exemplified by the addition compounds formed by the trihalides of the elements of Group 13 (p. 237); it is also the basis of much of the chemistry of the

transition elements. The precise nature of the bond between a transition metal ion and a ligand varies enormously and the term “donor atom” is often used in situations where its literal meaning should not be assumed. Although inevitably the line of demarcation is rather ill-defined, it is conventional to distinguish two extremes. On the one hand, are those cases in which the bond may be considered profitably as a single $\sigma$ bond, or even a purely electrostatic interaction, and in which the metal has an oxidation state of $+2$ or higher. On the other hand, are those cases where the bonding is multiple, the ligand acting simultaneously as both a $\sigma$ donor and a $\pi$ acceptor (p. 922) and in which the metal usually has a formal oxidation state of $+1$ or less, though the significance of such values is often unclear. Compounds of the former type are commonly described as “classical” or “Werner” complexes since it was through the investigation of such materials that A. Werner in the period 1893–1913 laid the foundations of coordination chemistry(2) (see also p. 912). Compounds of the latter type are exemplified by the carbonyls and other organometallic compounds.

19.2 Types of Ligand

Ligands are most conveniently classified according to the number of potential donor atoms which they contain and are known as uni-, bi-, ter-, quadri-, quinqi- and sexi-dentate accordingly as the number is 1, 2, 3, 4, 5 or 6. Unidentate ligands may be simple monatomic ions such as halide ions, or polyatomic ions or molecules which contain a donor atom from Groups 16, 15 or even 14 (e.g. CN$^-$). Bidentate ligands are frequently chelating ligands (from Greek χηλή, crab’s claw) and, with the metal ion, produce chelate rings(3) which in the case of the most commonly occurring bidentate ligands are 5- or 6-membered, e.g.: see Fig. 19.1. Terdentate ligands produce 2 ring systems when coordinated to a single metal ion and in consequence may impose structural limitations on the complex, particularly where rigidity is introduced by the incorporation of conjugated double bonds within the rings. Thus diethylenetriamine, dien (1), being flexible is stereochemically relatively undemanding, whereas terpyridine, terpy (2), can only coordinate when the 3 donor nitrogen atoms and the metal ion are in the same plane.

Quadridentate ligands produce 3, and in some cases 4, rings on coordination, and so even greater restrictions on the stereochemistry of the complex may be imposed by an

---

Types of ligand

The appropriate choice of ligand. The open-chain ligand triethylenetetramine, trien (3), is, like dien, flexible and undemanding, whereas triethylaminetriamine, tren, i.e. $\text{N(CH}_2\text{CH}_2\text{NH}_2)_3$, is one of the so-called “tripod” ligands which are quite unable to give planar coordination but instead favour trigonal bipyramidal structures (4). By contrast, the highly conjugated phthalocyanine

\[\text{(5)}\]

which is an example of the class of macrocyclic ligands of which the crown ethers have already been mentioned (p. 96), forces the complex to adopt a virtually planar structure and has proved to be a valuable model for the naturally occurring porphyrins which, for instance, are involved in haem (p. 1100), $\text{B}_12$ (p. 1138) and the chlorophylls (p. 125). Another well-known ligand, which has been used to synthesize oxygen-carrying molecules, is bis(salicylaldehyde)ethylenediamine, salen (6). Quinquidenate and sexdentate ligands are most familiarly exemplified by the anions derived from ethylenediaminetetraacetic acid, edta$^4^-$ i.e. \((\text{HO}_2\text{CCH}_2)_2\text{N(CH}_2\text{CH}_2\text{N(CH}_2\text{CO}_2\text{H})}_2\), which is used with remarkable versatility in the volumetric analysis of metal ions. As the fully ionized anion, edta$^4^-$, it has 4 oxygen and 2 nitrogen donor atoms and has the flexibility to wrap itself around a variety of metal ions to produce a pseudo-octahedral complex involving five 5-membered rings as in (7).

In the incompletely ionized form, edtaH$^3^-$, one of the oxygen atoms is no longer able to coordinate to the metal and the anion is quinquidentate. Ambidentate ligands possess more than 1 donor atom and can coordinate through either one or the other. This leads to the possibility of “linkage” isomerism (p. 920). The commonest examples are the ions NO$_2^-$ (p. 463) and SCN$^-$ (p. 325). Such ligands can also coordinate via both donor sites simultaneously, thereby acting as bridging ligands.

In the case of organometallic compounds the most satisfactory way of classifying the ligands

\[\text{(6)}\]

\[\text{(7)}\]

---

is by the number of C atoms attached to (or closely associated with) the metal atom. This essentially structural criterion can be established by several techniques and is more definite than other features such as the presumed number of electrons involved in the bonding. The number of attached carbon atoms is called the hapticity of the organic group (Greek ηάπτεψις, haptein, to fasten) and hapticities from 1 to 8 have been observed. Monohapto groups are specified as \( \eta^1 \), dihapto as \( \eta^2 \), etc. This classification will form the basis of the later discussion of organometallic compounds (pp. 924).

19.3 Stability of Coordination Compounds

Because complexes are not generally prepared from their components in the gaseous phase, measurements of their stability necessarily imply a comparison with the stability of some starting material. The overwhelming majority of quantitative measurements have been made in aqueous solutions when the complex in question is formed by the ligand displacing water from the aquo complex of the metal ion. If, for simplicity, we take the case where \( L \) is a unidentate ligand and ignore charge, then the process can be represented as a succession of steps for which the stepwise stability (or formation) constants \( K \) are as shown:\(^\dagger\)

\[
\begin{align*}
\text{M(H}_2\text{O)}_n + L &\iff ML(H}_2\text{O)}_{n-1} + H_2O; \quad K_1 = \frac{[ML(H}_2\text{O)}_{n-1}]}{[M(H}_2\text{O)}_n][L]} \\
\text{ML}_{n-1}(\text{H}_2\text{O}) + L &\iff ML_n + H_2O; \quad K_n = \frac{[ML_n]}{[ML_{n-1}H}_2\text{O}][L]} \\
\text{M(H}_2\text{O)}_n + nL &\iff ML_n + nH_2O; \quad \beta_n = \frac{[ML_n]}{[M(H}_2\text{O)}_n][L]^n}
\end{align*}
\]

By convention the displaced water is ignored since its concentration is essentially constant. The overall stability (or formation) constant \( \beta_n \) can clearly be expressed in terms of the stepwise constants:

\[
\beta_n = K_1 \times K_2 \times \ldots \times K_n
\]

These are thermodynamic constants which relate to the system when it has reached equilibrium, and must be distinguished from any considerations of kinetic lability or inertness which refer to the speed with which that equilibrium is attained.

A vast amount of data\(^5\) has been accumulated from which a number of generalizations can be inferred concerning the factors which determine the stabilities of such complexes. Some of these are as follows:

(i) The metal ion and its charge. For a given metal and ligand the stability is generally greater if the oxidation state of the metal is \(+3\) rather than \(+2\). Furthermore, the stabilities of corresponding complexes of the bivalent ions of the first transition series, irrespective of the

\(^\dagger\) These constants are expressed here in terms of concentrations which means that the activity coefficients have been assumed to be unity. When pure water is the solvent this will only be true at infinite dilution, and so stability constants should be obtained by taking measurements over a range of concentrations and extrapolating to zero concentration. In practice, however, it is more usual to make measurements in the presence of a relatively high concentration of an inert electrolyte (e.g. 3 M NaClO\(_4\)) so as to maintain a constant ionic strength, thereby ensuring that the activity coefficients remain essentially constant. Stability constants obtained in this way (sometimes referred to as "concentration quotients" or "stoichiometric stability constants") are true thermodynamic stability constants referred to the standard state of solution in 3 M NaClO\(_4\)(aq), but they will, of course, differ from stability constants referred to solution in the pure solvent as standard state.

particular ligand involved, usually vary in the Irving-Williams\(^6\) order (1953):

\[
\text{Mn}^{II} < \text{Fe}^{II} < \text{Co}^{II} < \text{Ni}^{II} < \text{Cu}^{II} > \text{Zn}^{II}
\]

which is the reverse of the order for the cation radii (p. 1295). These observations are consistent with the view that, at least for metals in oxidation states +2 and +3, the coordinate bond is largely electrostatic. This was a major factor in the acceptance of crystal field theory (see pp. 921–3).

(ii) The relationship between metal and donor atom.\(^{6a}\) Some metal ions (known as class-a acceptors or alternatively as “hard” acids) form their most stable complexes with ligands containing N, O or F donor atoms. Others (known as class-b acceptors or alternatively as “soft” acids) form their most stable complexes with ligands whose donor atoms are the heavier elements of the N, O or F groups. The metals of Groups 1 and 2 along with the inner transition elements and the early members of the transition series (Groups 3 → 6) fall into class-a. The transition elements Rh, Pd, Ag and Ir, Pt, Au, Hg comprise class-b, while the remaining transition elements may be regarded as borderline (Fig. 19.2). The difference between the class-a elements of Group 2 and the borderline class-b elements of Group 12 is elegantly and colourfully illustrated by the equilibrium

\[
[\text{CoCl}_4]^{2-} + 6\text{H}_2\text{O} \rightleftharpoons [\text{Co(H}_2\text{O})_6]^{2+} + 4\text{Cl}^- \quad \text{Blue} \rightarrow \text{Pink}
\]

If \(\text{Ca}^{II}\) is added it pushes the equilibrium to the left by bonding preferentially to \(\text{H}_2\text{O}\), whereas \(\text{Zn}^{II}\), with its partial b character (p. 1206), prefers the heavier \(\text{Cl}^-\) and so pushes the equilibrium to the right.

It seems that, as suggested by Ahrland \textit{et al.}\(^7\) in 1958, this distinction can be explained at least partly on the basis that class-a acceptors are the

---

more electropositive elements which tend to form their most stable complexes with ligands favouring electrostatic bonding, so that, for instance, the stabilities of their complexes with halide ions should decrease in the order

\[ F^- > Cl^- > Br^- > I^- \]

Class-b acceptors on the other hand are less electropositive, have relatively full d orbitals, and form their most stable complexes with ligands which, in addition to possessing lone-pairs of electrons, have empty π orbitals available to accommodate some charge from the d orbitals of the metal. The order of stability will now be the reverse of that for class-a acceptors, the increasing accessibility of empty d orbitals in the heavier halide ions for instance, favouring an increase in stability of the complexes in the sequence

\[ F^- < Cl^- < Br^- < I^- \]

(iii) The type of ligand. In comparing the stabilities of complexes formed by different ligands, one of the most important factors is the possible formation of chelate rings. If L is a unidentate ligand and L-L a bidentate ligand, the simplest illustration of this point is provided by comparing the two reactions:

\[ \text{M(aq)} + 2\text{L(aq)} \rightleftharpoons \text{ML}_2(\text{aq}) \]

for which \( \beta_L = \frac{[\text{ML}_2]}{[\text{M}][\text{L}]^2} \)

and

\[ \text{M(aq)} + \text{L-L(aq)} \rightleftharpoons \text{ML-L (aq)} \]

for which \( \beta_{L-L} = \frac{[\text{ML-L}]}{[\text{M}][\text{L-L}]} \)

or alternatively by considering the replacement reaction obtained by combining them:

\[ \text{ML}_2(\text{aq}) + \text{L-L(aq)} \rightleftharpoons \text{ML-L(aq)} + 2\text{L(aq)} \]

for which \( K = \frac{[\text{ML-L}][\text{L}]^2}{[\text{ML}_2][\text{L-L}]} = \frac{\beta_{L-L}}{\beta_L} \)

Experimental evidence shows overwhelmingly that, providing the donor atoms of L and L-L are the same element and that the chelate ring formed by the coordination of L-L does not involve undue strain, L-L will replace L and the equilibrium of the replacement reaction will be to the right. This stabilization due to chelation is known as the chelate effect\(^8\) and is of great importance in biological systems as well as in analytical chemistry.

The effect is frequently expressed as \( \beta_{L-L} > \beta_L \) or \( K > 1 \) and, when values of \( \Delta H^\circ \) are available, \( \Delta G^\circ \) and \( \Delta S^\circ \) are calculated from the thermodynamic relationships

\[ \Delta G^\circ = -RT \ln \beta \quad \text{and} \quad \Delta G^\circ = \Delta H^\circ - T \Delta S^\circ \]

On the basis of the values of \( \Delta S^\circ \) derived in this way it appears that the chelate effect is usually due to more favourable entropy changes associated with ring formation. However, the objection can be made that \( \beta_L \) and \( \beta_{L-L} \), as just defined have different dimensions and so are not directly comparable. It has been suggested that to surmount this objection concentrations should be expressed in the dimensionless unit “mole fraction” instead of the more usual mol dm\(^{-3}\). Since the concentration of pure water at 25°C is approximately 55.5 mol dm\(^{-3}\), the value of concentration expressed in mole fractions \( \text{conc in mol dm}^{-3}/55.5 \)Thus, while \( \beta_L \) is thereby increased by the factor (55.5)\(^2\), \( \beta_{L-L} \) is increased by the factor (55.5)\(^2\) so that the derived values of \( \Delta G^\circ \) and \( \Delta S^\circ \) will be quite different. The effect of this change in units is shown in Table 19.1 for the Cd\(^{11}\) complexes of \( L = \text{methylamine} \) and \( L-L = \text{ethylenediamine} \). It appears that the entropy advantage of the chelate, and with it the chelate effect itself, virtually disappears when mole fractions replace mol dm\(^{-3}\).

The resolution of this paradox lies in the assumptions about standard (reference), states which are unavoidably involved in the above definitions of \( \beta_L \) and \( \beta_{L-L} \). In order to ensure that \( \beta_L \) and \( \beta_{L-L} \) are dimensionless (as they have to be if their logarithms are to be used) when concentrations are expressed in units which have dimensions, it is necessary to use the ratios of the actual concentrations to the concentrations of

\]

some standard state. Accordingly, the expression for any β should incorporate an additional factor composed of standard state concentrations, and the expression $\Delta G^\circ = -RT \ln \beta$ should have an additional term involving the logarithm of this factor. Not to include this factor and this term inevitably implies the choice of standard states of concentration = 1 in whatever units are being used. Only in this way can the factor associated with β be 1 and its logarithm zero. It should be stressed, however, that irrespective of these definitional niceties, it remains true as stated above that chelating ligands which form unstrained complexes always tend to displace their monodentate counterparts under normally attainable experimental conditions.

Probably the most satisfactory model with which to explain the chelate effect is that proposed by G. Schwarzenbach\(^9\) If L and L-L are present in similar concentrations and are competing for two coordination sites on the metal, the probability of either of them coordinating to the first site may be taken as equal. However, once one end of L-L has become attached it is much more likely that the second site will be won by its other end than by L, simply because its other end must be held close to the second site and its effective concentration where it matters is therefore much higher than the concentration of L. Because $\Delta G^\circ$ refers to the transfer of the separate reactants at concentrations = 1 to the products, also at concentrations = 1, it is clear from this model that the advantage of L-L over L, as denoted by $\Delta G^\circ$ or β, will be greatest when the units of concentration are such that a value of 1 corresponds to a dilute solution. Conversely, where a value of 1 corresponds to an exceedingly high concentration, the advantage will be much less and may even disappear. In normal practice even a concentration of 1 mol dm$^{-3}$ is regarded as high, and a concentration of 1 mole fraction is so high as to be of only hypothetical significance, so it need cause no surprise that the choice of the latter unit should lead to rather bizarre results.

The chelate effect is usually most pronounced for 5- and 6-membered rings. Smaller rings generally involve excessive strain while increasingly large rings offer a rapidly decreasing advantage for coordination to the second site. Naturally the more rings there are in a complex the greater the total increase in stability. If a multidentate ligand is also cyclic, and there are no unfavourable steric effects, a further increase in the stability of its complexes accrues. Favourable entropy changes can again be invoked to explain this *macrocyclic effect*. Since a macrocyclic ligand has very little rotational entropy even before coordination, the net increase in entropy when it does coordinate is expected to be even greater than in the case of a comparable non-cyclic ligand.

---

19.4 The Various Coordination Numbers\(^{10}\)

In 1893 at the age of 26, Alfred Werner\(^{\dagger}\) produced his classic coordination theory.\(^{(2,11)}\) It is said that, after a dream which crystallized his ideas, he set down his views and by midday had written the paper which was the starting point for work which culminated in the award of the Nobel Prize for Chemistry in 1913. The main thesis of his argument was that metals possess two types of valency: (i) the primary, or ionizable, valency which must be satisfied by negative ions and is what is now referred to as the “oxidation state”; and (ii) the secondary valency which has fixed directions with respect to the central metal and can be satisfied by either negative ions or neutral molecules. This is the basis for the various stereochemistries found amongst coordination compounds. Without the armoury of physical methods available to the modern chemist, in particular X-ray crystallography, the early workers were obliged to rely on purely chemical methods to identify the more important of these stereochemistries. They did this during the next 20 y or so, mainly by preparing vast numbers of complexes of various metals of such stoichiometry that the number of isomers which could be produced would distinguish between alternative stereochemistries.

The term “secondary valency” has been superseded by the term “coordination number”. This may be defined as the number of donor atoms associated with the central metal atom or ion. For many years a distinction was made between coordination number in this sense and in the crystallographic sense, where it is the number of nearest-neighbour ions of opposite charge in an ionic crystal. Though the former definition applies to species which can exist independently in the solid or in solution, while the latter applies to extended lattice systems, the distinction is rather artificial, particularly in view of the fact that crystal field theory (one of the theories of bonding most commonly applied to coordination compounds) assumes that the coordinate bond is entirely ionic! Indeed, the concept can be extended to all molecules. TiCl\(_4\), for instance, can be regarded as a complex of Ti\(^{4+}\) with 4 Cl\(^{-}\) ions in which one lone-pair of electrons on each of the latter is completely shared with the Ti\(^{4+}\) to give essentially covalent bonds.

The most commonly occurring coordination numbers for transition elements are 4 and 6, but all values from 2 to 9 are known and a few examples of even higher ones have been established. The more important factors determining the most favourable coordination number for a particular metal and ligand are summarized below. However it is important to realize that, with so many factors involved, it is not difficult to provide facile explanations of varying degrees of plausibility for most experimental observations, and it is therefore prudent to treat such explanations with caution.

(i) If electrostatic forces are dominant the attractions between the metal and the ligands should exceed the destabilizing repulsions between the ligands. The attractions are proportional to the product of the charges on the metal and the ligand whereas the repulsions are proportional to the square of the ligand charge. High cation charge and low ligand charge should consequently favour high coordination numbers, e.g. halide ions usually favour higher coordination numbers than does O\(^{2-}\).

(ii) There must be an upper limit to the number of molecules (atoms) of a particular ligand which can physically be fitted around a particular cation. For monatomic ligands this limit will be dependent on the radius ratio of cation and anion, just as is the case with extended crystal lattices.

(iii) Where covalency is important the distribution of charge is equalized by the transference

---

\(^{\dagger}\) Born in Mulhouse, Alsace, in 1866, he was French by birth, German in upbringing, and, working in Zürich, he became a Swiss citizen in 1894.
of charge in the form of lone-pairs of electrons from ligands to cation. The more polarizable the ligand the lower the coordination number required to satisfy the particular cation though, if back-donation of charge from cation to ligand via suitable \( \pi \) orbitals is possible, then more ligands can be accommodated. Thus the species most readily formed with Fe\(^{III} \) in aqueous solutions are \([\text{FeF}_3(\text{H}_2\text{O})]^{2-}\) for the non-polarizable \( \text{F}^- \), \([\text{FeCl}_4]^{-}\) for the more polarizable \( \text{Cl}^- \), but \([\text{Fe(CN)}_6]^{3-}\) for \( \text{CN}^- \) which, though it is even more polarizable, also possesses empty antibonding \( \pi \) orbitals suitable for back-donation. Thus the species most readily formed with Fe\(^{III} \) in aqueous solutions are \([\text{FeF}_3(\text{H}_2\text{O})]^{2-}\) for the non-polarizable \( \text{F}^- \), \([\text{FeCl}_4]^{-}\) for the more polarizable \( \text{Cl}^- \), but \([\text{Fe(CN)}_6]^{3-}\) for \( \text{CN}^- \) which, though it is even more polarizable, also possesses empty antibonding \( \pi \) orbitals suitable for back-donation.

(iv) The availability of empty metal orbitals of suitable symmetries and energies to accommodate electron-pairs from the ligands must also be important in covalent compounds. This is probably one of the main reasons why the lowest coordination numbers (2 and 3) are to be found in the Ag, Au, Hg region of the periodic table where the \( d \) shell has been filled. However, it would be unwise to draw the converse conclusion that the highest coordinations are found amongst the early members of the transition and inner-transition series because of the availability of empty \( d \) or \( f \) orbitals. It seems more likely that these high coordination numbers are achieved by electrostatic attractions between highly charged but rather large cations and a large number of relatively non-polarizable ligands.

Representative examples of the stereochemistries associated with each of the various coordination numbers will now be discussed.

**Coordination number 2**

Examples of this coordination number are virtually confined to linear \( D_{\text{coh}} \) complexes of Cu\(^{I} \), Ag\(^{I} \), Au\(^{I} \), and Hg\(^{II} \) of which a well-known instance is the ammine formed when ammonia is added to an aqueous solution of Ag\(^{II} \): \([\text{H}_3\text{N}^-\text{Ag}^-\text{NH}_3]^+\)

**Coordination number 3\(^{(12)} \)**

This is rather rare and even in \([\text{HgI}_3]^-\), the example usually cited, the coordination number is dependent on the counter cation. In \([\text{SMe}_3][\text{HgI}_3]\) the Hg\(^{II} \) lies at the centre of an almost equilateral triangle of iodide ions (\( D_{3h} \)) whereas in \([\text{NMe}_4][\text{HgI}_3]\) the anion apparently polymerizes into loosely linked chains of 4-coordinate Hg\(^{II} \). Other examples feature bulky ligands, e.g. the trigonal planar complexes \([\text{Fe}[\text{N(SiMe}_3)_2]]\), \([\text{Cu}[(\text{SC(NH}_2)_2]_3]\) and \([\text{Cu}(\text{SPPh}_3)_3]\)ClO\(_4\)

**Coordination number 4**

This is very common and usually gives rise to stereochemistries which may be regarded essentially as either tetrahedral \( T_d \) or (square) planar \( D_{4h} \). Where a complex may be thought to have been formed from a central cation with a spherically symmetrical electron configuration, the ligands will lie as far from each other as possible, that is they will be tetrahedrally disposed around the cation. This has already been seen in complex anions such as BF\(_4^-\) and is also common amongst complexes of transition metals in their group oxidation states and of d\(^5 \) and d\(^{10} \) ions. \([\text{MnO}_4]^-\), \([\text{Ni(CO)}_4]\) and \([\text{Cu(py)}_4]^+\), respectively, exemplify these types. Central cations with other d configurations, in particular d\(^8 \), may give rise to a square-planar stereochemistry and the complexes of Pd\(^{II} \) and Pt\(^{II} \) are predominantly of this type. Then again, the difference in energy between tetrahedral and square-planar forms may be only slight, in which case both forms may be known or, indeed, interconversions may be possible as happens with a number of Ni\(^{II} \) complexes (p. 1159). In the \( \text{M}_2\text{CuX}_4 \) series of complexes of Cu\(^{II} \), variation of \( M \) and \( X \) gives complex anions with stereochemistries ranging from square planar, e.g. \((\text{NH}_4)_2[\text{CuCl}_4]\), to almost tetrahedral, e.g. \( \text{Cs}_2[\text{CuBr}_4] \). Figure 19.3 shows that the change from square planar to tetrahedral requires a 90° rotation of one \( L_L \) pair and a 19\(^\circ \) change in the LML angles, and a continuous range of distortions from one extreme to the other would appear to be feasible.

---

Four-coordinate complexes provide good examples of the early use of preparative methods for establishing stereochemistry. For complexes of the type $[\text{Ma}_2\text{b}_2]$, where a and b are unidentate ligands, a tetrahedral structure cannot produce isomerism whereas a planar structure leads to cis and trans isomers (see below). The preparation of 2 isomers of $[\text{PtCl}_2(\text{NH}_3)_2]$, for instance, was taken as good evidence for their planarity.\footnote{On the basis of this evidence alone it is logically possible that one isomer could be tetrahedral. Early coordination chemists, however, assumed that the directions of the "secondary valencies" were fixed, which would preclude this possibility. X-ray structural analysis shows that, in the case of Pt$^{II}$ complexes, they were correct.}

Coordination number 5

Five-coordinate complexes are far more common than was once supposed and are now known for all configurations from d$^1$ to d$^9$. Two limiting stereochemistries may be distinguished (Fig. 19.4). One of the first authenticated examples of 5-coordination was $[\text{VO(acac)}_2]$ which has the square-pyramidal $C_{4v}$ structure with the $=\text{O}$ occupying the unique apical site. However, many of the complexes with this coordination number have structures intermediate between the two extremes and it appears that the energy required for their interconversion is frequently rather small. Because of this stereochemical non-rigidity a number of 5-coordinate compounds behave in a manner described as "fluxional". That is, they exist in two or more configurations which are chemically equivalent and which interconvert at such a rate that some physical measurement (commonly nmr) is unable to distinguish the separate configurations and instead "sees" only their time-average. If $\text{ML}_5$ has a trigonal bipyramidal $D_{3h}$ structure then 2 ligands must be "axial" and 3 "equatorial", but interchange via a square-pyramidal intermediate is possible (Fig. 19.5). This mechanism has been suggested as the reason why the $^{13}\text{C}$ nmr spectrum of trigonal bipyramidal $\text{Fe(CO)}_5$ (p. 1104) fails to distinguish two different kinds of carbon nuclei. See also the discussion of $\text{PF}_5$ on p. 499.

Coordination number 6

This is the most common coordination number for complexes of transition elements. It can be seen by inspection that, for compounds of the type $[\text{Ma}_3\text{b}_3]$, the three symmetrical structures (Fig. 19.6) can give rise to 3, 3 and 2 isomers respectively. Exactly the same is true for compounds of the type $[\text{Ma}_2\text{b}_2]$. In order to determine the stereochemistry of 6-coordinate complexes very many examples of such compounds were prepared, particularly with $\text{M} = \text{Cr}^{III}$ and $\text{Co}^{III}$, and in no case was more than 2 isomers found. This, of course, was only negative evidence for the octahedral structure, though the
The various coordination numbers

neither the planar nor trigonal prismatic structures can give rise to such optical isomers. Nevertheless, it cannot be assumed that every 6-coordinate complex is octahedral. In 1923 the first example of trigonal prismatic coordination was reported for the infinite layer lattices of MoS$_2$ and WS$_2$. A limited number of further examples are now known following the report in 1965 of the structure of [Re(S$_2$C$_2$Ph$_2$)$_3$] (Fig. 19.7). Intermediate structures also occur and can be defined by the “twist angle” which is the angle through which one face of an octahedron has been rotated with respect to the opposite face as “viewed along” a threefold axis of the octahedron. A twist angle of 60° suffices to convert an octahedron into a trigonal prism:

In fact the vast majority of 6-coordinate complexes are indeed octahedral or distorted octahedral. In addition to the twist distortion just considered distortions can be of two other types: trigonal and tetragonal distortions which mean compression or elongation along a threefold and a fourfold axis of the octahedron respectively (Fig. 19.8).

Figure 19.5 The interconversion of trigonal bipyramidal configurations via a square-pyramidal intermediate. Notice that the $L_1$ ligands, which in the left-hand tbp are axial, become equatorial in the right-hand tbp and simultaneously 2 of the $L_2$ ligands change from equatorial to axial.

Figure 19.6 Possible stereochemistries for 6-coordination.

sheer volume of it made it rather compelling. More positive evidence was provided by Werner, who in 1914 achieved the first resolution into optical isomers of an entirely inorganic compound, since

Coordination and Organometallic Compounds

Ch. 19

Figure 19.8 Distortions of octahedral geometry.

Coordination number 7

There are three main stereochemistries for complexes of this coordination number: pentagonal bipyramidal $D_{5h}$, capped trigonal prismatic $C_{2v}$, and capped octahedral $C_{3v}$, the last two being obtained by the addition of a seventh ligand either above one of the rectangular faces of a trigonal prism or above a triangular face of an octahedron respectively. These structures may conveniently be visualized as having the ligating atoms which form the coordination polyhedra on the surfaces of circumscribed spheres (Fig. 19.9).

As with other high coordination numbers, there seems to be little difference in energy between these structures. Factors such as the number of counter ions and the stereochemical requirements of chelating ligands are probably decisive and a priori arguments are unreliable in predicting the geometry of a particular complex. $[\text{ZrF}_7]^{3-}$ and $[\text{HfF}_7]^{3-}$ have the pentagonal bipyramidal structure, whereas the bivalent anions, $[\text{NbF}_7]^{2-}$ and $[\text{TaF}_7]^{2-}$ are capped trigonal prismatic. The capped octahedral structure is exemplified by $[\text{NbOF}_6]^{3-}$.

Coordination number 8

The most symmetrical structure possible is the cube $O_h$ but, except in extended ionic lattices such as those of CsCl and CaF$_2$, it appears that inter-ligand repulsions are nearly always (but see p. 1275) reduced by distorting the cube, the two most important resultant structures being the square antiprism $D_{4h}$ and the dodecahedron $D_{2d}$ (Fig. 19.10).

Again, these forms are energetically very similar; distortions from the idealized structures make it difficult to specify one or other, and the particular structure actually found must result from the interplay of many factors. $[\text{TaF}_8]^{3-}$, $[\text{ReF}_8]^{2-}$ and $[\text{Zr(acac)}_4]$ are square antiprismatic, whereas $[\text{ZrF}_8]^{4-}$ and $[\text{Mo(CN)}_8]^{4-}$ are dodecahedral. The nitrates $[\text{Co(NO}_3)_4]^{2-}$ and $\text{Ti(NO}_3)_4$ may both be regarded as dodecahedral, the former with some distortion. Each nitrate ion is bidentate but the 2

119.4 The various coordination numbers

Figure 19.10 (a) Conversion of cube to square antiprism by rotation of one face through 45° (b) Conversion of cube into dodecahedron.

oxygen atoms are necessarily close together so that the structure of the complexes is probably more easily visualized from the point of view of the 4 nitrogen atoms which form a flattened tetrahedron around the metal (p. 966).

Coordination number 9

The stereochemistry of most 9-coordinate complexes approximates to the tri-capped trigonal prism $D_{3h}$, formed by placing additional ligands above the three rectangular faces of a trigonal prism:

Amongst the known examples of this arrangement are a number of $[\text{M(H}_2\text{O)}_9]^{3+}$ hydrates of lanthanide salts and $[\text{ReH}_9]^{2-}$. The latter is interesting in that it is presumably only the small size of the H ligand which allows such a high coordination number for rhenium. Very occasionally 9-coordination results in a capped square antiprismatic $C_{4v}$ arrangement in which the ninth ligand lies above one of the square faces, e.g. the Cl-bridged $[[\text{LaCl(H}_2\text{O)}_7]_2]^{4+}$.

Coordination numbers above 9

Such high coordination numbers are not common and it is difficult to generalize about their structures since so few have been accurately determined. They are found mainly with ions of the early lanthanide and actinide elements and it is therefore tempting to assume that the availability of empty and accessible f orbitals is necessary for their formation. However, it appears that the bonding is predominantly ionic and that the really important point is that these are the elements which provide stable cations with charges high enough to attract a large number of anions and yet are large enough to ensure that the inter-ligand repulsions are not unacceptably high. $K_2[\text{Th(O}_2\text{CCO)}_2\text{H}_2\text{O})_2],2\text{H}_2\text{O}$ (bicapped square antiprism $D_{4d}$) and $[\text{La(edta)(H}_2\text{O)}_4]$ afford examples of 10-coordination. Higher coordination numbers are reached only by chelating ligands such as $\text{NO}_3^-$, $\text{SO}_4^{2-}$, and 1,8-naphthyridine (8) with donor atoms close together (i.e. ligands with only a small “bite”). $[\text{La(dapbaH)}(\text{NO}_3)_3]$, is a good example (see

![Image of coordination number 9](image_url)

![Image of coordination number 9](image_url)

![Image of coordination number 9](image_url)
also p. 1276): in it the 5 donor atoms of the dapbaH, i.e. 2,6-diacetylpyridinebis(benzoic acid hydrazone) (9), are situated in a plane, with the N atoms (but not the donor oxygens) of the 3 bidentate nitrates in a second plane at right angles to the first. Ce₂Mg₃(NO₃)₁₂.2₄H₂O contains 12-coordinate Ce in the complex ion [Ce(NO₃)₆]⁻². This has a distorted icosahedral stereochemistry, though it is more easily visualized as an octahedral arrangement of the nitrogen atoms around the Ce III. Another example is [Pr(naph)₆]³⁺ where naph is 1,8-naphthyridine (8).

Higher coordination numbers (up to 16) are known, particularly among organometallic compounds (pp. 940–3) and metal borohydrides (p. 168).

In addition to coordination compounds in which a central metal atom is surrounded by a polyhedral array of donor atoms, a large and rapidly increasing number of “cluster” compounds is known in which a group of metal atoms is held together largely by M–M bonds. Where more than three metal atoms are involved, they themselves form polyhedral arrays which may be considered as conceptual intermediates between mononuclear classical complexes and the non-molecular lattice structures of binary and ternary compounds of transition metals. A distinction is sometimes made between “clusters” which owe their stability to M–M bonds, and “cages” which are held together by ligand bridges, but the distinction is not rigidly adhered to.

Cluster and cage structures are widespread in the chemistry of main group elements, being particularly extensive in the case of boron (Chap. 6). For transition elements the principal areas of interest are the lower halides of elements towards the left of the d-block, and carbonyls of elements towards the right of the d-block, the latter being an especially active area. The possibility that metal clusters of high nuclearity might mimic the behaviour of metal surfaces (the “surface-cluster analogy”) has stimulated synthetic chemists to search for materials with high catalytic activity. Such materials, particularly if soluble, should also provide better insight into the catalytic activity of metal surfaces. Unfortunately these objectives have so far proved largely elusive and in only a few cases can catalytic activity be attributed confidently to a cluster itself rather than to its fragmentation products.

These and other classes of cluster compounds will be dealt with more fully in later chapters devoted to the chemistry of the metals involved.

19.5 Isomerism

Isomers are compounds with the same chemical composition but different structures, and the possibility of their occurrence in coordination compounds is manifest. Their importance in the early elucidation of the stereochemistries of complexes has already been referred to and, though the purposeful preparation of isomers is no longer common, the preparative chemist must still be aware of the diversity of the compounds which can be produced. The more important types of isomerism are listed below.

Conformational isomerism

In principle this type of isomerism (also known as “polytopal” isomerism) is possible with any coordination number for which there is more than one known stereochemistry. However, to actually occur the isomers need to be of comparable stability, and to be separable there...
must be a significant energy barrier preventing their interconversion. This behaviour is confined primarily to 4-coordinate nickel(II), an example being \([\text{NiCl}_2\{\text{P(CH}_2\text{Ph})\text{Ph}_2\}_2]\) which is known in both planar and tetrahedral forms (p. 1160).

**Geometrical isomerism**

This is of most importance in square-planar and octahedral compounds where ligands, or more specifically donor atoms, can occupy positions next to one another (cis) or opposite each other (trans) (Fig. 19.11).

![Figure 19.11 Cis and trans isomerism.](image)

A similar type of isomerism occurs for \([\text{M}_3\text{b}_3]\) octahedral complexes since each trio of donor atoms can occupy either adjacent positions at the corners of an octahedral face (facial) or positions around the meridian of the octahedron (meridional). (Fig. 19.12.) Geometrical isomers differ in a variety of physical properties, amongst which dipole moment and visible/ultraviolet spectra are often diagnostically important.

**Optical isomerism**

Optical isomers, enantiomorphs or enantiomers, as they are also known, are pairs of molecules which are non-superimposable mirror images of each other. Such isomers have the property of chirality (from Greek χεῖρ, hand), i.e. handedness, and virtually the only physical or chemical difference between them is that they rotate the plane of polarized light, one of them to the left and the other to the right. They are consequently designated as laevo (l or −) and dextro (d or +) isomers.

A few cases of optical isomerism are known for planar and tetrahedral complexes involving unsymmetrical bidentate ligands, but by far the most numerous examples are afforded by octahedral compounds of chelating ligands, e.g. \([\text{Cr(oxalate)}_3]^{2−}\) and \([\text{Co(edta)}]^{−}\) (Fig. 19.13).
Where unidentate ligands are present, the ability to effect the resolution of an octahedral complex (i.e. to separate 2 optical isomers) is proof that the 2 ligands are cis to each other. Resolution of \([\text{PtCl}_2(\text{en})_2]^2^-\) therefore shows it to be cis while of the 2 known geometrical isomers of \([\text{CrCl}_2(\text{en})(\text{NH}_3)_2]^+\) the one which can be resolved must have the cis-cis structure since the trans form would give a superimposable, and therefore identical, mirror image:

Ionization isomerism

This type of isomerism occurs when isomers produce different ions in solution, and is possible in compounds which consists of a complex ion with a counter ion which is itself a potential ligand. The pairs: \([\text{Co(NH}_3)_5(\text{NO}_2)]\text{SO}_4, [\text{Co(NH}_3)_5(\text{SO}_4)]\text{NO}_3\) and \([\text{PtCl}_2(\text{NH}_3)_4]\text{Br}_2, [\text{PtBr}_2(\text{NH}_3)_4]\text{Cl}_2,\) and the series \([\text{CoCl}(\text{en})_2(\text{NO}_2)]\text{SCN}, [\text{CoCl}(\text{en})_2(\text{SCN})]\text{NO}_2, [\text{Co(en)}_2(\text{NO}_2)(\text{SCN})]\text{Cl}\) are examples of ionization isomers.

A subdivision of this type of isomerism, known as “hydrate isomerism”, occurs when water may be inside or outside the coordination sphere. It is typified by \(\text{CrCl}_3.6\text{H}_2\text{O}\) which exists in the three distinct forms \([\text{Cr(H}_2\text{O})_6]\text{Cl}_3\) (violet), \([\text{CrCl(}\text{H}_2\text{O})_3]\text{Cl}_2.\text{H}_2\text{O}\) (pale green), and \([\text{CrCl}_2(\text{H}_2\text{O})_4]\text{Cl}_2.\text{H}_2\text{O}\) (dark green). These are readily distinguished by the action of AgNO\(_3\) in aqueous solution which immediately precipitates 3, 2 and 1 chloride ions respectively.

Linkage isomerism

This is in principle possible in any compound containing an ambidentate ligand. However, that such a ligand can under different circumstances coordinate through either of the 2 different donor atoms is by no means a guarantee that it will form isolable linkage isomers with the same cation. In fact, in only a very small proportion of the complexes of ambidentate ligands can linkage isomers actually be isolated, and these are confined largely to complexes of NO\(_2^-\) (p. 463) and, to a lesser extent, SCN\(^-\) (p. 325). Examples are:

\[
[\text{Co(en)}_2(\text{NO}_2)_2]^-, [\text{Co(en)}_2(\text{ONO})_2]^-
\]

and

\[
[\text{Pd(PPh}_3)_2(\text{NCS})_2], [\text{Pd(PPh}_3)_2(\text{SCN})_2]
\]

It should be noted that, by convention, the ambidentate ligand is always written with its donor atom first, i.e. NO\(_2\) for the nitro, ONO for the nitrito, NCS for the N-thiocyanato and SCN for the S-thiocyanato complex. Differences in infrared spectra arising from the differences in bonding are often used to distinguish between such isomers.

Coordination isomerism

In compounds made up of both anionic and cationic complexes it is possible for the distribution of ligands between the ions to vary and so lead to isomers such as:

\[
[\text{Co(en)}_3][\text{Cr(CN)}_6], [\text{Cr(en)}_3][\text{Co(CN)}_6]
\]

\[
[\text{Cu(NH}_3)_4][\text{PtCl}_4], [\text{Pt(NH}_3)_4][\text{CuCl}_4]
\]

\[
[\text{Pt}^{II}(\text{NH}_3)_4][\text{Pt}^{IV}\text{Cl}_6], [\text{Pt}^{IV}(\text{NH}_3)_4\text{Cl}_2][\text{Pt}^{II}\text{Cl}_4]
\]

It can be seen that other intermediate isomers are feasible but in the above cases they have not been isolated. Substantial differences in both physical and chemical properties are to be expected between coordination isomers.

When the two coordinating centres are not in separate ions but are joined by bridging groups, the isomers are often distinguished as “coordination position isomers” as is the case for:
The coordinate bond

Polymerization isomerism

Compounds whose molecular compositions are multiples of a simple stoichiometry are polymers, strictly, only if they are formed by repetition of the simplest unit. However, the name "polymerization isomerism" is applied rather loosely to cases where the same stoichiometry is retained but where the molecular arrangements are different. The stoichiometry PtCl₂(NH₃)₂ applies to the 3 known compounds, [Pt(NH₃)₄][PtCl₄], [Pt(NH₃)₂][PtCl₃(NH₃)]₂, and [PtCl(NH₃)₃][PtCl₄] (in addition to the cis and trans isomers of monomeric [PtCl₂(NH₃)₂]). There are actually 7 known compounds with the stoichiometry Co(NH₃)₃(NO₂)₃. Again it is clear that considerable differences are to be expected in the chemical properties and in physical properties such as conductivity.

Ligand isomerism

Should a ligand exist in different isomeric forms then of course the corresponding complexes will also be isomers, often described as "ligand isomers". In [CoCl(en)₂(NH₂C₆H₄Me)]Cl₂, for instance, the toluidine may be of the o-, m- or p- form.

19.6 The Coordinate Bond

(see also p. 198)

The concept of the coordinate bond as an interaction between a cation and an ion or molecule possessing a lone-pair of electrons can be accepted before specifying the nature of that interaction. Indeed, it is now evident that in different complexes the bond can span the whole range from electrostatic to covalent character. This is why the various theories which have been accorded popular favour at different times have been acceptable and useful even though based on apparently incompatible assumptions. This dichotomy is reflected in the now obsolete adjectives "dative-covalent", "semi-polar" and "co-ionic", which have been used to describe the coordinate bond. The first of these descriptions arises from the idea advanced by N. V. Sidgwick in 1927, that the coordinate bond is a covalent bond formed by the donation of a lone-pair of electrons from the donor atom to the central metal. Since noble gases are extremely unreactive, and compounds in which atoms have attained the electronic configuration of a noble gas either by sharing or transferring electrons also tend to be stable, Sidgwick further suggested that, in complexes, the metal would tend to surround itself with sufficient ligands to ensure that the number of electrons around it (its "effective atomic number" or EAN) would be the same as that of the next noble gas. If this were true then a metal would have a unique coordination number for each oxidation state, which is certainly not always the case. However, the EAN rule is still of use in rationalizing the coordination numbers and structures of simple metal carbonyls.

In his valence bond theory (VB), L. Pauling extended the idea of electron-pair donation by considering the orbitals of the metal which would be needed to accommodate them, and the stereochemical consequences of their hybridization (1931–3). He was thereby able to account for much that was known in the 1930s about the stereochemistry and kinetic behaviour of complexes, and demonstrated the diagnostic value of measuring their magnetic properties. Unfortunately the theory offers no satisfactory explanation of spectroscopic properties and so was

---

eventually superseded by crystal field theory (CF).

About the same time that VB theory was being developed, CF theory was also being used by H. Bethe, J. H. van Vleck and other physicists to account for the colours and magnetic properties of hydrated salts of transition metals (1933–6). It is based on what, to chemists, appeared to be the outrageous assumption that the coordinate bond is entirely electrostatic. Nevertheless, in the 1950s a number of theoretical chemists used it to interpret the electronic spectra of transition metal complexes. It has since been remarkably successful in explaining the properties of MII and MIII ions of the first transition series, especially when modifications have been incorporated to include the possibility of some covalency. (The theory is then often described as ligand field theory, but there is no general agreement on this terminology.)

In order to take full account of both ionic and covalent character, recourse must be made to molecular orbital theory (MO) which, like the VB and CF theories, originated in the 1930s. It has gained increasing ground with the development of powerful high-speed computers and the ready accessibility of software programmes which enable either semi-empirical or complex ab initio calculations to be carried out reliably and rapidly. There is still a place, however, for the pictorial representation of localized two-centre or three-centre bonds in elementary descriptions of bonding.

The fundamental assumption of MO theory is that metal and ligand orbitals will overlap and combine, providing they are of the correct symmetries to do so and have similar energies. In one approximation the appropriate AOs of the metal and atomic or molecular orbitals of the ligand, are used to produce the MOs by the linear combination of atomic orbitals (LCAO) method. Since combination of metal and ligand orbitals of widely differing energies can be neglected, only valence orbitals are considered.

In the case of an octahedral complex ML₆, the metal has six σ orbitals, i.e. the e₈ pair of the nd set, together with the (n + 1)s and the three (n + 1)p. The ligands each have one

σ orbital (containing the lone-pair of electrons) and these are combined to give orbitals with the correct symmetry to overlap with the metal σ orbitals (Fig. 19.14). The 6 electron pairs from the ligands are placed in the six lowest MOs, leaving the non-axial, and hence non-σ-bonding, metal t₂g and the antibonding e₈* orbitals to accommodate the electrons originally on the metal. This central portion of the figure is the same as the e₈/t₄g splitting defined in CF theory, with the difference that the e₈* orbitals now have some ligand character which implies covalency. The lower in energy the ligand orbitals are with respect to the AOs of the metal the nearer is the bonding to the electrostatic extreme. Conversely, the nearer in energy the ligand orbitals are to the AOs of the metal the more nearly can the bonding be described as electron pair donation by the ligand as in VB theory. Indeed, the metal character of the bonding MOs is derived from just those metal orbitals used in VB theory to produce the d⁵sp³ hybrids which accommodate the electron pairs donated by the ligands.

If the ligand possesses orbitals of π as well as σ symmetry the situation is drastically changed.
because of the overlap of these orbitals with the $t_{2g}$ orbitals of the metal. Two situations may arise. Either the ligand $\pi$ orbitals are empty and of higher energy than the metal $t_{2g}$, or they are filled and of lower energy than the metal $t_{2g}$ orbitals (Fig. 19.15). The former in effect increases $\Delta_0$, the separation of the $t_{2g}$ and $e_g^*$ orbitals, and is the more important case, including ligands such as CO, NO$^+$ and CN$^-$. This type of covalency, called $\pi$ bonding or back bonding, provides a plausible explanation for the stability of such compounds as the metal carbonyls (pp. 926–9).

If $\Delta_0$ is large enough then electrons which would otherwise remain unpaired in the $e_g$ orbitals may instead be forced to pair in the lower $t_{2g}$ orbitals. For metal ions with d$^4$, d$^5$, d$^6$ and d$^7$ configurations therefore two possibilities arise depending on the magnitude of $\Delta_0$. If $\Delta_0$ is small (compared with electron–electron repulsion energies within one orbital) then the maximum possible number of electrons remain unpaired and the configurations are known as “spin-free” or “high-spin”. If $\Delta_0$ is large then electrons are forced to pair in the lower $t_{2g}$ set and the configurations are known as “spin-paired” or “low-spin”. This is summarized in Fig. 19.16.

![Figure 19.15](image1.png) Possible effects of $\pi$ bonding on $\Delta_0$: (a) when ligand $\pi$ orbitals are empty, and (b) when ligand $\pi$ orbitals are filled.

![Figure 19.16](image2.png) The possible high-spin and low-spin configurations arising as a result of the imposition of an octahedral crystal field on a transition metal ion.
Similar MO treatments are possible for tetrahedral and square planar complexes but are increasingly complicated.

19.7 Organometallic Compounds

This section gives a brief overview of the vast and burgeoning field of organometallic chemistry. The term organometallic is somewhat vague since definitions of organo and metallic are themselves necessarily imprecise. We use the term to refer to compounds that involve at least one close M–C interaction: this includes metal complexes with ligands such as CO, CO₂, CS₂ and CN⁻ but excludes "ionic" compounds such as NaCN or Na acetate; it also excludes metal alkoxides M(OR), and metal complexes with organic ligands such as C₅H₅N, PPh₃, OEt₂, SMe₂, etc., where the donor atom is not carbon.

A permissive view is often taken in the literature of what constitutes a "metal" and the elements B; Si, Ge; As, Sb; Se and Te are frequently included for convenience and to give added perspective. However, it is not helpful to include as metals all elements less electronegative than C since this includes I, S and P. Metal carbides (p. 297) and graphite intercalation compounds (p. 293) are also normally excluded. Further treatment of organometallic compounds will be found throughout the book under each individual element.

No area of chemistry produces more surprises and challenges and the whole field of organometallic chemistry continues to be one of great excitement and activity. A rich harvest of new and previously undreamed of structure types is reaped each year, the rewards of elegant and skilful synthetic programmes being supplemented by an unusual number of chance discoveries and totally unsuspected reactions. Synthetic chemists can take either a buccaneering or an intellectual approach (or both); structural chemists are able to press their various techniques to the limit in elucidating the products formed; theoretical chemists and reaction kineticists, though badly outpaced in predictive work, provide an invaluable underlying rationale for various aspects of the continually evolving field and just occasionally run ahead of the experimentalists; industrial chemists can exploit and extend the results by developing numerous catalytic processes of immense importance. The field is not new, but was transformed in 1952 by the recognition of the "sandwich" structure of dicyclopentadienyliron (ferrocene).(22,23) Compendia and extended reviews(24–27) are available on various aspects, and continued progress is summarized in annual volumes.(28,29)

The various classes of ligands and attached groups that occur in organometallic compounds are summarized in Table 19.2, and these will be briefly discussed in the following paragraphs. Aspects which concern the general chemistry of carbon will be emphasized in order to give coherence and added significance to the more detailed treatment of the organometallic chemistry of individual elements given in other sections, e.g. Li (p. 102), Be (p. 127), Mg (p. 131), etc.

---

Similar MO treatments are possible for tetrahedral and square planar complexes but are increasingly complicated.

19.7 Organometallic Compounds

This section gives a brief overview of the vast and burgeoning field of organometallic chemistry. The term organometallic is somewhat vague since definitions of organo and metallic are themselves necessarily imprecise. We use the term to refer to compounds that involve at least one close M–C interaction: this includes metal complexes with ligands such as CO, CO₂, CS₂ and CN⁻ but excludes "ionic" compounds such as NaCN or Na acetate; it also excludes metal alkoxides M(OR), and metal complexes with organic ligands such as C₅H₅N, PPh₃, OEt₂, SMe₂, etc., where the donor atom is not carbon.

A permissive view is often taken in the literature of what constitutes a "metal" and the elements B; Si, Ge; As, Sb; Se and Te are frequently included for convenience and to give added perspective. However, it is not helpful to include as metals all elements less electronegative than C since this includes I, S and P. Metal carbides (p. 297) and graphite intercalation compounds (p. 293) are also normally excluded. Further treatment of organometallic compounds will be found throughout the book under each individual element.

No area of chemistry produces more surprises and challenges and the whole field of organometallic chemistry continues to be one of great excitement and activity. A rich harvest of new and previously undreamed of structure types is reaped each year, the rewards of elegant and skilful synthetic programmes being supplemented by an unusual number of chance discoveries and totally unsuspected reactions. Synthetic chemists can take either a buccaneering or an intellectual approach (or both); structural chemists are able to press their various techniques to the limit in elucidating the products formed; theoretical chemists and reaction kineticists, though badly outpaced in predictive work, provide an invaluable underlying rationale for various aspects of the continually evolving field and just occasionally run ahead of the experimentalists; industrial chemists can exploit and extend the results by developing numerous catalytic processes of immense importance. The field is not new, but was transformed in 1952 by the recognition of the "sandwich" structure of dicyclopentadienyliron (ferrocene). </table>

(a) Many ligands can bond in more than one way: e.g. allyl can be $\eta^1$ ($\sigma$-allyl) or $\eta^3$ ($\pi$-allyl); cyclooctatetraene can be $\eta^4$ (1,3-diene), $\eta^4$ (chelating, 1,5-diene), $\eta^6$ (1,3,5-triene), $\eta^8$ (bis-1,2,3-5,6,7-$\pi$-allyl), $\eta^8$ (1,3,5,7-tetraene), etc.

#### 19.7.1 Monohapto ligands

Alkyl and aryl derivatives of many main-group metals have already been discussed in previous chapters, and compounds such as PbMe$_4$ and PbEt$_4$ are made on a huge scale, larger than all other organometallics put together (p. 371). The alkyl and aryl groups are usually regarded as 1-electron donors but it is important to remember that even a monohapto 1-electron donor can bond simultaneously to more than 1 metal atom, e.g. to 2 in Al$_2$Me$_6$ (p. 259), 3 in Li$_4$Bu$_4$ (p. 105) and 4 in [Li$_4$Me$_4$]$_n$. Similarly, an $\eta^1$ ligand such as CO, which is often regarded as a 2-electron donor, can bond simultaneously to either 1, 2 or 3 metal atoms (p. 928). There is thus an important distinction to be drawn between (a) hapticity (the number of C atoms in the organic group that are closely associated with a metal atom), (b) metal connectivity (the number of M atoms simultaneously bonded to the organic group), and (c) the number of ligand electrons formally involved in bonding to the metal atom(s). The metal connectivity is also to be distinguished from the coordination number of the C atom, which also includes all other atoms or groups attached to it: e.g. the bridging C atoms in Al$_2$Me$_6$ are monohapto with a metal connectivity of 2 and a coordination number of 5.

Although zinc alkyls were first described by E. Frankland in 1849 and the alkyls and aryls of most main group elements had been prepared and often extensively studied during the subsequent 100 y, very few such compounds were known for the transition metals even as recently as the late 1960s. The great burst of more recent activity stems from the independent suggestion (30, 31) that M-C bonds involving transition elements are not inherently weak and that kinetically stable complexes can be made by a suitable choice of organic groups. In particular, the use of groups which have no $\beta$-hydrogen atom (e.g. $-\text{CH}_2\text{Ph}$, $-\text{CH}_3\text{Ph}$, etc.)

–CH₂CMe₃, or –CH₂SiMe₃) often leads to stable complexes since this prevents at least one facile decomposition route namely β-elimination.

The reverse reaction (formation of metal alkyls by addition of alkenes to M–H) is the basis of several important catalytic reactions such as alkene hydrogenation, hydroformylation, hydroboration, and isomerization. A good example of decomposition by β-elimination is the first-order intramolecular reaction:

\[
[\text{Pt(Bu)}₂(\text{PPh}_3)_₂] → 1\text{-C}_₆\text{H}_₈
\]

\[
+ [\text{Pt(Bu)}(\text{H})(\text{PPh}_3)_₂] → n\text{-C}_₄\text{H}_{₁₀} + [\text{Pt(PPh}_3)_₂]
\]

β-Elimination reactions have been much studied but should not be over emphasized since other decomposition routes must also be considered. Amongst these are:

- homolytic fission, e.g. \(\text{HgPh}_₂ → \text{Hg} + 2\text{Ph}\)
- reductive elimination, e.g. \([\text{Au}^{III}\text{Me}_₃(\text{PPh}_3)] → [\text{Au}^{I}\text{Me}(\text{PPh}_3)] + \text{C}_₂\text{H}_₆\)
- binuclear elimination (or formation of Bu radicals) e.g.

\[
2[\text{Cu(Bu)(PBu}_₃)] → 2\text{Cu} + 2\text{PBu}_₃
\]

\[+ n\text{-C}_₄\text{H}_{₁₀} + 1\text{-C}_₄\text{H}_₈\]

- α-Elimination to give a carbene complex, e.g.

\[
[\text{Ta(CH}_₂\text{CMe}_₃)_₃\text{Cl}_₂] + 2\text{LiCH}_₂\text{CMe}_₃ → 2\text{LiCl} + “[\text{Ta(CH}_₂\text{CMe}_₃)_₃]” α\text{-elim}
\]

\[
\text{CMe}_₄ + [\text{Ta(CH}_₂\text{CMe}_₃)_₃(–C}<\text{H}<\text{CMe}_₃)]
\]

Stabilization of \(η^1\)-alkyl and -aryl derivatives of transition metals can be enhanced by the judicious inclusion of various other stabilizing ligands in the complex, even though such ligands are known not to be an essential prerequisite. Particularly efficacious are potential \(π\) acceptors (see below) such as AsPh₃, PPh₃, CO or \(η^5\)-C₅H₅ in combination with the heavier transition metals since the firm occupation of coordination sites prevents their use for concerted decomposition routes. Steric protection may also be implicated. Similar arguments have been used to interpret the observed increase in stability of \(η^1\) complexes in the sequence alkyl < aryl < \(o\)-substituted aryl < ethynyl (–C≡CH).

The next group of \(η^1\) ligands comprise the iso electronic species, CO, CN⁻ and RNC. They are closely related to other 14-electron (10 valence electron) ligands such as N₂ and NO⁺ (and also to tertiary phosphines and arsines, and to organic sulfides, selenides, etc.), and it is merely the presence of C as the donor atom which classifies their complexes as organometallics. All have characteristic donor properties that distinguish them from simple electron-pair donors (Lewis bases, p. 198) and these have been successfully interpreted in terms of a synergic or mutually reinforcing interaction between \(σ\) donation from ligand to metal and \(π\) back donation from metal to ligand as elaborated below. CO is undoubtedly the most important and most widely studied of all organometallic ligands and it is the prototype for this group of so-called \(π\)-acceptor ligands. The currently accepted view of the bonding is represented diagrammatically in Figs. 19.17 and 19.18. Figure 19.17 shows a schematic molecular orbital energy level diagram for the heteronuclear diatomic molecule CO.

The AOs lie deeper in O than in C because of the higher effective nuclear charge on O; consequently O contributes more to bonding MOs and C contributes more to the antibonding MOs. It can be seen that all the bonding MOs are filled and, in this description, the CO molecule can be said to have a triple bond :C=O: with the lone-pair on carbon weakly available for donation to an acceptor. The top part (a) of Fig. 19.18 shows the formation of a \(σ\) bond by donation of the lone-pair into a suitably directed hybrid orbital on M, and the lower part (b) shows the accompanying back donation from a filled metal \(d\) orbital into the vacant antibonding CO orbital having \(π\) symmetry (one node) with respect to the bonding axis. This
Figure 19.17  Schematic molecular energy level diagram for CO. The 1s orbitals have been omitted as they contribute nothing to the bonding. A more sophisticated treatment would allow some mixing of the 2s and 2p\(_z\) orbitals in the bonding direction (z) as implied by the orbital diagram in Fig. 19.18.

Figure 19.18  Schematic representation of the orbital overlaps leading to M–CO bonding: (a) \(\sigma\) overlap and donation from the lone-pair on C into a vacant (hybrid) metal orbital to form a \(\sigma\) M–C bond, and (b) \(\pi\) overlap and the donation from a filled d\(_z^2\) or d\(_{yz}\) orbital on M into a vacant antibonding \(\pi^*\) orbital on CO to form a \(\pi\) M\(\rightarrow\)C bond.

at once interprets why CO, which is a very weak \(\sigma\) donor to Lewis acids such as BF\(_3\) and AlCl\(_3\), forms such strong complexes with transition elements, since the drift of \(\pi\)-electron density from M to C tends to make the ligand more negative and so enhances its \(\sigma\)-donor power. The pre-existing negative charge on CN\(^-\) increases its \(\sigma\)-donor propensity but weakens its effectiveness as a \(\pi\) acceptor. It is thus possible to rationalize many chemical
Table 19.3  Known neutral binary metal carbonyls. Osmium also forms Os₅(CO)₁₆, Os₅(CO)₁₉, Os₆(CO)₁₈, Os₆(CO)₂₀, Os₇(CO)₂₁ and Os₈(CO)₂₃. Carbonyls of elements in the shaded area are either very unstable or anionic or require additional ligands besides CO for stabilization

observations by noting that effectiveness as a σ donor decreases in the sequence CN⁻ > RNC > NO⁺ ~ CO whereas effectiveness as a π acceptor follows the reverse sequence NO⁺ > CO >> RNC > CN⁻. By implication, back donation into antibonding CO orbitals weakens the CO bond and this is manifest in the slight increase in interatomic distance from 112.8 pm in free CO to ~115 pm in many complexes. There is also a decrease in the C–O force constant, and the drop in the infrared stretching frequency from 2143 cm⁻¹ in free CO to 2125–1850 cm⁻¹ for terminal COs in neutral carbonyls has been interpreted in the same way.

The occurrence of stable neutral binary carbonyls is restricted to the central area of the d block (Table 19.3), where there are low-lying vacant metal orbitals to accept σ-donated lone-pairs and also filled d orbitals for π back donation. Outside this area carbonyls are either very unstable (e.g. Cu, Ag, p. 1199), or anionic, or require additional ligands besides CO for stabilization. As with boranes and carboranes (p. 181), CO can be replaced by isoelectronic equivalents such as 2e⁻, H⁻, 2H⁺ or L. Mean bond dissociation energies \( \bar{D}(M-CO)/kJ\,mol^{-1} \) increase in the sequence Cr(CO)₆ 109, Mo(CO)₆ 151, W(CO)₆ 176, and in the sequence Mn₂(CO)₁₀ 100, Fe(CO)₅ 121, Co₂(CO)₈ 138, Ni(CO)₄ 147.

CO can act as a terminal ligand, as an unsymmetrical or symmetrical bridging ligand (\( \mu_2\)-CO) or as a triply bridging ligand (\( \mu_3\)-CO):

In all these cases CO is \( \eta^1 \) but the connectivity to metal increases from 1 to 3. It is notable that in the \( \mu_2\)-bridging carbonyls the angle M–C(O)–M is usually very acute (\( 77–80^\circ \)), whereas in organic carbonyls the C–C(O)–C angle is typically 120–124°. This suggests a fundamentally differing bonding mode in the two cases and points to the likelihood of a 2-electron 3-centre bond (p. 158) for the bridging metal carbonyls. The hapticity can also rise, and structural determinations indicate that one or both of the \( \pi^* \) orbitals in CO contribute to \( \eta^2 \) bonding to 1 or 2 M atoms.\(^{(32)}\) A bis-\( \eta^1 \)-bridging mode has also been detected in an AlPh₃ adduct,\(^{(33)}\) reminiscent of the bridging mode in the isoelectronic CN⁻ ligand (p. 322):

Numerous examples of metal carbonyls will be found in later chapters dealing with the chemistry of the individual transition metals. CO also has an unrivalled capacity for stabilizing metal clusters and for inserting into M–C bonds (p. 309). Synthetic routes include:

(a) direct reaction, e.g.:
\[
\begin{align*}
\text{Ni} + 4\text{CO} & \xrightarrow{300^\circ/1 \text{ atm}} \text{Ni(CO)}_4 \\
\text{Fe} + 5\text{CO} & \xrightarrow{200^\circ/200 \text{ atm}} \text{Fe(CO)}_5
\end{align*}
\]

(b) reductive carbonylation, e.g.:
\[
\begin{align*}
\text{OsO}_4 + 9\text{CO} & \xrightarrow{250^\circ/350 \text{ atm}} \text{Os(CO)}_5 + 4\text{CO}_2 \\
\text{RuI}_3 + 5\text{CO} + 3\text{Ag} & \xrightarrow{175^\circ/250 \text{ atm}} \text{Ru(CO)}_5 + 3\text{AgI} \\
\text{WCl}_6 + 3\text{Fe(CO)}_5 & \xrightarrow{100^\circ} \text{W(CO)}_6 + 3\text{FeCl}_2 + 9\text{CO}
\end{align*}
\]

(c) photolysis or thermolysis, e.g.:
\[
\begin{align*}
2\text{Fe(CO)}_5 & \xrightarrow{h\nu} \text{Fe}_2(\text{CO})_9 + \text{CO} \\
2\text{CO}_2(\text{CO})_8 & \xrightarrow{70^\circ} \text{Co}_4(\text{CO})_{12} + 4\text{CO}
\end{align*}
\]

The remaining classes of monohapto organic ligands listed in Table 19.2 are carbene (==CR$_2$), carbyne (==CR), and carbido (C). Stable carbene complexes were first reported in 1964 by E. O. Fischer and A. Maasböl.\(^{(34)}\) Initially they were of the type \([\text{W(CO)}_5(\text{C} \equiv \text{C})_{\text{OMe}} \text{R}\]) and it was not until 1968 that the first homonuclear carbene complex was reported \([\text{Cr(CO)}_5(\text{C} \equiv \text{C})_{\text{CPh}} \text{CPh}]\); isolation of a carbene containing the parent methylene group :CH$_2$ was not achieved until 1975.\(^{(35)}\)

\[
\begin{align*}
\text{[Ta(}\eta^5\text{-C}_5\text{H}_5\text{)}_2\text{Me}_3\text{]} & \xrightarrow{\text{PPh}_3\text{CBF}_4} \text{[Ta(}\eta^5\text{-C}_5\text{H}_5\text{)}_2\text{Me}_2\text{]}^+ \\
\text{BF}_4^- & \xrightarrow{\text{base}} \text{[Ta(}\eta^5\text{-C}_5\text{H}_5\text{)}_2(\text{Me})\text{(CH}_2\text{)}]
\end{align*}
\]

Other preparative routes are:

\[
\begin{align*}
\text{[W(CO)}_6\text{]} + \text{LiR} & \xrightarrow{\text{Et}_2\text{O}} \text{[W(CO)}_5\text{]}(\text{C} \equiv \text{C})_{\text{OMe}} \text{R} \\
\text{[W(CO)}_5\text{]}(\text{C} \equiv \text{C})_{\text{OMe}} \text{R} & \xrightarrow{-20^\circ} \text{thf} \text{Me}_5\text{OBF}_4
\end{align*}
\]

The metal is in the formal oxidation state zero. As expected, the M–C bonds are somewhat shorter than M–R bonds to alkyls, but they are noticeably longer than M–CO bonds suggesting only limited double-bond character M==C, e.g.:

\[
\begin{align*}
\text{[Ta(}\eta^5\text{-C}_5\text{H}_5\text{)}_2(\text{Me})(\text{CH}_2\text{})]\ & \xrightarrow{\text{Ta}\text{-CH}_2} 220.6 \text{ pm} \\
\text{[Ta(}\eta^5\text{-C}_5\text{H}_5\text{)}_2(\text{Me})(\text{CH}_2\text{})]\ & \xrightarrow{\text{Ta}\text{-CH}_3} 225 \text{ pm}
\end{align*}
\]

Carbene complexes are highly reactive species.\(^{(36)}\)

Carbene complexes were first made in 1973 by the unexpected reaction of methoxycarbene

---

complexes with boron trihalides:

\[
[M(CO)_3(C(OMe)R)] + BX_3 \quad \xrightarrow{\text{pentane, low temp}} \quad [M(CO)_3(=CR)X] + CO + BX_2(OMe)
\]

\(M = \text{Cr, Mo, W}; \ R = \text{Me, Et, Ph}; \ X = \text{Cl, Br, I}\)

Several other routes are now also available in which \(BX_3\) is replaced by \(\text{AlCl}_3\), \(\text{GaCl}_3\), \(\text{Al}_2\text{Br}_6\), \(\text{Ph}_3\text{PBr}_2\), e.g.:

\[
[W(CO)_5(C(OMe)Ph)] + \text{Al}_2\text{Br}_6 \quad \xrightarrow{\text{pentane, } -30^\circ} \quad [\text{WBr(CO)}_4(=\text{CPh})] + \text{CO} + \text{Al}_2\text{Br}_5(OMe)
\]

X-ray studies reveal the expected short \(M-CR\) distance, but the bond angle at the carbyne \(C\) atom is not always linear. Some structural data are annexed, see below. A compound which features all three types of \(\eta^1\) ligand, alkyl, alkylidene and alkylidyne, is the red, square-pyramidal tungsten(VI) complex \([W(\equiv\text{CCMe}_3)(=\text{CHCMe}_3)-(\text{CH}_2\text{CMe}_3)(\text{Me}_2\text{PCH}_2\text{CH}_2\text{PMe}_2)])\) in which the \(W-C\) distance is 226 pm to neopentyl, 194 pm to neopentylidene, and 176 pm to the apical neopentylidyne ligand; the corresponding \(W-C-C\) angles are 125°, 150° and 175° respectively.\(^{[37]}\)

### 19.7.2 Dihapto ligands

Reference to Table 19.2 places this section in context. The first complex between a hydrocarbon and a transition metal was isolated by the Danish chemist W. C. Zeise in 1825 and in the following years he characterized the pale-yellow compound now formulated as \(\text{K}[\text{Pt}(\eta^2-\text{C}_2\text{H}_4)\text{Cl}_3].\text{H}_2\text{O}]\). Zeise's salt, and a few closely related complexes such as the chloro-bridged binuclear compound \([\text{Pt}_2(\eta^2-\text{C}_2\text{H}_4)(\mu_2-\text{Cl})_2\text{Cl}_2]\), remained as chemical curiosities and a considerable theoretical embarrassment for over 100 years but are now seen as the archetypes of a large family of complexes based on the bonding of unsaturated organic ligands.

† The original reaction was obscure: Zeise heated a mixture of \(\text{PtCl}_2\) and \(\text{PtCl}_4\) in \(\text{EtOH}\) under reflux and then treated the resulting black solid with aqueous \(\text{KCl}\) and \(\text{HCl}\) to give ultimately the cream-yellow product. Subsequently the compound was isolated by direct reaction of \(\text{C}_2\text{H}_4\) with \(\text{K}_2[\text{PtCl}_4]\) in aqueous \(\text{HCl}\).
Dihapto ligands

Figure 19.19 Structure of the anion of Zeise’s salt, \([\text{Pt}(\eta^2-C_2\text{H}_2)\text{Cl}_3]^-\); standard deviations are Pt–Cl 0.2 pm; Pt–C 0.3 pm, and C–C 0.4 pm.

molecules to transition metals. The structure of the anion of Zeise’s salt has been extensively studied and neutron diffraction data\(^{38}\) are in Fig. 19.19. Significant features are (a) the C=C bond is perpendicular to the PtCl\(_3\) plane and is only 3.8 pm longer than in free C\(_2\)H\(_4\), (b) the C\(_2\)H\(_4\) group is significantly distorted from planarity, each C being 16.4 pm from the plane of 4H, (c) the angle between the normals to the CH\(_2\) planes is 32.5°, and (d) there is an unambiguous trans-effect (p. 1163), i.e. the Pt–Cl distance trans to C\(_2\&\) is longer than the 2 cis-Pt–Cl distances by 3.8 pm (19 standard deviations).

The key to our present understanding of the bonding in Zeise’s salt and all other alkene complexes stems from the perceptive suggestion by M. J. S. Dewar in 1951 that the bonding involves electron donation from the \(n\) bond of the alkene into a vacant metal orbital of \(\sigma\) symmetry; this idea was modified and elaborated by J. Chatt and L. A. Duncanson in a seminal paper in 1953 and the Dewar–Chatt–Duncanson theory forms the basis for most subsequent discussion. The bonding is considered to arise from two interdependent components as illustrated schematically in Fig. 19.20 (a) and (b). In the first part, \(\sigma\) overlap between the filled \(\pi\) orbital of ethene and a suitably directed vacant hybrid metal orbital forms the “electron-pair donor bond”. This is reinforced by the second component, (b), which derives from overlap of a filled metal d orbital with the vacant antibonding orbital of ethene; these orbitals have \(\pi\) symmetry with respect to the bonding axis and allow M→C\(_2\) \(\pi\) back bonding to assist the \(\sigma\)C\(_2\)→M bond synergically as for CO (p. 927). The flexible interplay of these two components allows a wide variety of experimental observations to be rationalized: in particular the theory convincingly interprets the orientation of the alkene with respect to the metal and the observed lengthening of the C–C bond. However, the details of the distortion of the alkene from planarity are less easy to quantify on the model and evidence is accumulating which suggests that the extent of \(\pi\) back bonding may have been overemphasized for some systems in the past. At the other extreme back donation may become so dominant that C–C distances approach values to be expected for a single bond and the interaction would be described as oxidative addition to give a metallacyclopropane ring involving two 2-electron 2-centre M–C bonds (see Fig. 19.20(c)).

For example, tetracyanoethylene has a formal C=C double bond (133.9 pm) in the free ligand but in the complex \([\text{Pt}\{\text{C}_2\text{CN}_4\}(\text{PPh}_3)_2]\) the C–C distance (152 pm) is that of a single bond and the CN groups are bent away from the

Pt and 2P atoms; moreover, the 2P and 2C that are bonded to Pt are nearly coplanar, as expected for Pt$^{II}$ but not as in (tetrahedral) 4-coordinate Pt$^0$ complexes. [Rh(C$_2$F$_4$)Cl(PPh$_3$)$_2$] affords another example of the tendency to form a metallacyclopropane-type complex (C–C 141 pm) with pseudo-5-coordinate Rh$^{III}$ rather than a pseudo-4-coordinate $\eta^2$-alkene complex of Rh$^1$. However, the two descriptions are not mutually exclusive and, in principle, there can be a continuous gradation between them.

Compounds containing M–$\eta^2$-alkene bonds are generally prepared by direct replacement of a less strongly bound ligand such as a halide ion (cf. Zeise’s salt), a carbonyl, or another alkene. Chelating dialkene complexes can be made similarly, e.g. with cis-cis-cycloocta-1,5-diene (cod):

Numerous examples are given in later sections dealing with the chemistry of individual transition metals. Few, if any, $\eta^2$-alkene or -diene complexes have been reported for the first three transition-metal groups (why?), but all later groups are well represented, including Cu$^1$, Ag$^I$ and Au$^I$. Indeed, an industrial method for the separation of alkenes uses the differing stabilities of their complexes with CuCl. For many metals it is found that increasing alkyl substitution of the alkene lowers the stability of the complex and that trans-substituted alkenes give less stable complexes than do cis-substituted alkenes. For Rh$^1$ complexes F substitution of the alkene enhances the stability of the complex and Cl substitution lowers it.

Alkyne complexes have been less studied than alkene complexes but are similar. Preparative routes are the same and bonding descriptions are also analogous. In some cases, e.g. the pseudo-4-coordinate complex [Pt($\eta^2$-C$_2$Bu$_2$)Cl$_2$(4-toluidine)] (Fig. 19.21) the C≡C bond remains short and the alkyne group is normal to the plane of coordination; in others, e.g. the pseudo-3-coordinate complex [Pt($\eta^2$-C$_2$Ph$_2$)-(PPh$_3$)$_2$] (Fig. 19.22), the alkyne group is almost in the plane (14°) and the attached substituents are bent back to an angle of 140° suggesting a formulation intermediate between 3-coordinate Pto and 4-coordinate Pt$^{II}$. One important difference between alkynes and alkenes is that the former have a triple bond which can be described in terms of a $\sigma$ bond and two mutually perpendicular $\pi$ bonds. The possibility thus arises that $\eta^2$-alkynes can function as bridging ligands and several such complexes have been characterized.
§19.7.3 Trihapto ligands

The possibility that the allyl group \( \text{CH}_2=\text{CH}-\text{CH}_2- \) can act as an \( \eta^3 \) ligand was recognized independently by several groups in 1960 and since then the field has flourished, partly because of its importance in homogeneous catalysis and partly because of the novel steric possibilities and interconversions that can be studied by proton nmr spectroscopy. Many synthetic routes are available of which the following are representative.

(a) Allyl Grignard reagent:

\[ \text{NiBr}_2 + 2\text{C}_3\text{H}_5\text{MgBr} \rightarrow 2\text{MgBr}_2 + [\text{Ni}(\eta^3-\text{C}_3\text{H}_5)_2] \] (also Pd, Pt)

A mixture of cis and trans isomers is obtained:

\[ \begin{array}{c}
\text{Ni} \\
\text{Ni}
\end{array} \]

Tris-(\eta^3-allyl) complexes \([\text{M}(\eta^3-\text{C}_3\text{H}_5)_3]\) can be prepared similarly for V, Cr, Fe, Co, Rh, Ir, and tetrakis complexes \([\text{M}(\eta^3-\text{C}_3\text{H}_5)_4]\) for Zr, Th, Mo and W.

(b) Conversion of \( \eta^1 \)-allyl to \( \eta^3 \)-allyl:

\[ \text{Na}[\text{Mn}(\text{CO})_5] \stackrel{\text{C}_3\text{H}_5\text{Cl}}{\text{hv or } 80^\circ} \rightarrow [\text{Mn}(\text{CO})_5(\eta^1-\text{C}_3\text{H}_5)] \]

\[ [\text{Mn}(\text{CO})_4(\eta^3-\text{C}_3\text{H}_5)] + \text{CO} \]

Similarly many other \( \eta^1 \)-allyl carbonyl complexes convert to \( \eta^3 \)-allyl complexes with loss of 1 CO.

(c) From allylic halides (e.g. 2-methylallyl chloride):

\[ \text{Na}_2\text{PdCl}_4 + \text{C}_4\text{H}_7\text{Cl} + \text{CO} + \text{H}_2\text{O} \rightarrow 100\% \text{ yield} \]

\[ \frac{1}{2}\text{[Pd}_2(\eta^3-\text{C}_4\text{H}_7)_2(\mu_2-\text{Cl}_2)] + 2\text{NaCl} + 2\text{HCl} + \text{CO}_2 \]

\[ \text{MeOH} \]

(d) Oxidative addition of allyl halides, e.g.:

\[
[\text{Fe}^0(\text{CO})_5] + \text{C}_3\text{H}_5\text{I} \rightarrow [\text{Fe}^{II}(\eta^3-\text{C}_3\text{H}_5)(\text{CO})_3] + 2\text{CO}
\]

\[
[\text{Co}^+\eta^2-\text{C}_3\text{H}_5)(\text{CO})_3] + \text{C}_3\text{H}_5\text{I} \rightarrow [\text{Co}^{II}(\eta^3-\text{C}_3\text{H}_5)(\eta^5-\text{C}_5\text{H}_5)] + 2\text{CO}
\]

(e) Elimination of HCl from an alkene metal halide complex, e.g.

\[
2\text{PdCl}_2 + \text{CH}_2 = \text{C} \rightarrow \text{PdCl}_2 + \text{CH}_2 = \text{CMe} 
\]

The bonding in \(\eta^3\)-allylic complexes can be described in terms of the qualitative MO theory illustrated in Fig. 19.23. The \(p_z\) orbitals on the 3 allylic C atoms can be combined to give the 3 orbitals shown in the upper part of Fig. 19.23, each retains \(\pi\) symmetry with respect to the \(C_3\) plane but has, in addition, 0, 1 or 2 nodes perpendicular to this plane. The metal orbitals of appropriate symmetry to form bonding MOs with these 3 combinations are shown in the lower part of Fig. 19.23. The extent to which these orbitals are, in fact, involved in bonding depends on their relative energies, their radial diffuseness and the actual extent of orbital overlap. Electrons to fill these bonding MOs can be thought of as coming both from the allylic \(\pi\)-electron cloud and from the metal, and the possibility of "back donation" from filled metal hybrid orbitals also exists. Experimental observables which must be interpreted in any quantitative treatment are the variations (if any) in the \(M-C\) distances to the 3 C atoms and the tilt of the \(C_3\) plane to the bonding plane of the metal atom.

In addition to acting as an \(\eta^1\) and an \(\eta^3\) ligand, the allyl group can also act as a bridging ligand by \(\eta^1\) bonding to one metal atom and \(\eta^2\) bonding via the alkene function to a second metal atom. For example \([\text{Pt}_2(\text{acac})_2(\eta^1,\eta^3-\text{C}_3\text{H}_5)_2]\) has the dimeric structure shown in Fig. 19.24. The compound was made from \([\text{Pt}(\eta^3-\text{C}_3\text{H}_5)_2]\) by treatment first with HCl to give polymeric \([\text{Pt}(\eta^3-\text{C}_3\text{H}_5)_2]\) and then with thallium(I) acetylace-tonate.

Many \(\eta^3\)-allyl complexes are fluxional (p. 914) at room temperature or slightly above,
and this property has been extensively studied by $^1$H nmr spectroscopy. Exceedingly complex patterns can emerge. The simplest interchange that can occur is between those H atoms which are on the side nearer the metal (syn) and those which are on the side away from the metal (anti) probably via a short-lived $\eta^1$-allyl metal intermediate. The fluxional behaviour can be slowed down by lowering the temperature, and separate resonances from the various types of H atom are then observed. Fluxionality can also sometimes be quenched by incorporating the allylic group in a ring system which restricts its mobility.

19.7.4 Tetrahapto ligands

Conjugated dienes such as butadiene and its open-chain analogues can act as $\eta^4$ ligands; the complexes are usually prepared from metal carbonyl complexes by direct replacement of 2CO by the diene. Isomerization or rearrangement of the diene may occur as indicated schematically below:

No new principles are involved in describing the bonding in these complexes and appropriate combinations of the 4p$_\pi$ orbitals on the diene system can be used to construct MOs with the metal-based orbitals for donation and back donation of electron density. As with ethene, two limiting cases can be envisaged which can be represented schematically as in Fig. 19.25. Consistent with

---

this view, the C–C distances in diene complexes vary and the central C(2)–C(3) distance is often less than the two outer C–C distances.

Cyclobutadiene complexes are also well established though they must be synthesized by indirect routes since the parent dienes are either unstable or non-existent. Four general routes are available:
(a) Dehalogenation of dihalocyclobutenes, e.g.:
\[
\begin{array}{c}
\text{Me} \\
\text{Cl} \\
\text{Me} \\
\text{Cl}
\end{array}
\xrightarrow{\text{Ni(CO)}_4}
\begin{array}{c}
\text{Me} \\
\text{Me} \\
\text{Me} \\
\text{Cl}
\end{array}
\]
(b) Cyclodimerization of alkynes, e.g. with cyclopentadienyl-(cycloocta-1,5-diene)cobalt:
\[
2\text{PhC=CPH} \xrightarrow{[\text{Co(C}_2\text{H}_2\text{(C}_6\text{H}_{12})]} \text{Co(}\eta^5\text{C}_3\text{H}_5)
\]
(c) From metallacyclopentadienes:
\[
\begin{array}{c}
\text{Ph} \\
\text{Li} \\
\text{Ph}
\end{array}
\xrightarrow{\text{Me}_2\text{SnCl}_2}
\begin{array}{c}
\text{Ph} \\
\text{Sn} \\
\text{Me}_2
\end{array}
\]
(d) Ligand exchange from other cyclobutadiene complexes, e.g.:
\[
\frac{1}{2}[\text{Pd}_2\text{Br}_2(\eta^4\text{-C}_4\text{Ph}_4)_2] \xrightarrow{\text{Fe(CO)}_3}
\]
A schematic interpretation of the bonding in cyclobutadiene complexes can be given within the framework outlined in the preceding sections and this is illustrated in Fig. 19.26.

Figure 19.26  Orbitals used in describing the bonding in metal-$\eta^2$-cyclobutadiene complexes. The sign convention and axes are as in Fig. 19.23.
19.7.5 Pentahapto ligands

The importance of bis(cyclopentadienyl)iron [Fe(\(\eta^5\)-C\(_5\)H\(_5\))\(_2\)] in the development of organometallic chemistry has already been alluded to (p. 924). The compound, which forms orange crystals, mp 174\(^\circ\)C, has extraordinary thermal stability (>500\(^\circ\)) and a remarkable structure which was unique when first established. It also has an extensive aromatic-type reaction chemistry which is reflected in its common name “ferrocene”. The molecular structure of ferrocene in the crystalline state features two parallel cyclopentadienyl rings: at one time these rings were thought to be staggered (\(D_{sd}\)) as in Fig. 19.27a and b since only this was compatible with the molecular inversion centre required by the crystallographic space group (\(C_{2h}^3\), \(Z = 2\)). However, gas-phase electron diffraction data suggest that the equilibrium structure of ferrocene is eclipsed (\(D_{sh}\)) as in Fig. 19.27c rather than staggered, with rather low barrier to internal rotation of \(~4\) kJ mol\(^{-1}\). X-ray crystallographic\(^{40}\) and neutron diffraction studies\(^{41}\) confirm this general conclusion, the space-group symmetry requirement being met by a disordered arrangement of nearly eclipsed molecules (rotation angle between the rings \(~9^\circ\) rather than \(0^\circ\) for precisely eclipsed or \(36^\circ\) for staggered conformation). Below 169 K the molecules become ordered, the rotation angle remaining \(~9^\circ\). The perpendicular distance between the rings is 325 pm (cf. graphite 335 pm) and the mean interatomic distances are Fe–C 203 ± 2 pm and C–C 139 ± 6 pm. The Ru and Os analogues [M(\(\eta^5\)-C\(_5\)H\(_5\))\(_2\)] have similar molecular structures with eclipsed parallel C\(_5\) rings. A molecular-orbital description of the bonding can be developed along the lines indicated in

previous sections. Because of the importance of ferrocene, numerous calculations have been made of the detailed sequence of energy levels in the molecule; though these differ slightly depending on the assumptions made and the computational methods adopted, there is now a general consensus concerning the main features of the bonding as shown in the Panel.

A general preparative route to $\eta^5$-$C_5H_5$ compounds is the reaction of NaC$_5$H$_5$ with a metal halide or complex halide in a polar solvent such as thf, Me$_2$O (bp $-23^\circ$), (MeO)C$_2$H$_4$(OMe), or HC(O)NMe$_2$:

$$C_5H_6 + \text{Na} \rightarrow \text{[NaC}_5\text{H}_5\text{]} \rightarrow \text{[M(}\eta^5\text{-C}_5\text{H}_5\text{)L}_n\text{] + NaX}$$

### A Molecular Orbital Description of the Bonding in $[\text{Fe(}\eta^5\text{-C}_5\text{H}_5\text{)}_2]$

The 5 $p_z$ atomic orbitals on the planar C$_5$H$_5$ group can be combined to give 5 group MOs as shown in Fig. A; one combination has the full symmetry of the ring ($e_1$) and there are two doubly degenerate combinations ($e_2$ and $e_3$) having respectively 1 and 2 planar nodes at right angles to the plane of the ring. These 5 group MOs can themselves be combined in pairs with a similar set from the second C$_5$H$_5$ group before combining with metal orbitals. Each of the combinations [(ligand orbitals) + (metal orbitals)] leads, in principle, to a bonding MO of the molecule, providing that the energy of the two component sets is not very different. There are an equal number of antibonding combinations with the sign [(ligand orbitals) − (metal orbitals)].

![Figure A](image-url)  
**Figure A** The $\pi$ molecular orbitals formed from the set of $p_z$ orbitals of the C$_5$H$_5$ ring.

Calculation of the detailed sequence of energy levels arising from these combinations poses severe computational problems but a schematic indication of the sequence (not to scale) is shown in Fig. B. Thus, starting from the foot of the figure, the $e_{1u}$ bonding MO is mainly ligand-based with only a slight admixture of the Fe 4s and 3d_{xy} orbitals. Similarly, the $e_{2u}$ level has little, if any, admixture of the even higher-lying Fe 4p_{xy} orbital with which it is formally able to combine. The $e_{1g}$ MO arises from the bonding combination of the ligand $e_{1g}$ orbitals with Fe 3d_{xy} and 3d_{yz}, and this is the main contribution to the stability of the complex; the corresponding antibonding $e_{1g}^{\prime}$ are unoccupied in the ground state but will be involved in optical transitions. The $e_{1u}$ bonding MOs are again mainly ligand-based but with some contribution from Fe 4p_{xy} and 4p_{yz}, etc. It can be seen that there is room for just 18 electrons in bonding and nonbonding MOs and that the antibonding MOs are unoccupied. In terms of electron counting the 18 electrons can be thought of as originating from the Fe atom (8e) and the two C$_5$H$_5$ groups (2 × 5e) or from an Fe$^{II}$ ion (6e) and two C$_5$H$_5^-$ groups (2 × 6e).

Panel continues
Figure B  A qualitative molecular orbital diagram for ferrocene. The subscripts \( g \) and \( u \) refer to the parity of the orbitals: \( g \) (German \textit{gerade}, even) indicates that the orbital (or orbital combination) is symmetric with respect to inversion, whereas the subscript \( u \) (\textit{ungerade}, odd) indicates that it is antisymmetric with respect to inversion. Only orbitals with the same parity can combine.

The stability of \([\text{Fe}(\eta^5-C_5H_5)_2]\) compared with the 19 electron system \([\text{Co}(\eta^5-C_5H_5)_2]\) and the 20-electron system \([\text{Ni}(\eta^5-C_5H_5)_2]\) is readily interpreted on this bonding scheme since these latter species have 1 and 2 easily oxidizable electrons in the antibonding \( e_{2g}^* \) orbitals. Similarly, \([\text{Cr}(\eta^5-C_5H_5)_2]\) (16e) and \([\text{V}(\eta^5-C_5H_5)_2]\) (15e) have unfilled bonding MOs and are highly reactive. However, attachment of additional groups or ligands destroys the \( D_{5h} \) (or \( D_{5h} \)) symmetry of the simple metalloocene and this modifies the orbital diagram. This also happens when ferrocene is protonated to give the 18-electron cation \([\text{Fe}(\eta^5-C_5H_5)_2]^+\) and when the (bent) isoelectronic neutral molecules \([\text{Re}(\eta^5-C_5H_5)_3]\) \(\text{(p. 1067)}\) and \([\text{Mo}(\eta^5-C_5H_5)_2\text{H}_2]\) \(\text{(p. 1038)}\) are considered. An excellent discussion of the bonding in such “bent metalloynes” has been given.\(^{(42)}\)

A very convenient though somewhat less general method is to use a strong nitrogen base to deprotonate the \( C_5H_5 \):

\[
2C_5H_6 + 2\text{NET}_2\text{H} + \text{FeCl}_2 \xrightarrow{\text{excess of amine}} \ [\text{Fe}(\eta^5-C_5H_5)_2] + [\text{NET}_2\text{H}_2]\text{Cl}
\]

An enormous number of \( \eta^5-C_5H_5 \) complexes is now known. Thus the isoelectronic yellow \( \text{Co}^1 \) species \([\text{Co}(\eta^5-C_5H_5)_2]^+\) is stable in aqueous solutions and its salts are thermally stable to \( \sim 400^\circ \). The bright-green paramagnetic complex \([\text{Ni}(\eta^5-C_5H_5)_2]\), mp 173°, is fairly stable as a solid but is rapidly oxidized to \([\text{Ni}(\eta^5-C_5H_5)_2]^+\). In contrast, the scarlet, paramagnetic complex \([\text{Cr}(\eta^5-C_5H_5)_2]\), mp 173°, is very air sensitive; it dissolves in aqueous HCl to give \( C_5H_6 \) and a blue cation which is probably \([\text{Cr}(\eta^5-C_5H_5)_2\text{Cl}(\text{H}_2\text{O})_n]^+\). Other stoichiometries are exemplified by \([\text{Ti}(\eta^5-C_5H_5)_3]\) and \([\text{M}(\eta^5-C_5H_5)_4]\), where \( M \) is Zr, Hf, Th.

\(^{(42)}\) J. W. \textsc{Lauher} and R. \textsc{Hoffman}, \textit{J. Am. Chem. Soc.} \textbf{98}, 1729–42 (1976), and references therein.
Innumerable derivatives have been synthesized in which one or more $\eta^5$-C$_5$H$_5$ group is present in a mononuclear or polynuclear metal complex together with other ligands such as CO, NO, H or X. It should also be borne in mind that C$_5$H$_5$ can act as an $\eta^1$-ligand by forming a $\sigma$ M–C bond and mixed complexes are sometimes obtained, e.g. [Be($\eta^1$-C$_5$H$_5$)$_2$($\eta^5$-C$_5$H$_5$)] (see p. 130). Likewise:

\[
\begin{align*}
\text{MoCl}_5 & \xrightarrow{\text{NaC}_5\text{H}_5} [\text{Mo}(\eta^1\text{-C}_5\text{H}_5)_3(\eta^5\text{-C}_5\text{H}_5)] \\
\text{NbCl}_5 & \xrightarrow{\text{NaC}_5\text{H}_5} [\text{Nb}(\eta^1\text{-C}_5\text{H}_5)_2(\eta^5\text{-C}_5\text{H}_5)_2]
\end{align*}
\]

Such $\eta^1$-C$_5$H$_5$ complexes are often found to be fluxional in solution at room temperature, the 5 H atoms giving rise to a single sharp $^1$H nmr resonance. At lower temperatures the spectrum usually broadens and finally resolves into the expected complex spectrum at temperatures which are sufficiently low to prevent interchange on the nmr time scale (~10^-3 s). Numerous experiments have been devised to elucidate the mechanism by which the H atoms become equivalent and, at least in some systems, it seems likely that a non-dissociative (unimolecular) 1,2-shift occurs.

**19.7.6 Hexahapto ligands**

Arenes such as benzene and its derivatives can form complexes precisely analogous to ferrocene and related species. Though particularly exciting when first recognized as $\eta^6$ complexes in 1955 these compounds introduce no new principles and need only be briefly considered here. Curiously, the first such compounds were made as long ago as 1919 when F. Hein reacted CrCl$_3$ with PhMgBr to give compounds which he formulated as “polyphenylchromium” compounds [CrPh$_n$]$^0, +1$ ($n = 2, 3,$ or 4); their true nature as $\eta^6$-arene complexes of benzene and diphenyl was not recognized until over 35 y later.$^{(43)}$ The best general method for making bis($\eta^6$-arene) metal complexes is due to E. O. Fischer and W. Hafner (1955) who devised it originally for dibenzenechromium — the isoelectronic analogue of ferrocene: CrCl$_3$ was reduced with Al metal in the presence of C$_6$H$_6$, using AlCl$_3$ as a catalyst:

\[
3\text{CrCl}_3 + 2\text{Al} + \text{AlCl}_3 + 6\text{C}_6\text{H}_6 \xrightarrow{140^\circ\text{press}} 3[\text{Cr}(\eta^6\text{-C}_6\text{H}_6)_2]^+\text{[AlCl}_4]^-
\]

The yield is almost quantitative and the orange-yellow Cr$^+$ cation can be reduced to the neutral species with aqueous dithionite:

\[
[\text{Cr}(\eta^6\text{-C}_6\text{H}_6)_2]^+ + \frac{1}{2}\text{S}_2\text{O}_4^{2-} + 2\text{OH}^- \longrightarrow [\text{Cr}(\eta^6\text{-C}_6\text{H}_6)_2] + \text{SO}_3^{2-} + \text{H}_2\text{O}
\]

Dibenzenechromium(0) forms dark-brown crystals, mp 284°, and the molecular structure (Fig. 19.28) comprises plane parallel rings in eclipsed configuration above and below the Cr atom ($D_{6h}$); the C–H bonds are tilted slightly towards the metal and, most significantly, the C–C distances show no alternation around the rings. A bonding scheme can be constructed as for ferrocene (p. 938) using the six $p_z$ orbitals on each benzene ring.

Bis ($\eta^6$-arene) metal complexes have been made for many transition metals by the Al/AlCl$_3$ reduction method and cationic species [M($\eta^6$-Ar)$_2$]$^{n+}$ are also well established for $n = 1, 2,$ and 3. Numerous arenes besides benzene have been used, the next most common being 1,3,5-Me$_3$C$_6$H$_3$ (mesitylene) and C$_6$Me$_6$. Reaction of arenes with metal carbonyls in high-boiling solvents or under the influence of ultraviolet light results in the displacement of 3CO and the formation of arene–metal carbonyls:

\[
\text{Ar} + [\text{M(CO)}_6] \xrightarrow{hv\text{ or heat}} [\text{M}(\eta^6\text{-Ar})(\text{CO})_3] + 3\text{CO}
\]

Heptahapto and octahapto ligands

For Cr, Mo and W the benzenetricarbonyl complexes are yellow solids melting at 162°, 125°, and 140°, respectively. The structure of [Cr(η<sup>6</sup>-C<sub>6</sub>H<sub>6</sub>)(CO)<sub>3</sub>] is in Fig. 19.29. In general, η<sup>6</sup>-arene complexes are more reactive than their η<sup>5</sup>-C<sub>5</sub>H<sub>5</sub> analogues and are thermally less stable.

19.7.7 Heptahapto and octahapto ligands

Treatment of cycloheptatriene complexes of the type [M(η<sup>6</sup>-C<sub>7</sub>H<sub>8</sub>)(CO)<sub>3</sub>] (M = Cr, Mo, W) with Ph<sub>3</sub>C<sup>+</sup>BF<sub>4</sub><sup>-</sup> results in hydride abstraction to give orange-coloured η<sup>7</sup>-cycloheptatrienyl (or tropyl-Ium) complexes:

In some cases the loss of hydrogen may occur spontaneously, e.g.:

\[ [V(\eta^5-C_5H_5)(CO)_3] + C_7H_8 \rightarrow [V(\eta^7-C_7H_7)] + 3CO + \frac{1}{2}H_2 \]

The purple paramagnetic complex [V(η<sup>5</sup>-C<sub>5</sub>H<sub>5</sub>)(η<sup>7</sup>-C<sub>7</sub>H<sub>7</sub>)] and the dark-brown diamagnetic complex [V(η<sup>7</sup>-C<sub>7</sub>H<sub>7</sub>)(CO)<sub>3</sub>] both feature symmetrical planar C<sub>7</sub> rings as illustrated in Fig. 19.30. The bonding appears to be similar to that in η<sup>5</sup>-C<sub>5</sub>H<sub>5</sub> and η<sup>6</sup>-C<sub>6</sub>H<sub>6</sub> complexes but, as expected from the large number of bonding electrons formally provided by the ligand, its complexes are restricted to elements in the early part of the transition series, e.g. V, Cr, Mo, Mn<sup>1</sup>. For [V(η<sup>5</sup>-C<sub>5</sub>H<sub>5</sub>)(η<sup>7</sup>-C<sub>7</sub>H<sub>7</sub>)] the rings are “eclipsed” as shown, and a notable feature of the structure is the substantially closer approach of the C<sub>7</sub>H<sub>7</sub> ring to the V atom, suggesting that equality of V–C distances to the 2 rings is the controlling factor; consistent with this V–C(7 ring) is 225 pm and V–C(5 ring) is 223 pm. In addition to acting as an
$\eta^7$ ligand, cycloheptatrienyl can also bond in the $\eta^5, \eta^3$, and even $\eta^1$ mode (see ref. 44 on p. 943).

Octahapto ligands are rare but cyclooctatetraene fulfils this role in some of its complexes — the metal must clearly have an adequate number of unfilled orbitals and be large enough to bond effectively with such a large ring. Th, Pa, U, Np and Pu satisfy these criteria and the complexes $[M(\eta^8-C_8H_8)_2]$ have been shown by X-ray crystallography to have eclipsed parallel planar rings (Fig. 19.31). The deep-green U complex can be made by reducing $C_8H_8$ with K in dry thf and then reacting the intense yellow solution of $K_2C_8H_8$ with $UCl_4$:

$$2C_8H_8 + 4K \xrightarrow{-30^\circ} 2K_2C_8H_8 \xrightarrow{0^\circ} UCl_4/thf$$

$[U(\eta^8-C_8H_8)_2] + 4KCl$

The compound inflames in air but is stable in aqueous acid or alkali solutions. The colourless complex $[Th(\eta^8-C_8H_8)_2]$, yellow complexes $[Pa(\eta^8-C_8H_8)_2]$ and $[Np(\eta^8-C_8H_8)_2]$ and the cherry red compound $[Pu(\eta^8-C_8H_8)_2]$ are prepared similarly. One of the very few
examples of $\eta^8$ bonding to a d-block element is in the curious complex $\text{Ti}_2(\text{C}_8\text{H}_8)_3$. As shown in Fig. 19.32, two of the ligands are planar $\eta^8$ donors whereas the central puckered ring bridges the 2 Ti atoms in a bis-$\eta^4$-mode. It is made by treating $\text{Ti(OBu}^n)_4$ with $\text{C}_8\text{H}_8$ in the presence of $\text{AlEt}_3$.

In addition to acting as an $\eta^5$ ligand, $\text{C}_8\text{H}_8$ can coordinate in other modes$^{(44)}$ some of which are illustrated in Fig. 19.33. Many of these complexes show fluxional behaviour$^{(45)}$ in solution (p. 935) and the distinction between the various types of bonding is not as clear-cut as implied by the limiting structures in Fig. 19.33.

---

20
Scandium, Yttrium, Lanthanum and Actinium

20.1 Introduction

In 1794 the Finnish chemist J. Gadolin, while examining a mineral that had recently been discovered in a quarry at Ytterby, near Stockholm, isolated what he thought was a new oxide (or “earth”) which A. G. Ekeberg in 1797 named yttria. In fact it was a mixture of a number of metal oxides from which yttrium oxide was separated by C. G. Mosander in 1843. This is actually part of the fascinating story of the “rare earths” to which we shall return in Chapter 30. The first sample of yttrium metal, albeit very impure, was obtained by F. Wöhler in 1828 by the reduction of the trichloride by potassium.

Four years before isolating yttria, Mosander extracted lanthanum oxide as an impurity from cerium nitrate (hence the name from Greek λανθάνειν, to hide), but it was not until 1923 that metallic lanthanum in a relatively pure form was obtained, by electrolysis of fused halides.

Scandium, the first member of the group, is also present in the Swedish ores from which yttrium and lanthanum had been extracted, but in only very small amounts and, probably for this reason, its discovery was delayed until 1879 when L. F. Nilsen isolated a new oxide and named it scandia. A few years later and with larger amounts at his disposal, P. T. Cleve prepared a large number of salts from this oxide and was able to show that it was the oxide of a new element whose properties tallied very closely indeed with those predicted by D. I. Mendeleev for ekaboron, an element missing from his classification (p. 29). It was only in 1937 that the metal itself was prepared by the electrolysis of molten chlorides of potassium, lithium and scandium, and only in 1960 that the first pound of 99% pure metal was produced.

The final member of the group, actinium, was identified in uranium minerals by A. Debierre in 1899, the year after P. and M. Curie had discovered polonium and radium in the same minerals. However, the naturally occurring isotope, $^{227}\text{Ac}$, is a $\beta^-$ emitter with a half-life of 21.77 y and the intense $\gamma$ activity of its decay products makes it difficult to study.
20.2 The Elements

20.2.1 Terrestrial abundance and distribution

With the exception of actinium, which is found naturally only in traces in uranium ores, these elements are by no means rare though they were once thought to be so: Sc 25, Y 31, La 35 ppm of the earth’s crustal rocks, (cf. Co 29 ppm). This was, no doubt, at least partly because of the considerable difficulty experienced in separating them from other constituent rare earths. As might be expected for class-a metals, in most of their minerals they are associated with o xoanions such as phosphate, silicate and to a lesser extent carbonate.

Scandium is very widely but thinly distributed and its only rich mineral is the rare thortveitite, Sc₂Si₂O₇ (p. 348), found in Norway, but since scandium has only small-scale commercial use, and can be obtained as a byproduct in the extraction of other materials, this is not a critical problem. Yttrium and lanthanum are invariably associated with lanthanide elements, the former (Y) with the heavier or “Yttrium group” lanthanides in minerals such as xenotime, M₃[PO₄] and gadolinite, M₂₋₃Sc₂O₁₀ (M²⁺ = Fe, Be), and the latter (La) with the lighter or “cerium group” lanthanides in minerals such as monazite, M₃[PO₄] and bastnaesite, M₃[CO₃]F. This association of similar metals is a reflection of their ionic radii. While La³⁺ is similar in size to the early lanthanides which immediately follow it in the periodic table, Y³⁺, because of the steady fall in ionic radius along the lanthanide series (p. 1234), is more akin to the later lanthanides.

20.2.2 Preparation and uses of the metals

Some scandium is obtained from thortveitite, which contains 35–40% Sc₂O₃, but most is obtained as a byproduct in the processing of uranium ores which contain only about 0.02% Sc₂O₃, and in the production of tungsten. Its applications, for instance in laser crystals and coatings, are highly specialized and the amount consumed is low, though increasing.

Yttrium and lanthanum are both obtained from lanthanide minerals and the method of extraction depends on the particular mineral involved. Digestions with hydrochloric acid, sulfuric acid, or caustic soda are all used to extract the mixture of metal salts. Prior to the Second World War the separation of these mixtures was effected by fractional crystallizations, sometimes numbered in their thousands. However, during the period 1940–45 the main interest in separating these elements was in order to purify and characterize them more fully. The realization that they are also major constituents of the products of nuclear fission effected a dramatic sharpening of interest in the USA. As a result, ion-exchange techniques were developed and, together with selective complexation and solvent extraction, these have now completely supplanted the older methods of separation (p. 1228). In cases where the free metals are required, reduction of the trifluorides with metallic calcium can be used.

Yttrium has important roles in the field of electronics, providing the basis of the phosphors used to produce the red colour on television screens and, in the form of garnets such as Y₃Fe₅O₁₂, being employed as microwave filters in radar. Because of its low neutron absorption cross-section, yttrium has potential as a moderator in nuclear reactors though this use has yet to be developed. It was, however, the announcement in 1986/87 of the high temperature superconductors, La₂₋ₓSrₓCuO₄ and YBa₂Cu₃O₇₋ₓ which produced the highest, though as yet unfulfilled, hopes of commercial exploitation. The latter compound has a critical temperature, Tc ~ 95 K, below which it is...
superconducting. This temperature, crucially, can be attained using liquid nitrogen rather than liquid helium as refrigerant and a continuing spate of publications on these and related materials has been generated (p. 1182).

Lanthanum has also found modest uses. Its oxide is an additive in high-quality optical glasses to which it imparts a high refractive index (sparkle) and has been suggested for a variety of catalytic uses. “Mischmetal”, an unseparated mixture of lanthanide metals containing about 25% La, is used in making lighter flints, and more importantly in the production of alloy steels. (p. 1232).

Actinium occurs naturally as a decay product of $^{235}\text{U}$:

$$^{235}\text{U} \rightarrow ^{231}\text{Pa} \rightarrow ^{227}\text{Ac}$$

but the half-lives are such that one tonne of the naturally occurring uranium ore contains on average only about 0.2 mg of Ac. An alternative source is the neutron irradiation of $^{226}\text{Ra}$ in a nuclear reactor:

$$^{226}\text{Ra} + ^{1}\text{n} \rightarrow ^{227}\text{Ac} \rightarrow ^{227}\text{Th}$$

(a) This value is for the radioisotope with the longest half-life ($^{227}\text{Ac}$).
A regular variation in atomic properties occurs in passing from B and Al to Group 3 than to heavier congeners in Group 13 (p. 223). However, the presence of a d electron on each of the atoms of this group (in contrast to the p electron in the atoms of B, Al and the other elements in Group 13) has consequences which can be seen in some of the bulk properties of the metals. For instance, the mps and bps (Fig. 20.2), along with the enthalpies associated with these transitions, all show discontinuous increases in passing from Al to Sc rather than to Ga, indicating that the d electron has a more cohesive effect than the p electron. It appears that this is due to d electrons forming more localized bonds within the metals. Thus, although Sc, Y and La have typically metallic (hcp) structures (with other metallic modifications at higher temperatures),
their electrical resistivities are much higher than that of Al (Fig. 20.3). Admittedly, resistivity is a function of thermal vibrations of the crystal lattice as well as of the degree of localization of valence electrons, but even so the marked changes between Al and Sc seem to indicate a marked reduction in the mobility of the d electron of the latter.

### 20.2.4 Chemical reactivity and trends

The general reactivity of the metals increases down the group. They tarnish in air — La rapidly, but Y much more slowly because of the formation of a protective oxide coating — and all burn easily to give the oxides $\text{M}_2\text{O}_3$. They react with halogens at room temperature and with most non-metals on warming. They reduce water with evolution of hydrogen, particularly if finely divided or heated, and all dissolve in dilute acid. Strong acids produce soluble salts whereas weak acids such as HF, $\text{H}_3\text{PO}_4$ and $\text{H}_2\text{C}_2\text{O}_4$ produce sparingly soluble or insoluble salts.

In the main, the chemistry of these elements concerns the formation of a predominantly ionic $+3$ oxidation state arising from the loss of all 3 valence electrons and giving a well-defined cationic aqueous chemistry. Because of this, although each member of this group is the first member of a transition series, its chemistry is largely atypical of the transition elements. The variable oxidation states and the marked ability to form coordination compounds with a wide variety of ligands are barely hinted at in this group although materials containing the metals in low oxidation states can be prepared (see p. 949) and a limited organometallic (predominantly cyclopentadienyl) chemistry has developed. Differences in chemical behaviour within the group are largely a consequence of the differing sizes of the $\text{M}^{III}$ ions. Scandium, the lightest of these elements, with the smallest ionic radius, is the least basic and the strongest complexing agent, with properties not unlike those of aluminium. Its aqueous solutions are appreciably hydrolysed and its oxide has some acidic properties. On the other hand, lanthanum and actinium (in so far as its properties have been examined) show basic properties approaching those of calcium.

Most structural studies have relied exclusively on the use of X-ray techniques but these elements have nuclei, $^{45}\text{Sc}$, $^{89}\text{Y}$ and $^{139}\text{La}$ with abundances in excess of 99.9% and $I = \frac{7}{2}, \frac{1}{2}, \frac{7}{2}$ respectively. The application of nmr studies is therefore
becoming increasingly important,\(^4\) mainly on solutions but also for solid-state work.\(^5\)

### 20.3 Compounds of Scandium, Yttrium, Lanthanum and Actinium

#### 20.3.1 Simple compounds\(^6\)

The oxides, M\(_2\)O\(_3\), are white solids which can be prepared directly from the elements. In Sc\(_2\)O\(_3\) and Y\(_2\)O\(_3\) the metals are 6-coordinate but the larger La\(^{III}\) ion adopts this structure only at elevated temperatures, a 7-coordinate structure being normally more stable. When water is added to La\(_2\)O\(_3\) it “slakes” like lime with evolution of much heat and a hissing sound. The hydroxides, M(OH)\(_3\), (or in the case of scandium possibly the hydrated oxide) are obtained as gelatinous precipitates from aqueous solutions of the metal salts by addition of alkali hydroxide. In the case of scandium only, this precipitate can be dissolved in an excess of conc NaOH to give anionic species such as \([\text{Sc(OH)}\(_6\)]^{3-}\). Yttrium and lanthanum hydroxides possess only basic properties, and the latter especially will absorb atmospheric CO\(_2\) to form basic carbonates.

Dissolution of the oxide or hydroxide in the appropriate acid provides the most convenient method for producing the salts of the colourless, diamagnetic M\(^{III}\) ions. Such solutions, especially those of Sc\(^{III}\), are significantly hydrolysed with the formation of polymeric hydroxy species.

With the exception of the fluorides, the halides are all very water-soluble and deliquescent. Precipitation of the insoluble fluorides can be used as a qualitative test for these elements. The distinctive ability of Sc\(^{III}\) to form complexes is illustrated by the fact that an excess of F\(^-\) causes the first-precipitated ScF\(_3\) to redissolve as [ScF\(_6\)]\(^{3-}\); indeed, M\(_3\)[ScF\(_6\)], M = NH\(_4\), Na, K, were isolated as long ago as 1914. The anhydrous halides are best prepared by direct reaction of the elements rather than by heating the hydrates which causes hydrolysis. Heating the hydrated chlorides, for instance, gives Sc\(_2\)O\(_3\), YOC\(_1\) and LaOCl respectively, though to produce AcOCl it is necessary to use superheated steam. The anhydrous halides illustrate nicely the effects of ionic size on the coordination number of the metal\(^2\). In all four of its halides scandium is 6-coordinate. So too is yttrium except in its fluoride where it has eight near neighbours and one slightly further away (8 + 1). The larger lanthanum however has 9 + 2 coordination in its fluoride, but is 9-coordinate in its chloride and bromide and 8-coordinate in its iodide.

Sulfates and nitrates are known and in all cases they decompose to the oxides on heating. Double sulfates of the type M\(_2^{III}\)(SO\(_4\))\(_3\).3Na\(_2\)SO\(_4\).12H\(_2\)O can be prepared, and La (unlike Sc and Y) forms a double nitrate, La(NO\(_3\))\(_3\).2NH\(_4\)NO\(_3\).4H\(_2\)O, which is of the type once used extensively in fractional crystallization procedures for separating individual lanthanides.

Reaction of the metals with hydrogen produces highly conducting materials with the composition MH\(_2\), similar to the metallic nonstoichiometric hydrides of the subsequent transition elements (pp. 66–7). Except in the case of ScH\(_2\), further H\(_2\) can then be absorbed causing a diminution of electrical conductivity until materials similar to the ionic hydrides of the alkaline-earth metals, and with the limiting composition MH\(_3\), are produced. The dihydrides, though ostensibly containing the divalent metals, are probably best considered as pseudo-ionic compounds of M\(^{3+}\) and 2H\(^-\) with the extra electron in a conduction band. However, the question of the type of bonding is still controversial, as was explained more fully in Chapter 3 (p. 66).

Another example of a “divalent” metal of this group, but which in fact is probably entirely analogous to the dihydrides, is LaI\(_2\). However, the most extensive set of examples of these metals in low formal oxidation states is provided by the binary and ternary halides produced by

---

prolonged heating of the reactants in sealed tantalum or niobium vessels to temperatures sometimes in excess of 1000°C. Starting with ScX₃ and Sc metal along with the appropriate alkali metal halide, several compounds of the series M’₂ScX₃ have been obtained containing octahedrally coordinated Sc” in linear [ScX₅⁻] chains(7). ScCl₃ + Sc yield no less than five reduced phases, dark-coloured and sensitive to oxygen and moisture(*)

\[ \text{Sc}_7\text{Cl}_{12} \text{Cl}^- \text{consists of discrete [Sc}_6\text{Cl}_{12} \text{]}^{3-} \text{clusters, similar to the M}_6\text{Cl}_{12} \text{clusters of Nb and Ta (p. 991), along with separate Sc}^{3+} \text{ions;} \]

\[ \text{Sc}_5\text{Cl}_8 \text{is best regarded as (ScCl}_2^+ \text{)}_{n^-} \text{(ScCl}_6^- \text{)}_{n} \text{, in which edge-sharing ScCl}_6 \text{octahedra and edge-sharing Sc}_6 \text{octahedra lie in parallel chains;} \]

\[ \text{Sc}_2\text{Cl}_4 \text{and its Br analogue are of unknown structure, as are reported La}_2\text{X}_3 \text{phases, though Y}_2\text{Cl}_3 \text{and Y}_2\text{Br}_3 \text{have been shown to consist of parallel chains of Y}_6 \text{octahedra, the chains being linked by Cl atoms;} \]

\[ \text{Sc}_7\text{Cl}_{10} \text{is composed of a double chain of Sc}_6 \text{octahedra sharing edges, and a parallel chain of ScCl}_6 \text{octahedra;} \]

\[ \text{ScCl} \text{made up of close-packed layers of Sc and Cl atoms in the sequence Cl-Sc-Sc-Cl has, like analogous Y and La materials with Cl and Br, since been shown to have been stabilised by interstitial H impurity.} \]

The ability of B, C and N as well as H to stabilize many of these reduced phases is at once a major preparative problem(11) and also a source of an expanding area of cluster chemistry of which Sc₇X₁₂Z (Z = C; X = Br, I; Z = B; X = I), best regarded as Sc(ScₓX₁₂Z), are examples.(12)

### 20.3.2 Complexes(13,14)

Compared to later elements in their respective transition series, scandium, yttrium and lanthanum have rather poorly developed coordination chemistries and form weaker coordinate bonds, lanthanum generally being even less inclined to form strong coordinate bonds than scandium. This is reflected in the stability constants of a number of relevant 1:1 metal-edta complexes:

<table>
<thead>
<tr>
<th>Metal ion</th>
<th>Sc⁻³</th>
<th>Y⁻³</th>
<th>La⁻³</th>
<th>Fe⁻³</th>
<th>Co⁻³</th>
</tr>
</thead>
<tbody>

<td>log₁₀ K₁</td>
<td>23.1</td>
<td>18.1</td>
<td>15.5</td>
<td>25.5</td>
<td>36.0</td>
</tr>
</tbody>
</table>

This may seem somewhat surprising in view of the charge of +3 ions, but this is coupled with appreciably larger ionic radii and also with greater electropositive character which inhibits covalent contribution to their bonding. Lanthanum of course exhibits these characteristics more clearly than Sc, and, while La and Y closely resemble the lanthanide elements, Sc has more similarity with Al. Even Sc however is a class-a acceptor, complexing most readily with O-donor ligands particularly if chelating. Complexes with N-donor and halide ligands are less well-characterized and those with S-donors are largely confined to the Y and La complexes with dithiocarbamates and dithiophosphinates, [M(Sc₂CNEt₂)₃] and [M(Sc₂P(C₆H₁₁)₂)₃].

The complex anion [ScF₆]³⁻ has already been mentioned and, while there is a fairly extensive series of halo complexes with a

---

variety of stereochemistries, they must normally be prepared\textsuperscript{(15)} by dry methods to avoid hydrolysis, and iodo complexes are invariably unstable. Other complexes such as [Sc(dmso)\textsubscript{6}]\textsuperscript{3+} (where dmso is dimethylsulfoxide, Me\textsubscript{2}SO), [Sc(bipy)\textsubscript{3}]\textsuperscript{3+}, [Sc(bipy)\textsubscript{2}(NCS)\textsubscript{2}]\textsuperscript{+} and [Sc(bipy)\textsubscript{2}Cl\textsubscript{2}]\textsuperscript{+} exhibit scandium’s usual coordination number of 6. Data for corresponding Y and La compounds are limited but in [Y(OH)(H\textsubscript{2}O)\textsubscript{2}(phen)\textsubscript{2}]Cl\textsubscript{4}.2(phen).MeOH the yttrium is 8-coordinate with square antiprismatic geometry,\textsuperscript{(16)} and in [La(NO\textsubscript{3})\textsubscript{3}(bipy)\textsubscript{2}] the lanthanum is 10-coordinate. This is illustrative of the general trend in moving down the group that coordination numbers greater than 6 become the rule rather than the exception. It seems likely that in aqueous solutions, in the absence of other preferred ligands, Y\textsuperscript{III} is directly coordinated to 8 water molecules and La\textsuperscript{III} to 9 and in M(OH)\textsubscript{3}, (M = Y, La) the metal ion is 9-coordinate with a stereochemistry approximating to tri-capped trigonal prismatic.

A coordination number of 8 is probably the most characteristic of La and possibly even of Y, with the square antiprim and the dodecahedron being the preferred stereochemistries. The acac complexes referred to below are good examples of the former type, while Cs[Y(CF\textsubscript{3}COCHCOCF\textsubscript{3})\textsubscript{4}] typifies the latter. On the basis of ligand–ligand repulsions the cubic arrangement is expected to be much less favoured in discrete complexes, but, nonetheless, the complex [La(bipyO\textsubscript{2})\textsubscript{4}]ClO\textsubscript{4}, in which bipyO\textsubscript{2} is 2,2′-bipyridine dioxide, has been shown to be very nearly cubic.

\begin{center}
\includegraphics[width=0.5\textwidth]{cubic_prism}
\end{center}

The gradation of properties within this group is also illustrated by the oxalates and β-diketonates which are formed. On addition of alkali-metal oxalate to aqueous solutions of M\textsuperscript{III}, oxalate precipitates form but their solubilities in an excess of the alkali-metal oxalate decrease very markedly down the group. Scandium oxalate dissolves readily with evidence of such anionic species as [Sc(C\textsubscript{2}O\textsubscript{4})\textsubscript{2}]\textsuperscript{−}. Yttrium oxalate also dissolves to some extent but lanthanum oxalate dissolves only slightly. All three elements form acetylacetonates: that of scandium is usually anhydrous, [Sc(acac)\textsubscript{3}], and presumably pseudo-octahedral: [Y(acac)\textsubscript{3}(H\textsubscript{2}O)] is 7-coordinate with a capped trigonal prismatic structure (p. 916); [Y(acac)\textsubscript{3}(H\textsubscript{2}O)\textsubscript{2}].H\textsubscript{2}O and [La(acac)\textsubscript{3}(H\textsubscript{2}O)\textsubscript{3}] are 8-coordinate with distorted square-antiprismatic structures (p. 917); the scandium compound can be sublimed without decomposition whereas the yttrium and lanthanum compounds decompose at about 500°C and dehydration without decomposition or polymerization is difficult.

The alkoxides and aryloxides, particularly of yttrium have excited recent interest.\textsuperscript{(17)} This is because of their potential use in the production of electronic and ceramic materials,\textsuperscript{(18)} in particular high temperature superconductors, by the deposition of pure oxides (metallo-organic chemical vapour deposition, MOCVD). They are moisture sensitive but mostly polymeric and involatile and so attempts have been made to inhibit polymerization and produce the required volatility by using bulky alkoxide ligands. M(OR)\textsubscript{3}, R = 2,6-di-tert-butyl-4-methylphenoxy, are indeed 3-coordinate (pyramidal) monomers but still not sufficiently volatile. More success has been achieved with fluorinated alkoxides, prepared by reacting the parent alcohols with the metal tris-(bis-trimethylsilylamides):

\begin{align*}
[M\{N(SiMe\textsubscript{3})\textsubscript{2}\}\textsubscript{3}] + 3ROH & \quad \rightarrow \quad M(OR)\textsubscript{3} \\
+ 3(Me\textsubscript{3}Si)\textsubscript{2}NH, \text{eg} \quad R &= \quad (CF\textsubscript{3})\textsubscript{2}MeC–
\end{align*}

The Y and La compounds, though polymeric, are surprisingly volatile but, using

\begin{itemize}
\item[(15)] G. MEYER, p. 145–58 in ref. 6.
\end{itemize}
thf as solvent, volatile octahedral monomers 
[M(OR)$_3$(thf)$_3$], M = Y, La, are obtained. With 2,6-diphenylphenolate ligands the coordination number 5 is stabilized in the distorted trigonal-bipyramidal [La(Odpp)$_3$(thf)$_2$.](thf). EDTA complexes of La and the lanthanides are known. K[La(edta)(H$_2$O)$_3$].5H$_2$O is a 9-coordinate complex but steric constraints imposed by the edta produce deviations from a tricapped trigonal prismatic structure. [La(edtaH)$_4$.](H$_2$O)$_4$.3H$_2$O is 10-coordinate and its structure is probably best regarded as being based on the same structure but with an extra water “squeezed” between the three coordinated water molecules.

The highest coordination numbers of all are attained with the aid of chelating ligands, such as SO$_4^{2-}$ and NO$_3^-$, with very small “bites” (p. 917). In La$_2$(SO$_4$)$_3$.9H$_2$O there are actually two types of La$^{III}$, one being coordinated to 12 oxygens in SO$_4^{2-}$ ions while the other is coordinated to 6 water molecules and 3 oxygens in SO$_4^{2-}$ ions. In [Y(NO$_3$)$_5$]$^{2-}$ the Y$^{III}$ is 10-coordinate and in [Sc(NO$_3$)$_3$]$^{2-}$, even though one of the nitrate ions is only unidentate (p. 469), the coordination number of 9 is extraordinarily high for scandium.

---

The low symmetries of many of the above highly coordinated species, which appear to be determined largely by the stereochemical requirements of the ligands, together with the fact that these high coordination numbers are attained almost exclusively with oxygen-donor ligands, are consistent with the belief that the bonding is essentially of an electrostatic rather than a directional covalent character.

### 20.3.3 Organometallic compounds

In view of the electronic structures of the elements of this group, little interaction with π-acceptor ligands is to be expected, though cocondensation of metal vapours with an excess of the bulky ligand, 1,3,5-tri-tert-butylbenzene at 77 K yields the unstable sandwich compounds [M(η6-Bu3C6H3)2], M = Sc, Y which are the first examples of these metals in oxidation state zero. The organometallic chemistry of this group, as of the lanthanides, is instead dominated by compounds involving cyclopentadiene and its methyl-substituted derivatives. Though many are thermally stable, they are invariably sensitive to moisture and oxygen. The first to be prepared were the ionic cyclopentadienides, M(C5H5)2, formed by the reactions of anhydrous MCl3 with NaC5H5 in tetrahydrofuran and purified by vacuum sublimation at 200–250°C. The solids are polymeric, [Sc(C5H5)3] being made up of zig-zag chains of {Sc(η5-C5H5)2} groups joined by η1:η1-C5H5 bridges, whereas in the lanthanum analogue the zig-zag chains of {La(η5-C5H5)2} groups are joined by η5:η2-C5H5 bridges (Fig. 20.4a). They are reactive compounds and form “tetrahedral” monomers, [M(C5H5)L] with neutral ligands such as ammonia and phosphines.

The M(C5H5)2Cl compounds, which are actually Cl-bridged dimers, [(C5H5)M(μ-Cl)2-M(C5H5)], provide an extensive substitution chemistry in which μ-Cl can be replaced by a variety of ligands including H, CN, NH2, MeO and alkyl groups.

Monomeric alkyl compounds of the form MR3 have also been obtained for Sc and Y, where the alkyl groups are of the types Me3SiCH2 and Me2CCH2 which are bulky and contain no β hydrogen atoms (p. 926).

---

Titanium, Zirconium and Hafnium

21.1 Introduction

In 1791 William Gregor, a Cornish vicar and amateur chemist, examined sand from the local river Helford. Using a magnet he extracted a black material (now called ilmenite) from which he removed iron by treatment with hydrochloric acid. The residue, which dissolved only with difficulty in concentrated sulfuric acid, was the impure oxide of a new element, and Gregor proceeded to discover the reactions which were to form the basis of the production of virtually all TiO₂ up to about 1960. Four years later the German chemist M. H. Klaproth independently discovered the same oxide (or "earth"), in a sample of ore now known to be rutile, and named the element titanium after the Titans who, in Greek mythology, were the children of Heaven and Earth condemned to live amongst the hidden fires of the earth. Klaproth had previously (1789) isolated the oxide of zirconium from a sample of zircon, ZrSiO₄. Various forms of zircon (Arabic zargun) have been known as gemstones since ancient times. Impure samples of the two metals were prepared by J. J. Berzelius (Sweden) in 1824 (Zr) and 1825 (Ti) but samples of high purity were not obtained until much later. M. A. Hunter (USA) reduced TiCl₄ with sodium in 1910 to obtain titanium, and A. E. van Arkel and J. H. de Boer (Netherlands) produced zirconium in 1925 by their iodide-decomposition process (see below).

The discovery of hafnium was one of chemistry’s more controversial episodes. In 1911 G. Urbain, the French chemist and authority on “rare earths”, claimed to have isolated the element of atomic number 72 from a sample of rare-earth residues, and named it celtium. With hindsight, and more especially with an understanding of the consequences of H. G. J. Moseley’s and N. Bohr’s work on atomic structure, it now seems very unlikely that element 72 could have been found in the necessary concentrations along with rare earths. But this knowledge was lacking in the early part of the century and, indeed, in 1922 Urbain and A. Dauvillier claimed to have X-ray evidence to support the discovery. However, by that time Niels Bohr had developed his atomic theory and so was confident that element 72 would be a

21.2.2 Preparation and uses of the metals

Viable methods of producing the metals from oxide ores have to surmount two problems. In the first place, reduction with carbon is not possible because of the formation of intractable carbides (p. 299), and even reduction with Na, Ca or Mg is unlikely to remove all the oxygen. In addition, the metals are extremely reactive at high temperatures and, unless prepared in the absence of air, will certainly be contaminated with oxygen and nitrogen.

In 1932 Wilhelm Kroll of Luxembourg produced titanium by reducing TiCl₄ with calcium and then later (1940) with magnesium and even sodium. The expense of this process was a severe deterrent to any commercial use of titanium. However, the metal has a very low density (~57% that of steel) combined with good mechanical strength and, in fact, when alloyed with small quantities of such metals as Al and Sn, has the highest strength:weight ratio of any of the engineering metals. Accordingly, about 1950, a demand developed for titanium for the manufacture of gas-turbine engines, and this demand has rapidly increased as production and fabrication problems have been overcome. Its major uses are still in the aircraft industry.

21.2.1 Terrestrial abundance and distribution

Titanium, which comprises 0.63% (i.e. 6320 ppm) of the earth’s crustal rocks, is a very abundant element (ninth of all elements, second of the transition elements), and, of the transition elements, only Fe, Ti and Mn are more abundant than zirconium (0.016%, 162 ppm). Even hafnium (2.8 ppm) is as common as Cs and Br.

That these elements have in the past been considered unfamiliar has been due largely to the difficulties involved in preparing the pure metals and also to their rather diffuse occurrence. Like their predecessors in Group 3, they are classified as type-a metals and are found as silicates and oxides in many silicaceous materials. These are frequently resistant to weathering and so often accumulate in beach deposits which can be profitably exploited.

The two most important minerals of titanium are ilmenite (FeTiO₃) and rutile (TiO₂). The former is a black sandy material mined in Canada, the USA, Australia, Scandinavia and Malaysia, while the latter is mined principally in Australia. Zirconium’s main minerals are zircon (ZrSiO₄)

and baddeleyite (ZrO₂) mined mainly in Australia, the Republic of S. Africa, USA and the former USSR and invariably containing hafnium, most commonly in quantities around 2% of the zirconium content. Only in a few minerals, such as alvite, MSiO₄.xH₂O (M = Hf, Th, Zr), does the hafnium content occasionally exceed that of zirconium. As a result of the lanthanide contraction (p. 1232) the ionic radii of Zr and Hf are virtually identical and their association in nature parallels their very close chemical similarity.

for the production of both engines and airframes, but it is also widely used in chemical processing and marine equipment. Current world production capacity is estimated to exceed 120,000 tonnes per annum, though actual production is less than this. The Kroll method still dominates the industry: in this ilmenite or rutile is heated with chlorine and carbon, e.g.:

\[ 2\text{FeTiO}_3 + 7\text{Cl}_2 + 6\text{C} \rightarrow 2\text{TiCl}_4 + 2\text{FeCl}_3 + 6\text{CO} \]

The TiCl₄ is fractionally distilled from FeCl₃ and other impurities and then reduced with molten magnesium in a sealed furnace under Ar, at 900°C:

\[ \text{TiCl}_4 + 2\text{Mg} \rightarrow \text{Ti} + 2\text{MgCl}_2 \]

Molten MgCl₂ is tapped off periodically and, after cooling, residual MgCl₂ and any excess of magnesium are removed by leaching with water and dilute hydrochloric acid or by distillation, leaving titanium “sponge” which, after grinding and cleaning with aqua regia (1:3 mixture of concentrated nitric and hydrochloric acids), is melted under argon or vacuum and cast into ingots. The use of sodium instead of magnesium requires little change in the basic process but gives a more readily leached product. This yields titanium metal in a granular form which is fabricated by somewhat different techniques and has been preferred by some users.

Zirconium, too, is produced commercially by the Kroll process, but the van Arkel-de Boer process is also useful when it is especially important to remove all oxygen and nitrogen. In this latter method the crude zirconium is heated in an evacuated vessel with a little iodine, to a temperature of about 200°C when ZrI₄ volatilizes. A tungsten or zirconium filament is simultaneously electrically heated to about 1300°C. This decomposes the ZrI₄ and pure zirconium is deposited on the filament. As the deposit grows the current is steadily increased so as to maintain the temperatures. The method is applicable to many metals by judicious adjustment of the temperatures. Zirconium has a high corrosion resistance and in certain chemical plants is preferred to alternatives such as stainless steel, tantalum and tantalum. It is also used in a variety of alloy steels and, when added to niobium, forms a superconducting alloy which retains its superconductivity in strong magnetic fields. The small percentage of hafnium normally present in zirconium is of no detriment in these cases and may even improve its properties, but a further important use for zirconium is as a cladding for uranium dioxide fuel rods in water-cooled nuclear reactors. When alloyed with ~1.5% tin, its corrosion resistance and mechanical properties, which are stable under irradiation, coupled with its extremely low absorption of “thermal” neutrons, make it an ideal material for this purpose. Unfortunately, hafnium is a powerful absorber of thermal neutrons (600 times more so than Zr) and its removal, though difficult, is therefore necessary. Solvent extraction methods, taking advantage of the different solubilities of, for instance, the two nitrates in tri-n-butyl phosphate or the thiocyanates in hexone (methyl isobutyl ketone) have been developed and reduce the hafnium content to less than 100 ppm. The neutron absorbing ability of hafnium is not always disadvantageous, however, since it is the reason for hafnium’s use for reactor control rods in nuclear submarines. Hafnium is produced in the same ways as zirconium but on a much smaller scale. For rutherfordium see p. 1281.

### 21.2.3 Properties of the elements

Table 21.1 summarizes a number of properties of these elements. The difficulties in attaining high purity has led to frequent revision of the estimates of several of these properties. Each element has a number of naturally occurring isotopes and, in the case of zirconium and hafnium, the least abundant of these is radioactive, though with a very long half-life (26Zr, 2.76%, 3.6 × 10¹⁷ y; 174Hf, 0.162%, 2.0 × 10¹⁵ y).

The elements are all lustrous, silvery metals with high mps and they have typically metallic hcp structures which transform to bcc at high temperatures (882°C, 870°C and 1760°C for Ti, Zr and Hf). They are better conductors of

</table>

heat and electricity than their predecessors in Group 3 but are not to be regarded as “good” conductors in comparison with most other metals. The enthalpies of fusion, vaporization and atomization have also increased, indicating that the additional d electron has in each case contributed to stronger metal bonding. As was noticed in comparing groups 3 and 13, similarly for groups 4 and 14, the d electrons of the first group contribute more effectively to the metal–metal bonding in the bulk materials than do the p electrons of the heavier members of the latter group (Ge, Sn, Pb). Figure 21.1 illustrates the consequent discontinuous increases in mp, bp and enthalpy of atomization in passing from C and Si to Ti, Zr and Hf, rather than to Ge, Sn and Pb.

The mechanical properties of these metals are markedly affected by traces of impurities such as O, N and C which have an embrittling effect on the metals, making them difficult to fabricate.

The effect of the lanthanide contraction on the metal and ionic radii of hafnium has already been mentioned. That these radii are virtually identical for zirconium and hafnium has the result that the ratio of their densities, like that of their atomic weights, is very close to Zr:Hf = 1:2.0. Indeed, the densities, the transition temperatures and the neutron-absorbing abilities are the only common properties of these two elements which differ

Figure 21.1 Trends in some properties of elements of Groups 4 and 14.

(a) Melting points and boiling points.  
(b) Enthalpies of atomization.
significantly. This close similarity of second and third members is noticeable in all subsequent groups of the transition elements but is never more pronounced than here.

### 21.2.4 Chemical reactivity and trends

The elements of this group are relatively electropositive but less so than those of Group 3. If heated to high temperatures they react directly with most non-metals, particularly oxygen, hydrogen (reversibly), and, in the case of titanium, nitrogen (Ti actually burns in N\textsubscript{2}). When finely divided the metals are pyrophoric and for this reason care is necessary when machining them to avoid the production of fine waste chips. In spite of this inherent reactivity, the most noticeable feature of these metals in the massive form at room temperature is their outstanding resistance to corrosion, which is due to the formation of a dense, adherent, self-healing oxide film. This is particularly striking in the case of zirconium. With the exception of hydrofluoric acid (which is the best solvent, probably because of the formation of soluble fluoro complexes) mineral acids have little effect unless hot. Even when hot, aqueous alkalis do not attack the metals. The presence of oxidizing agents such as nitric acid frequently reduces the reactivity of the metals by ensuring the retention of the protective oxide film.

The chemistry of hafnium has not received the same attention as that of titanium or zirconium, but it is clear that its behaviour follows that of zirconium very closely indeed with only minor differences in such properties as solubility and volatility being apparent in most of their compounds. The most important oxidation state in the chemistry of these elements is the group oxidation state of +4. This is too high to be ionic, but zirconium and hafnium, being larger, have oxides which are more basic than that of titanium and give rise to a more extensive and less-hydrolysed aqueous chemistry. In this oxidation state, particularly in the case of the dioxide and tetrachloride, titanium shows many similarities with tin which is of much the same size. A large number of coordination compounds of the M\textsuperscript{IV} metals have been studied\textsuperscript{4} and complexes such as [MF\textsubscript{6}]\textsuperscript{2–} and those with O- or N- donor ligands are especially stable.

The M\textsuperscript{IV} ions, though much smaller than their triply charged predecessors in Group 3, are, nonetheless, sufficiently large, bearing in mind their high charge, to attain a coordination number of 8 or more, which is certainly higher than is usually found for most transition elements. Eight is not a common coordination number for the first member, titanium, but is very well known for zirconium and hafnium, and the spherical symmetry of the d\textsuperscript{0} configuration allows a variety of stereochemistries.

Lower oxidation states are rather sparsely represented for Zr and Hf. Even for Ti they are readily oxidized to +4 but they are undoubtedly well defined and, whatever arguments may be advanced against applying the description to Sc, there is no doubt that Ti is a “transition metal”. In aqueous solution Ti\textsuperscript{III} can be prepared by reduction of Ti\textsuperscript{IV}, either with Zn and dilute acid or electrolytically, and it exists in dilute acids as the violet, octahedral [Ti(H\textsubscript{2}O)\textsubscript{6}]\textsuperscript{3+} ion (p. 970). Although this is subject to a certain amount of hydrolysis, normal salts such as halides and sulfates can be separated. Zr\textsuperscript{III} and Hf\textsuperscript{III} are known mainly as the trihalides or their derivatives and have no aqueous chemistry since they reduce water. Table 21.2 (p. 960) gives the oxidation states and stereochemistries found in the complexes of Ti, Zr and Hf along with illustrative examples. (See also pp. 1281–2.)

M–C σ bonds are not strong and, as might be expected for metals with so few d electrons, little help is available from synergic π bonding: for instance, of the simple carbonyls only Ti(CO)\textsubscript{6} has been reported, and that only on the basis of spectroscopic evidence. However, as will be seen on p. 972, the discovery that titanium compounds can be used to

---

Titanium Dioxide as a Pigment (See page 961)

Of all white pigments, TiO_2 is now the most widely used: the impressive growth in demand is shown in Table A.(5)

Its major use is in the manufacture of paint, and other important uses are as a surface coating on paper and as a filler in rubber and plastics.

The value of TiO_2 as a pigment is due to its exceptionally high refractive index in the visible region of the spectrum. Thus although large crystals are transparent, fine particles scatter light so strongly that they can be used to produce films of high opacity. Table B gives the refractive indices of a number of relevant materials. In the manufacture of TiO_2, either the anatase or the rutile form is produced depending on modifications in the process employed. Because of its slightly higher refractive index, rutile has a somewhat greater opacity and most of the TiO_2 currently produced is of this form.

In addition to these optical properties, TiO_2 is chemically inert which is why it displaced "white lead", 2PbCO_3.Pb(OH)_2 in industrial atmospheres this formed PbS (black) during the production of or weathering of the paint and was also a toxic hazard. Unfortunately the naturally occurring forms of TiO_2 are invariably coloured, sometimes intensely, by impurities, and expensive processing is required to produce pigments of acceptable quality. The two main processes in use are the sulfate process and the chloride process (Fig. A, p. 960), which account for approximately 56% and 44% respectively of total world production. The principal reactions of the chloride process are:

\[
2\text{TiO}_2 + 3\text{C} + 4\text{Cl}_2 \xrightarrow{950^\circ C} 2\text{TiCl}_4 + \text{CO}_2 + 2\text{CO}
\]

and

\[
\text{TiCl}_4 + \text{O}_2 \xrightarrow{1000-1400^\circ C} \text{TiO}_2 + 2\text{Cl}_2
\]

It is most economical when high-grade ores are used, becoming less economical with poorer feed materials containing iron, because of the production of chloride wastes from which the chlorine cannot be recovered. By contrast the sulfate process cannot make use of rutile which does not dissolve in sulfuric acid, but is able to operate on lower grade ores. However, the capital cost of plant for the sulfate process is higher, and disposal of waste has proved environmentally more difficult, so that most new plant is designed for the chloride process.

The physical properties of the base pigments produced from both processes are further improved by slurring in water and selectively precipitating on the finely divided particles a surface coating of SiO_2, Al_2O_3, or TiO_2 itself.

catalyse the polymerization of alkenes (olefins) turned organo-titanium chemistry into a topic of major commercial importance and has produced an extensive chemistry. The organometallic chemistry of Zr and Hf, though less developed than that of Ti, has grown rapidly in recent years.

21.3 Compounds of Titanium, Zirconium and Hafnium

The binary hydrides (p. 64), borides (p. 145), carbides (p. 299) and nitriles (p. 417) are hard, refractory, nonstoichiometric materials with metallic conductivities. They have already been discussed in relation to comparable compounds of other metals in earlier chapters.

21.3.1 Oxides and sulfides

The main oxides are the dioxides. In fact, TiO₂ is by far the most important compound formed by the elements of this group, its importance arising predominantly from its use as a white pigment (see Panel, p. 959). It exists at room temperature in three forms—rutile, anatase and brookite, each of which occurs naturally. Each contains 6-coordinate titanium but rutile is the most common form, both in nature and as produced commercially, and the others transform into it on heating. The rutile structure is based on a slightly distorted hcp of oxygen atoms with half the octahedral interstices being occupied by titanium atoms. The octahedral coordination of the titanium atoms and trigonal planar coordination of the oxygen can be seen in Fig. 21.2. This is a structure commonly adopted by ionic dioxides and difluorides where the relative sizes of the ions are such as to favour 6-coordination (i.e. when the radius ratio of cation:anion lies in the range 0.73 to 0.41).<sup>(6)</sup>

Anatase and brookite are both based on cubic rather than hexagonal close packing of oxygen atoms, but again the titanium atoms occupy half the octahedral interstices. TiO₂ melts at 1892 ± 30°C when heated in an atmosphere of O₂; when heated in air the compound tends to lose oxygen and then melts at 1843 ± 15°C (TiO₁.985). Though it is unreactive, rutile can be reduced with difficulty to give numerous nonstoichiometric oxide phases, the more important of which are the Magnéli-type phases TiₙO₂ₙ₋₁ (4 ≤ n ≤ 9), the lower oxides Ti₅O₅ and Ti₄O₃, and the broad, nonstoichiometric phase TiOₓ (0.70 ≤ x ≤ 1.30). The Magnéli phases TiₙO₂ₙ₋₁ are built up of slabs of rutile-type structure with a width of nTiO₆ octahedra and with adjacent slabs mutually related by a crystallographic shear which conserves oxygen atoms by an increased sharing

---

between adjacent octahedra. Ti₄O₇ is metallic at room temperature but the other members of the series tend to be semiconductors.

Of the lower oxides Ti₃O₅ is a blue-black material prepared by the reduction TiO₂ with H₂ at 900°C; it shows a transition from semiconductor to metal at 175°C. Ti₂O₃ is a dark-violet material with the corundum structure (p. 243); it is prepared by reacting TiO₂ and Ti metal at 1600°C and is generally resistant to most reagents except oxidizing acids. It has a narrow composition range \( x = 1.49-1.51 \) in TiO₂ and undergoes a semiconductor-to-metal transition above \( \sim 200^\circ \)C.

TiO, a bronze coloured, readily oxidized material, is again prepared by the reaction of TiO₂ and Ti metal. It has a defect rock-salt structure which tolerates a high proportion of vacancies (Schottky defects) in both Ti and O sites and so is highly nonstoichiometric with a composition range at 1700°C of TiO₀₇₅ to TiO₁₂₅. This range diminishes somewhat at lower temperatures and, at equilibrium below about 900°C, various ordered phases separate with smaller ranges of composition-variation, e.g. TiO₀₉₋ TiO₁₁ and TiO₁₂₅ (i.e. Ti₄O₉). In this latter compound the tetragonal unit cell can be thought of as being related to the NaCl-type structure: there are 10 Ti sites and 10 oxygen sites but 2 of the Ti sites are vacant in a regular or ordered way to generate the structure of Ti₄O₉. A high-temperature (>3000°C) form of TiO has been prepared with the unusual feature of Ti²⁺ in a trigonal prismatic array of oxygen atoms.(7a)

Finally, oxygen is soluble in metallic titanium up to a composition of TiO₀₅ with the oxygen atoms occupying octahedral sites in the hcp metal lattice: distinct phases that have been crystallographically characterized are Ti₆O, Ti₃O and Ti₂O. It seems likely that in all these reduced oxide phases there is extensive metal–metal bonding.

In the case of zirconium and hafnium there is little evidence of stable phases other than MO₂, and at room temperature ZrO₂ (baddeleyite) and the isomorphous HfO₂ have a structure in which the metal is 7-coordinate (Fig. 21.2(b)). ZrO₂ has at least two more high-temperature modifications (tetragonal above 1100°C and cubic, fluorite-type, above 2300°C) but it is notable that, presumably because of the greater size of Zr compared to Ti, neither of them has the 6-coordinate rutile structure. ZrO₂ is unreactive, has a low coefficient of thermal expansion, and a very high melting point (2710 ± 25°C) and is therefore a useful refractory material, being used in the manufacture of crucibles and furnace cores. However, the phase change at 1100°C severely restricts the use of pure ZrO₂ as a refractory because repeated thermal cycling through this temperature causes cracking and disintegration — the problem is avoided by using solid solutions of CaO or MgO in the ZrO₂ since these retain the cubic fluorite structure throughout the temperature range. ZrO₂ has also recently been produced in fibrous form suitable for weaving into fabrics, as already mentioned for Al₂O₃ (p. 244), and its chemical inertness and refractivity — coupled with an apparent lack of toxicity — can be expected to lead to increasing applications as an insulator and for the filtration of corrosive liquids. Production of ZrO₂ concentrates in 1991 was about 870 000 t, Australia being the most important source.

The sulfides have been less thoroughly examined than the oxides but it is clear that a number of stable phases can be produced and nonstoichiometry is again prevalent (p. 679). The most important are the disulfides, which are semiconductors with metallic lustre. TiS₂ and ZrS₂ have the CdI₂ structure (p. 1211) in which the cations occupy the octahedral sites between alternate layers of hcp anions.

### 21.3.2 Mixed (or complex) oxides

Although the dioxides, MO₂, are notable for their inertness, particularly if they have been heated, fusion or firing at high temperatures (sometimes up to 2500°C) with the stoichiometric
amounts of appropriate oxides produces a number of “titanates”, “zirconates”, and “hafnates”. The titanates are of two main types: the orthotitanates $M_i^2TiO_4$ and the metatitanates $M_i^1TiO_3$. The names are misleading since the compounds almost never contain the discrete ions $[TiO_4]^{4-}$ and $[TiO_3]^{2-}$ analogous to phosphates or sulfites. Rather, the structures comprise three-dimensional networks of ions which are of particular interest and importance because two of the metatitanates are the archetypes of common mixed metal oxide structures.

When $M_i^1$ is approximately the same size as $Ti^{IV}$ (i.e. $M = Mg, Mn, Fe, Co, Ni$) the structure is that of ilmenite, $FeTiO_3$, which consists of hcp oxygens with one-third of the octahedral interstices occupied by $M_i^1$ and another third by $Ti^{IV}$. This is essentially the same structure as corundum ($Al_2O_3$, p. 243) except that in that case there is only one type of cation which occupies two-thirds of the octahedral sites.

If, however, $M_i^1$ is significantly larger than $Ti^{IV}$ (e.g. $M = Ca, Sr, Ba$), then the preferred structure is that of perovskite,$^8$ $CaTiO_3$. This can be envisaged as a ccp array of calcium and oxygen atoms, with the former regularly disposed, and the titanium atoms then occupying octahedral sites formed by oxygen atoms only and so being as remote as possible from the calciums (Fig. 21.3). The $Ba^{II}$ ion is so large and expands the perovskite lattice to such an extent that the titanium is too small to fill the octahedral interstice which accommodates it. This leads to ferroelectric and piezoelectric behaviour as discussed in Chapter 3 (p. 57). In consequence, $BaTiO_3$ has found important applications in the production of compact capacitors (because of its high permittivity) and as a ceramic transducer in devices such as microphones and gramophone pick-ups. For such purposes it compares favourably with Rochelle salt (sodium potassium tartrate, $NaKC_4H_4O_6$) in terms of thermal stability, and with quartz in terms of the strength of the effect.

$M_2^1TiO_4$ ($M = Mg, Zn, Mn, Fe, Co$) have the spinel structure ($MgAl_2O_4$, p. 248) which is the third important structure type adopted by many mixed metal oxides; in this the cations occupy both octahedral and tetrahedral sites in a ccp array of oxide ions. $Ba_2TiO_4$, although having the same stoichiometry, is unique amongst titanates in that

---

it contains discrete \([\text{TiO}_4]^{4-}\) ions which have a somewhat distorted tetrahedral structure.

High-temperature reduction of \(\text{Na}_2\text{TiO}_3\) with hydrogen produces nonstoichiometric materials, \(\text{Na}_x\text{TiO}_2\) \((x = 0.20-0.25)\), called titanium “bronzes” by analogy with the better-known tungsten bronzes (p. 1016). They have a blue-black, metallic appearance with high electrical conductivity and are chemically inert (even hydrofluoric acid does not attack them).

“Zirconates” and “hafnates” can be prepared by firing appropriate mixtures of oxides, carbonates or nitrates. None of them are known to contain discrete \([\text{MO}_4]^{4-}\) or \([\text{MO}_3]^{2-}\) ions. Compounds \(\text{M}^{IV}\text{ZrO}_3\) usually have the perovskite structure whereas \(\text{M}^{IV}\text{ZrO}_4\) frequently adopt the spinel structure.

### 21.3.3 Halides

The most important of these are the tetrahalides, all 12 of which are known. The titanium compounds (Table 21.3) show an interesting gradation in colour, the charge-transfer band moving steadily to lower energies (i.e. absorbing increasingly in the visible region of the spectrum) as the anion becomes more easily oxidized (\(\text{F}^-\) to \(\text{I}^-\)) by the small, highly polarizing titanium cation. The larger \(\text{Zr}^{IV}\) and \(\text{Hf}^{IV}\), however, do not have the same polarizing effect and their tetrahalides are all white solids; the fluorides are involatile but the other tetrahalides sublime readily at temperatures in the range 320–430°C.

Though numerous preparative methods are possible besides the direct action of the halogen on the metal, convenient general procedures are as follows:

- **Tetrafluorides** by the action of anhydrous HF on the tetrachloride;
- **Tetrachlorides and tetrabromides** by passing the halogen over the heated dioxide in the presence of a reducing agent such as carbon (this reaction is central to the chloride process for manufacturing \(\text{TiO}_2\), p. 959);
- **Tetraiodides** by the iodination of the dioxide with aluminium triiodide at a temperature of 130–400° depending on the metal \((3\text{M}_2\text{O}_3 + 4\text{AlI}_3 \rightarrow 3\text{M}_4\text{I}_4 + 2\text{Al}_2\text{O}_3)\).

Not all the structures have been determined but in the vapour phase all the tetrahalides of titanium and probably all those of zirconium and hafnium have monomeric, tetrahedral structures. In the solid, \(\text{TiF}_4\) is a polymer consisting of corner-sharing \(\{\text{TiF}_6\}\) octahedra,\(^{8a}\) but the other tetrahalides of titanium retain the tetrahedral configuration around the metal even in the solids. The larger zirconium exhibits higher coordination numbers. Thus solid \(\text{MF}_4\) contain 8-coordinate (square antiprismatic) metal atoms while the tetrachlorides and bromides are polymers consisting of zigzag chains of edge-sharing \(\{\text{MX}_6\}\) octahedra.

All the tetrahalides, but especially the chlorides and bromides, behave as Lewis acids dissolving in polar solvents to give rise to series of addition compounds; they also form complex anions with halides. They are all hygroscopic and hydrolysis follows the same pattern as complex formation, with the chlorides and bromides being more vulnerable than the fluorides and iodides. \(\text{TiCl}_4\) fumes in and is completely hydrolysed by moist air \((\text{TiCl}_4 + 2\text{H}_2\text{O} \rightarrow \text{TiO}_2 + 4\text{HCl})\); a variety of intermediate hydrolysis products, such as the oxochlorides \(\text{MOCI}_2\), can be formed with aqueous HCl of varying concentration. Even in conc HCl, \(\text{ZrCl}_4\) gives \(\text{ZrOCl}_2\cdot 8\text{H}_2\text{O}\). This contains the tetrameric cation \([\text{Zr}_4(\text{OH})_8(\text{H}_2\text{O})_{16}]^{8+}\) in which the 4 zirconium atoms are connected in a ring by 4 pairs of \(\text{OH}^-\) bridges and each zirconium atom is dodecahedrally coordinated to 8 oxygen atoms. The fluorides are less susceptible

to hydrolysis and, though aqueous HF produces the oxofluorides, MOF₂, the hydrates TiF₄·2H₂O, MF₄·3H₂O, and MF₄·3H₂O (M = Zr, Hf) can be produced. Rather curiously the trihydrates of ZrF₄ and HfF₄ actually have different structures, though both contain 8-coordinated metal atoms. The zirconium compound is essentially dimeric [(H₂O)₃F₃Zr(μ-F)₂ZrF₃(H₂O)₃] with dodecahedral Zr, whereas the hafnium compound consists of infinite chains of octahedral [>HfF₂(H₂O)₂(μ-F)₂] with the third water molecule held in the lattice.

Besides being important as an intermediate in one of the processes for making TiO₂, TiCl₄ is also used to produce Ziegler-Natta catalysts (p. 972) for the polymerization of ethylene (ethene) and is the starting point for the production of most of the commercially important organic titanium compounds (in most cases these are actually titanium alkoxides rather than true organometallic compounds). The iodides MI₄ are all utilized in the van Arkel-de Boer process for producing pure metals (p. 956).

All the trihalides except HfF₃ have been prepared, the most general method being the high-temperature reduction of the tetrahalide with the metal, though a variety of other methods have been used especially for the titanium compounds. Since the tetrahalides are quite stable to reduction, lower halides are not easily prepared in a pure state, incomplete reactions and the presence of excess metal being common. Apart from TiF₃, which, as expected for a d¹ ion, has a magnetic moment of 1.85 BM at room temperature, and only shows signs of magnetic interactions below about 60 K, all compounds have low magnetic moments, indicative of appreciable M–M bonding. They are coloured, halogen-bridged polymers in which one third of the octahedral interstices of an hcp lattice of halide ions is occupied by metal atoms. In the cases of α-TiCl₃ and α-TiBr₃ this takes the form of the “BiF₃” structure which is comprised of layers of edge-sharing octahedra; the remainder adopt the “β-TiCl₃” structure, comprised of chains of face-sharing octahedra. In most, if not all, of the latter cases M–M bonds occur between pairs of metal atoms as a result of distortions leading, in the case of ZrI₃ for instance, to alternate Zr–Zr distances of 317.2 and 350.7 pm. TiF₃ also differs in being stable in air unless heated whereas the others show reducing properties; indeed, ZrX₃ and HfX₃ reduce water and so have no aqueous chemistry, but aqueous solutions of TiX₃ are stable if kept under an inert atmosphere. Hexahydrates TiX₃·6H₂O are well known and the chloride is notable in that, like its chromium(III) analogue, it exhibits hydrate isomerism, existing as violet [Ti(H₂O)₆]³⁺Cl⁻ and green [TiCl₂(H₂O)₄]⁺Cl⁻·2H₂O.

TiX₂ (X = Cl, Br, I) have been prepared by reduction of TiX₄ with Ti metal and are black solids with the CdI₂ structure (p. 1211) but their low magnetic moments again indicate extensive M–M bonding. They are very strongly reducing and decompose water. Ti₇X₁₆ (X = Cl, Br) have also been prepared. They are black crystalline solids sensitive to hydrolysis and oxidation and can be regarded as being composed of octahedrally coordinated TiIV and TiV in the ratio of 1:6 (i.e. TiCl₄·6TiCl₂) with the bivalent metal ions arranged in triangular groups involving Ti–Ti bonds. Incorporation of KCl in the chloride reaction mix yields the structurally related KTi₄Cl₁₁ but the structural diversity of reduced Ti halides does not yet match that of Zr.

Products of the high temperature (typically 750–850°C) reduction of ZrX₄ (X = Cl, Br, I) with Zr metal in various proportions, have provided intriguing structural problems. Black phases initially thought to be ZrX₂ and made up of Zr₆X₁₂ clusters, isostructural with the well-known [M₆X₁₂]ⁿ⁺ clusters of Nb and Ta, were subsequently shown to contain

---

impurity atoms situated inside the Zr\textsubscript{6} octahedra which they actually stabilize. The materials are correctly formulated as Zr\textsubscript{6}X\textsubscript{12}Z and, if alkali metal halides are incorporated in the reaction mix a whole series of phases based on the [Zr\textsubscript{6}X\textsubscript{12}Z] cluster unit is obtained, of which the chlorides and iodides have so far been most thoroughly studied. Z is most commonly H, Be, B, C or N (dark orange to red products), but may also be Cr, Mn, Fe or Co (green, blue or purple products). In all cases the same basic Zr\textsubscript{6}X\textsubscript{12}Z cluster unit is involved, though several structure types result from the differing ways in which these are connected.\textsuperscript{(13)} In most cases it appears that stability is attained when 14 electrons are available for cluster bonding (i.e. total number of valence electrons from Zr\textsubscript{6} and Z, adjusted for overall charge, less 12 required by X\textsuperscript{-12}) where Z is a main-group element, but 18 electrons where Z is a transition element. It has been suggested that the presence of Z is essential for the stabilisation of these clusters, but Zr\textsubscript{6}Cl\textsubscript{12}(PM\textsubscript{2}Ph)\textsubscript{6} appears to consist entirely of empty Zr\textsubscript{6}Cl\textsubscript{12} clusters with a phosphine attached externally to each Zr atom.\textsuperscript{(14)}

By contrast, ZrCl and ZrBr, also prepared by the high temperature reduction of ZrX\textsubscript{4} with the metal, appear to be genuine binary halides. They are comprised of hcp double layers of metal atoms surrounded by layers of halide ions, leading to metallic conduction in the plane of the layers, and they are thermally more stable than the less reduced phases. ZrI has not been obtained, possibly because of the large size of the iodide ion, and, less surprisingly, attempts to prepare reduced fluorides have been unsuccessful.

### 21.3.4 Compounds with oxoanions

Because of the high ratio of ionic charge to radius, normal salts of Ti\textsuperscript{IV} cannot be prepared from aqueous solutions, which only yield basic, hydrolysed species. Even with Zr\textsuperscript{IV} and Hf\textsuperscript{IV}, normal salts such as Zr(NO\textsubscript{3})\textsubscript{4}.5H\textsubscript{2}O and Zr(SO\textsubscript{4})\textsubscript{2}.4H\textsubscript{2}O can only be isolated if the solution is sufficiently acidic, whilst basic salts and anionic complexes are readily obtained. Several oxometal(IV) compounds (i.e. “titanyl”, “zirconyl”) have been isolated but do not contain discrete MO\textsuperscript{2+} ions, being polymeric in the solid state. Thus, TiOSO\textsubscript{4}.H\textsubscript{2}O contains chains of −Ti−O−Ti−O− with each Ti being approximately octahedrally coordinated to 2 bridging oxygen atoms, 1 water molecule and an oxygen atom from each of 3 sulfates; ZrO(NO\textsubscript{3})\textsubscript{2} is also an oxygen-bridged chain, though hydroxy bridging, as in ZrOCl\textsubscript{2}.8H\textsubscript{2}O mentioned above, is more common. By contrast, ion-exchange studies on aqueous solutions of Ti\textsuperscript{IV} in 2M HClO\textsubscript{4} are consistent with the presence of monomeric doubly-charged cationic species rather than polymers, though it is not clear whether the predominant species is [TiO]\textsuperscript{2+} or [Ti(OH)\textsubscript{2}]\textsuperscript{2+}.

The anhydrous nitrates can be prepared by the action of N\textsubscript{2}O\textsubscript{5} on MCl\textsubscript{4}. Ti(NO\textsubscript{3})\textsubscript{4} is a white sublimable and highly reactive compound (mp 58°C) in which the bidentate nitrate ions are disposed tetrahedrally around the titanium which thereby attains a coordination number of 8 (Fig. 21.4). Infrared evidence suggests that Zr(NO\textsubscript{3})\textsubscript{4} is isostructural but hafnium nitrate

![Figure 21.4](image-url) The molecular structure of Ti(NO\textsubscript{3})\textsubscript{4}. Eight O atoms form a dodecahedron around the Ti and the 4 N atoms form a flattened tetrahedron.

---

sublimes under vacuum at 100°C as the adduct Hf(NO₃)₄·N₂O₅.

Zirconium phosphates (α-form: Zr(HPO₄)₂·H₂O, β-form: Zr(HPO₄)₂·2H₂O) have layered structures with cation-exchange properties due to the replaceable, acidic hydrogens. Intercalation of organic molecules causes swelling of the structures and increases their versatility as ion-exchangers.

In oxidation states lower than +4, only Ti³⁺ forms a sulfate and this gives rise to the alums, MTi(SO₄)₂·12H₂O (M = Rb, Cs), containing the octahedral hexaaquotitanium(III) ion.

21.3.5 Complexes⁴,¹⁵

Oxidation state IV (d⁰)

A very large number of these complexes, particularly of titanium, have been prepared and, as is to be expected for the d⁰ configuration, they are invariably diamagnetic. Hydrolysis, resulting in polymeric species with –OH– or –O– bridges, is common especially with titanium and is still a preparative problem with zirconium and hafnium, though acidic solutions if sufficiently dilute (<10⁻⁴ M) probably contain the Zr⁴⁺(aq) ion.¹⁶ A coordination number of 6 is the most usual for Ti⁴⁺ but 7- and even 8-coordination is possible. However, these high coordination numbers are much more characteristic of Zr⁴⁺ and Hf⁴⁺, whose complexes are more labile (consistent with greater electrostatic character in the bonding). Furthermore, because changes in geometry entail smaller changes in energy for higher coordination numbers, these include a greater variety of stereochemistries.

The neutral and anionic adducts of the halides constitute a large proportion of the complexes of Ti⁴⁺, and the alkoxides (also prepared from TiCl₄) are of commercial importance (p. 968).

adduct with TiCl₄ which is monomeric and so presumably 7-coordinate. [TiCl₄L] adducts are usually 6-coordinate dimers with double chloride bridges.

Octahedral, anionic complexes, [MX₆]²⁻, show a marked increase in susceptibility to hydrolysis and consequent difficulty in preparation, in passing from the stable fluorides to the heavier halides, with the result that the hexaiodo complexes cannot be isolated. The fluorozirconates and fluoroconfused display considerable variety, complexes of the types [MF₇]³⁻, [M₂F₁₄]⁶⁻, and [MF₈]₄⁻ having been prepared, often by fusion of the appropriate fluorides. In Na₃ZrF₇ the anion has the 7-coordinate pentagonal bipyramidal structure; in Li₆[BeF₄][ZrF₈] the zirconium anion is 8-coordinate, dodecahedral (distorted); in Cu₆[ZrF₈].12H₂O it is 8-coordinate, square antiprismatic, and in Cu₃[ZrF₁₄].18H₂O dimerization by the edge-sharing of two square antiprisms maintains 8-coordination. Stoichiometry does not, however, define coordination type, and this is very well illustrated by the ostensibly [MF₆]²⁻ complexes which may contain 6-, 7-, or 8-coordinate Zr⁴⁺ or Hf⁴⁺ depending on the counter anion. In R₂MF₆, M is indeed octahedrally coordinated, but in (NH₄)₂MF₆ and K₂MF₆ polymerization occurs to give respectively 7- and 8-coordinate species.

Alkoxides of all 3 metals are well characterized but it is those of titanium which are of particular importance. The solvolysis of TiCl₄ with an alcohol yields a dialkoxide:

\[
\text{TiCl}_4 + 2\text{ROH} \rightarrow \text{TiCl}_2(\text{OR})_2 + 2\text{HCl}
\]

If dry ammonia is added to remove the HCl, then the tetraalkoxides can be produced:

\[
\text{TiCl}_4 + 4\text{ROH} + 4\text{NH}_3 \rightarrow \text{Ti(OR)}_4 + 4\text{NH}_4\text{Cl}
\]

These alkoxides are liquids or sublimable solids and, unless the steric effects of the alkyl chain prevent it, apparently attain octahedral coordination of the titanium by polymerization (Fig. 21.6). The lower alkoxides are especially sensitive to moisture, hydrolysing to the dioxide. Application of these “organic titanates” (as they are frequently described) can therefore give a thin, transparent, and adherent coating of TiO₂ to a variety of materials merely by exposure to the atmosphere. In this way they are used to waterproof fabrics and also in heat-resistant paints. They are also used on glass and enamels which, after firing, retain a coating of TiO₂ which confers a resistance to scratching and often enhances the appearance. However, the most important commercial application is in the production of “thixotropic” paints which do not “drip” or “run”. For this the Ti(OR)₄ is chelated with ligands such as β-diketonates to give products of the type [Ti₂(OR)₄(L-L)] which are water soluble and more resistant to hydrolysis. In concentrations of 1% or less, they form gels with the cellulose ether colloids used to thicken latex paints and so produce the desired characteristics. Titanium tartrate complexes, probably dimeric species such as [Ti₂(tartrate)₂(OR)₄], are also useful catalysts in asymmetric epoxidations of allylic alcohols.(17)

One of the most sensitive methods for estimating titanium (or, conversely, for estimating H₂O₂) is to measure the intensity of the orange colour produced when H₂O₂ is added to acidic solutions of titanium(IV). The colour is due(18) to the peroxo complex, [Ti(O₂)(OH)(H₂O)]⁺, though alkaline solutions are needed before crystalline solids such as M₄[1/2Ti(O₂)F₅] or M₂[1/2Ti(O₂)(SO₄)₂]₉

Figure 21.6 Two representations of the tetrameric structure of [Ti(OEt)₄]₄.

can be isolated. The peroxo ligand is apparently bidentate, the 2 oxygen atoms being equidistant from the metal (see also p. 615).

Not surprisingly, in view of their greater size, zirconium and hafnium show a greater preference than titanium for O-donor ligands as well as for high coordination numbers, and this is shown by the greater variety of \( \beta \)-diketonates, carboxylates and sulfato complexes which they form. Bis-\( \beta \)-diketonates such as \([\text{MCl}_2(\text{acac})_2]\) of all 3 metals are made by the reaction of \text{MCl}_4 and the \( \beta \)-diketone in inert solvents such as benzene. They are octahedral with cis-chlorides. In addition, Zr and Hf form the monomeric, 7-coordinate \([\text{MCl}(\text{acac})_3]\) complexes which have a distorted pentagonal bipyramidal stereochemistry. Also, providing alkali is present to remove the labile proton, Zr and Hf will yield the tetrakis complexes in aqueous solution:

\[
\text{MCl}_2 + 4\text{acacH} + \text{Na}_2\text{CO}_3 \rightarrow [\text{M(acac)}_4]
\]

These too are monomeric, and the 8-coordinate structure has a square-antiprismatic arrangement of oxygen atoms around M.

Monocarboxylates of the types \([\text{Zr(carbox)}_4]\), \([\text{ZrO(carbox)}_3(\text{H}_2\text{O})_1]\) and \([\text{ZrO(OH)(carbox)-}(\text{H}_2\text{O})_1]\) are well known, as are the corresponding dicarboxylates. It is interesting that the tetrakis(oxalates), \(\text{Na}_4[\text{M(C}_2\text{O}_4)_4]\).3\text{H}_2\text{O}, adopt the dodecahedral stereochemistry in contrast to the square-antiprismatic stereochemistry of \([\text{M(acac)}_4]\), possibly because the smaller “bite” of the oxalate ion compared to that of acac favours the dodecahedral form (p. 916). It may also be noted that, although optical and geometrical isomerism is conceivable for these stereochemistries, intramolecular rearrangement of the ligands is too rapid for sets of isomers of the above compounds (or, indeed, of any compound of Zr\text{IV} or Hf\text{IV}) to have \(T_d\) symmetry (Fig. 21.7), with triple-hydrogen bridges, implying two types of hydrogen. Yet the proton nmr distinguishes only one type of proton, so that rapid intramolecular rearrangement is indicated. The structure of the hafnium compound has not been determined but its properties are so similar that its structure may be assumed to be the same. Both compounds are rather unstable, have virtually the same mp (~29°C) and are the most volatile compounds yet known for zirconium and hafnium. The type of bonding involved is a matter of some uncertainty. The volatility is indicative of covalency, but how many electrons the borohydride groups should be regarded as donating to the metal is open to doubt.

**Oxidation state III (d\(^{1}\))**

The coordination chemistry of this oxidation state is virtually confined to that of titanium. Reduction of zirconium and hafnium from the quadrivalent to the tervalent state is not easy and cannot be attempted in water which is itself reduced by Zr\text{III} and Hf\text{III}. A few adducts of the trihalides of these two elements with N- or P- donor ligands have been prepared. ZrBr\(_3\) treated with liquid ammonia yields a hexaammine stable to room temperature.
but NH₃ is readily lost and the chloride only retains 2.5NH₃ at room temperature.(19) Pyridine, 2,2′-bipyridyl and 1,10-phenanthroline also coordinate, but structural data are sparse. Phosphines are characterized rather better and reduction of MCl₄ with Na/Hg in the presence of the ligand yields air-sensitive compounds with edge-sharing, bi-octahedral structures:(20)

\[(\text{PR}_3)_2\text{Cl}_2\mu\text{-Cl}\text{MCl}_2\text{(PR}_3)_2\]  

(M = Zr, Hf; PR₃ = PMe₃P)

Analogous iodides with PR₃ = PMe₃ have also been prepared,(21) and the diamagnetism of all these compounds is indicative of M–M bonds, though these are rather long (~310 pm for the chlorides and ~340 pm for the iodides).

Titanium(III) is also prone to aerial oxidation. Most of the complexes of titanium(III) are octahedral and are produced by reacting TiCl₃ with an excess of the ligand, giving rise to stoichiometries such as [TiL₆]X₃, [TiL₄X₂]X, [TiL³X₃] and M₂[TiX₆] (L = neutral unidentate ligand, X = singly charged anion) (Table 21.4) together with corresponding complexes involving multidentate ligands.

The first of these types is most familiarly represented by the hexaaquo ion which is present in acidic aqueous solutions and, in the solid state, in the alum CsTi(SO₄)₂.12H₂O. In fact few other neutral ligands besides water form a [TiL₆]³⁺ complex. Urea is one of these few and [Ti(OCN)₂H₄]₃, in which the urea ligands coordinate to the titanium via their oxygen atoms, is one of the compounds of titanium(III) most resistant to oxidation.

Hydrate isomerism of TiCl₃.6H₂O, yielding [TiCl₂(H₂O)₄]⁺Cl⁻ as one of the isomers, has already been referred to (p. 965) and analogous complexes are formed by a variety of alcohols. Neutral complexes, [TiL₃X₃] have been characterized for a variety of ligands such as tetrahydrofuran (C₄H₈O), dioxan (C₄H₈O₂), acetonitrile, pyridine and picoline, while anionic complexes [TiX₆]⁻ (X = F, Cl, Br, NCS) have been prepared by electrolytic reduction of melts or by other nonaqueous methods. An interesting binuclear complex, (NMe₄)-[Ti(H₂O)₄F₂][TiF₆].H₂O is obtained by reacting TiCl₃ with NMe₄F in dimethylformamide. It contains trans-[Ti(III)(H₂O)₄F₂]⁺ cations and [TiIVF₆]²⁻ anions.(22)

Interpretation of the electronic spectrum of Ti(III) in aqueous solution was an early landmark in the development of Crystal Field Theory, the observed broad band being assigned to the \(2E_g \leftrightarrow 2T_{2g} \) transition (promotion of an electron from a \(t_{2g} \) to an \(e_g \) orbital). However, the absorption band actually observed for this and for other octahedral complexes of Ti(III) is never of the symmetrical shape expected for a single transition, but is rather an asymmetrical peak with a (usually) distinct shoulder on the low-energy side.(4) The whole absorption “envelope” is apparently made up of two superimposed bands whose positions are indicated in Table 21.4 and which are generally assumed to be a consequence of the Jahn–Teller effect (p. 1021) acting on the excited term. The value of 10Dq is usually identified with the energy of the stronger of the two bands rather than an average, and the results in Table 21.4 indicate that this varies with the ligand in the order:

\[\text{Br}^- < \text{Cl}^- < \text{urea} < \text{NCS}^- < \text{F}^- < \text{H}_2\text{O}\]

which agrees with the spectrochemical series established for other metals.

The \(t_{2g} \) ground configuration in a perfectly octahedral crystal field is expected to produce a magnetic moment of approx. 1.86 BM at room temperature, decreasing to zero at 0 K. Although observed magnetic moments of Ti(III) compounds do indeed decrease with temperature, the effects of distortions (which split the ground \(2T_{2g} \) term) and partial covalency of the metal–ligand bond (which delocalizes the single electron from the

$^a$The band "envelope" is asymmetrical with insufficient resolution to identify the position of the weaker component.

metals) lead to lower values at room temperature (see Table 21.4) and less temperature dependence than would have been expected.$^{(23)}$

Amongst the few complexes of Ti$^{III}$ which have been shown to be non-octahedral are [TiBr$_3$(NMe$_3$)$_2$] and [Ti[N(SiMe$_3$)$_2$]$_3$]. The former has a 5-coordinate, trigonal bipyramidal structure while the latter is one of a series of complexes of tervalent metals which have a 3-coordinate, planar structure. It appears that the silylamide ligands are simply too bulky for the Ti$^{III}$ ion to accommodate more than three of them, and this consideration overrides any preference which the metal might have for a higher coordination number.

Lower oxidation states

Apart from Ti$^0$ and the lower halides already mentioned, the chemistry of these metals in oxidation states lower than 3 is not well established. Addition compounds of the type [TiCl$_2$L$_2$] can be formed with difficulty with ligands such as dimethylformamide and acetonitrile, but their magnetic properties suggest that they also are polymeric with appreciable metal–metal bonding. However, the electronic spectra of Ti$^{II}$ in TiCl$_2$/AlCl$_3$ melts and also of Ti$^{II}$ incorporated in NaCl crystals (prepared by the reaction of CdCl$_2$ and titanium in molten NaCl and subsequent sublimation of Cd metal) have been shown to be as expected for a $d^2$ ion in an octahedral field.

The versatility of cyanide and bipyridyl ligands has been used to stabilize low oxidation states. By using potassium in liquid ammonia, K$_3$Ti$^{III}$(CN)$_6$ is reduced to K$_2$Ti$^{II}$(CN)$_4$ and TiBr$_3$ + KCN to K$_4$Ti$^{II}$(CN)$_4$. With ZrBr$_3$ and M'CN (M$^I$ = K, Rb) in liquid ammonia, ammonolysis occurs and zerrovalent Zr is produced:

$$4\text{ZrBr}_3 + 5\text{M'}\text{CN} + 6\text{NH}_3 \rightarrow \text{M'}_2\text{Zr(CN)}_5 + 3\text{ZrBr}_3(\text{NH}_2) + 3\text{NH}_4\text{Br}$$

Reduction of MCl$_4$ (M = Ti, Zr) in tetrahydrofuran by lithium in the presence of bipyridyl yields a series of darkly coloured, very air-sensitive compounds of the types [M(bipy)$_3$], Li[M(bipy)$_3$] and Li$_2$[M(bipy)$_3$] with varying amounts of solvent of crystallization, implying oxidation states of 0, −1 and −2. However, delocalization of charge in the $\pi^*$ orbitals of the ligands facilitates reduction of the ligands and assigning oxidation states to the metals under these circumstances is a purely formal exercise. A more “realistic” claim to zero oxidation state in Zr and Hf compounds is provided by [M(\eta$_3$-PhMe)$_2$(PMe$_3$)]. Metal vapour was produced from an “electron-gun furnace” and condensed with an excess of toluene and trimethylphosphine at −196°C. On warming up, a dark-green solution was produced from which the pure solids were isolated.

Ziegler–Natta Catalysts

The original ICI process for producing polythene involved the use of high temperatures and pressures but K. Ziegler discovered that, in the presence of a mixture of TiCl₄ and AlEt₃ in a hydrocarbon solvent, the polymerization will take place at room temperature and atmospheric pressure. G. Natta then showed that by suitable modification of the catalyst stereoregular polymers of almost any alkene (olefin), CH₂=CHR, can be produced. In general, these catalysts can be formed from an alkyl of Li, Be or Al together with a halide of one of the metals of Groups 4 to 6 in an oxidation state less than its maximum. As a result of their work, Ziegler and Natta were jointly awarded the 1963 Nobel Prize for Chemistry. Because of its commercially sensitive nature, much of the voluminous literature on this subject is in the form of patents, but a great deal of work has also been directed at ascertaining the mechanism of the catalyst. The initial reaction of TiCl₄ and AlEt₃ produces insoluble TiCl₃ (alternatively, preformed TiCl₃ can be used). The most plausible sequence of events on the surface of this catalyst is then as illustrated in Fig. A:

(a) one of the chlorine atoms coordinated to a titanium atom is replaced by an ethyl group from AlEt₃,
(b) then, because the titanium atom on the surface of the solid has a vacant coordination site, a molecule of ethylene (ethene) can attach itself;
(c) migration of the ethyl group to the ethylene by a well-known process known as “cis-insertion” occurs.

The result of this cis-insertion is that a vacant site is left behind, and this can be occupied by another ethylene molecule and steps (a) and (b) repeated indefinitely.

The efficacy of the catalyst seems to lie in the fact that in the case of propylene (CH₂=CH–CH₃), for instance, the steric hindrance inherent in the surface coordination sites ensures that the polymer which is produced is stereoregular. Such a stereoregular polymer is stronger and has a higher mp than the non-regular (so-called “atactic”) polymer. Furthermore, while the titanium provides bonds sufficiently strong to be able to hold the olefin and the alkyl in the correct orientations for reaction, they are not so strong as to prevent the migration which is essential to the reaction. For an alternative suggestion for the mechanism of catalysis, see p. 261.

Figure A Possible mechanism of Ziegler–Natta catalyst.

21.3.6 Organometallic compounds

Until the 1950s this was an unexplored area of chemistry, but then two events occurred:

---

27 See pp. 475–547 of ref. 24.
In sharp contrast to the Group 14 elements Ge, Sn and Pb, Group 4 metals form relatively few alkyl and aryl compounds and those which are known are very unstable to both air and water. Thermal stabilization is provided by ligands which lack β-hydrogens (p. 926) or are bulky. Thus MEt₄ are unknown; MMe₄ can be prepared by the reactions of LiMe and MCl₄ in ether at low temperatures, but the yellow titanium and the red zirconium compounds decompose to the metals at temperatures above -20 and -15°C respectively; M(CH₂SiMe₃)₄ of all three metals are stable at room temperature. Another homoletic alkyl is of interest because of its unusual structure. X-ray analysis has shown the anion of [Li(tmed)]₂[ZrMe₆] to be the first ML₆ complex to have a trigonal bipyramidal structure and nmr studies indicate that this is retained in solution.⁴⁸

Perhaps because of inadequate or non-existent back-bonding (p. 923), the only neutral, binary carbonyl so far reported is Ti(CO)₆ which has been produced by condensation of titanium metal vapour with CO in a matrix of inert gases at 10–15 K, and identified spectroscopically. By contrast, if MCl₄ (M = Ti, Zr) in dimethoxy-ethane is reduced with potassium naphthalenide in the presence of a crown ether (to complex the K⁺) under an atmosphere of CO, [M(CO)₆]²⁻ salts are produced.⁴⁹ These not only involve the metals in the exceptionally low formal oxidation state of -2 but are thermally stable up to 200 and 130°C respectively. However, the majority of their carbonyl compounds are stabilized by π-bonded ligands, usually cyclopentadienyl,⁵⁰ as in [M(η⁵-C₅H₅)₂(CO)₂] (Fig. 21.8).

Indeed, it is the cyclopentadienyls which provide the major part of the organometallic chemistry of this group and they are known for metal oxidation states of IV, III and II though III

Figure 21.8 Molecular structure of [M(η⁵-C₅H₅)₂-(CO)₂]. For M = Ti the C₅H₅ rings are “eclipsed” as shown here, but for M = Hf they are “staggered”. Essentially the same structure is found in other [M(η³-C₅H₅)₂L₂] molecules, but the conformation of the two C₅H₅ rings varies in an apparently unsystematic manner.

Figure 21.9 (a) Molecular structure of (a) Ti(C₅H₅)₄. (b) Zr(C₅H₅)₄.

and II are rather sparsely represented for Zr and Hf. The compounds M(C₅H₅)₄ are prepared from MCl₄ and NaC₅H₅ and the structure of the green-black titanium compound is shown in Fig. 21.9a. It is therefore formulated as [Ti(η¹-C₅H₅)₂(η⁵-C₅H₅)₂] (p. 940). Rather surprisingly, the ¹H nmr distinguishes only one type of proton at room temperature and it is evident that fluxional processes render all 20 protons indistinguishable. The yellow hafnium analogue is isostructural but the yellow-orange zirconium compound contains 1 monohapto- and 3 pentahapto-rings, [Zr(η¹-C₅H₅)(η³-C₅H₅)₃] Fig. 21.9b. This formulation is unexpected since it entails a formally 20-electron

---

configuration; the two compounds also provided the first authenticated example of a structural difference in the organometallic chemistries of Zr and Hf.

Best known of all are the bis(cyclopentadienyls) of the type \([\text{M}(\eta^5-\text{C}_5\text{H}_5)_2\text{X}_2]\), the halides being prepared again by the action of NaC\(_5\text{H}_5\) on MC\(_4\). \([\text{Ti}(\eta^5-\text{C}_5\text{H}_5)_2\text{Cl}_2]\) is stable to air, has an extensive aqueous chemistry and is the starting point for most bis(cyclopentadienyl) titanium chemistry. Replacement of \(X\) by SCN, \(\text{N}_3\), \(-\text{NR}_2\), \(-\text{OR}\) or \(-\text{SR}\) is also possible and in all cases the structures are distorted tetrahedral with both rings pentahapto (Fig. 21.8). Interesting derivatives of the type \([\text{C}_5\text{H}_5\text{Ti}(\text{CH}_2)_4]\) have also been produced. Amongst the many other reactions of the dihalides, ring replacement to give compounds such as \([\text{Ti}(\text{C}_5\text{H}_5)_3\text{X}]\) and reductions to \([\text{Ti}(\text{C}_5\text{H}_5)_2\text{X}]\) and \([\text{Ti}(\text{C}_5\text{H}_5)_2]\) may be noted. The last of these is of interest as a potential analogue of ferrocene. Several preparative routes have been suggested, and the usual product is a dark-green, pyrophoric, diamagnetic dimer, though a monomeric isomer may be produced in some cases as an intermediate. The structure of the dimer has been shown by X-ray crystallography\(^{(30a)}\) to be that in Fig. 21.10a, confirming earlier results based on \(^{13}\text{C}\) nmr. Attempts to prepare a zirconium analogue have yielded a variety of products, some dinuclear others polymeric but, as with titanium, no true mononuclear metallocene. A number of cyclopentadienyl and related compounds of titanium and zirconium have been found to absorb molecular nitrogen, which in some cases can be recovered in a reduced form (i.e. as ammonia or hydrazine) upon hydrolysis, and the first example of dinitrogen complexation by a non-cyclopentadienyl Ti system has recently been reported.\(^{(31)}\) While this has obvious interest as a potential route to nitrogen fixation, a compound which can be regenerated and so act catalytically has so far proved elusive.

Although the chemistry of zirconium in its lower oxidation states is still relatively unexplored, it is developing. Examples which offer the possibility of further exploitation include the blue, paramagnetic zirconium(III) compound\(^{(32)}\) \([\text{L}_2\text{Zr}(\mu-\text{Cl})_2\text{ZrL}_2]\) \([\text{L} = \text{C}_5\text{H}_5(\text{SiMe}_3)_2-1,3]\), and the “sandwich” and “half-sandwich” compounds derived from cycloheptatriene: red

---

Amongst these are bis(cyclopentadienyl) and bis(β-diketonate) derivatives, some of which are undergoing clinical trials, in the hope that they will provide more extensive application than cisplatin (pp. 1163–4).

Vanadium, Niobium and Tantalum

22.1 Introduction

The discoveries of all three of these elements were made at the beginning of the nineteenth century and were marked by initial uncertainty and confusion due, in the case of the heavier pair of elements, to the overriding similarity of their chemistries. (See p. 1282 for element 105, dubnium.)

A. M. del Rio in 1801 claimed to have discovered the previously unknown element 23 in a sample of Mexican lead ore and, because of the red colour of the salts produced by acidification, he called it erythronium. Unfortunately he withdrew his claim when, 4 years later, it was (incorrectly) suggested by the Frenchman, H. V. Collett-Desotils, that the mineral was actually basic lead chromate. In 1830 the element was “rediscovered” by N. G. Sefström in some Swedish iron ore. Because of the richness and variety of colours found in its compounds he called it columbium, and the mineral columbite, in honour of its country of origin. Meanwhile in Sweden A. G. Ekeberg was studying some Finnish minerals and in 1802 claimed to have identified a new element which he named tantalum because of the difficulty he had had in dissolving the mineral in acids.† It was subsequently thought that the two elements were one and the same, and this view persisted until at least 1844 when H. Rose examined a columbite sample and showed that two distinct elements were involved.

† The classical allusion refers to Tantalus, the mythical king of Phrygia, son of Zeus and a nymph, who was condemned for revealing the secrets of the gods to man; one of his punishments was being made to stand in Tartarus up to his chin in water, which constantly receded as he stooped to drink. As Ekeberg wrote (1802): “This metal I call tantalum . . . partly in allusion to its incapacity, when immersed in acid, to absorb any and be saturated.”
One was Ekeberg's tantalum and the other he called niobium (Niobe was the daughter of Tantalus). Despite the chronological precedence of the name columbium, IUPAC adopted niobium in 1950, though columbium is still sometimes used in US industry. Impure niobium metal was first isolated by C. W. Blomstrand in 1866 by the reduction of the chloride with hydrogen, but the first pure samples of metallic niobium and tantalum were not prepared until 1907 when W. von Bolton reduced the fluorometallates with sodium.

22.2 The Elements

22.2.1 Terrestrial abundance and distribution

The abundances of these elements decrease by approximately an order of magnitude from V to Nb and again from Nb to Ta. Vanadium has been estimated to comprise about 136 ppm (i.e. 0.0136%) of the earth's crustal rocks, which makes it the nineteenth element in order of abundance (between Zr, 162 ppm, and Cl, 126 ppm); it is the fifth most abundant transition metal after Fe, Ti, Mn and Zr. It is widely, though sparsely, distributed; thus although more than 60 different minerals of vanadium have been characterized, there are few concentrated deposits and most of it is obtained as a coproduct along with other materials. Its major commercial source is the titaniferrous magnetites of South Africa, the former USSR and China. One of its important minerals is the polysulfide, patronite, VS₄, but, being a class-a metal, it is more generally associated with oxygen. For example, vanadinite approximates to lead chloride vanadate, PbCl₂.₃Pb₂(VO₄)₂, and carnotite to potassium uranyl vanadate, K(UO₂)(VO₄)₁.₅H₂O. Vanadium is also found in some crude oils, in particular those from Venezuela and Canada, and can be recovered from the oil residues and from flue dusts after burning.

The crustal abundances of niobium and tantalum are 20 ppm and 1.7 ppm, comparable to N (19 ppm), Ga (19 ppm), and Li (18 ppm), on the one hand, and to As (1.8 ppm) and Ge (1.5 ppm), on the other. Of course, in view of their chemical similarities. Nb and Ta usually occur together, and their most widespread mineral, (Fe,Mn)₂Nb₂O₆ (M = Nb, Ta), is known as columbite or tantalite, depending on which metal preponderates. Until the 1950s, this was the major source of both metals, with significant amounts obtained also as a byproduct of the extraction of tin in SE Asia and Nigeria. The discovery of a huge, high grade (2.5% Nb₂O₅) deposit of pyrochlore, NaCaNb₂O₆F, in Brazil totally changed the pattern. Nb is now obtained chiefly from Brazil; Ta from Australia, Canada and SE Asia but its production is heavily dependent on demand for Sn.

22.2.2 Preparation and uses of the metals

Because it is usually produced along with other metals, the availability of vanadium and the economics of its production are intimately connected with the particular coproduct involved.

The usual extraction procedure is to roast the crushed ore, or vanadium residue, with NaCl or Na₂CO₃ at 850°C. This produces sodium vanadate, NaVO₃, which is leached out with water. Acidification with sulfuric acid to pH 2–3 precipitates "red cake", a polyvanadate which, on fusing at 700°C, gives a black, technical grade vanadium pentoxide. Reduction is then necessary to obtain the metal, but, since about 80% of vanadium produced is used as an additive to steel, it is usual to effect the reduction in an electric furnace in the presence of iron or iron ore to produce ferrovanadium, which can then be used without further refinement. Carbon was formerly used as the reductant, but it is difficult to avoid the formation of an intractable carbide, and so it has been superseded by aluminium or, more commonly, ferrosilicon (p. 330) in which case lime is also added to remove the silica as a slag of calcium silicate. If pure vanadium metal is required it can

---

be obtained by reduction of \( \text{VCl}_5 \) with \( \text{H}_2 \) or \( \text{Mg} \), by reduction of \( \text{V}_2\text{O}_5 \) with \( \text{Ca} \), or by electrolysis of partially refined vanadium in fused alkali metal chloride or bromide.

The benefit of vanadium as an additive in steel is that it forms \( \text{V}_4\text{C}_3 \) with any carbon present, and this disperses to produce a fine-grained steel which has increased resistance to wear and is stronger at high temperatures. Such steels are widely used in the manufacture of springs and high-speed tools. In 1995, world consumption of vanadium metal, alloys and concentrates exceeded 33,000 tonnes of contained vanadium.

Production of niobium and tantalum is on a smaller scale and the processes involved are varied and complicated. Alkali fusion, or digestion of the ore with acids can be used to solubilize the metals, which can then be separated from each other. The process originally developed by M. C. Marignac in 1866 and in use for a century utilized the fact that in dil HF tantalum tends to form the sparingly soluble \( \text{K}_2\text{TaF}_7 \), whereas niobium forms the soluble \( \text{K}_3\text{NbOF}_5\cdot\text{H}_2\text{O} \). Nowadays it is more usual to employ a solvent extraction technique. For instance, tantalum can be extracted from dilute aqueous HF solutions by methyl isobutyl ketone, and increasing the acidity of the aqueous phase allows niobium to be extracted into a fresh batch of the organic phase. The metals can then be obtained, after conversion to the pentoxides, by reduction with \( \text{Na} \) or \( \text{C} \), or by the electrolysis of fused fluorides. In 1995, world production of contained metal was in the region of 18,000 tonnes for Nb and 1000 tonnes for Ta.

Niobium finds use in the production of numerous stainless steels for use at high temperatures, and Nb/Zr wires are used in superconducting magnets. The extreme corrosion-resistance of tantalum at normal temperatures (due to the presence of an exceptionally tenacious film of oxide) leads to its application in the construction of chemical plant, especially where it can be used as a liner inside cheaper metals. Its complete inertness to body fluids makes it the ideal material for surgical use in bone repair and internal suturing.

It is widely used by the electronics industry in the manufacture of capacitors, where the oxide film is an efficient insulator, and as a filament or filament support. Indeed, it was for a while widely used to replace carbon as the filament in incandescent light bulbs but, by about 1911, was, itself superseded by tungsten.

### 22.2.3 Atomic and physical properties of the elements

Some of the important properties of Group 5 elements are summarized in Table 22.1. Having odd atomic numbers, they have few naturally occurring isotopes; Nb only 1 and V and Ta 2 each, though the second ones are present only in very low abundance (\(^{50}\text{V} 0.250\%, \) \(^{180}\text{Ta} 0.012\%). As a consequence (p. 17) their atomic weights have been determined with considerable precision. On the other hand, because of difficulties in removing all impurities, reported values of their bulk properties have often required revision.

All three elements are shiny, silvery metals with typically metallic bcc structures. When very pure they are comparatively soft and ductile but impurities usually have a hardening and embrittling effect. When compared to the elements of Group 4 the expected trends are apparent. These elements are slightly less electropositive and are smaller than their predecessors, and the heavier pair Nb and Ta are virtually identical in size as a consequence of the lanthanide contraction. The extra \( d \) electron again appears to contribute to stronger metal–metal bonding in the bulk metals, leading in each case to a higher mp, bp and enthalpy of atomization. Indeed, these quantities reach their maximum values in this and the following group. In the first transition series, vanadium is the last element before some of the \((n - 1)d\) electrons begin to enter the inert electron-core of the atom and are therefore not available for bonding. As a result, not only is its mp the highest in the series but it is the last element whose compounds in the group oxidation state (i.e. involving all \((n - 1)d\) and \(ns\) electrons) are not strongly oxidizing. In the second and
22.2.4 Chemical reactivity and trends

The elements of Group 5 are in many ways similar to their predecessors in Group 4. They react with most non-metals, giving products which are frequently interstitial and nonstoichiometric, but they require high temperatures to do so. Their general resistance to corrosion is largely due to the formation of surface films of oxides which are particularly effective in the case of tantalum. Unless heated, tantalum is appreciably attacked only by oleum, hydrofluoric acid or, more particularly, a hydrofluoric/nitric acid mixture. Fused alkalis will also attack it. In addition to these reagents, vanadium and niobium are attacked by other hot concentrated mineral acids but are resistant to fused alkali.

The most obvious factor in comparing the chemistry of the three elements is again the very close similarity of the second and third members although, in this group, slight differences can be discerned as will be discussed shortly. The third series the entry of (n – 1)d electrons into the electron core is delayed somewhat and it is molybdenum and tungsten in Group 6 whose mps are the highest.

The most obvious factor in comparing the chemistry of the three elements is again the very close similarity of the second and third members although, in this group, slight differences can be discerned as will be discussed shortly. The stability of the lower oxidation states decreases as the group is descended. As a result, although each element shows formal oxidation states from +5 down to −3, the most stable one in the case of vanadium under normal conditions is the +4, and even the +3 and +2 oxidation states (which are admittedly strongly reducing) have well-characterized cationic aqueous chemistries; by contrast most of the chemistries of niobium and tantalum are confined to the group oxidation state +5. Of the halogens, only the strongly oxidizing fluorine produces a pentahalide of vanadium, and the other vanadium(V) compounds are based on the oxohalides and the pentoxide. The pentoxide also gives rise to the complicated but characteristic aqueous chemistry of the polymerized vanadates (isopolyvanadates) which anticipates the even more extensive chemistry of the polymolybdates and polytungstates; this is only incompletely mirrored by niobium and tantalum.

The +4 oxidation state, which for Nb and Ta is best represented by their halides, is most notable for the uniquely stable VO²⁺ (vanadyl) ion which retains its identity throughout a wide variety of reactions and forms many complexes. Indeed it is probably the most stable diatomic ion known. The M⁴⁺ ions have only slightly smaller radii...

(a)Tetraakis(dithioacetato)vanadium(V) was originally classified as dodecahedral. Re-examination has shown that its unit cell in fact contains two independent metal sites. One is indeed dodecahedral but the other is square antiprismatic; C. W. HAIGH, Polyhedron 14, 2871–8 (1995).

than those of Group 4, and, again, coordination numbers as high as 8 are found. In the +5 state, however, only Nb and Ta are sufficiently large to achieve this coordination number with ligands other than bidentate ones with very small “bites”, such as the peroxo group. Table 22.2 illustrates the various oxidation states and stereochemistries of compounds of V, Nb and Ta.

Niobium and tantalum provide no counterpart to the cationic chemistry of vanadium in the +3 and +2 oxidation states. Instead, they form a series of “cluster” compounds based on octahedral M₆X₁₂ units. The occurrence of such compounds is largely a consequence of the strength of metal–metal bonding in this part of the periodic table (as reflected in high enthalpies of atomization), and similar cluster compounds are found also for molybdenum and tungsten.

Compounds containing M–C σ-bonds are frequently unstable and do not give rise to an extensive chemistry (p. 999). Vanadium forms a neutral (paramagnetic) hexacarbonyl which, though not very stable, contrasts with that of titanium in that it can at least be prepared in
quantity. All three elements give a number of \( \eta^5 \)-cyclopentadienyl derivatives.

22.3 Compounds of Vanadium, Niobium and Tantalum\(^{(2,3)}\)

The binary hydrides (p. 67), borides (p. 148), carbides (p. 299), and nitrides (p. 418) of these metals have already been discussed and will not be described further except to note that, as with the analogous compounds of Group 4, they are hard, refractory and nonstoichiometric materials with high conductivities. The intriguing cryo-compound \([V(N_2)_6]\) has been isolated by cocondensing V atoms and \(N_2\) molecules at 20–25 K; it has an infrared absorption at 2100 cm\(^{-1}\) and its d-d and charge-transfer spectra are strikingly similar to those of the isoelectronic 17-electron species \([V(CO)_6]\).

22.3.1 Oxides

Table 22.3 gives the principal oxides formed by the elements of this group. Besides the 4 oxides of vanadium shown, a number of other phases of intermediate composition have been identified and the lower oxides in particular have wide ranges of homogeneity. \(V_2O_5\) is orange yellow when pure (due to charge transfer) and is the final product when the metal is heated in an excess of oxygen, but contamination with lower oxides is then common and a better method is to heat ammonium “metavanadate”:

\[
2NH_4VO_3 \rightarrow V_2O_5 + 2NH_3 + H_2O
\]

On the basis of simple radius ratio arguments, vanadium(V) is expected to be rather large for tetrahedral coordination to oxygen, but rather small for octahedral coordination. It is perhaps not surprising therefore that, though the structure of \(V_2O_5\) is somewhat complicated, it consists essentially of distorted trigonal bipyramids of \(V_2O_5\) sharing edges to form zigzag double chains. Another, metastable, form has been prepared which differs from the normal one in the relative dispositions of adjacent parallel chains.\(^{(4)}\) \(V_2O_5\) is homogeneous over only a small range of compositions but loses oxygen reversibly on heating, which is probably why it is such a versatile catalyst. For instance, it catalyses the oxidation of numerous organic compounds by air or hydrogen peroxide, and the reduction of olefins (alkenes) and of aromatic hydrocarbons by hydrogen, but most importantly it catalyses the oxidation of \(SO_2\) to \(SO_3\) in the contact process for the manufacture of sulfuric acid (p. 708). For this purpose it replaced metallic platinum which, besides being far more expensive, was also prone to “poisoning” by impurities such as arsenic. \(V_2O_5\) is amphoteric. It is slightly soluble in water, giving a pale yellow, acidic solution. It dissolves in acids producing salts of the pale-yellow dioxovanadium(V) ion, \([VO_2]^+\), and in alkalis producing colourless solutions which, at high pH, contain the orthovanadate ion, \(VO_4^{3-}\). At intermediate pHs a series of hydrolysis-polymerization reactions occur yielding the isopolyvanadates to be discussed in the next section. It is also a mild oxidizing agent and in aqueous solution is reduced by, for instance, hydrohalic acids to vanadium(IV). In the solid, mild reduction with \(CO\), \(SO_2\), or fusion with oxalic acid gives the deep-blue \(VO_2\).

At room temperature \(VO_2\) has a rutile-like structure (p. 961) distorted by the presence of pairs of vanadium atoms bonded together. Above 70°C, however, an undistorted rutile

---

structure is adopted as the atoms in each pair separate, breaking the localized V–V bonds and releasing the bonding electrons, so causing a sharp increase in electrical conductivity and magnetic susceptibility. It is again amphoteric, dissolving in non-oxidizing acids to give salts of the blue oxovanadium(IV) (vanadyl) ion \([\text{VO}^{2+}]\), and in alkali to give the yellow to brown vanadate(IV) (hypovanadate) ion \([\text{VO}_4^{3-}]\) or at high pH \([\text{VO}_4^{4-}]\). Like the vanadium(V) system, a number of polyanions are produced at intermediate pH. Between V\(_2\)O\(_5\) and V\(_2\)O\(_3\) is a succession of phases V\(_{n}\)O\(_{2n+1}\) of which V\(_3\)O\(_7\), V\(_4\)O\(_9\) and V\(_5\)O\(_{13}\) have been characterized.

Further reduction with H\(_2\), C or CO produces a series of discrete chemical-shear phases (Magnéli phases) of general formula V\(_n\)O\(_{2n+1}\) based on a rutile structure with periodic defects (p. 961), before the black, refractory sesquioxide V\(_2\)O\(_3\) is reached. Examples are V\(_4\)O\(_7\), V\(_5\)O\(_9\), V\(_6\)O\(_{11}\), V\(_7\)O\(_{13}\) and V\(_8\)O\(_{15}\). The oxides VO, V\(_2\)O\(_3\) and V\(_3\)O\(_5\) also conform to the general formula V\(_n\)O\(_{2n+1}\), but this is a purely formal relation and their structures are not related by chemical-shear to those of the Magnéli phases.

V\(_2\)O\(_3\) has a corundum structure (p. 243) and is notable for the transition occurring as it is cooled below about 170 K when its electrical conductivity changes from metallic to insulating in character. Chemically it is entirely basic, dissolving in aqueous acids to give blue or green vanadium(III) solutions which are strongly reducing. On still further reducing the oxide system, the corundum structure is retained down to compositions as low as VO\(_{1.35}\), after which the grey metallic monoxide VO, with a defect rock-salt structure, is formed. This too is markedly nonstoichiometric with a composition range from VO\(_{0.8}\) to VO\(_{1.3}\). In all, therefore, at least 13 distinct oxide phases of vanadium have been identified between VO\(_{1.1}\) and V\(_2\)O\(_3\).

Niobium and tantalum also form various oxide phases but they are not so extensive or well characterized as those of vanadium. Their pentoxides are relatively much more stable and difficult to reduce. As they are attacked by conc HF and will dissolve in fused alkali, they may perhaps be described as amphoteric, but inertness is the more obvious characteristic. Their structures are extremely complicated and Nb\(_2\)O\(_5\) in particular displays extensive polymorphism. It is interesting to note that the polymorphs of Nb\(_2\)O\(_5\) and Ta\(_2\)O\(_5\) are by no means all analogous.

High temperature reduction of Nb\(_2\)O\(_5\) with hydrogen gives the bluish-black dioxide NbO\(_2\) which has a distorted rutile structure. As in V\(_2\)O\(_3\) the distortion is caused by pairs of metal atoms evidently bonded together, but the distortion is in a different direction. Between Nb\(_2\)O\(_5\) and NbO\(_2\) there is a homologous series of structurally related phases of general formula Nb\(_{3n+1}\)O\(_{8n-2}\) with \(n = 5, 6, 7, 8\) (i.e. Nb\(_{19}\)O\(_{46}\), Nb\(_{11}\)O\(_{27}\) and Nb\(_{25}\)O\(_{62}\)). In addition, oxides of formula Nb\(_{12}\)O\(_{29}\) and Nb\(_{47}\)O\(_{116}\) have been reported: the numerical relationship to Nb\(_2\)O\(_5\) is clear since Nb\(_{12}\)O\(_{29}\) is (12Nb\(_2\)O\(_5\)-2O) and 2Nb\(_{47}\)O\(_{116}\) (or Nb\(_{94}\)O\(_{232}\)) is (47Nb\(_2\)O\(_5\)-3O). Further reduction produces the grey monoxide NbO which has a cubic structure and metallic conductivity but differs markedly from its vanadium analogue in that its composition range is only NbO\(_{0.982}\) to NbO\(_{1.008}\). The structure is a unique variant of the rock-salt NaCl structure (p. 242) in which there are vacancies (Nb) at the eight corners of the unit cell and an O vacancy at its centre (Fig. 22.1). The structure could therefore be described as a vacancy-defect NaCl structure Nb\(_{0.75}\)O\(_{0.25}\)O\(_{0.75}\)O\(_{0.25}\), but as all the vacancies are ordered it is better to consider it as a new structure type in which both Nb and O form 4 coplanar bonds. The central feature is a 3D framework of Nb\(_6\) octahedral clusters (Nb–Nb 298 pm, cf. Nb–Nb 285 pm in Nb metal) and this accounts for the metallic conductivity of the compound. The structure is reminiscent of the structure-motif of the lower halides of Nb and Ta (p. 992) and the retention of the Nb\(_6\) clusters rather than the adoption of the ionic NaCl-type structure can similarly be related to the high heats of sublimation of Nb and neighbouring metals.

(For a fuller discussion of the bonding, see ref. 5.)

The heavier metal tantalum is distinctly less inclined than niobium to form oxides in lower oxidation states. The rutile phase TaO₂ is known but has not been studied, and a cubic rock-salt-type phase TaO with a narrow homogeneity range has also been reported but not yet fully characterized. Ta₂O₅ has two well-established polymorphs which have a reversible transition temperature at 1355°C but the detailed structure of these phases is too complex to be discussed here.

22.3.2 Polymetallates

The amphoteric nature of V₂O₅ has already been noted. In fact, if the colourless solution produced by dissolving V₂O₅ in strong aqueous alkali such as NaOH is gradually acidified, it first deepens in colour, becoming orange to red as the neutral point is passed; it then darkens further and, around pH 2, a brown precipitate of hydrated V₂O₅ separates and redissolves at still lower pHs to give a pale-yellow solution. As a result of spectrophotometric studies there is general agreement that the predominant species in the initial colourless solution is the tetrahedral VO₄³⁻ ion and, in the final pale-yellow solution, the angular VO₂⁺ ion. In the intervening orange to red solutions a complicated series of hydrolysis-polymerization reactions occur, which have direct counterparts in the chemistries of Mo and W and to a lesser extent Nb, Ta and Cr. The polymerized species involved are collectively known as isopolymetallates or isopolyanions. The determination of the equilibria involved in their formation, as well as their stoichiometries and structures, has been a confused and disputed area, some aspects of which are by no means settled even now. That this is so is perfectly understandable because:

(i) Some of the equilibria are reached only slowly (possibly months in some cases) and it is likely that much of the reported work has been done under non-equilibrium conditions.

(ii) Often in early work, solid species were crystallized from solution and their stoichiometries, quite unjustifiably as it turns out, were used to infer the stoichiometries of species in solution.

(iii) When a series of experimental measurements has been made it is usual to see what combination of plausible ionic species will best account for the

---

observed data. However, the greater the complexity of the system, the greater the number of apparently acceptable models there will be, and the greater the accuracy required if the measurements are to distinguish reliably and unambiguously between them.

Of the many experimental techniques which have been used in this field, the more important are: pH measurements, cryoscopy, ion-exchange and ultraviolet/visible spectroscopy for studying the stoichiometry of the equilibria, and infrared/Raman and nmr spectroscopy for studying the structures of the ions in solution, where oxygen-17 and metal atom nmr spectroscopy are playing an increasingly important role. Probably the best summary of our current understanding of the vanadate system is given by Fig. 22.2. This shows how the existence of the various vanadate species depends on the pH and on the total concentration of vanadium. Their occurrence can be accounted for by protonation and condensation equilibria such as the following:

In alkaline solution:

\[
\begin{align*}
[\text{VO}_4^{3-}] + \text{H}^+ & \rightleftharpoons [\text{HVO}_4^{2-}] \\
2[\text{HVO}_4^{2-}] & \rightleftharpoons [\text{V}_2\text{O}_7^{4-}] + \text{H}_2\text{O} \\
[\text{HVO}_4^{2-}] + \text{H}^+ & \rightleftharpoons [\text{H}_2\text{VO}_4^-] \\
3[\text{H}_2\text{VO}_4^-] & \rightleftharpoons [\text{V}_3\text{O}_9^{3-}] + 3\text{H}_2\text{O} \\
4[\text{H}_2\text{VO}_4^-] & \rightleftharpoons [\text{V}_4\text{O}_{12}^{4-}] + 4\text{H}_2\text{O}
\end{align*}
\]

In acid solution:

\[
\begin{align*}
10[\text{V}_3\text{O}_9^{3-}] + 15\text{H}^+ & \rightleftharpoons 3[\text{HV}_{10}\text{O}_{28}^{5-}] + 6\text{H}_2\text{O} \\
[\text{H}_2\text{VO}_4^-] + \text{H}^+ & \rightleftharpoons \text{H}_3\text{VO}_4 \\
[\text{HV}_{10}\text{O}_{28}^{5-}] + \text{H}^+ & \rightleftharpoons [\text{H}_2\text{V}_{10}\text{O}_{28}^{6-}] \\
\text{H}_3\text{VO}_4 + \text{H}^+ & \rightleftharpoons \text{VO}_2^+ + 2\text{H}_2\text{O} \\
[\text{H}_2\text{V}_{10}\text{O}_{28}^{6-}] + 14\text{H}^+ & \rightleftharpoons 10\text{VO}_2^+ + 8\text{H}_2\text{O}
\end{align*}
\]

In these equilibria the site of protonation in the species \([\text{HVO}_4^{2-}], [\text{H}_2\text{VO}_4^-]\) etc., is an oxygen atom (not vanadium); a more precise representation would therefore be \([\text{VO}_3(\text{OH})]^2-\), \([\text{VO}_2(\text{OH})_2]^\text{--}\) etc. However, the customary formulation is retained for convenience (cf. \(\text{HNO}_3, \text{HSO}_4^-, \text{H}_2\text{SO}_4\), etc.).

![LIVE GRAPH](image)

**Figure 22.2** Occurrence of various vanadate and polyvanadate species as a function of pH and total concentration of vanadium.
It is evident from Fig. 22.2 that only in very dilute solutions are monomeric vanadium ions found and any increase in concentrations, particularly if the solution is acidic, leads to polymerization. $^{51}$V nmr work indicates that, starting from the alkaline side, the various ionic species are all based on 4-coordinate vanadium(V) in the form of linked VO$_4$ tetrahedra until the decavanadates appear. These evidently involve a higher coordination number, but whether or not it is the same in solution as in the solids which can be separated is uncertain. However, it is interesting to note that similarities between the vanadate and chromate systems cease with the appearance of the decavanadates which have no counterpart in chromate chemistry. The smaller chromium(VI) is apparently limited to tetrahedral coordination with oxygen, whereas vanadium(V) is not.

More information is of course available on the structures of the various crystalline vanadates which can be separated from solution. Traditionally, the colourless salts obtained from alkaline solution were called ortho-, pyro-, or meta-vanadates by analogy with the phosphates of corresponding stoichiometry. “Ortho”-vanadates, M$_3$VO$_4$(aq), apparently contain discrete, tetrahedral, VO$_4^{3-}$ ions; “pyro”-vanadates, M$_4$V$_2$O$_7$(aq), contain dinuclear [V$_2$O$_7$$^{3-}$] ions consisting of 2 VO$_4$ tetrahedra sharing a corner; the structures of “meta”-vanadates depend on the state of hydration (Fig. 22.3) but in no cases do they involve discrete VO$_3^{3-}$ ions. Anhydrous metavanadates such as NH$_4$VO$_3$ contain infinite chains of corner-linked VO$_4$ tetrahedra, while hydrated metavanadates, such as KVO$_3$.H$_2$O, contain infinite chains of approximately trigonal bipyramidal VO$_3$ units, not unlike those in V$_2$O$_5$. From the bright orange, acidic solutions, orange, crystalline decavanadates such as Na$_6$V$_{10}$O$_{28}$.18H$_2$O are obtained: the anion [V$_{10}$O$_{28}$$^{6-}$] is made up of 10 VO$_6$ octahedra, two representations of which are shown in Fig. 22.2. $^{51}$V and $^{17}$O nmr evidence shows that this is present in solution, and it can also be crystallized$^{10}$ in which outer oxygen atoms of the polyanion are protonated$^{\dagger}$, while refluxing the tetra-n-butyl ammonium salt of the decavanadate in acetonitrile has been shown$^{11}$ to yield the dark-red inclusion compound [(n-C$_4$H$_9$N)$_4$[MeCN$\subset$(V$_{12}$O$_{32}$)$^{3+}$] in which the MeCN molecule sits inside the now basket-shaped polyanion.

Because of potential applications in catalysis and in providing convenient models for biological systems (for example, the chemical similarities of VO$_{n+}$ and Fe$^{n+}$ may be harnessed to study iron storage and transport proteins), a more diverse chemistry has so far been developed for reduced polyvanadates exhibiting a whole range of V$^V$ to V$^IV$ ratios. At the reduced extreme of this range, prolonged heating (4 days at 200°C) of NH$_4$VO$_3$ and EtC(CH$_2$OH)$_3$ produces black crystals of the V$^IV$ compound$^{11}$ (NH$_4$)$_4$[V$_{16}$O$_{16}$[EtC(CH$_2$O)$_3$]$_4$].4H$_2$O, in the anion of which, twelve of the oxygen atoms in the V$_{10}$O$_{28}$ cluster are provided by bridging alkoxy groups. The same research workers have also used this hydrothermal technique to prepare another decavanadate(IV) material which contains chiral, interpenetrating double helices of vanadium phosphate units.$^{12}$ Still higher nuclearity is found in the dark brown M$_{12}$[V$_{18}$O$_{42}$].nH$_2$O crystallized from alkaline solutions of VO$_2$. The anion consists this time of VO$_5$ square pyramids, the bases of which by corner- and edge-sharing form an almost spherical cavity of diameter $\sim$450 pm (Fig. 22.3f). It has the extraordinary ability to encapsulate negatively charged ions, as in

$\dagger$ Although protonation usually occurs on outer oxygen atoms (Fig. 22.3e), an exception is provided by [NH$_3$(C$_6$H$_{13}$)][V$_{10}$O$_{28}$H$_2$] in which the protons have been located on triply linked, inner oxygen atoms. See P. ROMAN, A. ARANZABE, A. LUCUE, J. M. G.-ZORILLA and M. M.-RIPOLL, J. Chem. Soc., Dalton Trans., 2225-31 (1995).

(a) Anhydrous metavanadates, (e.g. $\text{NH}_2\text{VO}_3$) consisting of infinite chains of corner-shared $\text{VO}_4$ tetrahedra.

(b) Hydrated metavanadates, (e.g. $\text{KVO}_3\cdot\text{H}_2\text{O}$) consisting of infinite chains of edge-shared $\text{VO}_5$ trigonal bipyramids.

(c) The $[\text{M}_6\text{O}_{19}]^{8-}$ (M = Nb, Ta) ions made up of 6 $\text{MO}_6$ octahedra (one is obscured).

(d) The decavanadate, $[\text{V}_{10}\text{O}_{28}]^{6-}$, ion made up of 10 $\text{VO}_6$ octahedra (2 are obscured).

(e) An alternative representation of $[\text{V}_{10}\text{O}_{28}]^{6-}$ emphasizing the $\text{V}–\text{O}$ bonds.

(f) Polyhedral cavity of $[\text{V}_{10}\text{O}_{28}]^{12-}$. Each square represents the base of a $\text{VO}_3$ unit whose apex points outwards; and the triangles are "gaps" between pyramids.

**Figure 22.3** The structures of some isopoly-anions in the solid state using, where relevant, the conventional representation in which each polyhedron contains a metal atom and each vertex of a polyhedron represents an oxygen atom.

the compounds,\(^{(13)}\) $\text{M}_n[\text{H}_4\text{V}_{18}\text{O}_{42}\text{X}].n\text{H}_2\text{O}$ ($\text{M} = \text{Cs}, n = 12, \text{X} = \text{Br, I}; \text{M} = \text{K}, n = 16, \text{X} = \text{Cl}$). Amongst the mixed, $\text{V}^\text{V}, \text{V}^\text{IV}$ polyvanadates nuclearities up to 34 have been attained,\(^{(14)}\) as in $\text{K}_{10}[\text{V}_{34}\text{O}_{82}].2\text{O}_2\text{H}_2\text{O}$. In these materials the coordination of the metal can be octahedral ($\text{V}^\text{V}, \text{V}^\text{IV}$), square pyramidal ($\text{V}^\text{V}, \text{V}^\text{IV}$), trigonal bipyramidal ($\text{V}^\text{V}$) and tetrahedral ($\text{V}^\text{V}$), and the magnetic moment per $\text{V}^\text{IV}$ atom decreases as the proportion of $\text{V}^\text{IV}$ atoms increases (indicating increasing $\text{M}–\text{M}$ interaction). To rationalize this rich variety of structures it has been suggested\(^{(15)}\) that they may be conceptually derived from that of $\text{V}_2\text{O}_5$.

Heteropolyanions, in which an atom of a different element is incorporated, usually at the centre of a cage-like structure, are most abundant in Group 6 (p. 1013) but increasing numbers are to

be found in this group also. For vanadium(V) the [XV₁₄O₄₂]⁹⁻ ions (X = P, As) are composed of an X atom tetrrahedrally coordinated to four oxygen atoms at the centre of a "Keggin" anion (p. 1014) which is capped by two VO groups.(16) Reduced species, because of their lower overall anionic charge, allow the formation of clusters of higher nuclearity and several of these have been reported.(8)

Fusion of Nb₂O₅ and Ta₂O₅ with an excess of alkali hydroxides or carbonates, followed by dissolution in water, produces solutions of isopolyanions but not in the variety produced with vanadium. It appears that, down to pH 11, [M₆O₁₉]⁻ ions are present; in the case of niobium protonation occurs at lower pH to give [HNNb₆O₁₉]⁻. The presence of discrete MO₄³⁻ ions in strongly alkaline solutions is uncertain. Below pH ~ 7 for Nb and pH ~ 10 for Ta, precipitation of the hydrous oxides occurs. Salts such as K₅M₆O₁₉.16H₂O can be crystallized from the alkaline solutions and contain [M₆O₁₉]⁻ ions which are made up of octahedral groupings of 6 MO₆ octahedra (Fig. 22.3). A decaniobate, exactly analogous to the decavanadate, has also been isolated and it is possible that such species exist also in solution at low pH.

Most niobates and tantalates, however, are insoluble and may be regarded as mixed oxides in which the Nb or Ta is octahedrally coordinated and with no discrete anion present. Thus KMO₃, known inaccurately (since they have no discrete MO₃⁻ anions) as metaniobates and metatantalates, have the perovskite (p. 963) structure. Several of these perovskites have been characterized and some have ferroelectric and piezoelectric properties (p. 57). Because of these properties, LiNbO₃ and LiTaO₃ have been found to be attractive alternatives to quartz as "frequency filters" in communications devices.

A number of nonstoichiometric “bronzes” are also known(17) which, like the titanium bronzes already mentioned (p. 964) and the better known tungsten bronzes (p. 1016), are characterized by very high electrical conductivities and characteristic colours. For instance, SrₓNbO₃ (x = 0.7–0.95) varies in colour from deep blue to red as the Sr content increases. Fusion of mixtures of appropriate oxides of niobium and alkali metals produces black powders (shiny, golden single crystals) of NaNbO₁₈ (metallic conductance)(18) and KNbO₁₄ (semiconductor),(19) both of which are made up of NbVO₆ octahedra and Nb₆O₁₄ clusters analogous to the M₆X₁₂ halide cluster (p. 992). LiₓNbO₂ (x ~ 0.5) has been shown(20) to be a superconductor below 5 K, and is notable as the first superconductor involving an early transition metal oxide which has a layered rather than a 3D structure. It is, indeed, the search for better superconductors and battery electrode materials which is responsible for the upsurge in interest in early transition metal oxides, and further expansion of this area of chemistry is to be expected.

### 22.3.3 Sulfides, selenides and tellurides

All three metals form a wide variety of binary chalcogenides which frequently differ both in stoichiometry and in structure from the oxides. Many have complex structures which are not easily described, and detailed discussion is therefore inappropriate. The various sulfide phases are listed in Table 22.4: phases approximating to the stoichiometry MS have the NiAs-type structure (p. 556) whereas MS₂ have layer lattices related to MoS₂ (p. 1018), CdI₂, or CdCl₂ (p. 1212). Sometimes complex layer-sequences occur in which the 6-coordinate metal atom is alternatively octahedral and trigonal prismatic. Most of the phases exhibit

Metallic conductivity and magnetic properties range from diamagnetic (e.g. VS<sub>4</sub>), through paramagnetic (VS, V<sub>2</sub>S<sub>3</sub>), to antiferromagnetic (V<sub>7</sub>S<sub>8</sub>). Selenides and tellurides show a similar profusion of stoichiometries and structural types (Table 22.5).

In addition to these binary chalcogenides, many of which exist over wide ranges of composition because of the structural relation between the NiAs and CdI<sub>2</sub> structure types (p. 556), several ternary phases have been studied. Some, like BaVS<sub>3</sub> and BaTaS<sub>3</sub> have three-dimensional structures in which the Ba and V(Ta) are coordinated by 12 and 6 S atoms respectively. Other compounds such as the easily hydrolysed (NH₄)₃VS<sub>4</sub>, which has been known for over a century, and M<sub>3</sub>VS<sub>4</sub> (M = Na, K, Tl) prepared by heating stoichiometric amounts of the elements under vacuum<sup>21</sup> contain the discrete, tetrahedral [VS<sub>4</sub>]<sup>3-</sup> anion. The cluster chemistry of the thiometallates of this group, however, is not comparable to that of the oxometallates. It is very limited and whereas, for instance, (Et<sub>4</sub>N)<sub>3</sub>[M₆S₁₇]<sup>4-</sup>·3CH₃CN (M = Nb, Ta) contains a discrete [M₆S₁₇]<sup>4-</sup> anion,<sup>22</sup> the stoichiometrically analogous M<sub>4</sub>Nb₆O₁₇·0.3H₂O has an extended structure.

22.3.4 Halides and oxohalides

The known halides of vanadium, niobium and tantalum, are listed in Table 22.6. These are illustrative of the trends within this group which have already been alluded to. Vanadium(V) is only represented at present by the fluoride, and even vanadium(IV) does not form the iodide, though all the halides of vanadium(III) and vanadium(II) are known. Niobium and tantalum, on the other hand, form all the halides in the high oxidation state, and are in fact unique (apart only from protactinium) in forming pentafluorides. However in the +4 state, tantalum fails to form a fluoride and neither metal produces a trifluoride. In still lower oxidation states, niobium and tantalum give a number of (frequently nonstoichiometric) cluster compounds which can be considered to involve fragments of the metal lattice.

(a) Niobium and Ta also form a number of polynuclear halides in which the metal has non-integral oxidation states (see text).

VF₅ and all pentahalides of Nb and Ta can be prepared conveniently by direct action of the appropriate halogen on the heated metal. They are all relatively volatile, hydrolysable solids (indicative of the covalency to be anticipated in such a high oxidation state) in which the metals attain octahedral coordination by means of halide bridges (Fig. 22.4). VF₅ is an infinite chain polymer, whereas NbF₅ and TaF₅ are tetramers, and the chlorides and bromides are dimers. The colours vary from white fluorides, yellow chlorides, and orange bromides, to brown iodides. The decreasing energy of the charge-transfer bands responsible for these colours is a reflection of the increasing polarizability of the anions from F⁻ to I⁻, and for each anion usually the least readily reduced Ta produces the palest colour. All the pentahalides can be sublimed in an atmosphere of the appropriate halogen and they are then monomeric, probably trigonal bipyramidal. Potentially they are all Lewis acids but their ability to form adducts (LMX₅) diminishes and the iodides rarely do so.

The tetrahalides can be prepared by direct action of the elements. However, whereas VF₄ tends to disproportionate into VF₅ + VF₃ and must be sublimed from them, VCl₄ and VBr₄ tend to dissociate into VX₃ + ½X₂ and so require the presence of an excess of halogen. Even so, VBr₄ has only been isolated by quenching the mixed vapours at -78°C. VF₄ is a bright-green hygroscopic solid, probably consisting of fluorine-bridged VF₆ octahedra. VCl₄ is a red-brown oil, rapidly hydrolysed by water to give solutions of oxovanadium(IV) chloride, and magnetic and spectroscopic evidence indicate that
it consists of unassociated tetrahedral molecules. As far as its properties are known, the magenta-coloured VBr₄ is similar.

The Nb and Ta tetrahalides (except TaF₄ which is unknown, and NbI₄ which is prepared by thermal decomposition of NbI₅) are generally prepared by reduction of the corresponding pentahalide and are all readily hydrolysed. NbF₄ is a black involatile solid and its low magnetic moment suggests extensive metal–metal interaction, presumably via the intervening F⁻ ions since it consists of infinite sheets of NbF₆ octahedra (Fig. 22.5a). The chlorides, bromides and iodides are brown to black solids with a chain structure (Fig. 22.5b) in which pairs of metal atoms are displaced towards each other, so facilitating the interaction which leads to their diamagnetism.

The vanadium trihalides are all crystalline, polymeric solids in which the vanadium is 6-coordinate.VF₃ is prepared by the action of HF on heated VCl₃ and this, along with VBr₃ and VI₃, can be prepared by direct action of the elements under appropriate conditions. They are coloured and have magnetic moments slightly lower than the spin-only value of 2.83 BM corresponding to 2 unpaired electrons. Apart from the trifluoride, which is not very readily oxidized nor very soluble in water, they are easily oxidized by air and are very hygroscopic, forming aqueous solutions of [V(H₂O)₆]³⁺. As with the other lower halides of Nb and Ta, the trihalides are obtained by reduction or thermal decomposition of their pentahalides. Despite claims for the existence of NbF₃ and TaF₃ it is probable that these blue materials are

Figure 22.4 Alternative representations of: (a) infinite chains of vanadium atoms in VF₅, (b) tetrameric structures of NbF₅ and TaF₅, and (c) dimeric structure of MX₅ (M = Nb, Ta; X = Cl, Br).
Figure 22.5 Alternative representations of: (a) the sheet structure of NbF$_4$ and (b) the chain structure of MX$_4$ (M = Nb, Ta; X = Cl, Br, I) showing the displacement of the metal atoms which leads to diamagnetism.

actually oxide fluorides but, because O$^{2-}$ and F$^-$ are isoelectronic and very similar in size, they are difficult to distinguish by X-ray methods. The remaining 5 known trihalides of this pair of metals are dark coloured, rather unreactive materials. The Nb–Cl system has been the most thoroughly studied but the others appear to be entirely analogous. They are nonstoichiometric and the composition “MX$_3$” is best considered as a single unexceptional point within a broad homogeneous phase based on hcp halide ions. At one extreme is M$_3$X$_8$ (i.e. MX$_{2.67}$) in which one-quarter of the octahedral sites are empty and the others occupied by triangular groups of metal atoms. Of the 15 valence electrons provided by the 3 metal atoms, 8 are lost by ionization and transfer to the 8 Cl atoms and, of the remaining 7 available for metal–metal bonding, 6 are considered to be in bonding orbitals and 1 in a nonbonding orbital. This accounts for the magnetic moment of 1.86 BM for each trinuclear cluster in Nb$_3$Cl$_8$. Metal deficiency then produces stoichiometries to somewhat beyond MX$_3$ (i.e. MX$_{2.67}$–X$_8$) after which the MX$_4$ phase separates, containing pairs of interacting metal atoms, as already mentioned (i.e. M$_2$X$_8$).

In the still lower oxidation state, +2, the halides of vanadium on the one hand, and niobium and tantalum, on the other, diverge still further. The dihalides of V are prepared by reduction of the corresponding trihalides and have simple structures based on the close-packing of halide ions: the rutile structure (p. 961) for VF$_2$, and the CdI$_2$ structure (p. 1212) for the others. They are strongly reducing and hygroscopic, dissolving in water to give lavender-coloured solutions of [V(H$_2$O)$_6$]$_2^{2+}$. By contrast, high-temperature reductions of NbX$_5$ or TaX$_5$ with the metals (or Na or Al) yield a series of phases based on [M$_6$X$_{12}$]$^{n+}$ units consisting of octahedral clusters of metal atoms with the halogen atoms situated above each edge of the octahedra (Fig. 22.6). These may be surrounded by:

(a) Four similar units, with each of which a halogen atom is shared, producing a sheet structure with the composition [M$_6$X$_{12}$]X$_{4/2}$ = M$_6$X$_{14}$ (i.e. MX$_{2.3}$). These compounds are diamagnetic as a result of the metal–metal bonding.

(b) Six similar units, with each of which a halogen atom is shared, producing a
By incorporation of alkali metal halides in the reaction mix, materials of composition $M_4^+[M_6X_{12}]$ can be produced in which each $M_6X_{12}$ unit has a further six X atoms attached to its apices, so forming discrete clusters. Many of these cluster compounds are water-soluble and yield solutions in which the clusters are retained throughout chemical reactions. These reactions include attachment of a variety of ligands at the apical (or "terminal") sites as well as reversible oxidations of the clusters. Thus, it has been possible to isolate $\text{Rb}_4[\text{Nb}_4\text{Br}_{12}(\text{N}_3)_{6}] \cdot 2\text{H}_2\text{O}$ from aqueous methanolic solutions, and from aqueous alcoholic solutions of $[M_6X_{12}]X_2 \cdot 8\text{H}_2\text{O}$ ($M = \text{Nb, Ta}; X = \text{Cl, Br}$) the insoluble, diamagnetic compounds $[M_6X_{12}(\text{ROH})_6]X_2$. In these compounds all the terminal coordination sites are occupied by azide groups and aliphatic alcohols respectively. In addition $[M_6X_{12}]^{2+}$ (diamagnetic) can also be oxidized to $[M_6X_{12}]^{3+}$ (1 unpaired electron) and then to $[M_6X_{12}]^{4+}$ (diamagnetic), and compounds such as $M_6X_{14}$, $M_6X_{15}$ and $M_6X_{16}$, usually with 7 or 8 molecules of $\text{H}_2\text{O}$, can be crystallized. Although terminal ligands are generally more labile than the bridging halogen atoms, isomers of the green $[\text{Ta}_6\text{Cl}_{12}(\mu-\text{Cl})_2(\text{PR}_3)_4]$ in which the terminal chlorines are either cis or trans have been isolated by column chromatography. The isomerism was then retained when the individual isomers were oxidized by NOBF$_4$ or AgBF$_4$ to the orange to brown BF$_4^-$ salts of $[\text{Ta}_6\text{Cl}_{12}(\mu-\text{Cl})_2(\text{PR}_3)_4]^{n+}$ ($n = 1, 2$).

The $[M_6X_8]$ cluster unit in which halogen atoms are situated above each face of the $M_6$ octahedron is far less common here than in Group 6 (p. 1022) but does occur in the unusual compound, $\text{Nb}_6\text{I}_{11}$. This consists of a 3D array of six $[\text{Nb}_6\text{I}_8]$ units joined by shared iodines: $[\text{Nb}_6\text{I}_8]I_{6/2} = \text{Nb}_6\text{I}_{11}$. It absorbs hydrogen and, in 1967, provided the first example of a metal atom cluster with an encapsulated H atom at its centre. Both $\text{Nb}_6\text{I}_{11}$ and $\text{H}\text{Nb}_6\text{I}_{11}$ exhibit a "spin-crossover": 1 to 3 unpaired electrons at 274 K for the former, and diamagnetic to 2 unpaired electrons at 324 K for the latter.

The cluster compounds of this group may be regarded as intermediate between the $[M_6X_8]^{n+}$ type of Group 6 (p. 1022) which generally possess sufficient electrons (24) to allow M–M single bonds on each edge of the octahedron, and the comparatively electron-poor clusters of Groups 3 and 4 (p. 950 and 965) which generally require the presence of an interstitial atom to stabilize them.

The known oxohalides are listed in Table 22.7. They are generally prepared from the oxides but are not particularly well known and, as can be seen, are limited almost entirely to the oxidation states of +4 and +5.
22.3.5 Compounds with oxoanions

The group oxidation state of +5 is too high to allow the formation of simple ionic salts even for Nb and Ta, and in lower oxidation states the higher sublimation energies of these heavier metals, coupled with their ease of oxidation, again militates against the formation of simple salts of the oxoacids. As a consequence the only simple oxoanion salts are the sulfates of vanadium in the oxidation states +3 and +2. These can be crystallized from aqueous solutions as hydrates and are both strongly reducing. They give rise to blue-violet alums, MV(SO₄)₂.12H₂O, the ammonium alum being air-stable when dry, and to the reddish-violet Tutton’s salts, M₂V(SO₄)₂.6H₂O, the ammonium analogue of which is again relatively more stable to oxidation.

In the higher oxidation states partially hydrolysed species dominate the aqueous chemistry, the most important being the oxovanadium(IV), or vanadyl, ion VO²⁺. This gives the sulfate VOSO₄.5H₂O, containing monodentate sulfate and octahedrally coordinated vanadium, and the polymeric VOSO₄. Oxovanadium(V) species are not well characterized, outside the oxo-halides VOX₃, but in strongly acid solutions VO²⁺ is formed and reportedly gives the nitrate VO₂(NO₃). The VO₂⁺ ion is also found in anionic complexes such as [VO₂(oxalate)₂]³⁻ and in all cases the oxygens are mutually cis as they are in the isoelectronic MoO₂²⁺ (p. 1024). Niobium and tantalum produce a variety of complicated and ill-defined, but probably polymeric, species which include the nitrates, MO(NO₃)₃, sulfates such as Nb₂O(SO₄)₃, and double sulfates such as (NH₄)₆Nb₂O(SO₄)₇, all of which are extremely readily hydrolysed.

---

22.3.6 Complexes\(^{29,30}\)

Oxidation state \(V\) (\(d^0\))

Vanadium (V) has a great affinity for \(O\)-donors: the extensive chemistry of the polyoxometallates has already been discussed and complexes not involving oxygen, such as the white diamagnetic hexafluorovanadates, \(MVF_6\), are extremely susceptible to hydrolysis. If \(H_2O_2\) is added to aqueous solutions of \([VO_4]^{3-}\) a series of substituted products is obtained depending on \(pH\). Using Raman and \(^{51}\)V nmr spectroscopy to compare the solutions with compounds of known compositions and structures, suggests\(^{31}\) that the red-brown acidic solutions contain \([VO(O_2)(H_2O)_4]^+\) and that in progressively more alkaline solutions, \([VO(O_2)_2(H_2O)]^-\), \([VO_2(O_2)(H_2O)]^{3-}\) and \([VO_2(O_2)_2]^{3-}\) are among the species produced until, from strongly alkaline solutions, blue-violet crystals of \(M_3[VO_2]_4\cdot nH_2O\) (\(M = \text{Li, Na, K, NH}_4\)) are deposited. Like the corresponding Cr ion (p. 637), \([V(O_2)_2]^{3-}\) is 8-coordinate and dodecahedral, but such a high coordination number is not common for vanadium. Niobium and tantalum produce similar peroxo-compounds, e.g. pale yellow \(K_3[Nb(O_2)_2]\) and white \(K_3[Ta(O_2)_2]\).

However, most complexes of \(Nb^V\) and \(Ta^V\) are derived from the pentahalides. \(NbF_5\) and \(TaF_5\) dissolve in aqueous solutions of HF to give \([MOF_5]^{2-}\) and, if the concentration of HF is increased, \([MF_6]^-\). This is normally the highest coordination number attained in solution though some \([NbF_7]^{2-}\) may form, and \([TaF_7]^{2-}\) definitely does form, in very high concentrations of HF. However, by suitably regulating the concentration of metal, fluoride ion and HF, octahedral \([MF_6]^-\), capped trigonal prismatic \([MF_7]^{2-}\), and even square-antiprismatic \([MF_8]^{3-}\) salts can all be isolated. By contrast with the fluorides, aqueous solutions of \(MC_5\) and \(MBr_5\) (\(M = Nb, Ta\)) yield only oxochloro- and oxobromo-complexes, though the application of non-aqueous procedures allows their use as starting materials.

Niobium(V) is generally considered to be a class-a metal, but the \(SCN^-\) ligand yields a series of both \(N\)-bonded thiocyanato and \(S\)-bonded isothiocyanato complexes, e.g. \([Nb-(NCS)_n(SCN)_{6-n}]^-\) (\(n = 0, 2, 4, 5, 6\)). Furthermore, dithiocarbamates, dodecahedral \([M(S_2CNR_2)_4]^+\), and dithiolates,\(^{32}\) \([M(SCH_2CH_2S)_3]^-\) with stereochemistry midway between octahedral and trigonal-prismatic, are known for both Nb and Ta. The pentahalides of these two metals act as Lewis acids and form complexes of the type \(MX_5L\) with \(O, S, N, P,\) and As donor ligands.

Oxidation state \(IV\) (\(d^1\))

The tetrahalides are Lewis acids and produce a number of adducts with a variety of donor atoms, the most common coordination number being 6. \([VF_4L]\) (\(L = NH_3, py\)) are insoluble in common organic solvents, have magnetic moments of about 1.8 BM, and are thought to be fluoride-bridged polymers. \([VCl_4L]\) (\(L = py, MeCN, aldehydes, etc.\)) and \(VCl_4-(L-L)\) (\(L-L = bipy, phen, diars\)) are brown paramagnetic, readily hydrolysed compounds assumed to be 6-coordinate monomers. Similar compounds of Nb and Ta are also paramagnetic and the metal-metal bonding which led to the diamagnetism of the parent tetrahalides is presumed to have been broken to give adducts which again are 6-coordinate monomers. Hexahalo-complexes \([MX_6]^{2-}\) (\(M = V, X = F, Cl; M = Nb, Ta, X = Cl, Br\)) are known, the vanadium compounds being especially sensitive to moisture though stable to air.

---

Higher coordination numbers are also found. Vanadium and Nb produce the dodecahedral [MC14(diars)2] just like the Group 4 metals. This is probably the most common stereochemistry for this coordination number but others are possible; differences in energy are slight and this facilitates non-rigidity. For example the yellow-coloured solid K4[Nb(CN)8].2H2O contains dodecahedral niobium(IV) (like its molybdenum isomorph), whereas esr and infrared data suggest that, in solution, the anion has the square-antiprismatic configuration. Likewise, the deep-red niobium(III) complex K5[Nb(CN)8] adopts a dodecahedral (D2d) configuration for the anion in the crystal whereas the single 13C nmr signal in aqueous solution implies either a square-pyramidal (D4d) or fluxional (D2d) structure.

The major contrast with the Group 4 metals is the stability of VO2+ complexes which are the most important and the most widely studied of the vanadium(IV) complexes, and are the usual products of the hydrolysis of other vanadium(IV) complexes. VO2+ behaves as a class-a cation, forming stable compounds with F (especially), Cl, O, and N donor ligands. These “vanadyl” complexes are generally blue to green and can be cationic, neutral or anionic. They are very frequently 5-coordinate in which case the stereochemistry is almost invariably square pyramidal. [VO(acac)2] (Fig. 22.7) is the archetypal example of this geometry in coordination compounds. In this and in similar compounds the V=O bond length is ~157–168 pm which is about 50 pm shorter than the 4 equatorial V–O bonds. This, as well as spectroscopic evidence, is consistent with the formulation of the bond as double. A sixth ligand may be weakly bonded trans to the V=O to produce a distorted octahedral structure; the concomitant reduction in the stretching frequency of the V=O bond generally within the range, 985 ± 50 cm⁻¹ has been interpreted in terms of electron donation from this sixth ligand, thereby making the vanadium atom less able to accept charge from the oxygen and so reducing the bond order. Tetradentate Schiff bases, produced for instance by the condensation of salicylaldehyde with primary diamines, in most cases give entirely analogous compounds, but some are yellow and may be polymeric with the vanadium attaining 6-coordination by “stacking” so that the sixth position of each vanadium is occupied by the oxygen from the V=O beneath. The black [V(salen)4(μ-O)1][BF4]2 [H2salen = N,N'-ethylenebis(salicyldieneimine), p. 907] has recently been shown to be tetrameric with a linear V–O–V–O–V–O–V chain.33

In spite of the evident proclivity of VO2+ to form square pyramidal or distorted octahedral complexes, it must not be assumed that 5-coordination inevitably results in the former shape. [VOCl2(NMe3)2] is in fact trigonal bipyramidal (Fig. 22.8), no doubt because of a dominant steric effect of the bulky trimethylamine ligands rather than any electronic effect. Most oxovanadium(IV) complexes are magnetically simple, having virtually “spin-only” moments of 1.73 BM corresponding to 1 unpaired electron, but their electronic spectra are less easily understood. This is primarily due to the presence of a strong π contribution to the bond between the vanadium and the oxygen which makes it difficult to assign an unequivocal sequence to the molecular orbitals involved.34

Some square pyramidal derivatives of thiovanadyl, (V=S)2+, have also been prepared from the corresponding vanadyl complexes: deep magenta [VS(salen)] and [VS(acen)] [H2acen = N,N'-ethylenediacetylacetoneimine] by

---

The chemistry of vanadium(II) closely parallels that of titanium(II) and it likewise favours octahedral coordination. The interpretation of the electronic spectra of its complexes, as the prime examples of $d^2$ ions in an octahedral field, provided the stimulus for early preparative work in this area. In general, the spectra are characterized by two bands in the visible region with a further much more intense absorption in the ultraviolet. The two former bands are believed to arise from $d-d$ transitions and others from charge-transfer. Since the $d^2$ configuration in a cubic field is expected to give rise to three spin-allowed transitions it is assumed that the most energetic of these is obscured by the charge-transfer band. Table 22.8 gives data for some octahedral vanadium(II) complexes (see also ref. 34, pp. 400–6). It turns out, on examination of data such as these, that a coherent interpretation of the spectra is only possible if the bands are assigned (Fig. 22.9) as:

$$v_1 = \frac{3}{2} T_{2g}(F) + \frac{3}{2} T_{1g}(F)$$

$$v_2 = \frac{3}{2} T_{1g}(P) + \frac{3}{2} T_{1g}(F)$$

and the third, obscured one, therefore as:

$$v_3 = \frac{3}{2} A_{2g}(F) + \frac{3}{2} T_{1g}(F)$$

$B$ is the Racah “interelectronic repulsion parameter". It is included in Fig. 22.9 in order to retain generality and obviate the necessity of drawing separate diagrams for each $d^2$ metal ion. The expansion of $d$-electron charge on complexation reduces its value as compared to the value for the free-ion ($860 \text{ cm}^{-1}$). In general the electronic spectra of these 6-coordinate complexes are accounted for moderately well on the assumption of basically octahedral crystal fields, but the inclusion of trigonal distortions gives more satisfactory results. The magnetic moments of $d^2$ ions in perfectly octahedral fields are expected to involve “orbital contribution” which varies with temperature. In practice the moments at room temperature rarely exceed the spin-only value and their variation with temperature is less than anticipated for a $T$ ground term. This also is in accord with the presence of some distortion which splits the

---

Oxidation state III ($d^2$)

Until comparatively recently only vanadium had a significant $M^{III}$ coordination chemistry and even so the majority of its compounds are easily oxidized and must be prepared with air rigorously excluded. The usual methods are to use VCl$_3$ as the starting material, or to reduce solutions of vanadium(V) or (IV) electrolytically. However, the reduction of pentahalides of Nb and Ta by Na amalgam or Mg, has facilitated the expansion of Nb$^{III}$ and Ta$^{III}$ chemistry particularly with $S$- and $P$-donor ligands.

Figure 22.9  Energy Level diagram for a d$^2$ ion in an octahedral crystal field.

$3T_{2g}$ ground term and so reduces the temperature dependence of the magnetic moment.

Cationic complexes of the type [VL$_6$]$^{3+}$ of which [V(H$_2$O)$_6$]$^{3+}$ is the best-known example are actually rather rare, the action of NH$_3$ on VX$_3$ for instance, causing ammonolysis of the V–X bond to produce VX$_2$(NH$_2$)$_n$NH$_3$. Anionic [VX$_6$]$^{3-}$, [VX$_5$L]$^{2-}$, [VX$_4$L$_2$]$^{-}$ and neutral [VCl$_3$L$_3$] are more common. Dithiolates [V$_2$(SCH$_2$CH$_2$S)$_4$]$^{2-}$ with four sulfur atoms bridging the two vanadium atoms are also known (Fig. 22.10a), their diamagnetism and short V–V distances (260 pm) indicating M–M bonding.

In spite of the preponderance of 6-coordinate complexes, other coordination numbers are known: the ions [VCl$_4$]$^{-}$ and [VBr$_4$]$^{-}$ are tetrahedral and are notable in that 4-coordination with ligands other than O-donors is common only later in the transition series. Their spectra exhibit two bands in the regions of 9000 cm$^{-1}$ and 15 000 cm$^{-1}$ which are assigned to $3T_1(F)\rightarrow 3A_2$ and $3T_1(P)\rightarrow 3A_2$ transitions respectively, corresponding quite reasonably to values of $\Delta_t$ of about 5000 to 5500 cm$^{-1}$. Their magnetic moments too are about 2.7 BM and independent of temperature, as expected.

Neutral complexes of the type [VX$_3$(NMe$_3$)$_2$] (X = Cl, Br) are trigonal bipyramidal with the trimethylamines occupying the axial positions. By contrast [V[N(SiMe$_3$)$_2$)$_3$] has a 3-coordinate, planar structure, presumably because the bis (trimethylsilyl)amido ligands are too big for the V$^{III}$ to accommodate more. The 7-coordinate $K_3[V(CN)_{7.2}$H$_2$O has a pentagonal bipyramidal structure and is a rare example of a 7-coordinated transition metal complex which persists in solution and in which the ligand is not F$^-$. A few trinuclear oxo-centred carboxylates $[V_3O(RCOO)_{9}L_3]^+$ of a type more common for later transition metals (see Fig. 23.9, p. 1030) have been obtained, as well as $[Nb_3O_2(MeCOO)_6(thf)_3]^+$ whose structure differs essentially only in that there are two bridging O atoms above and below the Nb$_3$ plane.

With S- and P- donor ligands such as SMe$_2$ and PMe$_3$, M$_2$Cl$_6$L$_4$ (M = Nb, Ta) consisting of a pair of edge-sharing octahedra are formed. For Nb, but interestingly not for

Ta, tetranuclear, orange coloured derivatives Li$_4$[Nb$_4$S$_2$(SPh)$_{12}$]$^{38}$ and [Nb$_4$S$_2$(SPh)$_8$-(PMe$_2$R)$_4$] (R = Me, Ph)$^{39}$ have been shown to have a common and rather stable central unit of four Nb atoms in a square plane with two $\mu_4$-S atoms above and below it (Fig. 22.10b). The diamagnetism and average Nb–Nb separations of approx 282 pm are consistent with single bonds between adjacent Nb atoms.

**Oxidation state II** (d$^3$)

The coordination chemistry of this oxidation state is not well-developed. Vanadium(II) complexes are usually prepared by electrolytic or zinc reduction of acidic solutions of vanadium in one of its higher oxidation states. The resulting blue-purple solutions are strongly reducing, and reduction of the water is, in general, only prevented by the presence of acid. Several salts and double sulfates which contain the [V(H$_2$O)$_6$]$^{2+}$ ion are known and there are adducts of VCl$_2$ of the type [VCl$_2$L$_4$], where L is one of a number of O- or N-donor ligands. The spectroscopic and magnetic properties of these compounds are typical of a d$^3$ ion and their interpretation follows closely that for the chromium(III) ion (p. 1028). Also typical of a d$^3$ ion is the fact that vanadium(II) is kinetically inert and undergoes substitution reactions only slowly.

Other complexes of the type [VCl$_2$L$_2$] are distinguished by their colour (green) and magnetic moment (~3.2 BM), well below the spin-only value for 3 unpaired electrons, and some at least are halogen-bridged oligomers. Carboxylate derivatives such as the trinuclear [V$_3$(RCOO)$_6$(Me$_2$NCHCHNMe$_2$)$_2$] have recently been prepared$^{40}$ as has the binuclear [V$_2$(RNCHNR)$_4$] (R = p-MeC$_6$H$_4$).$^{41}$ The former contains an almost linear chain of V atoms held together by carboxylate bridges and, in the latter, the pair of V atoms bridged by the four ligands, are so close (197.8 pm) that a V=V bond is indicated (for single- and double-bonded V–V species, separations of approx. 260 and 220 pm, respectively, are common).

Organometallic compounds apart, oxidation states below +2 are best represented by complexes with tris-bidentate nitrogen-donor ligands such as 2,2'-bipyridyl. Reduction by LiAlH$_4$ in thf yields tris(bipyridyl) complexes in which the formal oxidation state of vanadium is +2 to −1. Magnetic moments are compatible with low-spin configurations of the metal but,

as with the analogous compounds of titanium, it may well be that they would be better regarded as complexes with reduced, i.e. anionic, ligands.

22.3.7 The biochemistry of vanadium\(^{41a}\)

Certain vertebrates have an astonishing ability to accumulate vanadium in their blood. For example, the ascidian seaworm *Phallusia mammilata* has a blood concentration of V up to 1900 ppm, which represents more than a millionfold concentration with respect to the sea-water in which it lives. The related organism *Ascidia nigra* has an even more spectacular accumulation with concentrations up to 1.45% V (i.e. 14500 ppm) in its blood cells, which also contain considerable concentrations of sulfuric acid (pH ~ 0). One possibility that has been mooted is that the ascidia accumulates vanadate and polyvanadate ions in mistake for phosphate and polyphosphates (p. 528).

Indeed, the observation that vanadate is a potent inhibitor of phosphate-recognizing enzyme systems was a great stimulus to work in this area, but it now seems likely that its action is more complicated than simple mimicry of phosphates.\(^{42}\) This is germane to obtaining an understanding of the antitumor activity of \([\text{V} \eta^5 - \text{C}_5\text{H}_5\text{SiMe}_3\text{Cl}_2]\).

A number of nitrogen-fixing bacteria contain vanadium and it has been shown that in one of these, *Azotobacter*, there are three distinct nitrogenase systems based in turn on Mo, V and Fe, each of which has an underlying functional and structural similarity.\(^{43}\) This discovery has prompted a search for models and the brown V-\(^{4+}\)

\([\text{Na}(\text{thf})]^+\)[\(\text{V}(\text{N}_2)_2(\text{dppe})_2\)] (dppe = \(\text{Ph}_2\text{PCH}_2\text{CH}_2\text{PPh}_2\)) has recently been prepared by reduction of VCl\(_3\) by sodium naphthalenide in the presence of dppe.\(^{44}\) Acidification achieves partial nitrogen fixation since one of the four N atoms is converted to NH\(_3\).

22.3.8 Organometallic compounds\(^{45}\)

The organometallic chemistry of this group developed rather slowly but there has been a surge of interest, especially in Nb and Ta, in the last decade or so. The chemistry of \(\sigma\) alkyls or aryls is less well developed than for many other elements but \([\text{V}^{\text{III}}(\text{CH}(\text{SiMe}_3)_2)_3]\), \([\text{V}^{\text{IV}}(\text{CH}_2\text{SiMe}_3)_4]\), and \([\text{V}^{\text{V}}\text{O}(\text{CH}_2\text{SiMe}_3)_3]\) have been isolated. In these compounds the possibility of decomposition by alkene elimination or other routes is circumvented by the absence of \(\beta\) hydrogen atoms (p. 926) and the bulkiness of the trimethylsilylmethyl groups. Complexes such as \([\text{MMe}_5(\text{dmpe})]\) (M = Nb, Ta; dmpe = \(\text{Me}_2\text{PCH}_2\text{CH}_2\text{PMe}_2\)) decompose spontaneously above room temperature and, although free TaMe\(_5\) has been isolated, it can explode spontaneously at room temperature even in the absence of air. Despite this instability, the Ta–Me bond itself is rather strong: thermochemical studies have shown that the mean bond dissociation energy \(D(\text{Ta}–\text{Me})\) in TaMe\(_5\) is 261 ± 6 kJ mol\(^{-1}\), which is substantially greater than, for example, the mean dissociation energy \(D(\text{W}–\text{CO})\) of 178 ± 3 kJ mol\(^{-1}\) in the kinetically much more stable W(CO)\(_6\). Expanding the coordination sphere of the metal by the addition of other ligands such as \(\text{C}_5\text{H}_5^-\), halides and phosphines often increases the thermal stability.

Reduction of MCl\(_5\) or MCl\(_3\) under an atmosphere of CO yields salts of the \([\text{M}(\text{CO}_6)]^-\) ions (M = V, Nb, Ta)\(^{46}\) which have the noble gas electron configuration. Using Na as reductant

---

with pyridine or diglyme as solvent requires high temperatures and pressures, but the application of high-energy ultrasound or the use of Mg/Zn as reductant allows less forcing conditions. In the case of the V salt, but not those of Nb and Ta, acidification and extraction with petroleum ether yields volatile, blue-green, pyrophoric crystals of V(CO)₆. Unlike other formally odd-electron transition metal carbonyls, this does not attain the noble gas configuration by dimerization and the formation of a M–M bond. It is in fact monomeric and isomorphous with Group 6 octahedral hexacarbonyls (p. 1037); it undergoes substitution reactions typical of metal carbonyls, but is unique amongst simple carbonyls in being paramagnetic with a moment at room temperature of 1.81 BM. Further reduction of [Na(diglyme)₂][M(CO)₆] with Na metal in liquid NH₃ yields the super-reduced 18-electron species [M(CO)₅]⁻ which contain M in their lowest known formal oxidation state (−3). Although sensitivity is somewhat dependent on the counter-ion involved, several of the salts of these ions are hazardously shock and temperature sensitive. Direct synthesis of V(CO)₆, V₂(CO)₁₂ and M(CO)ₙ (M = V, n = 1–5; M = Ta, n = 1–6) by condensation of vanadium vapour with CO in a matrix of noble gases is possible. The same technique has also been used to prepare the hexakis(dinitrogen) compound, [V(N₂)₆] (p. 981) which is isoelectronic and probably isostructural with the hexacarbonyl.

With the cyclopentadienyl ligand, vanadium forms the simple "sandwich" compound, "vanadocene", [V(η⁵-C₅H₅)₂] which is dark violet, paramagnetic (3 unpaired electrons) and extremely air-sensitive. Oxidative addition reactions are possible and provide compounds such as [V(η⁵-C₅H₅)₂Clₙ] (n = 1, 2, 3) and [V(η⁵-C₅H₅)₂R₂], while its reaction with dithioacetic acid produces the dark-brown tetramer [V₄(η⁵-C₅H₅)₄(S₄)], Fig. 22.11. With four V atoms, eight electrons are available for six V–V bonds and the implied bond order of 2/3 is consistent with the observed average V–V separation of 287.6 pm and magnetic moment of 2.65 BM at room temperature.

Niobium and tantalum do not form simple, thermally stable sandwich compounds. Niobocene is actually a dimer and a hydride (Fig. 22.12a). They do however form [M(η⁵-C₅H₅)₄] (p. 940) in which two rings are η⁵- and two η¹-bonded, and there are many bis(cyclopentadienyl) compounds of the types [M(η⁵-C₅H₅)₂X₂] and [M(η⁵-C₅H₅)₂R₂] in which, if the C₅H₅ is taken as a single ligand, the coordination geometry is pseudo-tetrahedral. [M(η⁵-C₅H₅)₂X₃] and [M(η⁵-C₅H₅)₂R₃] are also known.

An important compound is the mixed methyl-methylene derivative of bis(cyclopentadienyl)tantalum(V) prepared by the following sequence of high-yield reactions:

\[
\text{[Ta(η⁵-C₅H₅)₂Me₃]} \xrightarrow{\text{Ph₃C}^⁺\text{BF}_4^-} \text{[Ta(η⁵-C₅H₅)₂Me₂]}^+ + \text{Me₂P = CH}_2 \xrightarrow{\text{Ta(η⁵-C₅H₅)₂(CH₃)(=CH₂)}}
\]

The structure of the pale buff-coloured product is shown in Fig. 22.12b and this allows a direct comparison between the three Ta–C distances: Ta=C₇H₂ 203 pm, Ta=CH₃ 225 pm, and Ta=C(C₅H₅) 216 pm. It will also be noted that the two cyclopentadienyl rings are eclipsed and that the CH₂ group orients perpendicular to the C–Ta–C plane.

---

---
Figure 22.12 (a) The structure of dimeric \([\text{Nb}(\eta^5-C_5H_5)\text{H}-\mu-(\eta^5,\eta^1-C_5H_4)]_2\). The observed diamagnetism of this compound is consistent with the Nb–Nb bond shown. Each of the two bridging rings is \(\eta^3\)-bonded to one Nb and \(\eta^1\)-bonded to the other. (b) The structure of \([\text{Ta}(\eta^5-C_5H_5)_2(\text{CH}_3)(==\text{CH}_2)]\). (c) The structure of \([\text{Ta}_4(\eta^5-C_5\text{Me}_5)_4(\mu_2-O)_4(\mu_3-O)_2(\mu_4-O)(\text{OH})_2]\).

Cationic cyclopentadienyl complexes are not common in this group, but recent examples whose structures have been determined include \([\text{Nb}^V(\eta^5-C_5\text{H}_5)_2\text{Cl}_2]\text{BF}_4\) and \([\text{Nb}(\eta^5-C_5\text{H}_5)_2\text{L}_2]\text{BF}_4_2\) (\(\text{L} = \text{CNMe} \text{ and } \text{NCMe}\)) which have pseudo-tetrahedral symmetry. Mono(cyclopentadienyl), or “half-sandwich” poly-oxo complexes are of interest as hydrocarbon-soluble models for oxide catalysts. The action of water on \([\text{Ta}(\eta^5-C_5\text{Me}_5)(\text{PMe}_3)_2]\) yields the colourless \([\text{Ta}_4(\eta^5-C_5\text{Me}_5)_4\text{O}_7(\text{OH})_2]\) which has a tetranuclear “butterfly” core (Fig. 22.12c).

The chemistry of these metals with ring systems other than cyclopentadienyl has been little developed but, since larger rings afford more bonding electrons it would seem that the relatively electron-poor, early transition elements (see p. 941) should provide a field of study ripe for expansion. Reduction of \(\text{NbCl}_4\) by \(\text{Na/Hg}\) in \(\text{thf}\) in the presence of cycloheptatriene and \(\text{PMe}_3\) provides a convenient route and several \(\text{C}_7\)-ring compounds have been prepared including the blue-green, 17-electron complex \([\text{Nb}^4(\eta^7-C_7\text{H}_7)(\text{PMe}_3)_2]\) which is isomorphous with the previously described \(\text{Zr}\) analogue (Fig. 21.10c).

23

Chromium, Molybdenum and Tungsten

23.1 Introduction

The discoveries of these elements span a period of about 20 y at the end of the eighteenth century. In 1778 the famous Swedish chemist C. W. Scheele produced from the mineral molybdenite (MoS₂) the oxide of a new element, thereby distinguishing the mineral from graphite with which it had hitherto been thought to be identical. Molybdenum metal was isolated 3 or 4 y later by P. J. Hjelm by heating the oxide with charcoal. The name is derived from the Greek word for lead (μολυβδος, molybdos), owing to the ancient confusion between any soft black minerals which could be used for writing (this is further illustrated by the use of the names “plumbago” and “black lead” for graphite).

In 1781 Scheele, and also T. Bergman, isolated another new oxide, this time from the mineral now known as scheelite (CaWO₄) but then called “tungsten” (Swedish tung sten, heavy stone). Two years later the Spanish brothers J. J. and F. d’Elhuyar showed that the same oxide was a constituent of the mineral wolframite and reduced it to the metal by heating with charcoal. The name “wolfram”, from which the symbol of the element is derived, is still widely used in the German literature and is recommended by IUPAC, but the allowed alternative “tungsten” is used in the English-speaking world.

Finally, in 1797, the Frenchman L. N. Vauquelin discovered the oxide of a new element in a Siberian mineral, now known as crocoite (PbCrO₄), and in the following year isolated the metal itself by charcoal reduction. This was subsequently named chromium (Greek χρωμάτα, chroma, colour) because of the variety of colours found in its compounds. Since their discoveries the metals and their compounds have become vitally important in many industries and, as one of the biologically active transition elements, molybdenum has been the subject of a great deal of attention in recent years, especially in the field of nitrogen fixation (p. 1035).
23.2 The Elements

23.2.1 Terrestrial abundance and distribution

Chromium, 122 ppm of the earth’s crustal rocks, is comparable in abundance with vanadium (136 ppm) and chlorine (126 ppm), but molybdenum and tungsten (both ~1.2 ppm) are much rarer (cf. Ho 1.4 ppm, Tb 1.2 ppm), and the concentration in their ores is low. The only ore of chromium of any commercial importance is chromite, FeCr₂O₄, which is produced principally in southern Africa (where 96% of the known reserves are located), the former Soviet Union and the Philippines. Other less plentiful sources are crocoite, PbCrO₄, and chrome ochre, Cr₂O₃, while the gemstones emerald and ruby owe their colours to traces of chromium (pp. 107, 242).

The most important ore of molybdenum is the sulphide molybdenite, MoS₂, of which the largest known deposit is in Colorado, USA, but it is also found in Canada and Chile. Less important ores are wulfenite, PbMoO₄, and powellite, Ca(Mo,W)O₄.

Tungsten occurs in the form of the tungstates scheelite, CaWO₄, and wolframite, (Fe,Mn)WO₄, which are found in China (thought to have perhaps 75% of the world’s reserves), the former Soviet Union, Korea, Austria and Portugal.

23.2.2 Preparation and uses of the metals

Chromium is produced in two forms:(1)

(a) Ferrochrome by the reduction of chromite with coke in an electric arc furnace. A low-carbon ferrochrome can be produced by using ferrosilicon (p. 330) instead of coke as the reductant. This iron/chromium alloy is used directly as an additive to produce chromium-steels which are “stainless” and hard.

(b) Chromium metal by the reduction of Cr₂O₃. This is obtained by aerial oxidation of chromite in molten alkali to give sodium chromate, Na₂CrO₄, which is leached out with water, precipitated and then reduced to the Cr(III) oxide by carbon. The oxide can be reduced by aluminium (aluminothermic process) or silicon:

\[ \text{Cr}_2\text{O}_3 + 2\text{Al} \rightarrow 2\text{Cr} + \text{Al}_2\text{O}_3 \]
\[ 2\text{Cr}_2\text{O}_3 + 3\text{Si} \rightarrow 4\text{Cr} + 3\text{SiO}_2 \]

The main use of the chromium metal so produced is in the production of non-ferrous alloys, the use of pure chromium being limited because of its low ductility at ordinary temperatures. Alternatively, the Cr₂O₃ can be dissolved in sulphuric acid to give the electrolyte used to produce the ubiquitous chromium-plating which is at once both protective and decorative.

The sodium chromate produced in the isolation of chromium is itself the basis for the manufacture of all industrially important chromium chemicals. World production of chromite ores approached 12 million tonnes in 1995.

Molybdenum is obtained as a primary product but mainly as a byproduct in the production of copper. In either case MoS₂ is separated by flotation and then roasted to MoO₃. In the manufacture of stainless steel and high-speed tools, which account for about 85% of molybdenum consumption, the MoO₃ may be used directly or after conversion to ferromolybdenum by the aluminothermic process. Otherwise, further purification is possible by dissolution in aqueous ammonia and crystallization of ammonium molybdate (sometimes as the dimolybdate, \([\text{NH}_4]_2[\text{MoO}_2\text{O}_7]\), sometimes as the paramolybdate, \([\text{NH}_4]_6[\text{Mo}_7\text{O}_{24}]\cdot4\text{H}_2\text{O}\), depending on conditions), which is the starting material for the manufacture of molybdenum chemicals. Pure molybdenum, which finds important applications as a catalyst in a variety of petrochemical processes and as an electrode material, can be

---

obtained by hydrogen reduction of ammonium molybdate. In 1995 world production of molybdenum ores was equivalent to 130,000 tonnes of contained Mo.

The isolation of tungsten is effected by the formation of “tungstic acid” (hydrous WO₃), but the chemical route chosen depends on the ore being used. After pulverization and concentration of the ore:

(a) Wolframite is converted to soluble alkali tungstate either by fusing with NaOH and leaching the cooled product with water, or by protracted boiling with aqueous alkali. Acidification with hydrochloric acid then precipitates the tungstic acid.

(b) Scheelite is converted to insoluble tungstic acid by direct treatment with hydrochloric acid and separated from the soluble salts of other metals.

Tungstic acid is then roasted to WO₃ which is reduced to the metal by heating with hydrogen at 850°C. Half of the tungsten produced is used as the carbide, WC, which is extremely hard and wear-resistant and so ideal as a tool-tip. Other major uses are in the production of numerous heat-resistant alloys, but the most important use of the pure metal is still as a filament in electric light bulbs, in which role it has never been bettered since it was first used in 1908. In 1995, world production of tungsten ores contained 31,000 tonnes of tungsten.

Both molybdenum and tungsten are obtained initially in the form of powders and, since fusion is impracticable because of their high mps, they are converted to the massive state by compression and sintering under H₂ at high temperatures.

23.2.3 Properties of the elements

As can be seen from Table 23.1, which summarizes some of the important properties of Group 6, each of these elements has several naturally occurring isotopes which imposes limits on the precision with which their atomic weights have been determined, especially for Mo and W.

The elements all have typically metallic bcc structures and in the massive state are lustrous, silvery, and (when pure) fairly soft. However, the most obvious characteristic at least of

(a) Radius depends on whether Cr(II) is low-spin (ls) or high-spin (hs).
molybdenum and tungsten, is their refractive nature, and tungsten has the highest mp of all metals — indeed, of all elements except carbon. For this reason, metallic Mo and W are fabricated by the techniques of powder metallurgy and, in consequence, many of their bulk physical properties depend critically on the nature of their mechanical history.

As in the preceding transition-metal groups, the refractory behaviour and the relative stabilities of the different oxidation states can be explained by the role of the \((n-1)d\) electrons. Compared to vanadium, chromium has a lower mp, bp and enthalpy of atomization which implies that the 3d electrons are now just beginning to enter the inert electron core of the atom, and so are less readily delocalized by the formation of metal bonds. This is reflected too in the fact that the most stable oxidation state has dropped to +3, while chromium(VI) is strongly oxidizing:

\[
\frac{1}{2}\text{Cr}_2\text{O}_7^{2-} + 7\text{H}^+ + 3\text{e}^- \longrightarrow \text{Cr}^{3+} + 3\frac{1}{2}\text{H}_2\text{O}; \\
E^o = 1.33 \text{ V}
\]

For the heavier congenors, tungsten in the group oxidation state is much more stable to reduction, and it is apparently the last element in the third transition series in which all the 5d electrons participate in metal bonding.

### 23.2.4 Chemical reactivity and trends

At ambient temperatures all three elements resist atmospheric attack, which is why chromium is so widely used to protect other more reactive metals. They become more susceptible to attack at high temperatures, when they react with many non-metals giving frequently interstitial and non-stoichiometric products. Chromium reacts more readily with acids then does either molybdenum or tungsten though its reactivity depends on its purity and it can easily be rendered passive. Thus, it dissolves readily in dil HCl but, if very pure, will often resist dil H\(_2\)SO\(_4\); again, HNO\(_3\), whether dilute or concentrated, and aqua regia will render it passive for reasons which are by no means clear. In the presence of oxidizing agents such as KNO\(_3\) or KClO\(_3\), alkali melts rapidly attack the metals producing MO\(_4^{2-}\).

Once again the two heavier elements are closely similar to each other and show marked differences from the lightest element. This is reflected particularly in the relative stabilities of the oxidation states, all of which are known from +6 down to −2.

The stability of the group oxidation state +6 was referred to above and it may be further noted that, while chromium(VI) tends to form poly oxoanions, the diversity of these is but a pale shadow of that of the polymolybdates and polytungstates (p. 1009). Oxidation states +5 and +4 are represented by chromium largely as unstable intermediates, and +3 is much its most stable oxidation state, the symmetrical \(t\frac{1}{2}_g\) configuration leading to a coordination chemistry, the fecundity of which is exceeded only by that of cobalt(III). Chromium(II) is strongly reducing (Cr\(^{3+}\)/Cr\(^{2+}\), \(E^o - 0.41 \text{ V}\)) but it still has an extensive cationic chemistry. By contrast, the chemistry of molybdenum and tungsten in oxidation states +5 to +2 is dominated by clusters and multiple-bonded species which, particularly in the case of molybdenum, has produced an effusion of publications in recent years. This is due not only to the intrinsically interesting chemistry involved but also because of molybdenum’s role in biological processes and, catalytically, in the hydrodesulfurization (HDS) process for removing S-compounds from petroleum feedstocks. In the still lower oxidation states, found in compounds with \(\pi\)-acceptor ligands, the metals are quite similar.

Table 23.2 lists the oxidation states of the elements along with representative examples of their compounds. Coordination numbers as high as 12 can be attained, but those over 7 in the case of Cr and 9 in the cases of Mo and W involve the presence of the peroxy ligand or \(\pi\)-bonded aromatic rings systems such as \(\eta^7\)-C\(_5\)H\(_5\)^− or \(\eta^6\)-C\(_6\)H\(_6\).

23.3 Compounds of Chromium, Molybdenum and Tungsten

The binary borides (p. 145), carbides (p. 299), and nitrides (p. 418) have already been discussed. Suffice it to note here that the chromium atom is too small to allow the ready insertion of carbon into its lattice, and its carbide is consequently more reactive than those of its predecessors. As for the hydrides, only CrH is known which is consistent with the general trend in this part of the periodic table that hydrides become less stable across the d block and down each group.

23.3.1 Oxides

The principal oxides formed by the elements of this group are given in Table 23.3 above. CrO₃, as is to be expected with such a small cation, is a strongly acidic and rather covalent oxide with a mp of only 197°C. Its deep-red crystals are made up of chains of corner-shared CrO₄ tetrahedra. It is commonly called “chromic acid” and is generally prepared by the addition of conc H₂SO₄ to a saturated aqueous solution of a dichromate. Its strong oxidizing properties are widely used in organic chemistry. CrO₃ melts with some decomposition and, if heated above 220–250°C, it loses oxygen to give a succession of lower oxides until the green Cr₂O₃ is formed.

Like the analogous oxides of Ti, V and Fe, Cr₂O₃ has the corundum structure (p. 243), and it finds wide applications as a green pigment. It is a semiconductor and is antiferromagnetic below 35°C. Cr₂O₃ is the most stable oxide of chromium and is the final product of combustion of the metal, though it is more conveniently obtained by heating ammonium dichromate:

\[(\text{NH}_4)_2\text{Cr}_2\text{O}_7 \rightarrow \text{Cr}_2\text{O}_3 + \text{N}_2 + 4\text{H}_2\text{O}^+\]

When produced by such dry methods it is frequently unreactive but, if precipitated as the hydrous oxide (or “hydroxide”) from aqueous chromium(III) solutions it is amphoteric. It dissolves readily in aqueous acids to give an extensive cationic chemistry based on the [Cr(H₂O)_6]³⁺ ion, and in alkalis to produce complicated, extensively hydrolysed chromate(III) species (“chromites”).

The third major oxide of chromium is the brown-black, CrO₂, which is an intermediate product in the decomposition of CrO₃ to Cr₂O₃ and has a rutile structure (p. 961). It has metallic conductivity and its ferromagnetic properties lead to its commercial importance in the manufacture of magnetic recording tapes which are claimed to give better resolution and high-frequency response than those made from iron oxide. Other more or less stable phases with compositions between CrO₂ and CrO₃ have been identified but are of little importance.

The trioxides of molybdenum and tungsten differ from CrO₃ in that, though they are acidic and dissolve in aqueous alkali to give salts of
the MO₄²⁻ ions, they are insoluble in water and have no appreciable oxidizing properties, being the final products of the combustion of the metals. MoO₃ and WO₃ have mps of 795 and 1473°C respectively (i.e. much higher than for CrO₃) and their crystal structures are different. The white MoO₃ has an unusual layer structure composed of distorted Mo₆ octahedra while the yellow WO₃ (like ReO₃ see p. 1047) consists of a three-dimensional array of corner-linked WO₆ octahedra. In fact, WO₃ is known in at least seven polymorphic forms and is unique in being the only oxide of any element that can undergo numerous facile crystallographic transitions near room temperature. Thus the monoclinic ReO₃-type phase (which is slightly distorted from cubic by W–W interactions) transforms to a ferroelectric monoclinic phase when cooled to −43°C, and transforms to another monoclinic variety above +20°C; there are further transitions to an orthorhombic phase at 325° and to a succession of tetragonal phases at 725°, 900° and 1225°.

If either MoO₃ or WO₃ is heated in vacuo or is heated with the powdered metal, reduction occurs until eventually MO₂ with a distorted rutile structure (p. 961) is formed. In between these extremes, however, lie a variety of intensely coloured (usually violet or blue) phases whose structural complexity has excited great interest over many years. Following the pioneer work of the Swedish chemist A. Magnéli in the late 1940s these materials, which were originally thought to consist of a comparatively small number of rather grossly nonstoichiometric phases, are now known to be composed of a much larger number of distinct and accurately stoichiometric phases with formulae such as Mo₄O₁₁, Mo₁₇O₄₇, Mo₈O₂₃, W₁₈O₄₉ and W₂₀O₅₈. As oxygen is progressively eliminated, a whole series of MₓO₃₋ₓ stoichiometries is feasible between the MO₃ structure containing corner-shared MO₆ octahedra and the rutile structure consisting of edge-shared MO₆ octahedra. These are produced as slabs of corner-shared octahedra move so as to share edges with the octahedra of identical adjacent slabs. This is the phenomenon of crystallographic shear and occurs in an ordered fashion throughout the solid. The situation is further complicated by the formation of structures involving (a) 7-coordinate, and (b) 4-coordinate, alongside the more prevalent 6-coordinate, metal atoms. The reasons for the formation of these intermediate phases is by no means fully understood but, although their “nonstoichiometric” M:O ratios imply mixed valence compounds, their largely metallic conductivities suggest that the electrons released as oxygen is removed are in fact delocalized within a conduction band permeating the whole lattice.

Reduction of a solution of a molybdate(VI), or of a suspension of MoO₃, in water or acid by a variety of reagents including Sn²⁺, SO₂, N₂H₄, Cu/acid or Sn/acid, leads to the production of intense blue, sometimes transient, and probably colloidal products, referred to rather imprecisely as molybdenum blues. They appear to be oxide/hydroxide species of mixed valence, forming a series between the extremes of MoVI0₃ and MoV0(OH)₃, but a precise explanation of their colour is lacking. Their formation can be used as a sensitive test for the presence of reducing agents. The behaviour of tungsten is entirely analogous to that of molybdenum and, as will be seen presently, the reduction of heteropolyanions of these metals produces similar coloured products which may be distinguished from the above “blues” as “heteropoly blues” (though this is not always done).

The dioxides of molybdenum (violet) and tungsten (brown) are the final oxide phases produced by reduction of the trioxides with hydrogen; they have rutile structures sufficiently distorted to allow the formation of M–M bonds and concomitant metallic conductivity and diamagnetism. Strong heating causes disproportionation:

\[3\text{MO}_2 \rightarrow \text{M} + 2\text{MO}_3\]

---

6 See p. 148 of ref. 2.
Isopolymetallates

Acidification of aqueous solutions of the yellow, tetrahedral chromate ion, CrO$_4^{2-}$, initiates a series of labile equilibria involving the formation of the orange-red dichromate ion, Cr$_2$O$_7^{2-}$:

\[
\begin{align*}
\text{HCrO}_4^- & \rightleftharpoons \text{CrO}_4^{2-} + \text{H}^+ \\
\text{H}_2\text{CrO}_4 & \rightleftharpoons \text{HCrO}_4^- + \text{H}^+ \\
\text{Cr}_2\text{O}_7^{2-} + \text{H}_2\text{O} & \rightleftharpoons 2\text{HCrO}_4^- \\
\text{HCr}_2\text{O}_7^- & \rightleftharpoons \text{Cr}_2\text{O}_7^{2-} + \text{H}^+ \\
\text{H}_2\text{Cr}_2\text{O}_4 & \rightleftharpoons \text{HCr}_2\text{O}_7^- + \text{H}^+
\end{align*}
\]

However, estimates of equilibrium constants (see for instance, Comprehensive Coordination Chemistry, Vol. 3, p. 699) have been questioned and it appears that the concentration of HCrO$_4^-$ is much lower than was previously supposed, the ion being undetectable by Raman and uv-visible spectroscopic techniques.\(^{9b}\) Because of the lability of these equilibria the addition of the cations Ag$^+$, Ba$^{II}$ or Pb$^{II}$ to aqueous dichromate solutions causes their immediate precipitation as insoluble chromates rather than their more soluble dichromates. Polymerization beyond the dichromate ion is apparently limited to the formation of tri- and tetra-chromates (Cr$_3$O$_{10}^{2-}$ and Cr$_4$O$_{13}^{2-}$), which can be crystallized as alkali-metal salts from very strongly acid solutions. These anions, as well as the dichromate ion, are formed by the corner sharing of CrO$_4$ tetrahedra, giving Cr–O–Cr angles very roughly in the region of 120° (Fig. 23.1). The simplicity of this anionic polymerization of chromium, as compared to that shown by the elements of the preceding groups and the heavier elements of the present triad, is probably due to the small size of Cr$^{VI}$. This evidently limits it to tetrahedral rather than octahedral coordination with oxygen, whilst simultaneously favouring Cr–O double bonds and so inhibiting the sharing of attached oxygens.

Sodium dichromate, Na$_2$Cr$_2$O$_7$.2H$_2$O, produced from the chromate is commercially much
the most important compound of chromium. It yields a wide variety of pigments used in the manufacture of paints, inks, rubber and ceramics, and from it are formed a host of other chromates used as corrosion inhibitors and fungicides, etc. It is also the oxidant in many organic chemical processes; likewise, acidified dichromate solutions are used as strong oxidants in volumetric analysis:

\[
\text{Cr}_2\text{O}_7^{2-} + 14\text{H}^+ + 6\text{e}^- \rightarrow 2\text{Cr}^{3+} + 7\text{H}_2\text{O};
\]

\[E^o = 1.33\ \text{V}\]

For this purpose the potassium salt K$_2$Cr$_2$O$_7$ is preferred since it lacks the hygroscopic character of the sodium salt and may therefore be used as a primary standard.

The polymerization of acidified solutions of molybdenum(VI) or tungsten(VI) yields the most complicated of all the polyanion systems and, in spite of the fact that the tungsten system has been the most intensively studied, it is still probably the least well understood. This arises from the problem inevitably associated with studies of such equilibria, and which were noted (p. 983) in the discussion of the Group 5 isopolyanions. It must also be admitted that, whilst the observed structures of individual polyanions are reasonable, it is often difficult to explain why, under given circumstances, a particular degree of aggregation or a particular structure is preferred over other possibilities.

When the trioxides of molybdenum and tungsten are dissolved in aqueous alkali, the resulting solutions contain tetrahedral Mo$_6^{2-}$ ions and simple, or “normal”, molybdates and tungstates such as Na$_2$Mo$_4$ can be crystallized from them. If these solutions are made strongly acid, precipitates of yellow “molybdic acid”, MoO$_3$.2H$_2$O, or white “tungstic acid”, WO$_3$.2H$_2$O are obtained which convert to the monohydrates if warmed. At pHs between these two extremes, however, polymerization occurs and salts can be crystallized,\(^{(10)}\) the anions of which are almost invariably made up of Mo$_6$ octahedra. A plethora of physical techniques\(^{(7)}\) has been used to characterize these species and unravel the complexity of their structures. Examination of the alkali metal (or ammonium) and alkaline earth salts, particularly by X-ray analysis, forms the basis of classical studies of the isopoly-molybdates and -tungstates in the solid state. Modern nmr techniques (especially pulsed Fourier transform) have increasingly been used to study the solutions themselves. Even so it is only with great difficulty that the structure of an ion, determined in the solid, can be confirmed in solution.

Important differences distinguish the molybdenum and tungsten systems. In aqueous solution, equilibration of the molybdenum species is complete within a matter of minutes whereas for tungsten this may take several weeks; it also transpires that whereas the basic unit of most isopolymolybdates is an Mo$_6$ octahedron with a pair of cis-terminal oxygens, that of the isopolytungstates is more commonly an Mo$_6$ octahedron with only one terminal oxygen. The two must therefore be considered separately.

Undoubtedly the first major polyanion formed when the pH of an aqueous molybdate solution is reduced below about 6 is the heptamolybdate [Mo$_7$O$_{24}$]$^{6-}$, traditionally known as the paramolybdate:

\[
7\text{[MoO}_4^{2-} + 8\text{H}^+ \rightleftharpoons \text{[Mo}_7\text{O}_{24}]^{6-} + 4\text{H}_2\text{O}
\]

This may be crystallized from aqueous solution and, by the addition of diethylenetriamine, (H$_3$dien)$_2$[Mo$_7$O$_{24}$.4H$_2$O has been obtained\(^{(11)}\) as two distinct polymorphs. Both contain discrete [Mo$_7$O$_{24}$]$^{6-}$ ions but differ in the way these are packed in the crystals.

Anions with 8, and probably 16–18, Mo atoms also appear to be formed, before increasing acidity suffices to precipitate the hydrous oxide. It is clear from the above equation that the condensation of MoO$_4$ polyhedra to produce these large polyanions requires large quantities of strong acid as the supernumary oxygen atoms are removed in the form of water molecules. Careful

\(^{(10)}\) Inorganic Syntheses, 27, Chap. 3 pp. 71–135 (1990), gives several detailed preparations.

§23.3.2 Isopolymetallates

adjustment of acidity, concentration and temperature, often coupled with slow crystallization, can produce solids containing many other ions which appear not present in solution. Mixtures abound, but amongst the distinct species which have been characterized are: the dimolybdate, \([\text{Mo}_2\text{O}_7]^{2-}\); the hexamolybdate, \([\text{Mo}_6\text{O}_{19}]^{2-}\); and the octamolybdate, \([\text{Mo}_8\text{O}_{26}]^{4-}\), for which there are \(\alpha\)- and \(\beta\)-isomers. The latter is the one usually obtained from aqueous solutions, but large counter ions or non-aqueous solvents have been used to prepare the former. A third (\(\gamma\)), coordinatively unsaturated form containing two 5-coordinate Mo atoms has been suggested as an intermediate in the \(\alpha \rightleftharpoons \beta\) equilibrium, and has been isolated\(^{(12)}\) as the salt \([\text{Me}_3\text{N(CH}_2)_6\text{NMMe}_3]_2[\text{Mo}_8\text{O}_{26}]\cdot2\text{H}_2\text{O}\). Stabilization of the \(\gamma\)-configuration is also possible by completing the octahedral coordination spheres of the 5-coordinate Mo atoms with suitable ligands such as pyridine or pyrazole.\(^{(13)}\)

Figure 23.2 depicts the structures of these ions and it can be seen that the basic units are

MoO$_6$ octahedra which are joined by shared corners or shared edges, but not by shared faces. MoO$_4$ tetrahedra are also involved in [Mo$_2$O$_7^{2-}$]$_n$ and in a few other ions. The structure of [Mo$_{36}$O$_{112}$(H$_2$O)$_{16}$]$^{8-}$, one of the larger isopolyanions (but see Panel on p. 1015) consists predominantly of MoO$_6$ octahedra but includes, uniquely in the isopolymolybdates, MoO$_7$ pentagonal bipyramids.

The most important species produced by the progressive acidification of normal tungstate solutions are the paratungstates which, indeed, were the only ones reported prior to the mid-1940s. They are generally less soluble than the normal tungstates and can be crystallized over a period of several days. Further acidification produces metatungstates which are rather more soluble but will crystallize either on standing for some months or on prolonged heating of the solution. It seems that comparatively rapid condensation produces relatively soluble species which, if left, will very slowly condense further into less-soluble species. Early evidence suggested that the first paratungstate, A, to be formed in solution is a hexamer but evidence later accumulated that a heptamer is produced, just as with molybdates. For instance, potentiometric data obtained from dilute (0.1 and 0.001 molar) solutions of Na$_2$WO$_4$.2H$_2$O in the range pH 7.8–5 and treated by a “best-fit program”, indicated the presence of W$_6$, W$_7$ and W$_{12}$ species but with the W$_6$ always a minor component. More recently, $^{183}$W, $^{17}$O and $^1$H nmr spectra of 2 molar aqueous solutions of WO$_3$ and LiOH over the range pH 8–1.5 confirmed the presence of W$_7$ and W$_{12}$ species but found no evidence of W$_6$; they revealed a complicated series of equilibria in which a variety of protonations played a crucial role, and involving

Reaction scheme for the condensation of tungstate ions in aqueous solution.
Isopolymetallates

A W$_{11}$ species of uncertain composition.\(^{15}\) The much simplified reaction scheme at the foot of the previous page outlines the situation but it must be noted that concentration, temperature, rate of acidification and counter cation will all affect the details of a particular system.

Amongst the crystalline products obtained from aqueous solution are, (NH$_4$)$_{10}$[H$_2$W$_{12}$O$_{42}$].10H$_2$O, Na$_6$[H$_2$W$_{12}$O$_{40}$].29H$_2$O, K$_4$[W$_{10}$O$_{32}$].4H$_2$O and Na$_6$[W$_7$O$_{24}$].14H$_2$O. The compound Na$_5$[H$_3$W$_6$O$_{22}$].18H$_2$O has recently been precipitated by acetone from a non-equilibrated aqueous solution\(^{15a}\) and the structure of the anion may be considered to be derived from that of [W$_7$O$_{24}$]$^{6-}$ (which is like that of its Mo analogue, Fig. 23.2c) by removal of an outer octahedron from the middle row of three. Another hexatungstate, [W$_6$O$_{19}$]$^{2-}$ isostructural to its Mo analogue, can be obtained from methanolic solutions. Li$_{14}$[WO$_4$]$_3$(W$_2$O$_{16}$).4H$_2$O has also been crystallized from aqueous solution and shown to contain the discrete ion, [W$_4$O$_{16}$]$^{8-}$ though there is no direct evidence that this is present in solution. The structures\(^\dagger\) of these anions are described in Fig. 23.3.

Many attempts have been made to rationalize the structures and mechanisms of formation of polymetallates. Lipscomb observed that no individual MO$_6$ octahedral unit ever has more than two unshared, i.e. terminal oxygens (exceptions appear to be stable only in the solid state) and this has been explained on the basis of $\pi$-bonding between the metal and terminal oxygen atoms: more than two of these

\[^\dagger\] It is instructive to recall a particular problem facing early workers in establishing these structures by X-ray diffraction. Large scattering by the heavy tungsten atoms made it extremely difficult to locate the positions of the lighter oxygen atoms and this sometimes led to ambiguity in the assignment of precise structures (relative scattering O/W = (8/74)$^2$ = 1/86, cf. H/C = (1/6)$^2$ = 1/36). This is no longer a problem because of the greater precision of modern techniques of X-ray data acquisition and processing, but good-quality crystals are still necessary and these may be very difficult to produce.

Figure 23.3 Idealized structures of isopolytungstate ions. (a) [W$_4$O$_{16}$]$^{3-}$ (b) [W$_{10}$O$_{32}$]$^{9-}$, composed of two identical W$_5$O$_{16}$ groups. (c) The metatungstate ion, [H$_2$W$_{12}$O$_{40}$]$^{6-}$ (d) The paratungstate B ion, [H$_2$W$_{12}$O$_{42}$]$^{10-}$. As in the metatungstate, the protons appear to reside in the cavity of the ion but, unlike those of the metatungstate, exchange rapidly with protons from solvent water.

would so weaken and lengthen the trans-bonds holding the metal to the polyanion that it would become detached. Electrostatic repulsions between neighbouring metal ions will reinforce the distorting effect of M–O $\pi$-bonding, causing the metal ions to move off-centre in the MO$_6$ octahedra which are connected to each other. The effect increases as the mode of attachment changes from corner-sharing to edge-sharing. Thus, while the avoidance of unfavourably high, overall anionic charge favours edge-sharing as opposed to corner-sharing (thereby reducing the number of $O^{2-}$ ions), the off-centre distortions become increasingly difficult to accommodate as the size of the polyanion increases. Ultimately edge-sharing is no longer possible, and this stage is reached by W$^{VI}$ before it occurs with the smaller Mo$^{VI}$. Inspection of Figs. 23.2 and 23.3 shows the greater incidence of corner-sharing in the higher polytungstates than in...
the polymolybdates. Also, except in $\left[\text{M}_7\text{O}_{24}\right]^{6-}$, linear sets of 3 $\text{MO}_6$ octahedra on which the distortions are most difficult to accommodate are not found, triangular $\text{M} -- \text{M}$ sets being preferred. Why so few structures are common to both molybdenum and tungsten is less readily explained and, in spite of numerous suggestions, there is little general agreement about the mechanism of formation of polyanions except that it occurs by the addition of $\text{MO}_4$ tetrahedra.

Several mixed metal species, $\text{Mo/W}$, $\text{Mo/V}$, $\text{W/V}$ and $\text{W/Nb}$, in which some atoms of the parent metal are replaced, have been identified (see pp. 54–7 of ref. 7) but no new principles are as yet discernible.

### 23.3.3 Heteropolymetallates\(^\text{(7,8,9)}\)

In 1826 J. J. Berzelius found that acidification of solutions containing both molybdate and phosphate produced a yellow crystalline precipitate. This was the first example of a heteropolyanion and it actually contains the phosphomolybdate ion, $\left[\text{PMO}_{12}\text{O}_{40}\right]^{3-}$, which can be used in the quantitative estimation of phosphate. Since its discovery a host of other heteropolyanions have been prepared, mostly with molybdenum and tungsten but with more than 50 different heteroatoms, which include many non-metals and most transition metals — often in more than one oxidation state. Unless the heteroatom contributes to the colour, the heteropoly-molybdates and -tungstates are generally of varying shades of yellow. The free acids and the salts of small cations are extremely soluble in water but the salts of large cations such as $\text{Cs}^+$, $\text{Ba}^{2+}$ and $\text{Pb}^{2+}$ are usually insoluble. The solid salts are noticeably more stable thermally than are the salts of isopolyanions. Heteropoly compounds have been applied extensively as catalysts in the petrochemicals industry, as precipitants for numerous dyes with which they form “lakes” and, in the case of the Mo compounds, as flame retardants.

In these ions the heteroatoms are situated inside “cavities” or “baskets” formed by $\text{MO}_6$ octahedra of the parent $\text{M}$ atoms and are bonded to oxygen atoms of the adjacent $\text{MO}_5$ octahedra. The stereochemistry of the heteroatom is determined by the shape of the cavity which in turn depends on the ratio of the number of heteroatoms to parent atoms. Three major and a number of minor classes are found.

1:12, tetrahedral. These are found for both Mo and W but the latter are far more numerous and stable than the former. They occur with small heteroatoms such as $\text{P}^V$, $\text{As}^V$, $\text{Si}^{IV}$ and $\text{Ge}^{IV}$ which yield tetrahedral oxoanions, and they are the most readily obtained and best known of the heteropolyanions. Keggin\(^{16}\) first determined the structure of the phosphotungstate, which was known to be isomorphous with the metatungstate, and his name is given to this structure type (Fig. 23.3c). The hetero-atom, or in the case of metatungstate a pair of protons, is situated in the tetrahedral inner cavity of the parent ion (Panel opposite). For the tungstates, $\text{Fe}^{III}$, $\text{Co}^{II}$ and $\text{Zn}^{II}$ derivatives are known, the second of which is of interest: it is readily formed, since tetrahedrally coordinated $\text{Co}^{II}$ is not unusual, but oxidation yields $\left[\text{Co}^{III}\text{W}_{12}\text{O}_{40}\right]^{5-}$ in which the very unusual, high-spin, tetrahedral $\text{Co}^{III}$ is trapped. Nor is tetrahedral coordination common for $\text{Cu}^{II}$ but it is found in a recently reported\(^{17}\) polyanion of this class containing both $\text{Cu}^{II}$ and $2\text{H}$ as heteroatoms (giving an overall stoichiometry of $\left[\text{Cu}_{0.4}\text{(H}_2\text{)}_{0.6}\right]$ for the hetero “atom”). The structure of these compounds is now known as the $\alpha$-Keggin structure since an isomeric $\beta$-Keggin structure has been identified for the heteropolyanions, “$\text{XMo}_{12}$” ($\text{X} = \text{Si}, \text{Ge}, \text{P}, \text{As}$) and “$\text{XW}_{12}$” ($\text{X} = \text{Si}, \text{Ge}$). Also $\beta$-$\left[\text{H}_2\text{W}_{12}\text{O}_{40}\right]^{6-}$ has been implicated in the isopolytungstate equilibria.\(^{15}\) “Lacunary” ions, or their derivatives, are obtained by the nominal loss of one or more $\text{MO}_6$ octahedra (actually the stoichiometric loss of that number of $\text{MO}$...
Large Polymetallates

With the objective of producing model systems to mimic the metal oxide surfaces of catalysts, a great deal of effort has been devoted to the preparation of large polymetallate structures.

The α-Keggin structure of $\left[\text{PW}_{12}O_{40}\right]^{3-}$ and the metatungstate, $\left[H_2\text{W}_{12}O_{40}\right]^{6-}$ can be seen (Fig 23.3) to be composed of four identical "tritungstate" or $W_3$ groups. Each of these is made up of three edge-sharing $WO_6$ octahedra, and the four groups are linked to each other by corner-sharing so as to enclose the heteroatom. This is more clearly seen in A where one of the $W_3$ groups has been omitted and the oxygens which are nearest neighbours to the heteroatom are marked by dots. The β-Keggin structure, B, is derived from the α-form by rotation of one $W_3$ group (in this case the top one) through 60°. In principle, similar rotation of the other three $W_3$ groups would yield γ, δ and ε isomers.

The Dawson structure, C, can be visualized as being formed by removing the three basal octahedra from each of two α-Keggin ions which are then fused together. By omitting the four octahedra at the front, the oxygens associated with the 2 heteroatoms can be seen more clearly (D).

Still larger heteropolyanions are possible by using $\text{As}^{III}$ as the heteroatom. The lone-pair of electrons of this atom makes it too large to fit inside the Keggin ion, and the lacunary $[\text{AsW}_9O_{28}]^{9-}$ is formed instead. By judicious use of this as a “building block,” $[\text{As}_4\text{W}_{10}O_{48}]^{28-}$ has been prepared. Similar use of $[\text{P}_2\text{W}_{12}O_{48}]^{12-}$, produced by degrading the Dawson structure by raising the pH, has yielded $[\text{P}_4\text{W}_{48}O_{184}]^{40-}$.

The largest polymetallates so far reported, however, are the mixed valence ($\text{Mo}^{VI}$, $\text{Mo}^{V}$) nitrosyls obtained by the more straightforward, if less systematic, method of heating acidified aqueous solutions of $\text{MoO}_4$ and $\text{NH}_2\text{OH}$ with $\text{VO}_3$. Depending on concentration and whether the solutions are refluxed or heated without stirring, a variety of products has been obtained including the mixed metal $[\text{Mo}_{57}\text{V}_2\text{O}_{183}(\text{NO}_6(\text{H}_2\text{O})_{18})^{6-}$ and the spectacular $[\text{Mo}_{15}\text{O}_{420}(\text{NO})_{14}(\text{H}_2\text{O})_{10}]^{9-}$ ($n = 25 \pm 5$). Both are dark blue and are composed of edge- and corner-sharing $\text{MoO}_6$ octahedra and $[\text{Mo}(\text{NO})_6]$ pentagonal bipyramids, along with $\text{V}^{IV}\text{O}_6$ octahedra in the case of the former. The latter has the overall shape of a car (automobile) tyre and, in spite of its large molar mass, its large surface area, bristling with $\text{H}_2\text{O}$ and OH ligands, renders it readily soluble in water from which it can be recrystallized without decomposition in the absence of air.

units). The hetero atom is then held in an open “basket” rather than being totally enclosed. The most numerous of such ions are the Keggin derivatives, $[\text{XM}_{11}\text{O}_{39}]^{9-}$ (M = Mo, W; X = P, P).

---

As, Si, etc.) which are able to act as ligands to a variety of transition metal cations as well as to organometallic groups such as SnR, AsR and Ti ($\eta^3$-C$_5$H$_5$).

2:18, tetrahedral. If acidic solutions of the 1:12 anions [X$^-$M$_{12}$O$_{40}$]$^{3-}$ (X = P, As; M = Mo, W) are allowed to stand, the 2:18 [X$_2$M$_{18}$O$_{62}$]$^{6-}$ ions are gradually produced and can be isolated as their ammonium or potassium salts. The ion is best considered to be formed from two lacunary, 1:9 ions fused together and is generally known as the Dawson structure.

1:6, octahedral. These are formed with larger heteroatoms such as Te$^{VI}$, I$^{VII}$, Co$^{II}$ and Al$^{III}$ and are usually obtained from slightly acidic (pH 4–5) aqueous solutions. They adopt the Anderson structure in which the hetero-atom coordinates to 6 edge-sharing MO$_6$ octahedra in the form of a hexagon around the central XO$_6$ octahedron. It is noticeable that tungsten forms this type of ion less frequently than does molybdenum, which again probably reflects a greater readiness of molybdenum to form large structures based solely on edge-sharing, rather than corner-sharing, of octahedra. This is further reinforced by the less common, 1:9 octahedral type which is based solely on edge-sharing octahedra and of which tungsten apparently forms none. The best characterized examples are [Mn$^{III}$Mo$_9$O$_{32}$]$^{6-}$ and [Ni$^{II}$Mo$_9$O$_{32}$]$^{6-}$, prepared by the oxidation of X$^{II}$ molybdate solutions with peroxodisulfate, the kinetics of which have been investigated.\(^{20}\)

Mild and reversible reduction of 1:12 and 2:18 heteropoly-molybdates and -tungstates produces characteristic and very intense blue colours ("heteropoly blues") which find application in the quantitative determinations of Si, Ge, P and As, and commercially as dyes and pigments. The reductions are most commonly of 2 electron equivalents but may be of 1 and up to 6 electron equivalents. Many of the reduced anions can be isolated as solid salts in which the unreduced structure remains essentially unchanged and the heteroatom is not normally involved; i.e., even Fe$^{III}W_{12}$ is reduced to Fe$^{III}W^VW^VI$ not to Fe$^{II}W_{12}$, although Co$^{III}W_{12}$ is reduced to Co$^{II}W_{12}$. 1- or 2-electron reductions evidently occur on individual M atoms, producing a proportion of M$^V$ ions. Transfer of electrons from M$^V$ to M$^VI$ ions is then responsible for the intense "charge-transfer" absorption. In the highly reduced species, limited delocalization is probable.

### 23.3.4 Tungsten and molybdenum bronzes

These materials owe their name to their metallic lustre and are used in the production of "bronze" paints. They provide a further example of the formation of intense and characteristic colours by the reduction of oxo-species of Mo and W. The tungsten bronzes were the first to be discovered when, in 1823, F. Wöhler reduced a mixture of Na$_2$WO$_4$ and WO$_3$ with H$_2$ at red heat. The tungsten bronzes were the precursor of a whole series of nonstoichiometric materials of general formula M$_x$WO$_3$ ($x < 1$) in which M is an alkali metal cation and W has an oxidation state between +5 and +6. Corresponding materials can also be obtained in which M is an alkaline earth or lanthanide metal. The alkali-metal molybdenum bronzes\(^{21}\) are analogous to, but less well-known than, those of tungsten, being less stable and requiring high pressure for their formation; they were not produced until the 1960s. The lower stability of the molybdenum bronzes may be a consequence of the greater tendency of Mo$^V$ to disproportionate as compared to W$^V$.

Tungsten bronzes can be prepared by a variety of reductive techniques but probably the most general method consists of heating the normal tungstate with tungsten metal. They are extremely inert chemically, being resistant both to alkalis and to acids, even when hot and concentrated. Their colours depend in the proportion of M and W present. In the case of sodium

tungsten bronze the colour varies from golden yellow, when \( x \approx 0.9 \), through shades of orange and red to bluish-black when \( x \approx 0.3 \). Within this range of \( x \)-values the structure consists of corner-shared \( \text{WO}_6 \) octahedra\(^{\dagger} \) as in \( \text{WO}_3 \) (p. 1008), with \( \text{Na}^+ \) ions in the interstices — in other words an M-deficient perovskite lattice (p. 963). The observed electrical conductivities are metallic in magnitude and decrease linearly with increase in temperature, suggesting the existence of a conduction band of delocalized electrons. Measurements of the Hall effect (used to measure free electron concentrations) indicate that the concentration of free electrons equals the concentration of sodium atoms, implying that the conduction electrons arise from the complete ionization of sodium atoms. Several mechanisms have been suggested for the formation of this conduction band but it seems most likely that the \( t_{2g} \) orbitals of the tungsten overlap, not directly (since adjacent W atoms are generally more than 500 pm apart) but via oxygen \( \pi r \) orbitals, so forming a partly filled \( \pi^* \) band permeating the whole \( \text{WO}_3 \) framework. If the value of \( x \) is reduced below about 0.3 the resulting electrical properties are semiconducting rather than metallic. This change coincides with structural distortions which probably disrupt the mechanism by which the conduction band is formed and instead cause localization of electrons in \( t_{2g} \) orbitals of specific tungsten atoms.

\section*{23.3.5 Sulfides\(^{(2)} \), selenides and tellurides}

The sulfides of this triad, though showing some similarities in stoichiometry to the principal oxides (p. 1007), tend to be more stable in the lower oxidation states of the metals. Thus Cr forms no trisulfide and it is the di- rather than the tri-sulfides of Mo and W which are the more stable. However, tungsten (unlike Cr and Mo) does not form \( \text{M}_2\text{S}_3 \). Many of the compounds are nonstoichiometric, most are metallic (or at least semiconducting), and they exhibit a wide variety of magnetic behaviour encompassing diamagnetic, paramagnetic, antiferro-, ferri- and ferro-magnetic.

\( \text{Cr}_2\text{S}_3 \) is formed by heating powdered Cr with sulfur, or by the action of \( \text{H}_2\text{S}(\text{g}) \) on \( \text{Cr}_2\text{O}_3 \), \( \text{CrCl}_3 \) or Cr. It decomposes to \( \text{CrS} \) on being heated, via a number of intermediate phases which approximate in composition to \( \text{Cr}_3\text{S}_4 \), \( \text{Cr}_5\text{S}_6 \) and \( \text{Cr}_7\text{S}_8 \). The structural relationship between these various phases can most readily be understood by reference to the \( \text{NiAs}–\text{CdI}_2 \) structure motif. Removal of all the M atoms from alternate layers of the \( \text{NiAs} \) structure (p. 555) yields the \( \text{CdI}_2 \) layer lattice (p. 1212). Between these two extremes, removal of a proportion of M atoms results in the above phases as follows: if one quarter of the Cr atoms are removed from alternate layers \( \text{Cr}_7\text{S}_8 \) results; if one third, \( \text{Cr}_5\text{S}_6 \) results; if two thirds, \( \text{Cr}_4\text{S}_6 \) (ie \( \text{Cr}_2\text{S}_3 \)) results and if half, \( \text{Cr}_3\text{S}_4 \) results. Of these various phases \( \text{Cr}_2\text{S}_3 \) and \( \text{CrS} \) are semiconductors, whereas \( \text{Cr}_7\text{S}_8 \), \( \text{Cr}_5\text{S}_6 \) and \( \text{Cr}_3\text{S}_4 \) are metallic, and all exhibit magnetic ordering. The corresponding selenides \( \text{CrSe}, \text{Cr}_7\text{Se}_8, \text{Cr}_5\text{Se}_6, \text{Cr}_2\text{Se}_3, \text{Cr}_5\text{Se}_8 \) and \( \text{Cr}_7\text{Se}_{12} \) are broadly similar, as are the tellurides \( \text{CrTe}, \text{Cr}_7\text{Te}_8, \text{Cr}_5\text{Te}_6, \text{Cr}_3\text{Te}_4, \text{Cr}_2\text{Te}_3, \text{Cr}_5\text{Te}_8 \) and \( \text{CrTe}_{-2} \).

Of the many molybdenum sulfides which have been reported, only \( \text{MoS}, \text{MoS}_2 \) and \( \text{Mo}_2\text{S}_3 \) are well established. A hydrated form of the trisulfide of somewhat variable composition is precipitated from aqueous molybdate solutions by \( \text{H}_2\text{S} \) in classical analytical separations of molybdenum, but it is best prepared by thermal decomposition of the thiomolybdate, \( (\text{NH}_4)_2\text{MoS}_4 \). \( \text{MoS} \) is formed by heating the calculated amounts of Mo and S in an evacuated tube. The black \( \text{MoS}_2 \), however, is the most stable sulfide and, besides being the principal ore of Mo,
is much the most important Mo compound commercially. In 1923 its structure was shown by R. G. Dickinson and L. Pauling (in the latter’s first research paper) to consist of layers of MoS\textsubscript{2} in which the molybdenum atoms are each coordinated to 6 sulfides, but forming a trigonal prism rather than the more usual octahedron. This layer structure promotes easy cleavage and graphite-like lubricating properties, which have led to its widespread use as a lubricant both dry and in suspensions in oils and greases. It also has applications as a catalyst in many hydrogenation reactions and, even when the original catalyst takes the form of an oxide, it is likely that impurities (which often “poison” other catalysts) quickly produce a sulfide catalytic system. High-purity MoS\textsubscript{2} is normally prepared by heating the elements at 1000°C for several days. The reaction of anhydrous MoCl\textsubscript{5} and Na\textsubscript{2}S offers a promising alternative.\textsuperscript{(22)}

\[
2\text{MoCl}_5 + 5\text{Na}_2\text{S} \rightarrow 2\text{MoS}_2 + 10\text{NaCl} + \text{S}
\]

It is so exothermic as to burst into flame on mixing, and is complete within seconds.

WS\textsubscript{3} and WS\textsubscript{2} are similar to their molybdenum analogues and all 4 compounds are diamagnetic semiconductors.

Selenides and tellurides are, again, broadly similar to the sulfides in structure and properties.

The oxygen atoms of MO\textsubscript{x}\textsuperscript{2−} can be replaced successively by sulfur, and all four thiometallates, MO\textsubscript{3}S\textsuperscript{2−}, MO\textsubscript{2}S\textsubscript{2}\textsuperscript{−}, MOS\textsubscript{3}\textsuperscript{2−} and MS\textsubscript{4}\textsuperscript{2−} have been prepared; the thiomolybdates a century ago. They are useful reagents for the preparation of metal-sulfur clusters, and act as ligands, usually chelating but also as bridging groups.\textsuperscript{(23)}

MSe\textsubscript{4}\textsuperscript{2−} have also been known for a considerable time but are less familiar. They may be prepared conveniently by treating K\textsubscript{2}Se\textsubscript{3} with M(CO)\textsubscript{6} in dmf.\textsuperscript{(24)}

Remarkable physical properties are found in a series of ternary molybdenum chalcogenides, M\textsubscript{x}Mo\textsubscript{6}X\textsubscript{8}, known as Chevrel phases.\textsuperscript{(25)} The first of these was PbMo\textsubscript{6}S\textsubscript{8} but over 40 metals have been incorporated in the series, and both Se and Te analogues occur. These phases are black crystalline materials, prepared from the elements at temperatures of 1000–1100°C, and the [Mo\textsubscript{6}X\textsubscript{8}] cluster, composed of an octahedron of Mo atoms face-capped by X atoms, is the basic structural unit (cf Mo, W dihalides, p. 1022). The clusters are linked because the otherwise free apical coordination site of each Mo is occupied by an X atom of an adjacent cluster, while the M\textsubscript{x} atoms are intercalated in the channels between the clusters. That these bridges are strong, is evident from the observed intercluster Mo–Mo distances of only 310–360 pm compared to approx. 270 pm for Mo atoms within a cluster — which are not bridged. With x = 0, the metastable Mo\textsubscript{6}X\textsubscript{8} (obtained by “deintercalation” of M\textsubscript{x}Mo\textsubscript{6}X\textsubscript{8} with HCl, rather than by direct synthesis) has only 20 electrons per cluster (6 × 6 metal valence electrons less 2 × 8 used in bonding to X\textsubscript{8}). This is 4 short of the 24 required for Mo–Mo single bonds along each of the edges of the cluster, and may be the cause of the observed trigonal distortion. Intercalation of M\textsubscript{x} atoms provides up to 4 electrons which make good this deficit thereby strengthening and shortening the Mo–Mo bonds and reducing the distortion.\textsuperscript{†} PbMo\textsubscript{6}S\textsubscript{8} has 22 electrons per cluster. The electron “holes” facilitate conduction, and below 14 K it is a superconductor. This, and several other Chevrel phases retain their superconductivity in the presence of exceptionally strong magnetic fields, and attempts to produce technically acceptable superconductors by extruding filaments in a copper matrix have been

\textsuperscript{25} R. CHEVREL, M. HIRRIEN and M. SERGENT, Polyhedron 5, 87–94 (1986).
\textsuperscript{†} An alternative interpretation, supported by evidence from relevant molecular compounds is that the distortions are the result of intercluster M–X interactions (see p. 1031).
promising. Apparently, no tungsten analogues are yet known.

23.3.6 **Halides and oxohalides**

The known halides of chromium, molybdenum and tungsten are listed in Table 23.4. The observed trends are as expected. The group oxidation state of +6 is attained by chromium only with the strongly oxidizing fluorine, and even tungsten is unable to form a hexaiodide. Precisely the same is true in the +5 oxidation state, and in the +4 oxidation state the iodides have a doubtful or unstable existence. In the lower oxidation states all the chromium halides are known, but molybdenum has not yet been induced to form a difluoride nor tungsten a di- or

(a)It is probable that previously reported green samples were largely CrF₃; O. KRAMER and B. G. MÜLLER, *Z. anorg. allg. Chem.* 621, 1969–72 (1995).
tri-fluoride. Similarly, in the oxohalides (which are largely confined to the +6 and +5 oxidation states, see p. 1023) tungsten alone forms an oxoiodide, while only chromium (as yet) forms an oxofluoride in the lower of these oxidation states.

All the known hexahalides can be prepared by the direct action of the halogen on the metal and all are readily hydrolysed. The yellow CrF6, however, requires a temperature of 400°C and a pressure of 200–300 atms for its formation, and reduction of the pressure causes it to dissociate into CrF5 and F2 even at temperatures as low as −100°C. The monomeric and octahedral hexafluorides MoF6 and WF6 are colourless liquids and the former is strongly oxidizing. Only tungsten is known with certainty to produce other hexahalides and these are the dark-blue solids WCl6 and WBr6, the latter in particular being susceptible to reduction.

Of the pentahalides, chromium again forms only the fluoride which is a strongly oxidizing, bright red, volatile solid prepared from the elements using less severe conditions than for CrF6. MoFs and WF5 can be prepared by reduction of the hexahalides with the metal but the latter disproportionates into WF6 and WF4 if heated above about 80°C. They are yellow volatile solids, isostructural with the tetrameric (NbF5)4 and (TaF5)4 (Fig. 22.4b, p. 990). Similarity with Group 5 is again evident in the pentachlorides of Mo and W, MoCl5 being the most extensively studied of the pentahalides. These, respectively, black and dark-green solids are obtained by direct reaction of the elements under carefully controlled conditions and have the same dimeric structure as their Nb and Ta analogues (Fig. 22.4c, p. 990). WBr5 can be prepared similarly but is not yet well characterized.

The tetrahalides are scarcely more numerous or familiar than the hexa- and penta-halides, the 3 tetraiodides together with CrBr4 and CrCl4 being either of uncertain existence or occurring only at high temperatures in the gaseous phase. The most stable representatives are the fluorides: CrF4 is an unreactive solid; MoF4 is an involatile green solid; and WF4 begins to decompose only when heated above 800°. MoCl4 exists in two crystalline modifications: α-MoCl4 is probably made up of linear chains of edge-shared octahedra, whereas β-MoCl4 has a unique structure composed of hexameric cyclic molecules (MoCl4)6 generated by edge-shared {MoCl6} octahedra with Mo−Cl 220 pm, Mo−Cl 243 and 251 pm and Mo···Mo 367 pm. General preparative methods include controlled reaction of the elements, reduction of higher halides, and halogenation of lower halides. The tetrahalides of Mo and W are readily oxidized and hydrolysed and produce some adducts of the form MX4L2.

The trihalides show major differences between the 3 metals. All 4 of the chromium trihalides are known, this being much the most stable oxidation state for chromium; they can be prepared by reacting the halogen and the metal, though CrF3 is better obtained from HF and CrCl3 at 500°C. The fluoride is green, the chloride red-violet, and the bromide and iodide dark green to black. In all cases layer structures lead to octahedral coordination of the metal. CrCl3 consists of a ccp lattice of chloride ions with CrIII ions occupying two-thirds of the octahedral sites of alternate layers. The other alternate layers of octahedral sites are empty and, without the cohesive effect of the cations, easy cleavage in these planes is possible and this accounts for the flaky appearance. Stable, hydrated forms of CrX3 can also be readily obtained from aqueous solutions, and CrCl3·6H2O provides a well-known example of hydrate isomerism, mentioned on p. 920. In view of this clear ability of CrIII to aqurate it may seem surprising that anhydrous CrCl3 is quite insoluble in pure water (though it dissolves rapidly on the addition of even a trace of a reducing agent). It appears that the reducing agent produces at least some CrIII ions. Solubilization then follows as a result of electron transfer from [Cr(aq)]2+ in solution via a chloride bridge to CrIII in the solid, which leaves [Cr(aq)]3+ in solution and CrII in the solid. The latter is kinetically far more labile than CrIII and can readily leave the solid and aqurate, so starting the cycle again and rapidly dissolving the solid.
The Mo trihalides are obtained by reducing a higher halide with the metal (except for the triiodide which, being the highest stable iodide, is best prepared directly). They are insoluble in water and generally inert. MoCl₃ is structurally similar to CrCl₃ but is distorted so that pairs of Mo atoms lie only 276 pm apart which, in view of the low and temperature-dependent magnetic moment, is evidently close enough to permit appreciable Mo-Mo interaction. Electrolytic reduction of a solution of MoO₃ in aqueous HCl changes the colour to green, then brown, and finally red when complexes of the octahedral [MoCl₆]³⁻, [MoCl₅(H₂O)]²⁻ and [Mo₂Cl₉]³⁻ can be isolated using suitable cations. The diversity of the coordination chemistry of molybdenum(III) is, however, in no way comparable to that of chromium(III).

By contrast, the tungsten trihalides (the trifluoride is not known) are “cluster” compounds similar to those of Nb and Ta. The trichloride and tribromide are prepared by halogenation of the dihalides. The structure of the former is based on the [M₆X₁₂]⁺⁺⁺ cluster (Fig. 22.6) with a further 6 Cl atoms situated above the apical W atoms. WBr₃, on the other hand, has a structure based on the [M₆X₈]⁺⁺⁺ cluster (see Fig. 23.5), but as it is formed by only a 2-electron oxidation of [W₂Br₈]⁴⁻ it does not contain tungsten(III) and is best formulated as [W₂Br₈]⁶⁻(Br₄⁻)(Br⁻)₂, where (Br₄⁻) represents a bridging polybromide group. Electrolytic reduction of WO₃ in aqueous HCl fails to produce the mononuclear complexes obtained with molybdenum, but forms the green [W₂Cl₉]³⁻ ion. This and its Cr and Mo analogues provide an interesting reflection of the increasing strength of M-M bonding in the order Cr'< sub >Ⅲ</sub> < Mo'< sub >Ⅲ</sub> < W'< sub >Ⅲ</sub>. The structure consists of 2 MCl₆ octahedra sharing a common face (Fig. 23.4) which allows the possibility of direct M-M bonding. In the Cr ion the Cr atoms are 312 pm apart, being actually displaced in their CrO₆ octahedra away from each other. The magnetic moment of [Cr₂Cl₆]³⁻ is normal for a metal ion with 3 unpaired electrons and indicates the absence of Cr-Cr bonding. In [Mo₂Cl₆]³⁻ the Mo atoms are 267 pm apart and the magnetic moment is low and temperature dependent, indicating appreciable Mo-Mo bonding. Finally, [W₂Cl₉]³⁻ is diamagnetic: the metal atoms are displaced towards each other, being only 242 pm apart (compared to 274 pm in the metal itself), consistent with a W-W triple bond (p. 1030).

Anhydrous chromium dihalides are conveniently prepared by reduction of the trihalides with H₂ at 300–500°C, or by the action of HX (or I₂ for the diiodide) on the metal at temperatures of the order of 1000°C. They are all deliquescent and the hydrates can be obtained by reduction of the trihalides using pure chromium metal and aqueous HX. All have distorted octahedral structures as anticipated for a metal ion with the d⁴ configuration which is particularly susceptible to Jahn–Teller distortion†. This is typified by CrF₂, which adopts a distorted rutile structure in which

Figure 23.4 Structure of [M₂Cl₉]⁻ showing the M–M bond through the shared face of two inclined MCl₆ octahedra. See also Fig. 7.9, p. 240, for an alternative representation of the confacial biocahedral structure.

† A theorem proposed by H. A. Jahn and E. Teller (1937) states that a molecule in a degenerate electronic state will be unstable and will undergo a geometrical distortion that lowers its symmetry and splits the degenerate state. Jahn–Teller distortions are particularly important and well-documented for octahedrally coordinated metal ions whose e₉ orbitals (i.e. axial) are unequally occupied: r₁⁰e₁ (high-spin Cr' and Mn''), r₂⁸e₉ (low-spin Co' and Ni'') and r₂⁶e₉ (Cu''). They are generally manifested by an elongation of the bonds on one axis, and may be ascribed to the d₉ orbital containing 1
4 fluoride ions are 200 pm from the chromium atom while the remaining 2 are 243 pm away. The strongly reducing properties of chromium(II) halides contrast, at first sight surprisingly, with the redox stability of the molybdenum(II) halides. Even the tungsten(II) halides, which admittedly are also strong reducing agents (being oxidized to their trihalides), may by their very existence be thought to depart from the expected trend.

Of the various preparative methods available for the dihalides of Mo and W, thermal decomposition or reduction of higher halides is the most general. The reason for their enhanced stability lies in the prevalence of metal–atom clusters, stabilized by M–M bonding. All 6 of these dihalides (Mo and W do not form difluorides) are isomorphous, with a structure based on the \[\text{[M}_6\text{X}_8\text{]}^{4+}\] unit briefly mentioned above for WBr₃ (see also Chevrel phases p. 1018). It can be seen (Fig. 23.5) that in this cluster each metal atom has a free coordination position. In the dihalides themselves, these positions are occupied by 6X⁻ ions, 4 of them bridging to other \[\text{[M}_6\text{X}_8\text{]}^{4+}\] units, giving the composition \[\text{[M}_6\text{X}_8\text{]}\text{X}_2\text{X}_4/2 = \text{MX}_2\]. Although precise details of the bonding scheme are not settled it is clear that in each cluster the 6 metals contribute \(6 \times 6 = 36\) valence electrons of which 4 are transferred to the counter anions, so producing the net charge, and 8 are used in bonding to the 8 chlorines of the cluster. Twenty-four electrons remain which can provide M–M bonds along each of the 12 edges of the octahedron of metal atoms accounting for the observed diamagnetism. Unlike the \(\text{M}_6\) clusters of the “electron-poor” elements of groups 3, 4 and 5 (pp. 950, 965 and 992) the incorporation of interstitial atoms offers no additional stability and is not observed.

The six outer halide ions are readily replaced, leaving the \[\text{[M}_6\text{X}_8\text{]}^{4+}\] core intact throughout a variety of substitution reactions. The eight core halogens are far less labile, but prolonged heating (16 h at 500°C) of \[\text{[Mo}_6\text{Cl}_8\text{Br}_4\text{]}^{2-}\] for instance, has been shown by \(^{19}\text{F} \text{nmr}\) spectroscopy to yield a mixture containing all 22 possible isomers of the \[\text{[Mo}_6\text{Br}_n\text{Cl}_{8-n}\text{]}^{4+}\] cluster. Oxidation of WBr₂ with Br₂ yields brownish-black crystals of the molecular cluster compound \(\text{W}_6\text{Br}_{14}\) in which a non-bridging Br completes the coordination sphere of each metal atom in the \(\{\text{W}_6\text{Br}_8\}\) core.

The oxohalides of all three elements (Table 23.5) are very susceptible to hydrolysis and their oxidizing properties decrease in the order \(\text{Cr} > \text{Mo} > \text{W}\). They are yellow to red liquids or volatile solids; probably the best known is the deep-red liquid, chromyl chloride, \(\text{CrO}_2\text{Cl}_2\). It is most commonly encountered as the distillate in qualitative tests for chromium or chloride and can be obtained by heating a dichromate and chloride in conc \(\text{H}_2\text{SO}_4\); it is an extremely aggressive oxidizing agent. The Mo and W oxohalides

---

\(^{26}\) An amorphous form of MoCl₂ is also known, whose spectroscopic properties suggest the presence of tetranuclear units; see W. W. Beers and R. E. McCarley, Inorg. Chem. 24, 472–5 (1985).

Cr⁴⁺OCl₂ has been observed in the gaseous phase by means of mass spectrometry.(29)

are prepared by a variety of oxygenation and halogenation reactions which frequently produce mixtures, and many specific preparations have therefore been devised.(28) They are possibly best known as impurities in preparations of the halides from which air or moisture have been inadequately excluded, and their formation is indicative of the readiness with which metal–oxygen bonds are formed by these elements in high oxidation states.

### 23.3.7 Complexes of chromium, molybdenum and tungsten

#### Oxidation state VI (d⁰)

No halogeno complexes of the type [MX₆⁺⁺⁺]⁻ are known and, although homoleptic imido complexes, Li₂[M(NBu')₄] (M = Cr, Mo, W), containing tetrahedrally coordinated M⁶⁺ have been prepared,(32) the coordination chemistry of this oxidation state is centred mainly on oxo and peroxo complexes. The former class includes chromyl alkoxides(33) and adducts of tungsten oxohalides such as [WOX₅]⁻ and [WO₂X₄]²⁻ (X = F, Cl), but most are octahedral chelates of

---

the types $[\text{MO}_2 \text{X}_2(\text{L}-\text{L})]^3^4$ and $[\text{MO}_2(\text{L}-\text{L}^-)_2]$ (M = Mo, W). In the $\text{MO}_2^2+$ group of these compounds the oxygen atoms are mutually cis, thereby maximizing the $\text{O}(p\pi) \rightarrow \text{M}(d\sigma)$ bonding, and the group is reminiscent of the uranyl $\text{UO}_2^{2+}$ ion (p. 1273), though its chemistry is by no means as extensive and the latter is a linear ion. The best-known example of this type of compound is $[\text{MoO}_2(\text{oxinate})_2]$ used for the gravimetric determination of molybdenum; oxine is 8-hydroxyquinoline, i.e.

The peroxo-complexes provide further examples of the ability of oxygen to coordinate to the metals in their high oxidation states. The production of blue solutions when acidified dichromates are treated with $\text{H}_2\text{O}_2$ is a qualitative test for chromium. † The colour arises from the unstable $\text{CrO}_5$ which can, however, be stabilized by extraction into ether, and blue solid adducts such as $[\text{CrO}_5(\text{py})]$ can be isolated. This is more correctly formulated as $[\text{CrO}(\text{O}_2)\text{py}]$ and has an approximately pentagonal pyramidal structure (Fig. 23.6a). Bidentate ligands, such as phenanthroline and bipyridyl produce pentagonal bipyramidal complexes in which the second N-donor atom is loosely bonded trans to the $\equiv \text{O}$ (Fig. 23.6b). This 7-coordinate structure is favoured in numerous peroxo-complexes of Mo and W, and the dark-red peroxy anion $[\text{Mo}(\text{O}_2)_4]^2^-$ is 8-coordinate, with Mo–O 197 pm and O–O 155 pm.

**Oxidation state V (d$^1$)**

This is an unstable state for chromium and, apart from the fluoride and oxohalides already mentioned, it is represented primarily by the blue to black chromates of the alkali and alkaline earth metals and the red-brown tetraperoxochromate(V). The former contain the tetrahedral $[\text{CrO}_4]^{3-}$ ion and hydrolyse with disproportionation to Cr(II1) and Cr(VI). The latter can be isolated as rather more stable salts from alkaline solutions of dichromate treated with $\text{H}_2\text{O}_2$. These red salts contain the paramagnetic 8-coordinate, dodecahedral, $[\text{Cr}(\text{O}_2)_4]^{3-}$ ion, which is isomorphous with the corresponding complex ions of the Group 5 metals (p. 994). The $\eta^2$–$\text{O}_2$ groups are unsymmetrically coordinated, with Cr–O 185 and 195 pm and the O–O distance 141 pm.

The heavier elements have a much more extensive +5 chemistry including, in the case of molybdenum, a number of compounds of considerable biological interest which will be discussed separately (p. 1035). A variety of reactions involving fusion and nonaqueous

---

† The acidity is important. In alkaline solution $[\text{CrV}(\text{O}_2)_4]$ is produced, but from neutral solutions explosive violet salts, probably containing $[\text{CrVI}(\text{O}_2)_2\text{OH}]^-$, are produced.
solvents has been used to produce octahedral hexahalogeno complexes. These are very susceptible to hydrolysis, and the affinity of Mo\textsuperscript{V} for oxygen is further demonstrated by the propensity of MoCl\textsubscript{5} to produce green oxomolybdenum(V) compounds by oxygen-abstraction from appropriate oxygen-containing materials. This leads to a number of well-characterized complexes of the type [MoOC\textsubscript{13}L] and [MoOC\textsubscript{13}L\textsubscript{2}]. Oxomolybdenum(V) compounds are also obtained from aqueous solution and include monomeric species such as [MoOX\textsubscript{5}]\textsuperscript{2-} (X = Cl, Br, NCS) and dimeric, oxygen-bridged complexes such as [Mo\textsubscript{2}O\textsubscript{4}(C\textsubscript{2}O\textsubscript{4})\textsubscript{2}(H\textsubscript{2}O\textsubscript{2})\textsubscript{2}]\textsuperscript{2-} (Fig. 23.7) which may be considered to be derived from the orange-yellow aquo ion [Mo\textsubscript{2}O\textsubscript{4}(H\textsubscript{2}O\textsubscript{6})\textsubscript{2}]\textsuperscript{2+}. Whereas the monomeric compounds are paramagnetic with magnetic moments corresponding to 1 unpaired electron, the binuclear compounds are diamagnetic, or only slightly paramagnetic, suggesting appreciable metal–metal interaction occurring either directly or via the bridging oxygens.

Also of interest are the octacyano complexes, [M(CN)\textsubscript{8}]\textsuperscript{3-} (M = Mo, W), which are commonly prepared by oxidation of the Mo\textsuperscript{IV} analogues (using MnO\textsubscript{4} \textsuperscript{2-} or Ce\textsuperscript{IV}) and whose structures apparently vary, according to the environment and counter cation, between the energetically similar square-antiprismatic and dodecahedral forms.\textsuperscript{(35)}

**Oxidation state IV (d\textsuperscript{2})**

As for the previous oxidation state, the chemistries of Mo\textsuperscript{IV} and W\textsuperscript{IV} are much more extensive than that of Cr\textsuperscript{IV} which is largely confined to peroxo- and fluoro- complexes. [Cr(O\textsubscript{2})\textsubscript{2}(NH\textsubscript{3})\textsubscript{3}], which has a dark red-brown metallic lustre, may be obtained either by treating [Cr(O\textsubscript{2})\textsubscript{4}]\textsuperscript{3-} with warm aqueous ammonia or by the action of H\textsubscript{2}O\textsubscript{2} on ammoniacal solutions of (NH\textsubscript{4})\textsubscript{2}Cr\textsubscript{2}O\textsubscript{7}. It has a pentagonal bipyramidal structure in which the peroxo- groups occupy four of the planar positions, and the NH\textsubscript{3} molecules are replaceable by other ligands. The very hydrolysable salts of [CrF\textsubscript{6}]\textsuperscript{2-} are obtained by direct fluorination of anhydrous CrCl\textsubscript{3} and an alkali metal chloride.

More or less hydrolysable hexahalogeno salts of [MX\textsubscript{5}]\textsuperscript{2-} (M = Mo, X = F, Cl, Br; M = W, X = Cl, Br) are also known and the yellow octacyano compounds have provided structural interest ever since the classical work of J. L. Hoard in 1939 established K\textsubscript{4}[Mo(CN)\textsubscript{8}].2H\textsubscript{2}O as the first example of an 8-coordinate complex. This and its W analogue have dodecahedral (D\textsubscript{d}d) structures and their diamagnetism arises from the splitting of their d-orbitals which stabilizes one (probably the d\textsubscript{xy}) to such an extent that the two d electrons pair in it. The energy barrier between dodecahedral and square antiprismatic (D\textsubscript{4d}) structures is, however, small and the latter is obtained if the K\textsuperscript{+} counter cations are replaced by Cd\textsuperscript{2+}.\textsuperscript{36}Mo and W\textsuperscript{14N} nmr studies show\textsuperscript{(35a)} that the ion is dodecahedral in aqueous solution and that the equivalence of the eight CN groups (indicating the more symmetrical D\textsubscript{4d} form), implied by earlier \textsuperscript{13}C work, arises from rapid tumbling of the ion rather than fluxional rearrangement. Photolysis of the otherwise stable [M(CN)\textsubscript{8}]\textsuperscript{4-} solutions causes loss of four CN\textsuperscript{-} ions to give octahedral oxo compounds such as K\textsubscript{4}[MO\textsubscript{2}(CN)\textsubscript{4}].6H\textsubscript{2}O (M = Mo, W).

Other mononuclear complexes include the tetrahedral [Mo(NMe\textsubscript{2})\textsubscript{4}] and the octahedral Li\textsubscript{2}[Mo(NMe\textsubscript{2})\textsubscript{6}].2thf\textsuperscript{36} but recent interest in the chemistry of the Mo\textsuperscript{IV} ion has centred on the trinuclear oxo and thio complexes of Mo and W, particularly the former. They are of three main types. The first may be conceptually based on the [M\textsubscript{3}O\textsubscript{13}] unit found in the aquo ions [M\textsubscript{3}O\textsubscript{4}(H\textsubscript{2}O\textsubscript{9})\textsuperscript{4+} (M = Mo,\textsuperscript{37} W). It contains a

Trinuclear, M–M bonded species of Mo$^{IV}$ and W$^{IV}$. (a) (b) and (c) are alternative representations of the M$_3$O$_3$ unit: (a) emphasizes its relationship to the edge-sharing octahedra of the M$_3$ group in polymetallate ions; (b) shows the ($\mu_3$-O) ($\mu_2$-O)$_3$ bridges and M–M bonds of its M$_3$O$_4$ "incomplete cubane" core; and (c) emphasizes its triangular centre by viewing from the unoccupied corner of the cuboid. (d) and (e) offer the same perspective as (c) but of [M$_3$O$_2$(O$_2$CR)$_6$(H$_2$O)$_3$]$^{2+}$ and [M$_4$($\mu_3$-X)($\mu_1$-OR)(OR)$_9$] structures respectively.

Triangle of M–M bonded metals capped by a single oxygen on one side and on the other side three oxygens bridge each pair of metal atoms. It may be viewed either as a reduced form of the M$_3$ group found in polymetallate ions, or as an "incomplete cubane-type" of complex$^{(38)}$ (Fig. 23.8). Some, or all, of the nine water molecules of the aquo ion are replaceable by a variety of ligands including oxalate, edta and NCS$^-$, and thio derivatives$^{(38a)}$ containing M$_3$O$_2$S, M$_3$O$_2$S$_2$, M$_3$OS$_4$ and M$_3$S$_4$ cores have been prepared. In the mixed O/S species, S appears always to occupy the $\mu_3$-position. M–M bond lengths are about 250 pm for M$_3$O$_4$ species increasing to 270–280 pm for M$_3$S$_4$, there being very little difference between Mo and W compounds. Preparative routes vary but usually involve reduction from M$^{V}$ or M$^+$, often by the use of NaBH$_4$. Se and Te analogues of the Mo compounds are also known and an Se analogue for W has recently been reported.$^{(39)}$

The second type of trinuclear compounds containing [M$_3$O$_2$(O$_2$CR)$_6$(H$_2$O)$_3$]$^{2+}$ and obtained by the reaction of M(CO)$_6$ (M = Mo, W) with carboxylic acids, features a similar triangle of M–M bonded metal atoms but this time capped on both sides by $\mu_3$-O atoms (Fig. 23.8d). Complexes in which either one or both of these capping atoms are replaced by $\mu_3$-CR, alkylidene,

§23.3.7 Complexes of chromium, molybdenum and tungsten

groups are also obtainable and all these bicapped species are notable for their kinetic inertness. The third trinuclear type is that of the alkoxides $[M_3(\mu_3-X)(\mu_3-OR)(OR)_3] \ (M = Mo, W; \ X = O, NH)\[40\]$ which again are bicapped but with only single bridges spanning the $M-M$ bonds (Fig. 23.8e).

**Oxidation state III ($d^3$)**

This is by far the most stable and best-known oxidation state for chromium and is characterized by thousands of compounds, most of them prepared from aqueous solutions. By contrast, unless stabilized by $M-M$ bonding, molybdenum(III) compounds are sparse and hardly any are known for tungsten(III). Thus Mo, but not W, has an aquo ion $[Mo(H_2O)_6]^{3+}$, which gives rise to complexes $[MoX_6]^{3-} \ (X = F, Cl, Br, NCS)$. Direct action of acetylacetone on the hexachloromolybdate(III) ion produces the sublimable $[Mo(acac)_3]$ which, however, unlike its chromium analogue, is oxidized by air to Mo$^V$ products. A black Mo$^{III}$ cyanide, $K_4Mo(CN)_7.2H_2O$, has been precipitated from aqueous solution by the addition of ethanol. Its magnetic moment ($\sim 1.75$ BM) is consistent with 7-coordinate Mo$^{III}$ in which the loss of degeneracy of the $t_{2g}$ orbitals has caused pairing of 2 of the three $d$ electrons.

Chromium(III) forms stable salts with all the common anions and it complexes with virtually any species capable of donating an electron-pair. These complexes may be anionic, cationic, or neutral and, with hardly any exceptions, are hexacoordinate and octahedral, e.g.:

- $[CrX_6]^{3-} \ (X = \text{halide, CN, SCN, N}_3)$
- $[Cr(L-L)_3]^{3-} \ (L-L = \text{oxalate})$
- $[CrX_6]^{3+} \ (X = H_2O, NH_3)$
- $[Cr(L-L)_3]^{3+} \ (L-L = \text{en, bipy, phen})$
- $[Cr(L-L)_3] \ (L-L = \beta\text{-diketonates, amino-acid anions})$

There is also a multitude of complexes with 2 or more different ligands, such as the pentaammines $[Cr(NH_3)_5X]^{n+}$ which have been extensively used in kinetic studies. These various complexes are notable for their kinetic inertness, which is compatible with the half-filled $t_{2g}$ level arising from an octahedral $d^3$ configuration and is the reason why many thermodynamically unstable complexes can be isolated. Ligand substitution and rearrangement reactions are slow (half-times are of the order of hours), with the result that the preparation of different, solid, isomeric forms of a compound was the classical means of establishing stereochemistry and the reason why early coordination chemists devoted so much attention to Cr$^{III}$ complexes. For precisely the same reason, however, the preparation of these complexes is not always straightforward. Salts such as the hydrated sulfate and halides, which might seem obvious starting materials, themselves contain coordinated water or anions and these are not always easily displaced. Simple addition of the appropriate ligand to an aqueous solution of a Cr$^{III}$ salt is therefore not a usual preparative method, though in the presence of charcoal it is feasible in the case, for instance, of $[Cr(en)_3]^{3+}$. Some alternative routes, which avoid these pre-formed inert complexes, are:

(i) **Anhydrous methods**: ammine and amine complexes can be prepared by the reaction of $CrX_3$ with $NH_3$ or amine, and salts of $[CrX_6]^{3-}$ anions are best obtained by fusion of $CrX_3$ with the alkali metal salt.

(ii) **Oxidation of Cr(II)**: ammine and amine complexes can also be prepared by the aerial oxidation of mixtures of aqueous $[Cr(H_2O)_5]^{2+}$ (which is kinetically labile) and the appropriate ligands.

(iii) **Reduction of Cr(VI)**: $CrO_3$ and dichromates are commonly used to prepare such complexes as $K_3[Cr(C_2O_4)_3]$ and $NH_4[Cr(NH_3)_2(NCS)_2].H_2O$ (Reinecke’s salt).

The violet hexaaquo ion, $[Cr(H_2O)_6]^{3+}$, occurs in the chrome alums, $Cr_2(SO_4)_3MgSO_4.24H_2O$

$^{(a)}$Room temperature value of $\mu_e$.

Chromium(III) is the archetypal $d^3$ ion and the electronic spectra and magnetic properties of its complexes have therefore been exhaustively studied\(^{(41)}\) (see Panel). Data for a representative sample of complexes are given in Table 23.6.

One of the most obvious characteristics of $\text{Cr}^{III}$ is its tendency to hydrolyse and form polynuclear complexes containing OH$^-$ bridges. This is thought to occur by the loss of a proton from coordinated water, followed by coordination of the OH$^-$ so formed to a second cation:

$$\text{Cr}^{III} + \text{H}_2\text{O} \rightarrow \text{Cr}^{III} \cdot \text{H}_2\text{O}$$

The ease with which the proton is removed can be judged by the fact that the hexaaquo ion ($pK_a \sim 4$) is almost as strong an acid as formic acid. Further deprotonation and polymerization can occur and, as the pH is raised, the final product is hydrated chromium(III) oxide or "chromic hydroxide". Formation of this is the reason why amine complexes are not prepared by simple addition of the amine base to an aqueous solution of $\text{Cr}^{III}$. By methods which commonly start with $\text{Cr}^{III}$, binuclear compounds such as [(en)$_2$Cr($\mu_2$-OH)$_2$Cr(en)$_2$] and [(NH$_3$)$_3$Cr($\mu$-OH)Cr(NH$_3$)$_3$]X$_5$ are obtained. These have temperature-dependent magnetic moments, somewhat lower than those usual for octahedral $\text{Cr}^{III}$ and indicative of weak antiferromagnetic interaction via the bent Cr–O–H–Cr bridges. Stronger antiferromagnetic interaction (magnetic moment per metal atom at room temperature $\sim 1.3$ BM falling to zero below 100 K) is found in the oxo-bridged derivative of the latter compound:

$$[(\text{NH}_3)_5\text{Cr}(\mu$-$\text{OH})\text{Cr(NH}_3)_3]^{5+} \xrightarrow{\text{OH}^-} \text{H}^+$$

The linear Cr–O–Cr bridge evidently permits pairing of the d electrons of the 2 metal atoms via $d_{\sigma}-p_{\sigma}$ bonds, much more readily than the bent Cr–OH–Cr bridge. Blue [LCr($\mu_2$-O)(O$_2$CMe)$_2$CrL] ($L = 1,4,7$-trimethyl-$1,4,7$-triazacyclononane), produced similarly by

Electronic Spectra and Magnetic Properties of Chromium(III)

In an octahedral field the free-ion ground $^4F$ term of a $d^3$ ion is split into an $A$ and two $T$ terms which, along with the excited $^4T(P)$ term (Fig. A), give rise to the possibility of three spin-allowed $d-d$ transitions of which the one of lowest energy is a direct measure of the crystal field splitting, $\Delta$ or $10Dq$:

![Energy Level diagram for a d³ ion in an octahedral crystal field.](image)

Figure A  Energy Level diagram for a $d^3$ ion in an octahedral crystal field.

Assignment of the observed bands to these transitions, provides an estimate of $B$, the Racah “interelectron repulsion parameter.” Its value (Table 23.6) is invariably below that of the free-ion (1030 cm⁻¹) because the expansion of $d$-electron charge on complexation reduces the interelectronic repulsions.

The magnetic moment arising from the ground $^4A$ term is expected to be close to the spin-only value of 3.87 BM and independent of temperature. In practice, providing the compounds are mononuclear, these expectations are realized remarkably well apart from the fact that, as was noted for octahedral complexes of vanadium(III), the third high-energy band in the spectrum is usually wholly or partially obscured by more intense charge-transfer absorption.

In addition to the terms so far mentioned there are a number of spin doublets and, in the Cr$^{3+}$ ions of ruby (α-Al₂O₃, corundum, in which a small proportion of Al$^{3+}$ ions have been replaced by Cr$^{3+}$), two of these ($^2E$ and $^2T_{1g}$) lie just below the $^4T_{2g}$ ions excited to the $^4T_{2g}$ may decay back to the ground level with spontaneous emission of radiation but some will decay instead to the doublets, the small energy difference being converted to lattice vibrations. The rate of decay by spontaneous emission from the doublets to the ground level is however slow, being spin-forbidden, but can be induced by interaction with photons of the same energy as those to be emitted (i.e. stimulated emission). This situation is exploited in the ruby laser, in which a rod of ruby is irradiated by intense light of appropriate frequency to continually excite and re-excite the Cr$^{3+}$ ions to the $^4T_{2g}$ term. This optical pumping has the effect of steadily building up the population of the doublets. At suitable intervals the photons from the small proportion of ions which do spontaneously decay from the doublets are reflected by mirrors back through the rod where they interact with the excited ions, triggering their decay. This produces a burst of extremely intense radiation which is monochromatic, coherent and virtually non-divergent.

deprotonation of a pink, OH-bridged species but, crucially, with a 120° Cr-O-Cr bridge, shows only weak antiferromagnetic interaction. Examples of O atoms providing π pathways for antiferromagnetic interaction are also to be found among trinuclear compounds of Cr$^{3+}$.

---

Figure 23.9 Trinuclear compounds of CrIII: (a) \([\text{Cr}_3(\text{SCH}_2\text{CH}_2\text{O})_6]^{3-}\). (b) and (c) are alternative representations of \([\text{Cr}_3(\mu_3-\text{O})(\text{O}_2\text{CR})_6]^+\).

(PPh₄)₂Na[Cr₃(SCH₂CH₂O)₆], for instance, consists of three face-sharing octahedra in which the CrIII atoms are linearly aligned and the O-, S-donor ligands are arranged so that all bridging atoms are oxygens⁴⁴ (Fig. 23.9a). A whole series of “basic” carboxylates of the general type \([\text{Cr}_3\text{O}(\text{RCOO})_6\text{L}_3]^+\) show weak interactions and have the structure (Fig. 23.9b,c) common to carboxylates of other MIII atoms and containing a central \(\mu_3-\text{O}\).⁴⁵

Hydrolysed, polynuclear CrIII complexes are of considerable commercial importance in the dying and tanning industries. In the former the role is that of a mordant to the dye. In leather production it is necessary to treat animal hides to prevent putrefaction and to render them supple when dry. Traditionally, tannin was used, hence the name of the process, but this was superseded towards the end of the nineteenth century by solutions of chromium(III) sulfate. After soaking in sulfuric acid the hides are impregnated with the CrIII solution. This is subsequently made alkaline, when the polynuclear complexes form and bridge neighbouring chains of proteins, presumably by coordinating to the carboxyl groups of the proteins.

The bulk of the chemistry of MoIII and WIII is associated with M≡M bonded species⁴⁶ which have been extensively studied for over a decade. M₂X₆ compounds are commonly found with \(X = \text{NR}_2, \text{OR}, \text{CH}_2\text{SiMe}_3, \text{SAr}\) and more recently SeAr,⁴⁷ and are generally both oxygen- and moisture-sensitive. The usual preparative route is by reacting metal halides with LiNR₂ followed by ligand substitution of the M₂(NR₂)₆ so obtained, and the products are of the type \(X_3\text{M≡MX}_3\) in which the two MX₃ halves are staggered with respect to each other. The \(\sigma^2\pi^4\) triple bond is readily understood from the MO diagram of Fig. 23.12 (p. 1033), given that the two d³ metal ions contribute six electrons for M–M bonding. Neutral ligands can sometimes be added, to yield \(LX_3\text{M≡MX}_3L\), and a series of tetranuclear products has been obtained by dimerization of M₂(OR)₆.

---

The precise shape of the M₄ core can be varied by partial substitution of OR with halide, and ranges from square to "butterfly" but apparently never tetrahedral.\(^{48}\)

Another type of triply bonded species is represented by the purple and unusually air-stable, Cs₂[Mo₂(HPO₄)₄(H₂O)₂], prepared by the reaction of K₂MoCl₈.2H₂O and CsCl in aqueous H₃PO₄. Here the cation has the dinuclear structure more commonly found in the divalent carboxylates (see below) and the M≡M bond is supported by phosphate bridges.

Although having formal oxidation states of \(\frac{2}{3}\) per metal, it is opportune to mention here important molecular analogues of the Chevrel phases.\(^{49}\) M₆S₈(PEt₃)₆, (M = Mo, W) have the same octahedral [M₆S₈] core found in Chevrel phases (with the addition of terminal phosphines on each metal) but without the trigonal elongation found in the latter (p. 1018). That both are 20-electron clusters is compelling evidence that the distortion arises from intercluster interactions, which are absent in the molecular compounds, rather than because the number of cluster electrons is insufficient to form M−M bonds along all twelve edges of the octahedron.

**Oxidation state II (d⁴)**

For chromium, this oxidation state is characterized by the aqueous chemistry of the strongly reducing Cr⁺⁺ cation, and a noticeable tendency to form dinuclear compounds with multiple metal−metal bonds. This tendency is even more marked in the case of molybdenum but, perhaps surprisingly, is much less so in the case of tungsten.\(^1\) Though single M−M bonds are present in the [M₆X₈]⁺⁺ clusters of the dihalides of both Mo and W (p. 1022).

With the exception of the nitrate, which has not been prepared because of internal oxidation−reduction, the simple hydrated, sky-blue, salts of chromium(II) are best obtained by the reaction of the appropriate dilute acid with pure chromium metal, air being rigorously excluded. A variety of complexes is formed, especially with N-donor chelating ligands which commonly produce stoichiometries such as [Cr(L−L)₃]⁺⁺ and [Cr(L−L)₂X₂]. They (and other complexes of Cr⁺⁺) are generally extremely sensitive to atmospheric oxidation if moist, but are considerably more stable when dry, probably the most air-stable of all being the pale-blue hydrazinium sulfate, (N₂H₅)₂Cr⁺⁺(SO₄)₂. In the solid state this consists of linear chains of Cr⁺⁺ ions, bridged by SO₄²⁻ ions:

![Diagram](image)

The majority of Cr⁺⁺ complexes are octahedral and can be either high-spin \(t_{2g}e_{g}^{-}\) or low-spin \(t_{2g}^{-}\). The former are characterized by magnetic moments close to 4.90 BM and visible/ultraviolet spectra consisting typically of a broad band in the region of 16000 cm⁻¹ with another band around 10000 cm⁻¹. Since a d⁴ ion in a perfectly octahedral field can give rise to only one d−d transition it is clear that some lowering of symmetry has occurred. Indeed, this is expected as a consequence of the Jahn–Teller effect, even when the metal is surrounded by 6 equivalent donor atoms. The splitting of the free-ion ⁵D

---

\(^1\) A major reason for their comparative paucity is that the dinuclear acetate, which in the case of Mo is the most common starting material in the preparation of quadruply bonded dimeric complexes, is unknown for W.
term is shown in Fig. 23.10 and the two observed bands are assigned to superimposed \( ^5B_{2g} \leftarrow ^5B_{1g} \) and \( ^5E_g \leftarrow ^5B_{1g} \) transitions and to the \( ^5A_{1g} \leftarrow ^5B_{1g} \) transition respectively. The low-spin, intensely coloured compounds such as \( K_4[Cr(CN)_6]\cdot 3H_2O \) and \( [Cr(L\cdot L)_3]X_2\cdot nH_2O \) (\( L\cdot L = \text{bipy, phen; } X = \text{Cl, Br, I} \)) have magnetic moments in the range 2.74–3.40 BM and electronic spectra showing clear evidence of extensive \( \pi \) bonding, as is to be expected with such ligands.

Although distorted octahedral geometry is certainly the most usual, \( \text{Cr}^{\text{III}} \) has a varied stereochemistry, as indicated in Table 23.2 (p. 1006).

One of the best known of \( \text{Cr}^{\text{III}} \) compounds, and one which has often been used as the starting material in preparations of other \( \text{Cr}^{\text{III}} \) compounds, is the acetate, itself obtained by addition of sodium acetate to an aqueous solution of a \( \text{Cr}^{\text{III}} \) salt. The red colour of the hydrated acetate is in sharp distinction to the blue of the simple salts — a contrast reflected in its dinuclear, bridged structure (Fig. 23.11a). This structure is also found in the yellow \( [\text{Mo}_2(\mu,\eta^2\text{O}_2\text{CMe})_4] \) which is obtained by the action of acetic acid on \( [\text{Mo}(\text{CO})_6] \). Other carboxylates of \( \text{Cr} \) and \( \text{Mo} \) are familiar and the dinuclear structure is found also in the yellow alkali metal salts of \( [\text{Cr}_2(\text{CO}_3)_4]^4^- \) and the pink \( K_4[\text{Mo}_2(\text{SO}_4)_4]\cdot 2H_2O \) where the oxoanions \( \text{CO}_3^{2-} \) and \( \text{SO}_4^{2-} \) are the bridging groups. Although an exact structure determination is lacking it is likely that the violet dihydrate, obtained by partial dehydration of the blue “double sulphate” \( \text{Cs}_2\text{SO}_4\cdot \text{CrSO}_4\cdot 6\text{H}_2\text{O} \), is of the same type in which case the formula \( \text{Cs}_4[\text{Cr}_2(\mu,\eta^2\text{SO}_4)_4]\cdot (\text{H}_2\text{O})_2\cdot 2\text{H}_2\text{O} \) would be appropriate. \([\text{NBu}_4]_2[\text{Cr(NCS)}_4]\) exists in two forms in which the usual correlation between structure and colour of \( \text{Cr}^{\text{III}} \) salts is reversed.\(^{49a}\)

The red form contains the mononuclear, planar \( [\text{Cr(NCS)}_4]^2^- \) ion whereas the blue form contains the dinuclear \( [(\text{NCS})_3\text{Cr}(\mu-\text{NCS})\text{Cr(NCS)}_3]^4^- \) ion featuring bridging thiocyanates (p. 324).

The reaction of conc HCl and molybdenum acetate at 0°C produces the diamagnetic red anion \( [\text{Mo}_2\text{Cl}_8]^4^- \) (Fig. 23.11b) in which the 2 \( \text{MoCl}_4 \) are in the “eclipsed” orientation relative to each other and are held together solely by the Mo–Mo bond. At somewhat higher temperatures (∼50°C) the above reactants also produce the \( [\text{Mo}_2\text{Cl}_8\text{H}]^3^- \) ion which has the \( [\text{M}_2\text{Cl}_6]^3^- \) structure (Fig. 23.4) but with one of the bridging Cl atoms replaced by a H atom.

An abundance of dinuclear compounds with a wide range of bridging groups involving not only the O–C–O unit of the carboxylates but also N–C–O, N–C–N, N–N–N and C–C–O, or like \( [\text{Mo}_2\text{Cl}_8]^4^- \) with no bridging groups at all, are now known for \( \text{Cr}^{\text{III}} \) and \( \text{Mo}^{\text{III}} \), particularly the latter. \( \text{W}^{\text{III}} \) also forms a comparatively small number and analogues of the isoelectronic \( \text{Re}^{\text{III}} \) and \( \text{Tc}^{\text{III}} \) are well-known (p. 1058–9). The \( \text{Cr}^{\text{III}} \) compounds apart, all these compounds whether bridged or not are diamagnetic, have very short M–M distances and clearly involve M–M bonds the precise nature of which has excited considerable attention.\(^{46}\)

The best simple description of the \( d^4 \) systems is that shown in Fig. 23.12. The \( d_2^2, d_y^2 \) orbital is assumed to have been used in \( \sigma \) bonding to the ligands and the four \( d \) electrons on each metal atom are then used to form a M–M quadruple bond (\( \sigma + 2\pi + \delta \)) as originally proposed by B. N. Figgis and R. L. Martin for the bonding in dinuclear chromium(II) acetate (\( J. \text{Chem. Soc.} \) 3837–46 (1956)). The characteristic

Figure 23.11 (a) $[\text{M}_2(\mu,\eta^2-\text{O}_2\text{CMe})_4]$, $\text{M} = \text{Cr, Mo}$. In the case of Cr, but not Mo, the hydrate and other adducts can be formed by attachment of $\text{H}_2\text{O}$ (or in general, $\text{L}$) molecules as arrowed. (b) $[\text{Mo}_2\text{Cl}_8]^{3-}$.

Figure 23.12 Simplified MO diagram showing the formation of an $\text{M} - \text{M}$ quadruple bond in $\text{M}_2\text{L}_8$ systems of $\text{d}^4$ metal ions giving a ground configuration of $\sigma^2\pi^4\delta^2$ (the $d_{x^2-y^2}$, along with $p_x$, $p_y$ and $s$ orbitals of the metal ions are assumed to be used in the formation of $\text{M} - \text{L} \sigma$ bonds).
red colour arises from the visible absorption at 19\,000\,cm\(^{-1}\) which is readily ascribed to the \(\sigma^2\pi^4\delta^* \leftarrow \sigma^2\pi^4\delta^2\) transition. The same assignment is also made for the absorption at 14\,300\,cm\(^{-1}\) which is responsible for the blue colour of \([\text{Re}_2\text{Cl}_8]\)\(^{2-}\) (p. 1058). The eclipsed orientation noted in \([\text{MoCl}_{14}]^-\) provides strong confirmation of this bonding scheme since, without the \(\delta\) bond, this configuration would be sterically unfavourable. A variety of experimental techniques, which includes polarized single-crystal spectroscopy, photoelectron spectroscopy, and X-ray emission spectroscopy, has been used to further substantiate this view of the bonding. Accurately determined M–M distances provide the most readily available indication of bond strength. The shortest, and therefore presumably the strongest, bonds are found in those compounds with no axial ligands (i.e. like Fig. 23.11b or a, without the Ls). Dimolybdenum(II) compounds, which bind axial ligands only reluctantly, have M–M distances in the approximate range 204–220 pm (where corresponding W\(^{\text{II}}\) compounds are known, the W–W distances are about 10 pm longer), whereas the M–M distances in dichromium(II) compounds fall into two distinct ranges: 183–200 and 220–250 pm. The longer Cr–Cr distances refer to the Cr\(^{\text{II}}\) carboxylates and, in spite of the smaller size of the metal atom, are longer than for the Mo\(^{\text{II}}\) carboxylates.\(^*\) The Cr(II) carboxylates readily form axial adducts and measurements of magnetic susceptibility show that the acetate is inherently slightly paramagnetic, which has been confirmed recently by variable temperature nmr.\(^{50}\) This implies partial occupation of a low-lying spin triplet \((S = 1,\) two unpaired electrons\) and clearly indicates weaker M–M interaction than in the Mo\(^{\text{II}}\) and other Cr\(^{\text{II}}\) dinuclear compounds with shorter M–M distances. Whether this is a consequence, however, of the involvement of a different type of interaction in the Cr\(^{\text{II}}\) carboxylates — antiferromagnetic coupling between high-spin Cr\(^{2+}\) ions rather than just weak quadrupole bonding — has not yet been unequivocally decided.

Interesting spin transitions are also observed: Although the reddish-purple \([\text{Cr}_2(\text{dmpe})_2]\), \((\text{dmpe} = 1,2\text{-bis(dimethylphosphino)ethane})\) is low-spin, the purple-brown \([\text{Cr}_2(\text{depe})_2]\), \((\text{depe} = 1,2\text{-bis(diethylphosphino)ethane})\) is high-spin \((\mu = 4.87\text{BM})\) at room temperature but quite suddenly becomes low-spin \((\mu = 2.82\text{BM})\) at \(\sim 170\text{K}\)\(^{51}\). A spin transition, the first one for a second row transition metal, is also displayed by \(\text{cis-}[\text{Mo}(\text{OPri})_2(\text{bipy})_2]\), the reduction in \(\mu_{\text{e}}\) being more gradual, from 1.96 BM at 305 K to 1.04 BM at 91 K. It is suggested\(^{52}\) that the \(\pi\)-donor properties of the alkoxide ligands split the \(t_{2g}\) orbitals into “two below one” and that thermal equilibrium then results between the diamagnetic configuration in which the four d-electrons are paired in the lower two orbitals, and the paramagnetic configuration in which one electron is promoted to the upper orbital.

In contradistinction to this, weak ferromagnetism has been observed in a number of chloro and bromo complexes of the type \(\text{M}_2[\text{CrX}_4]\) \((\text{M} = \text{a variety of protonated amines and alkali metal cations, X = Cl, Br), which are analogous to previously known copper(II) complexes (p. 1192). They have magnetic moments at room temperature in the region of 6 BM (compared

\(^{*}\) To effect acceptable comparisons between compounds of different metals F. A. Cotton introduced the concept of the “formal shortness ratio” (FSR) which may be defined conveniently as \((M–M\text{ distance in compound}) / (M–M\text{ distance in metal})\). The compounds, \([\text{Cr}_2(2\text{-MeO-5-MeC}_6\text{H}_5)_4]\) and \(\text{Li}_6[\text{Cr}_2(\text{C}_6\text{H}_4\text{O}_4)_4]\)\(\text{Br}_2.6\text{Et}_2\text{O}\) have virtually the same M–M distance of 183 pm, the shortest known and yielding the smallest FSR of 183/256 = 0.715. For \([\text{Mo}_2(\mu_2\pi_2\text{O}_2\text{Me}_4)_4]\), FSR = 211/278 = 0.759 but, by contrast, for \([\text{Cr}_2(\mu_2\pi_2\text{O}_2\text{Me}_4)_4]\)\(\text{H}_2\text{O}\) FSR = 236/256 = 0.922. For comparison, the strongest homonuclear bonds for which bond energies are accurately known are N==N and C==C and their FSRs are 110/140 = 0.786 and 120.6/154 = 0.783 respectively.

to 4.9 BM expected for magnetically dilute Cr") and these increase markedly as the temperature is lowered, the ferromagnetic interactions evidently being transmitted via Cr–Cl–Cr bridges. The electronic spectra consist of the usual absorptions expected for tetragonally distorted octahedral complexes of Cr") but with two sharp and intense bands characteristically superimposed at higher energies (around 15 500 and 18 500 cm⁻¹). These are ascribed to spin-forbidden transitions intensified by the magnetic exchange.

Complexes in which the metal exhibits still lower oxidation states (such as 1, 0, −1, −II) occur amongst the organometallic compounds (pp. 1006 and 1037).

23.3.8 Biological activity and nitrogen fixation

It appears that chromium(III) is an essential trace element(52a) in mammalian metabolism and, together with insulin, is responsible for the clearance of glucose from the blood-stream. Tungsten too has been found to have a role in some enzymes converting CO₂ into formic acid but, from the point of view of biological activity, the focus of interest in this group is unquestionably on molybdenum.

In animal metabolism, oxomolybdoenzymes catalyse a number of oxidation processes. These oxidases contain Mo⁶+ coordinated to terminal O and S atoms, and their action appears to involve loss of an O or S atom along with reduction to Mo⁵+ or Mo⁴+. It is, however, the role of molybdenum in nitrogen fixation which has received most attention.

It is estimated that each year approximately 150 million tonnes of nitrogen are fixed biologically compared to 120 million tonnes fixed industrially by the Haber process (p. 421). In both cases N₂ is converted to NH₃, requiring the rupture of the N≡N triple bond which has the highest dissociation energy (945.41 kJ mol⁻¹) of any homonuclear diatomic molecule. This is an inescapable toll exacted by N₂ no matter how the fixation is achieved. In the Haber process it is paid by using high temperatures and pressures. Nature pays it by consuming 1 kg of glucose for every 14 g of N₂ fixed, but does so under ambient conditions. It is this last fact which provides the economic spur to achieve an understanding of the mechanism of the natural process.

Nitrogen fixation takes place in a wide variety of bacteria, the best known of which is *rhizobium* which is found in nodules on the roots of leguminous plants such as peas, beans, soya and clover. The essential constituents of this and all other nitrogen-fixing bacteria are:

(i) adenosine triphosphate (ATP) which is a highly active energy transfer agent (p. 528), operating by means of its hydrolysis which requires the presence of Mg²⁺;

(ii) ferredoxin, Fe₄S₄(SR)₄ (p. 1102), which is an efficient electron-transfer agent that can be replaced in artificial systems by reducing agents such as dithionite, [S₂O₄]²⁻;

(iii) a metallo-enzyme.

These metallo-enzymes are “nitrogenases” which have been isolated in an active form from several different bacteria and in a pure form from a number of these. The presence of Mo is not essential in all cases(53) (a vanadium nitrogenase is known — see p. 999) but is evidently a necessary component of most nitrogenases even though its precise function is unclear. These molybdenum nitrogenases consist of two distinct proteins. One, containing Fe but no Mo and therefore known as “Fe protein”, is yellow and extremely air-sensitive. Its molecular weight is about 60 000 and its structure involves an Fe₄S₄, ferredoxin-like cluster. The other protein contains both Mo and Fe and is known as “MoFe protein.” It is brown, air-sensitive, has a molecular weight in the approximate range 220 000 to 240 000, and

---

Figure 23.13 Metal centres in the FeMo protein of nitrogenase. (a) P-cluster pair. Each of the four outer Fe atoms is further coordinated to the S of a cysteine group. (b) FeMo cofactor. (Y is probably S, O or N.) Fe–Fe bridge distances are in the range 240–260 pm, suggesting weak Fe–Fe interactions. The Mo achieves 6-coordination by further bonds to N (of histidine) and two O atoms (of a chelating homocitrate), while the Fe at the opposite end of the cofactor is tetrahedrally coordinated by attachment of a cysteine. (c) Possible intermediate in the interaction of \( \text{N}_2 \) with FeMo cofactor.

contains the actual site of the \( \text{N}_2 \) reduction.† Most of the isolated forms of MoFe protein contain 2 atoms of Mo and about 30 atoms each of Fe and S. These atoms are arranged in 6 metal centres: 4 so-called P-clusters each made up of Fe\(_4\)S\(_4\) units, and 2 Fe–Mo cofactors (FeMoco) in which the Mo is thought to be present as Mo\(^{IV}\). Unfortunately, investigation of the structures of these proteins is hampered by the extreme sensitivity of nitrogenase to oxygen and the inherent difficulty of obtaining pure crystalline derivatives from biological materials. (Bacteria evidently protect nitrogenase from oxygen by a process of respiration, \( \text{O}_2 + \text{CO}_2 \), but if too much oxygen is present the system cannot cope and nitrogen fixation ceases.) The recent determination of the structure of the nitrogenase from *Azotobacter vinelandii*\(^{54}\) is therefore a remarkable achievement of X-ray crystallography, building upon results previously obtained from esr, Mössbauer spectroscopy and X-ray absorption spectroscopy (analysis of the “extended X-ray absorption fine structure” or EXAFS).\(^{55}\)

It turns out that each of the two FeMo cofactors consists of an Fe\(_4\)S\(_3\) and an Fe\(_3\)MoS\(_3\) incomplete cubane cluster. These are linked by two S bridges and a third bridging atom (Y), not identified with certainty, but possibly a well-ordered O or N or, alternatively, a less well-ordered S. Three atoms in each cluster are close enough to form interacting pairs across the bridge (Fig 23.13a). The P-clusters form two pairs, each pair consisting of two Fe\(_4\)S\(_4\) cubane clusters linked by two cysteine thiol bridges and a disulfide bond (Fig. 23.13b). Cleavage and re-formation of this disulfide bridge could provide the mechanism for a 2e\(^-\) redox process. Mössbauer studies suggest that, in their most reduced form, the iron atoms of the P-clusters are in the 2+ oxidation state, unprecedented in biological Fe\(_4\)S\(_4\) systems. The reduction of \( \text{N}_2 \) apparently involves the following steps:

(i) reduction by ferredoxin of the Fe protein’s Fe\(_4\)S\(_4\) cluster, which is situated in an exposed position at the surface of the protein;

---

† Isolated nitrogenases will also reduce other species such as CN\(^-\) and N\(_3\)\(^-\) containing a triple bond, as well as reducing acetylenes to olefins.

(ii) one-electron transfer from the Fe protein to a P-cluster pair of the FeMo protein, by a process involving the hydrolysis of ATP;
(iii) two-electron transfer, within the FeMo protein, from a P-cluster pair (whose environment is essentially hydrophobic) to an FeMo cofactor (whose environment is essentially hydrophilic);
(iv) electron and proton transfer to N₂ which is almost certainly attached to the FeMo cofactor.

The overall reaction can be represented as:
\[
N_2 + 8H^+ + 8e^- + 16Mg-ATP \rightarrow 2NH_3 + H_2 + 16(Mg-ADP + P_i), P_i = \text{inorganic phosphate.}
\]

Aspects of the process still requiring clarification include details of the electron flow between redox centres; the pathways for entry and exit of N₂, NH₃ and H₂ (presumably structural rearrangements are needed); the role of Mg-ATP; and the nature of the interaction between N₂ and the FeMo cofactor which is central to the whole process. Persuasive arguments had been advanced for an intermediate involving 2 Mo atoms bridged by N₂⁵⁶, yet in the determined structure the Mo atoms are too far apart to form a binuclear intermediate of this kind. On the other hand it has been plausibly suggested⁵⁵ that a reduced form of the FeMo cofactor might be sufficiently open at its centre to allow the insertion of Fe-N interactions replace weak Fe-Fe bonds (Fig. 23.13c). The concomitant weakening of the N≡N bond would facilitate subsequent reduction of the N₂ bridge.

Further developments in this field may be confidently expected.

### 23.3.9 Organometallic compounds (⁵⁷, ⁵⁸)

In this group a not-insignificant number of M–C σ-bonded compounds are known but are very unstable (MMe₆ is known only for W and this explodes in air and can detonate in a vacuum) unless stabilized either by ligands lacking β-hydrogen atoms (p. 925) or by dimerizing and forming M–M bonds. Thus trimethylsilylmethyl (–CH₂SiMe₃) yields [Cr(tms)₄] and the dimers [(tms)₃M≡M(tms)₃], (M = Mo, W). As with the preceding group, however, the bulk of organometallic chemistry is concerned with the metals in low oxidation states stabilized by π bonding ligands such as CO, cyclopentadienyl and, in this group, η₆-arenes. Cyanides have been discussed on pp. 1025–32.

Stable, colourless, crystalline hexacarboxyls, M(CO)₆, are prepared by reductive carboxylation of compounds (often halides) in higher oxidation states and are octahedral and diamagnetic as anticipated from the 18-electron rule (p. 1134). Replacement of the carbynol groups by either π-donor or σ-donor ligands is possible, giving a host of materials of the form [M(CO)₆-L₂] or [M(CO)₆-L₂(L-L)] (e.g. L = NO, NH₃, CN, PF₃; L-L = bipy, butadiene). [M(CO)₆X]⁻ ions (X = halogen, CN or SCN) are formed in this way. The low-temperature reaction (−78°) of the halogens with [Mo(CO)₆] or [W(CO)₆] (but not with [Cr(CO)₆]) produces the M⁺ carbonyl halides, [M(CO)₄L₂X₂] from which many adducts, [M(CO)₅L₂X₂], are obtained. Although not all of these have been fully characterized, those that have are 7-coordinated and mostly capped octahedral. Reduction of the hexacarboxyls with a borohydride in liquid ammonia forms dimeric [M₂(CO)₁₀]²⁻ which are isostructural with the isoelectronic [Mn₂(CO)₁₀] (p. 1062). Hydrolysis of these dimers produces the yellow hydrides [(CO)₅M-H-M(CO)₅] which maintain the 18 valence electron configuration by means of a 3-centre, 2-electron M–H–M bond. Neutron diffraction studies show these bridges to be nonlinear as expected, the actual degree of bending probably being influenced by crystal-packing forces arising from different counter-cations.

---

⁵⁸ pp. 277–402 of ref. 2.
related compound, \([\text{NEt}_4]^+\text{[H}_2\text{W}_2(\text{CO})_8]^{2-}\) is of interest because it has 2 hydrogen bridges and a \(W-W\) distance indicative of a \(W-W\) double bond (301.6 pm compared to about 320 pm for a \(W-W\) single bond) (Fig. 23.14). The compound also illustrates the improved refinement now possible with modern X-ray methods (p. 1013) and it was, in fact, the first case of the successful location of hydrogens bridging third-row transition metals. Reduction of the hexacarbonyls using Na metal in liquid \(\text{NH}_3\) yields the super-reduced, 18-electron species \([\text{M}(\text{CO})_6]^{4-}\).

\(\text{M}(\text{CO})_6\) and other Mo and W compounds catalyse alkene metathesis\(^\dagger\) by the formation of active alkylidene (p. 930) intermediates. This has stimulated the study of Mo and W alkylidenes (also alkylidyynes which are similarly active in alkyne metathesis)\(^{58}\).

Metallocenes, \([\text{M}^{II}(\eta^5-\text{C}_5\text{H}_5)_2]\), analogous to ferrocene would have only 16 valence electrons and could therefore be considered “electron deficient”. Chromocene can be formed by the action of sodium cyclopentadienide on \([\text{Cr}(\text{CO})_6]\). It is isomorphous with ferrocene but paramagnetic and much more reactive. Monomeric molybdocene and tungstocene polymerize above 10 K to red-brown polymeric solids, \([\text{M}^{II}(\text{C}_5\text{H}_5)_2]\). They are obtained by photolytic decomposition of yellow, \([\text{M}^{II}(\eta^5-\text{C}_5\text{H}_5)_2\text{H}_2]\) which are “bent” molecules (Fig 23.15a), themselves prepared by the action of \(\text{NaBH}_4\) on \(\text{MCl}_5\) and \(\text{NaC}_5\text{H}_5\) in thf. With Mo and W hexacarbonyls, conditions similar to those used to prepare chromocene produce only \([\eta^5-\text{C}_5\text{H}_5]\text{M}^{I}(\text{CO})_3\)]\(^2\), (Fig. 23.15b) in which dimerization achieves the 18-valence-electron configuration by means of an \(\text{M}-\text{M}\) bond. The chromium analogue of these dimers has one of the longest \(\text{M}-\text{M}\) bonds found in dinuclear transition metal compounds (328.1 pm). Its reactivity allows ready insertion of a variety of groups which includes S and Se yielding and can be used to convert propylene into ethylene for subsequent polymerization or oligomerization.

\(^\dagger\) This general reaction involves the cleavage of two \(\text{C}==\text{C}\) bonds and the formation of two new ones:

\[
\begin{align*}
\text{CH}_2==\text{CHR} & \quad \text{CH}_2 & \quad \text{CHR} \\
+ & \quad \text{CH}_2==\text{CHR} & \quad \text{CH}_2 & \quad \text{CHR}
\end{align*}
\]

---

**Figure 23.14** Structure of \([\text{H}_2\text{W}_2(\text{CO})_8]^{2-}\).

---

**Figure 23.15** (a) The “bent” molecules \([\text{M}^{II}(\eta^5-\text{C}_5\text{H}_5)_2\text{H}_2]\) (b) \([\text{M}^{I}(\eta^5-\text{C}_5\text{H}_5)(\text{CO})_3]\) \((\text{M} = \text{Mo, W})\).
products such as \([\text{Cr}_2(\eta^5\text{C}_5\text{H}_5)_2\text{(CO)}_4\text{E}_2]\), while cleavage of the bond with \(\text{Ph}_2\text{E}_2\) gives \([\text{Cr}(\eta^5\text{C}_5\text{H}_5)(\text{CO})_3\text{(EPH)}]\) (E = S, Se). Of the many other cyclopentadienyl derivatives the Mo and W halides \([\text{M}(\eta^5\text{C}_5\text{H}_5)_2\text{X}_2]\) and dimeric \([\text{M}_2(\eta^5\text{C}_5\text{H}_5)_2\text{X}_4]\), which are useful precursors in other syntheses, may be mentioned.

Of greater stability than the monomeric metallocenes in this group are the dibenzene sandwich compounds which are isoelectronic with ferrocene and of which the dark brown \([\text{Cr}(\eta^6\text{C}_6\text{H}_6)_2]\) was the first to be prepared (p. 940) and remains the best known. The green \([\text{Mo}(\eta^6\text{C}_6\text{H}_6)_2]\) and yellow-green \([\text{W}(\eta^6\text{C}_6\text{H}_6)_2]\) are also well characterized and all contain the metal in the formal oxidation state of zero. As the 12 C atoms in \([\text{M}(\eta^6\text{C}_6\text{H}_6)_2]\) are equidistant from the central metal atom, the coordination number of M is 12, though, of course, only 6 bonding molecular orbitals are primarily involved in linking the two ligand molecules to M. The compounds are more susceptible to oxidation than is the isoelectronic ferrocene and all are converted to paramagnetic salts of \([\text{M}^1(\eta^6\text{C}_6\text{H}_6)_2]^+\): the ease with which this process takes place increases in the order Cr < Mo < W. Since CO groups are evidently better \(\pi\)-acceptors than \(\text{C}_x\text{H}_x\), replacement of one of the benzene ligands in \([\text{M}(\text{C}_x\text{H}_x)_2]\) by three carbonyls giving, for instance, \([\text{Cr}(\eta^6\text{C}_6\text{H}_6)(\text{CO})_3]\), appreciably improves the resistance to oxidation because the electron density on the metal is lowered. \([\text{W}(\eta^6\text{C}_6\text{H}_6)_2]\) is reversibly protonated by dilute acids to give \([\text{W}(\eta^6\text{C}_6\text{H}_6)_2\text{H}]^+\).

As in the previous group, a potentially productive route into \(\text{C}_7\)-ring chemistry is provided by the reduction of a metal halide with \(\text{Na/Hg}\) in \(\text{thf}\) in the presence of cycloheptatriene. With \(\text{MoCl}_5\), \([\text{Mo}(\eta^7\text{C}_7\text{H}_7)(\eta^7\text{C}_7\text{H}_9)]\) is produced and a variety of derivatives have already been obtained.

---

24

Manganese, Technetium and Rhenium

24.1 Introduction

In terms of history, abundance and availability, it is difficult to imagine a greater contrast than exists in this group between manganese and its congeners, technetium and rhenium. Millions of tonnes of manganese are used annually, and its most common mineral, pyrolusite, has been used in glassmaking since the time of the Pharaohs. On the other hand, technetium and rhenium are exceedingly rare and were only discovered comparatively recently, the former being the first new element to have been produced artificially and the latter being the last naturally occurring element to be discovered.

Metallic manganese was first isolated in 1774 when C. W. Scheele recognized that pyrolusite contained a new element, and his fellow Swede, J. G. Gahn, heated the MnO₂ with a mixture of charcoal and oil. The purity of this sample of the metal was low, and high-purity (99.9%) manganese was only produced in the 1930s when electrolysis of Mn⁺⁺ solutions was used.

In Mendeleev’s table, this group was completed by the then undiscovered eka-manganese (Z = 43) and dvi-manganese (Z = 75). Confirmation of the existence of these missing elements was not obtained until H. G. J. Moseley had introduced the method of X-ray spectroscopic analysis. Then in 1925 W. Noddack, I. Tacke (later Frau Noddack) and O. Berg discovered element 75 in a sample of gadolinite (a basic silicate of beryllium, iron and lanthanides) and named it rhenium after the river Rhine. The element was also discovered, independently by F. H. Loring and J. F. G. Druce, in manganese compounds, but is now most usually recovered from the flue dusts produced in the roasting of CuMo ores.

The Noddacks also claimed to have detected element 43 and named it masurium after Masuren in Prussia. This claim proved to be incorrect, however, and the element was actually detected in 1937 in Italy by C. Perrier and E. Segré in a sample of molybdenum which had been bombarded with deuterons in the cyclotron of E. O. Lawrence in California. It was present in the form of the β⁻ emitters ⁹⁵mTc and ⁹⁷mTc.
with half-lives of 61 and 90 days respectively. The name technetium (from Greek τεχνητός, artificial) is clearly appropriate even though minute traces of the more stable $^{99}$Tc (half-life = $2.11 \times 10^5$ y) do occur naturally as a result of spontaneous fission of uranium.

24.2 The Elements

24.2.1 Terrestrial abundance and distribution

The natural abundance of technetium is, as just indicated, negligibly small. The concentration of rhenium in the earth’s crust is extremely low (of the order of $7 \times 10^{-8}$%, i.e. 0.0007 ppm) and it is also very diffuse. Being chemically akin to molybdenum it is in molybdenites that its highest concentrations (0.2%) are found. By contrast, manganese (0.106%, i.e. 1060 ppm of the earth’s crustal rocks) is the twelfth most abundant element and the third most abundant transition element (exceeded only by iron and titanium). It is found in over 300 different and widely distributed minerals of which about twelve are commercially important. As a class-a metal it occurs in primary deposits as the silicate. Of more commercial importance are the secondary deposits of oxides and carbonates such as pyrolusite (MnO$_2$), which is the most common, hausmannite (Mn$_3$O$_4$), and rhodochrosite (MnCO$_3$). These have been formed by weathering of the primary silicate deposits and are found in the former USSR, Gabon, South Africa, Brazil, Australia, India and China.

A further consequence of this weathering is that colloidal particles of the oxides of manganese, iron and other metals are continuously being washed into the sea where they agglomerate and are eventually compacted into the “manganese nodules” (so called because Mn is the chief constituent), first noted during the voyage of HMS Challenger (1872–6). Following a search in the Pacific organized by the University of California during the International Geophysical Year (1957), the magnitude and potential value of manganese nodules became apparent. More than $10^{12}$ tonnes are estimated to cover vast areas of the ocean beds and a further $10^7$ tonnes are deposited annually. The composition varies but the dried nodules generally contain between 15 and 30% of Mn. This is less than the 35% normally regarded as the lower limit required for present-day commercial exploitation but, since the Mn is accompanied not only by Fe but more importantly by smaller amounts of Ni, Cu and Co, the combined recovery of Ni, Cu and Co, with Mn effectively as a byproduct could well be economical if performed on a sufficient scale. The technical, legal, and political problems involved are enormous, but perhaps even more importantly, overcapacity in conventional means of production has so far inhibited the exploitation of these reserves.

24.2.2 Preparation and uses of the metals

Over ninety per cent of all the manganese ores produced are used in steel manufacture, mostly in the form of ferromanganese.$^{(1)}$ This contains about 80% Mn and is made by reducing appropriate amounts of MnO$_2$ and Fe$_2$O$_3$ with coke in a blast furnace or, if cheap electricity is available, in an electric-arc furnace. Dolomite or limestone is also added to remove silica as a slag. Where the Mn content is lower (because of the particular ores used) the product is known as silicomanganese (65–70% Mn, 15–20% Si) or spiegelisen (5–20% Mn). Where pure manganese metal is required it is prepared by the electrolysis of aqueous managanese(II) sulfate. Ore with an Mn content of over 8 million tonnes was produced in 1995, the most important sources being the former Soviet Union, the Republic of South Africa, Gabon and Australia.

All steels contain some Mn, and its addition in 1856 by R. Mushet ensured the success of the Bessemer process. It serves two main purposes. As a “scavenger” it combines with sulfur to form

---

Technetium in Diagnostic Nuclear Medicine

$^{99m}\text{Tc}$ is one of the most widely used isotopes in nuclear medicine. It is injected into the patient in the form of a saline solution of a compound, chosen because it will be absorbed by the organ under investigation, which can then be "imaged" by an X-ray camera or scanner. Its properties are ideal for this purpose: it decays into $^{99}\text{Tc}$ by internal transition and $\gamma$-emission of sufficient energy to allow the use of physiologically insignificant quantities (nmol or even pmol — a permissible dose of 1 mCi corresponds to 1.92 pmol of $^{99m}\text{Tc}$) and a half-life (6.01 h) short enough to preclude radiological damage due to prolonged exposure. It is obtained from $^{99}\text{Mo}$ ($t_1 = 65.94\ h$), which in turn is obtained from the fission products of natural or reactor uranium, or else by neutron irradiation of $^{98}\text{Mo}$.

Although details vary considerably, the $^{99}\text{Mo}$ is typically incorporated in a "generator" in the form of $\text{MoO}_4^{2-}$ absorbed on a substrate such as alumina where it decays according to the scheme:

$$^{99}\text{MoO}_4^{2-} \xrightarrow{\beta} ^{99m}\text{TeO}_4^- \xrightarrow{\gamma} ^{99}\text{TeO}_4^-$$

These generators can be made available virtually anywhere and, when required, $\text{TeO}_4^-$ is eluted from the substrate and reduced ($\text{Sn}^{11}$ is a common, but not the sole, reductant) in the presence of an appropriate ligand, ready for immediate use. A wide range of $N$-, $P$- and $S$-donor ligands has been used to prepare complexes of $\text{Tc}$, mainly in oxidation states III, IV and V, which are absorbed preferentially by different organs. Though the circumstances of clinical usage mean that the precise formulation of the compound actually administered is frequently uncertain, the imaging of brain, heart, lung, bone and tumours etc. is possible. It is the search for compounds of increased specificity which has stimulated most of the recent work on the coordination chemistry of $\text{Tc}$.

1 Interconversion between different oxidation states occurs easily for $\text{Tc}$ (see Section 24.2.4.), and its control often requires careful adjustment of pH and the relative excess of reductant used.

MnS which passes into the slag and prevents the formation of FeS which would induce brittleness, and it also combines with oxygen to form MnO, so preventing the formation of bubbles and pinholes in the cold steel. Secondly, the presence of Mn as an alloying metal increases the hardness of the steel. The hard, non-magnetic Hadfield steel containing about 13% Mn and 1.25% C, is the best known, and is used when resistance to severe mechanical shock and wear is required, e.g. for excavators, dredgers, rail crossings, etc.

Important, but less extensive, uses are found in the production of non-ferrous alloys. It is a scavenger in several Al and Cu alloys, while "manganese" is a well-known alloy (84% Cu, 12% Mn, 4% Ni) which is used in electrical instruments because the temperature coefficient of its resistivity is almost zero. A variety of other major uses have been found for Mn in the form of its compounds and these will be dealt with later under the appropriate headings.

Technetium is obtained from nuclear power stations where it makes up about 6% of uranium fission products and is recovered from these after storage for several years to allow the highly radioactive, short-lived fission products to decay. The original process used the precipitation of $[\text{AsPh}_4]^+\text{[ClO}_4^-]$ to carry with it $[\text{AsPh}_4]^+\text{[TcO}_4^-]$ and so separate the $\text{Tc}$ from other fission products, but solvent extraction and ion-exchange techniques are now used. The metal itself can be obtained by the high-temperature reduction of either $\text{NH}_4\text{TcO}_4$ or $\text{Tc}_2\text{S}_7$ with hydrogen. $^{99}\text{Tc}$ is the isotope available in kg quantities and the one used for virtually all chemical studies. Because of its long half-life it is not a major radiation hazard and, with standard manipulative techniques, can be safely handled in mg quantities. However, the main interest in $\text{Tc}$ is its role in nuclear medicine, and here it is the metastable $\gamma$-emitting isotope $^{99m}\text{Tc}$ which is used (see Panel).

In the roasting of molybdenum sulfide ores, any rhenium which might be present is oxidized to volatile Re$_2$O$_7$ which collects in the flue dusts and is the usual source of the metal via conversion to (NH$_4$)ReO$_4$ and reduction by H$_2$ at elevated temperatures. Being highly refractory and corrosion-resistant, rhenium metal would no doubt find widespread use were it not for its scarcity and consequent high cost. As it is, uses are essentially small scale. These include bimetallic Pt/Re catalysts for the production of lead-free, high octane petroleum products, high temperature superalloys for jet engine components, mass spectrometer filaments, furnace heating elements and thermocouples. World production is about 35 tonnes annually.

24.2.3 Properties of the elements

Some of the important properties of Group 7 elements are summarized in Table 24.1. Technetium is an artificial element, so its atomic weight depends on which isotope has been produced. The atomic weights of Mn and Re, however, are known with considerable accuracy. In the case of the former this is because it has only 1 naturally occurring isotope and, in the case of the latter, because it has only 2 and the relative proportions of these in terrestrial samples are essentially constant (185Re 37.40%, 187Re 62.60%).

In the solid state all three elements have typically metallic structures. Technetium and Re are isostuctural with hcp lattices, but there are 4 allotropes of Mn of which the α-form is the one stable at room temperature. This has a bcc structure in which, for reasons which are not clear, there are 4 distinct types of Mn atom. It is hard and brittle, and noticeably less refractory than its predecessors in the first transition series.

In continuance of the trends already noticed, the most stable oxidation state of manganese is +2, and in the group oxidation state of +7 it is even more strongly oxidizing than Cr(VI). Evidently the 3d electrons are more tightly held by the Mn atomic nucleus and this reduced delocalization produces weaker metallic bonding than in Cr. The same trends are also starting in the second and third series with Tc and Re, but are less marked, and Re in particular is very refractory, having a mp which is second only to that of tungsten amongst transition elements.

(a) This refers to $^{99}$Tc ($t_1$ 2.11 × 10$^5$ y). For $^{97}$Tc ($t_1$ 2.6 × 10$^6$ y) and $^{98}$Tc ($t_1$ 4.2 × 10$^6$ y) the values are 96.9064 and 97.9072 respectively.
24.2.4 Chemical reactivity and trends

Manganese is more electropositive than any of its neighbours in the periodic table and the metal is more reactive, especially when somewhat impure. In the massive state it is superficially oxidized on exposure to air but will burn if finely divided. It liberates hydrogen from water and dissolves readily in dilute aqueous acids to form manganese(I) salts. With non-metals it is not very reactive at ambient temperatures but frequently reacts vigorously when heated. Thus it burns in oxygen, nitrogen, chlorine and fluorine giving \( \text{Mn}_3\text{O}_4 \), \( \text{Mn}_3\text{N}_2 \), \( \text{MnCl}_2 \) and \( \text{MnF}_2 + \text{MnF}_3 \) respectively, and it combines directly with B, C, Si, P, As and S.

Technetium and rhenium metals are less reactive than manganese and, as is to be expected for the two heavier elements, they are closely similar to each other. In the massive form they resist oxidation and are only tarnished slowly in moist air. However, they are normally produced as sponges or powders in which case they are more reactive. Heated in oxygen they burn to give volatile heptaoxides (\( \text{M}_2\text{O}_7 \)), and with fluorine they give \( \text{TcF}_5 + \text{TcF}_6 \) and \( \text{ReF}_5 + \text{ReF}_7 \) respectively. \( \text{MS}_2 \) can also be produced by direct action. Although insoluble in hydrofluoric and hydrochloric acids, the metals dissolve readily in oxidizing acids such as \( \text{HNO}_3 \) and conc \( \text{H}_2\text{SO}_4 \) and also in bromine water, when “pertechnetic” and “perrhenic” acids (\( \text{HMO}_4 \)) are formed.

Because of the differing focus of interest in these elements their chemistries have not developed in parallel and the data on which strict comparisons might be based are not always available. Nevertheless many of the similarities and contrasts expected in the chemistry of transition elements are evident in this triad. The relative stabilities of different oxidation states in aqueous, acidic solutions are summarized in Table 24.2 and Fig. 24.1.

The most obvious features of Fig. 24.1 are the relative positions of the +2 oxidation states. For manganese this state, represented by the high-spin Mn\(^{II} \) cation, is much the most stable. This may be taken as an indication of the stability of the symmetrical \( d^5 \) electron configuration.

</tbody>
</table>

However, like the mp, bp and enthalpy of atomization, it also reflects the weaker cohesive forces in the metallic lattice since for Tc and Re, which have much stronger metallic bonding, the +2 state is of little importance and the occurrence of cluster compounds with M–M bonds is a dominant feature of rhenium(III) chemistry. The almost uniform slope of the plot for Tc presages the facile interconversion between oxidation states, observed for this element.

Another marked contrast is evident in the +7 oxidation state where the manganate(VII) (permanganate) ion is an extremely strong oxidizing agent but \( (\text{TcO}_4^-) \) and \( (\text{ReO}_4^-) \) show only mild oxidizing properties. Indeed, the greater stability of Tc and Re compared to Mn in any oxidation state higher than +2 is apparent, as will be seen more fully in the following account of individual compounds.

Table 24.3 lists representative examples of the compounds of these elements in their various oxidation states. The wide range of the oxidation states is particularly noteworthy. It arises from the fact that, in moving across the transition series, the number of d electrons has increased and, in this mid-region, the d orbitals have not yet sunk energetically into the inert electron core. The number of d electrons available for bonding is consequently maximized, and not
only are high oxidation states possible, but back donation of electrons from metal to ligand is also facilitated with resulting stabilization of low oxidation states.

A further point of interest is the noticeably greater tendency of rhenium, as compared to either manganese or technetium, to form compounds with high coordination numbers.

24.3 Compounds of Manganese, Technetium and Rhenium

Binary borides (p. 145), carbides (p. 297), and nitrides (p. 417) have already been mentioned.

Manganese, like chromium (and also the succeeding elements in the first transition series), is too small to accommodate interstitial carbon without significant distortion of the metal lattice. As a consequence it forms a number of often readily hydrolysed carbides with rather complicated structures.

Hydrido complexes are well-known but simple binary hydrides are not, which is in keeping with the position of these metals in the "hydrogen gap" portion of the periodic table (p. 67).

24.3.1 Oxides and chalcogenides

All three metals form heptoxides (Table 24.4) but, whereas TcO₇ and ReO₇ are the final products formed when the metals are burned in an excess of oxygen, Mn₂O₇ requires prior oxidation of the manganese to the +7 state. It separates as a reddish-brown explosive oil from the green

Solutions produced by the action of conc H₂SO₄ on a manganate(VII) salt. On standing, it slowly loses oxygen to form MnO₂ but detonates around 95°C and will explosively oxidize most organic materials. The molecule is composed of 2 corner-sharing MnO₄ tetrahedra with a bent Mn–O–Mn bridge. The liquid solidifies at 5.9°C to give red crystals in which the dimeric units persist with an Mn–O–Mn angle of 120.7°. The other 2 heptoxides are yellow solids whose volatility provides a useful means of purifying the elements and, as has been pointed out, is a crucial factor in the commercial production of rhenium (Tc₂O₇: mp 119.5°, bp 310.6°; Re₂O₇: mp 300.3°, bp 360.3°). In the vapour phase both consist of corner-sharing MO₄ tetrahedra but, whereas this structure is retained in the solid phase by Tc₂O₇ (linear Tc–O–Tc), solid Re₂O₇ has an unusual structure consisting of polymeric double layers of corner-sharing ReO₄ tetrahedra alternating with ReO₆ octahedra. The same basic unit, though this time discrete, is found in the dihydrate which is therefore best formulated as [O₂Re–O–ReO₃(H₂O)₂] and is obtained by careful evaporation of an aqueous solution of the heptoxide. The structure breaks down, however, if the solution is kept for a period of months. Crystals of perhenic acid monohydrate, HReO₄·H₂O, are deposited and consist of fairly regular ReO₄⁻ tetrahedra and H₃O⁺ ions linked by hydrogen bridges.

Only rhenium forms a stable trioxide. It is a red solid with a metallic lustre and is obtained by the reduction of Re₂O₇ with CO. ReO₃ has a structure in which each Re is octahedrally surrounded by oxygens.

Figure 24.2 The structure of ReO₃. Note the similarity to perovskite (p. 963) which can be understood as follows: if the Re atom, which is shown here with its full complement of 6 surrounding O atoms, is imagined to be the small cation at the centre of Fig. 21.3(a), then the perovskite structure is obtained by placing the large cations (Ca⁹⁺) into the centre of the cube drawn above and in the 7 other equivalent positions around the Re.

It has an extremely low electrical resistivity which decreases with decrease in temperature like a true metal: ρ₃₀₀Ƙ 10 μohm cm, ρ₁₀₀Ƙ 0.6 μohm cm. It is clear that the single valency electron on each Re atom is delocalized in a conduction band of the crystal. ReO₃ is unreactive towards water and aqueous acids and alkalis, but when boiled with conc alkali it disproportionates into ReO₄⁻ and ReO₂. A blue pentoxide Re₂O₅ has been reported but is also prone to disproportionation into +7 and +4 species.

The +4 oxidation state is the only one in which all three elements form stable oxides, but only in the case of technetium is this the most stable oxide. TcO₂ is the final product when any Tc/O

---

Applications of Manganese Dioxide\(^6\)

Although the primary use of manganese is in the production of steel, it also finds widespread and important uses in non-metallurgical industries. These frequently use the manganese as MnO\(_2\) but even where this is not the case the dioxide is invariably the starting material.

The largest non-metallurgical use of MnO\(_2\) is in the manufacture of dry-cell batteries (p. 1204) which accounts for about half a million tonnes of ore annually. The most common dry batteries are of the carbon-zinc Leclanché type in which carbon is the positive pole. MnO\(_2\) is incorporated as a depolarizer to prevent the undesirable liberation of hydrogen gas on to the carbon, probably by the reaction

\[
\text{MnO}_2 + \text{H}^+ + e^- \rightarrow \text{MnO(OH)}
\]

Only the highest quality MnO\(_2\) ore can be used directly for this purpose, and “synthetic dioxide”, usually produced electrolytically by anodic oxidation of manganese(II) sulfate, is increasingly employed.

The brick industry is another major user of MnO\(_2\) since it can provide a range of red to brown or grey tints. In the manufacture of glass its use as a decolourizer (hence “glassmaker’s soap”) is its most ancient application. Glass always contains iron at least in trace amounts, and this imparts a greenish colour; the addition of MnO\(_2\) to the molten glass produces red-brown Mn\(^{III}\) which equalizes the absorption across the visible spectrum so giving a “colourless”, i.e., grey glass. In recent times selenium compounds have replaced MnO\(_2\) for this application, but in larger proportions the latter is still used to make pink to purple glass.

The oxidizing properties of MnO\(_2\) are utilized in the oxidation of aniline for the preparation of hydroquinone which is important as a photographic developer and also in the production of dyes and paints.

In the electronics industry the advantages of higher electrical resistivity and lower cost of ceramic ferrites (M\(^{II}\)Fe\(_2\)O\(_4\)) (p. 1081) over metallic magnets have been recognized since the 1950s and the “soft” ferrites (M\(^{II}\) = Mn, Zn) are the most common of these. They are used on the sweep transformer and deflection yoke of a television set and, of course, MnO\(_2\), either natural or synthetic, is required in their production.

MnO\(_2\) is by far the most important oxide in this group, though it is not the most stable oxide of manganese, decomposing to Mn\(_2\)O\(_3\) above about 530°C and being a useful oxidizing agent. Hot concentrated sulfuric and hydrochloric acids reduce it to manganese(II):

\[
\begin{align*}
2\text{MnO}_2 + 2\text{H}_2\text{SO}_4 & \rightarrow 2\text{MnSO}_4 + \text{O}_2 + 2\text{H}_2\text{O} \\
\text{MnO}_2 + 4\text{HCl} & \rightarrow \text{MnCl}_2 + \text{Cl}_2 + 2\text{H}_2\text{O}
\end{align*}
\]

the latter reaction being formerly the basis of the manufacture of chlorine. It is, however, extremely insoluble and, as a consequence, often unreactive. As pyrolusite it is the most plentiful ore of manganese and it finds many industrial uses (see Panel).

The structural history of MnO\(_2\) is complex and confused due largely to the prevalence of nonstoichiometry and the fact that in its hydrated forms it behaves as a cation-exchanger. Many of the various polymorphs which have been reported are probably therefore simply impure forms. The only stoichiometric form is the so-called α-MnO\(_2\), which is that of pyrolusite and possesses the rutile structure (p. 961), but even here a range of composition from MnO\(_{1.93}\) to MnO\(_{2.0}\) is possible. α-MnO\(_2\) can be prepared by careful decomposition of manganese(II) nitrate but, when precipitated from aqueous solutions, for instance by reduction of alkaline MnO\(_4^-\), the hydrated MnO\(_2\) has a more open structure which exhibits cation-exchange properties and cannot be fully dehydrated without some loss of oxygen.

Apart from the black Re\(_2\)O\(_3\).2H\(_2\)O (which is readily oxidized to the dioxide and is prepared by boiling ReCl\(_3\) in air-free water) oxides of oxidation states below +4 are known only for manganese. Mn\(_3\)O\(_4\) is formed when any

---

oxide of manganese is heated to about 1000°C in air and is the black mineral, hausmannite. It has the spinel structure (p. 247) and as such is appropriately formulated as Mn\textsuperscript{II}Mn\textsuperscript{III}O\textsubscript{4}, with Mn\textsuperscript{II} and Mn\textsuperscript{III} occupying tetrahedral and octahedral sites respectively within a ccp lattice of oxide ions; there is, however, a tetragonal distortion due to a Jahn–Teller effect (p. 1021) on Mn\textsuperscript{III}. A related structure, but with fewer cation sites occupied, is found in the black γ-Mn\textsubscript{2}O\textsubscript{3} which can be prepared by aerial oxidation and subsequent dehydration of the hydroxide precipitated from aqueous Mn\textsuperscript{II} solutions. If MnO\textsubscript{2} is heated less strongly (say <800°C) than is required to produce Mn\textsubscript{3}O\textsubscript{4}, then the more stable α-form of Mn\textsubscript{2}O\textsubscript{3} results which has a structure involving 6-coordinate Mn but with 2 Mn–O bonds longer than the other 4. This is no doubt a further manifestation of the Jahn–Teller effect expected for the high-spin d\textsuperscript{4} Mn\textsuperscript{III} ion and is presumably the reason why Mn\textsubscript{2}O\textsubscript{3}, alone among the oxides of transition metal Mn\textsuperscript{III} ions, does not have the corundum (p. 242) structure.

Reduction with hydrogen of any oxide of manganese produces the lowest oxide, the grey to green MnO. This is an entirely basic oxide, dissolving in acids and giving rise to the aqueous Mn\textsuperscript{II} cationic chemistry. It has a rock-salt structure and is subject to nonstoichiometric variation (MnO\textsubscript{1.00} to MnO\textsubscript{1.045}), but its main interest is that it is a classic example of an antiferromagnetic compound. If the temperature is reduced below about 118 K (its Néel point), a rapid fall in magnetic moment takes place as the electron spins on adjacent Mn atoms pair-up. This is believed to take place by the process of “superexchange” by which the interaction is transferred through intervening, non-magnetic, oxide ions. (MnO\textsubscript{2} is also antiferromagnetic below 92 K whereas the alignment in Mn\textsubscript{3}O\textsubscript{4} results in ferrimagnetism below 43 K.)

The sulfides are fewer and less familiar than the oxides but, as is to be expected, favour lower oxidation states of the metals. Thus manganese forms MnS\textsubscript{2} which has the pyrite structure (p. 680) with discrete Mn\textsuperscript{II} and S\textsuperscript{2–II} ions and is converted on heating to MnS and sulfur. This green MnS is the most stable manganese sulfide and, like MnO, has a rock-salt structure and is strongly antiferromagnetic (T\textsubscript{N} = 121°C). Less-stable red forms are also known and the pale-pink precipitate produced when H\textsubscript{2}S is bubbled through aqueous Mn\textsuperscript{II} solutions is a hydrated form which passes very slowly into the green variety. The corresponding selenides are very similar: Mn\textsuperscript{II}Se\textsubscript{2} (pyrite-type), and MnSe (NaCl-type), antiferromagnetic with T\textsubscript{N} = 100°C.

Technetium and rhenium favour higher oxidation states in their binary chalcogenides. Both form black diamagnetic heptasulfides, M\textsubscript{2}S\textsubscript{7}, which are isomorphous and which decompose to M\textsuperscript{IV}S\textsubscript{2} and sulfur on being heated. These disulfides, unlike the pyrite-type Mn\textsuperscript{II}S\textsubscript{2}, contain monatomic S\textsuperscript{2–II} units. The diselenides are similar. Tc\textsubscript{2}S\textsubscript{2}, Tc\textsubscript{2}Se\textsubscript{2} and Re\textsubscript{2}S\textsubscript{2} feature trigonal prismatic coordination of M\textsuperscript{IV} by S (or Se) in a layer-lattice structure which is isomorphous with a rhombohedral polymorph of MoS\textsubscript{2}. Re\textsubscript{2}S\textsubscript{2} also has a layer structure but the Re\textsuperscript{IV} atoms are octahedrally coordinated.

Lower formal oxidation states are stabilized, however, by M–M bonding in ternary chalcogenides such as M\textsubscript{4}\textsuperscript{II}M\textsubscript{6}Q\textsubscript{12}, M\textsubscript{4}\textsuperscript{II}M\textsubscript{6}Q\textsubscript{13} (M\textsuperscript{II} = alkali metal; M = Re, Tc; Q = S, Se) and the recently reported\textsuperscript{7} M\textsubscript{10}M\textsubscript{6}S\textsubscript{14}. Their structures are all based on the face-capped, octahedral M\textsubscript{6}X\textsubscript{6} cluster unit found in Chevrel phases (p. 1018) and in the dihalides of Mo and W (p. 1022).

### 24.3.2 Oxoanions

The lower oxides of manganese are basic and react with aqueous acids to give salts of Mn\textsuperscript{II} and Mn\textsuperscript{III} cations. The higher oxides, on the other hand, are acidic and react with alkalis to yield oxoanion salts, but the polymerization which was such a feature of the chemistry of the preceding group is absent here.

Fusion of MnO₂ with an alkali metal hydroxide and an oxidizing agent such as KNO₃ produces very dark-green manganate(VI) salts (manganates) which are stable in strongly alkaline solution but which disproportionate readily in neutral or acid solution (see Fig. 24.1):

\[ 3\text{MnO}_4^{2-} + 4\text{H}^+ \rightarrow 2\text{MnO}_4^{-} + \text{MnO}_2 + 2\text{H}_2\text{O} \]

The deep-purple manganate(VII) salts (permanganates) may be prepared in aqueous solution by oxidation of manganese(II) salts with very strong oxidizing agents such as PbO₂ or NaBiO₃. They are manufactured commercially by alkaline oxidative fusion of MnO₂ followed by the electrolytic oxidation of manganate(VI):

\[ 2\text{MnO}_2 + 4\text{KOH} + \text{O}_2 \rightarrow 2\text{K}_2\text{MnO}_4 + 2\text{H}_2\text{O} \]

\[ 2\text{K}_2\text{MnO}_4 + 2\text{H}_2\text{O} \rightarrow 2\text{KMnO}_4 + 2\text{KOH} + \text{H}_2 \]

The most important manganate(VII) is KMnO₄ of which several tens of thousands of tonnes are produced annually. It is a well-known oxidizing agent, used analytically:

in acid solution:
\[ \text{MnO}_4^{-} + 8\text{H}^+ + 5\text{e}^- \rightarrow \text{Mn}^{2+} + 4\text{H}_2\text{O}; \quad E^\circ = +1.51 \text{ V} \]

in alkaline solution:
\[ \text{MnO}_4^{-} + 2\text{H}_2\text{O} + 3\text{e}^- \rightarrow \text{MnO}_2 + 4\text{OH}^-; \quad E^\circ = +1.23 \text{ V} \]

It is also important as an oxidizing agent in the industrial production of saccharin and benzoic acid, and medically as a disinfectant. It is increasingly being used also for purifying water, since it has the dual advantage over chlorine that it does not affect the taste, and the MnO₂ produced acts as a coagulant for colloidal impurities.

Reduction of KMnO₄ with aqueous Na₂SO₃ produces the bright-blue tetraoxomanganate(V) (hypomanganate), MnO₄³⁻, which has also been postulated as a reaction intermediate in some organic oxidations; it is not stable, being prone to disproportionation.

All [MnO₄]⁻ ions are tetrahedral with Mn—O 162.9 pm in MnO₄⁻ and 165.9 pm in MnO₄²⁻. K₂MnO₄ is isomorphous with K₂SO₄ and K₂CrO₄. By contrast, the only tetrahedral oxoanions of Tc and Re are the tetraoxotechnetate(VII) (pertechnetate) and tetraoxorhenate(VII) (perrhenate) ions. HTcO₄ and HReO₄ are strong acids like HMnO₄ and are formed when the heptoxides are dissolved in water. From such solutions dark-red crystals with the composition HTcO₄ in the case of technetium and, in the case of rhenium, yellowish crystals of Re₂O₇·2H₂O or HReO₄·H₂O (p. 1047) can be obtained.

\[ [\text{TcO}_4]^- \quad \text{and} \quad [\text{ReO}_4]^- \quad \text{provide the starting point for virtually all the Tc and Re chemistry. They are produced whenever compounds of Tc and Re are treated with oxidizing agents such as nitric acid or hydrogen peroxide and, although reduced in aqueous solution by, for instance, Sn²⁺, Fe²⁺, Ti³⁺ and I⁻, they are much weaker oxidizing agents than [MnO₄]⁻. In further contrast to [MnO₄]⁻ they are also stable in alkaline solution and are colourless whereas [MnO₄]⁻ is an intense purple. In fact, the absorption spectra of the 3 [MO₄⁻] ions are very similar, arising in each case from charge transfer transitions between O²⁻ and MVII, but the energies of these transitions reflect the relative oxidizing properties of MVII. Thus the intense colour of [MnO₄]⁻ arises because the absorption occurs in the visible region, whereas for [ReO₄]⁻ it has shifted to the more energetic ultraviolet, and the ion is therefore colourless. [TcO₄]⁻ is also normally colourless but the absorption starts on the very edge of the visible region and it may be that the red colour of crystalline HTcO₄, and other transient red colours which have been reported in some of its reactions, are due to slight distortions of the ion from tetrahedral symmetry causing the absorption to move sufficiently for it to "tail" into the blue end of the visible, thereby imparting a red coloration. [MO₄]⁻ ions might be expected to act as Lewis bases (cf ClO₄⁻ p. 868) and, indeed, several mono- and bis- [ReO₄]⁻ complexes with Co²⁺, Ni²⁺ and Cu²⁺ have been

characterized, and both unidentate and bridging modes identified.\(^8\)

Fusion of rhenates(VI) with a basic oxide yields so-called ortho- and meso-perrhenates (M₃ReO₆ and M₅ReO₅, M = Na, \(\frac{1}{2}\)Ca, etc.) while addition of rhenium metal to the fusion (and exclusion of oxygen) produces rhenate(VI) (e.g. Ca₃ReO₆). There is evidence suggesting the existence of [ReO₆]⁵⁻ and [ReO₆]⁶⁻ but it may be better to regard all these compounds as mixed oxides. In any case, it is clear that the coordination sphere of the metal has expanded compared to that of the smaller Mn in the tetrahedral [MnO₄]⁶⁻ ions. Comparable technetium compounds have also been prepared.

24.3.3 Halides and oxohalides

The known halides and oxohalides of this group are listed in Tables 24.5 and 24.6 respectively.

The highest halide of each metal is of course a fluoride: ReF₇ (the only thermally stable heptahalide of a transition metal), TcF₆, and MnF₄. This again indicates the diminished ability of manganese to attain high oxidation states when compared not only to Tc and Re but also to

chromium, which forms CrF₅ and CrF₆. The most interesting of the lower halides are the rhenium trihalides which exist as trimeric clusters which persist throughout much of the chemistry of Re⁺⁺⁺.

Apart from ReF₅, which is produced when ReF₆ is reduced by tungsten wire at 600°C, all the known penta-, hexa- and hepta- halides of Re and Tc can be prepared directly from the elements by suitably adjusting the temperature and pressure, although various specific methods have been suggested. They are volatile solids varying in colour from pale yellow (ReF₇) to dark brown (ReBr₅), and are readily hydrolysed by water with accompanying disproportionation into the comparatively more stable [MnO₄]⁻ and MnO₂, e.g.:

\[
3\text{ReCl}_5 + 8\text{H}_2\text{O} \rightarrow \text{HReO}_4 + 2\text{ReO}_2 + 15\text{HCl}
\]

Because of the tendency to produce mixtures of the halides, and the facile formation of oxohalides if air and moisture are not rigorously excluded (or even, in some cases, also by attacking glass), not all of these halides have been characterized as well as might be desired. There is spectroscopic evidence that ReF₇ has a pentagonal bipyramidal structure, and ReX₆ are probably octahedral. ReCl₅ is actually a dimer, Cl₄Re(μ-Cl)₂ReCl₄, in which the rhenium is octahedrally coordinated.

The tetrahalides are made by a variety of methods. MnF₄, being the highest halide formed by Mn, can be prepared directly from the elements, as can TcCl₄, which is the only thermally stable chloride of Tc. TcCl₄ is a red sublimable solid consisting of infinite chains of edge-sharing TcCl₆ octahedra. By contrast the

*Note: The table continues with detailed information about the properties of each halide.*
black ReCl₄, which is prepared by heating ReCl₃ and ReCl₅ in a sealed tube at 300°C, is made up of pairs of ReCl₆ octahedra which share faces (as in [W₂Cl₉]³⁻, p. 1021), these dimeric units then being linked in chains by corner-sharing. The closeness of the Re atoms in each pair (273 pm) is indicative of a metal–metal bond though not so pronounced as the more extensive metal–metal bonding found in Re³⁺ chemistry.

MnF₃ is a red-purple, reactive, but thermally stable solid; it is prepared by fluorinating any of the Mn²⁺ halides and its crystal lattice consists of MnF₆ octahedra which are distorted, presumably because of the Jahn–Teller effect expected for d⁴ ions. The Re³⁺ halides are obtained by thermal decomposition of ReCl₅, ReBr₅ and ReI₅. The dark-red chloride is composed of triangular clusters of chloride-bridged Re atoms with 1 of the 2 out-of-plane Cl on each Re bridging to adjacent trimeric clusters (Fig. 24.3). After allowing for the Re–Cl bonds, each Re³⁺ has a d⁴ configuration and the observed diamagnetism can be accounted for by assuming that these four d electrons on each Re are used in forming double bonds (σ + π) to its 2 Re neighbours. The Re–Re distance of 249 pm is consistent with this (cf. 275 pm in Re metal). Re₂Cl₄ can be sublimed under vacuum but the green colour of the vapour probably indicates breakdown of the cluster in the vapour phase. The compound dissolves in water to give a red solution which slowly hydrolyses to hydrated Re₂O₃, and in conc hydrochloric acid it gives a red solution which is stable to oxidation and from which can be precipitated hydrates of Re₂Cl₉ and a number of complex chlorides in which the trimeric clusters persist.(⁹)

Re₃Br₉ is similar to Re₂Cl₉ but the iodide, which is a black solid and is similarly trinuclear, differs in that it is thermally less stable and only 2 Re atoms in each cluster are linked to adjacent clusters, thereby forming infinite chains of trimeric units rather than planar networks.

Except for the possible existence of ReI₂, the only simple dihalides of this group that are known (so far) are those of manganese. They are pale-pink salts obtained by simply dissolving the metal or carbonate in aqueous HX. MnF₂ is insoluble in water and forms no hydrate, but the others form a variety of very water-soluble hydrates of which the tetrahydrates are the most common.

The oxohalides of manganese are green liquids (except MnO₂Cl₂ which is brown); they are notable for their explosive instability. MnO₃F can be prepared by treating KMnO₄ with fluorosulfuric acid, HSO₃F, whereas reaction of Mn₂O₇ with chlorosulfuric acid yields MnO₃Cl + MnO₂Cl₂ + MnOCl₃.

The oxohalides of technetium and rhenium are more numerous than those of manganese and are not so unstable, although all of them readily hydrolyse (with dis-proportionation to [MO₄]⁻ and MO₂ in the case of oxidation states +5 and +6). In this respect they may be regarded as being intermediate between the halides and the oxides which, in the higher oxidation states, are the more stable. Treatment of the oxides with the halogens, or the halides with oxygen are common preparative methods. The structures are not all

---

known with certainty, but ReOCl₄ may be noted as an example of a square-pyramidal structure.

**24.3.4 Complexes of manganese, technetium and rhenium**

**Oxidation state VII (d⁰)**

The coordination chemistry of this oxidation state is confined mainly to a few readily hydrolysed oxohalide complexes of Re such as KReO₂F₄. Exceptions to this limitation are provided by the isomorphous hydrides K₂MH₉ of Tc and Re which formally involve M⁺ and H⁻. The rhenium analogue was the first to be prepared as the colourless, diamagnetic product of the reduction of KReO₄ by potassium in aqueous diaminoethane (ethylenediamine). The elucidation of its structure (Fig. 24.4a) illustrates vividly the problems associated with identifying a novel compound when its isolation in a pure form is difficult and when conventional chemical analysis is unable to establish the stoichiometry with accuracy.† Several other hydrido complexes are known, of which the reddish-orange, dinuclear (Et₄N)₂[Re₂H₉(triphos)] may be mentioned. This is obtained by treatment of (Et₄N)₃[ReH₉(triphos)] with MeC(CH₂PPh₂)₃ in

† Only by using a wide range of physical techniques were these difficulties surmounted. The product was first thought to be K[Re(H₂O)₄] containing Re⁻¹ with a square-planar geometry, by analogy with the isoelectronic Pt⁰. The nmr spectrum, however, indicated the presence of an Re–H bond so the compound was reformulated as KReH₄·2H₂O. Fresh analytical evidence then suggested that earlier products had been impure and a further reformulation, this time as K₂ReH₈, was proposed. The observed diamagnetism could then only be accounted for by assuming metal–metal bonding between the implied d¹ rhenium(VI) atoms, but X-ray analysis showing the Re atoms to be 550 pm apart, precluded this possibility. The problem was finally resolved when a neutron diffraction study established the formula as K₂ReH₈ and the structure is tricapped trigonal prismatic. The nmr spectrum actually shows only one proton signal in spite of the existence of distinct capping and prismatic protons, and this is thought to be due to rapid exchange between the sites.
MeCN. The structure of the anion (Fig 24.4b) can be envisaged as a tridentate $[\text{ReH}_2]^2-$ ligand coordinated to Re(triphos)$^+$, and, since the metal atoms are only 259.4 pm apart, is said to involve an Re$\equiv$Re triple bond(12) (in which case the $[\text{ReH}_2]^2-$ should be regarded as tetradentate and its Re atom as 10-coordinated).

Oxidation state VI ($d^1$)

Again, fluoro and oxo complexes of rhenium predominate. The reaction of KF and ReF$_5$ in an inert PTFE vessel yields pink K$_2$[ReF$_6$], the anion of which has a square-prismatic structure; hydrolysis converts it to K[ReOF$_5$].

An interesting compound which is usually included in discussions of Re$^{VI}$ chemistry is the green crystalline dithiolate, $[\text{Re(S}_2\text{C}_2\text{Ph}_2)_3]$. This was the first authenticated example of a trigonal prismatic complex (Fig. 19.6, p. 915) but besides its structural interest it has, along with other complexes of such ligands, posed problems regarding the oxidation state of the metal. The ligand may be thought to coordinate in either of two extreme ways (or some intermediate state between them):

\[
\begin{align*}
\text{Ph} & \quad \text{C} & \quad \text{S} \\
\text{Ph} & \quad \text{C} & \quad \text{S}
\end{align*}
\]

The difference between the two extremes is essentially that, in the former, the Re retains its valence electrons in its d orbitals whereas in the latter it loses 6 of them to delocalized ligand orbitals. In either case paramagnetism is anticipated since rhenium has an odd number of valence electrons. The magnetic moment of 1.79 BM corresponding to 1 unpaired electron, and esr evidence showing that this electron is situated predominantly on the ligands, indicates that an intermediate oxidation state is involved but does not specify which one. Because of this uncertainty, dithiolate ligands, and others like them, have been expressively termed "non-innocent" ligands by C. K. Jørgensen.(13)

Oxidation state V ($d^2$)

This oxidation state is sparse in the case of Mn but is important in the pharmaceutical applications of Tc, and an extensive chemistry has been developed. Some fluoro complexes of Tc and Re such as the salts of $[\text{MF}_6]^-$ are known, but oxo compounds predominate and, in $[\text{MOCl}_3]^{2-}$ and $[\text{MOX}_4]^-$ ($X = \text{Cl, Br, I}$) for instance, other halides are also able to coordinate. $[\text{MOX}_4]^-$ is square pyramidal with apical M$=$O and the MO$^{3+}$ moiety is reminiscent of VO$^{2+}$, being found in other compounds (particularly those containing phosphines) and labilizing whatever ligand is trans to it. The ir stretching frequency of the M$=$O bond is conveniently used for its detection, lying in the range 890–1020 cm$^{-1}$ for Tc$=$O and generally about 20 cm$^{-1}$ lower for Re$=$O. The M$\equiv$N group also stabilizes the oxidation state, probably because the π bonds are able to reduce the charge on the M$^V$; it is found in compounds such as $[\text{MNX}_2(\text{PR}_3)_3]$ and $[\text{MNX}_2(\text{PR}_3)_2]$ (X = Cl, Br, I) produced when $[\text{MO}_4]^-$ is reduced by hydrazine in the presence of appropriate ligands, of which phosphines are especially useful.(14) The ir stretching frequency is again of diagnostic value being found in the approximate range of 1050–1100 cm$^{-1}$ for Tc$\equiv$N and 20 cm$^{-1}$ or so lower for Re$\equiv$N. Eight-coordinate and probably dodecahedral $[\text{ReCl}_4(\text{diars})_2]\text{ClO}_4$ has been prepared and the Tc analogue is notable as the first example of 8-coordinate technetium.

Oxidation state IV (d³)

This is apparently the highest oxidation state in which manganese is able to form complexes. Monomeric complexes are sparse, though K₂[MnX₆], where X = F, Cl, IO₃ and CN are known, but di- and poly-meric compounds are more numerous and have received attention as models for the water-oxidizing enzyme, Photosystem II,¹⁵ important in plant photosynthesis. An Mn(μ-O)₂Mn core is thought to be involved and the redox behaviour of compounds such as [(L-L)₂Mn(μ-O)₂Mn(L-L)]²⁺ (L-L = 1,10-phenanthroline, 2,2'-bipyridyl; n = 2, 3, 4, implying Mn³⁺-Mn³⁺, Mn³⁺-Mn⁴⁺ and Mn⁴⁺-Mn⁴⁺ pairings) has been studied.¹⁶ Schiff bases and carboxylate ligands have also been used and complexes with OH bridges and also triply bridged complexes have been produced. Fully oxidized Mn⁴⁺-Mn⁴⁺ species are often observed only electrochemically and not completely characterized. An exception is the Mn⁴⁺ tetramer, [Mn₄O₆(tacn)₄]⁴⁺ prepared by aerial oxidation of Mn²⁺ in the presence of 1,4,7-triazacyclononane. The core of this has the adamantane structure, each Mn being facially coordinated to one tacn and three μ₂-oxoxygenes (Fig. 24.5a).

Relatively few compounds of Tc⁴⁺ have radiopharmaceutical use, and its chemistry in this oxidation state has therefore been comparatively neglected. For both the heavier elements the preference for oxo compounds is diminishing while the tendency to form M–M multiple bonds has not yet acquired the importance to be found in more reduced states. The most important compounds are the salts of [MX₆]|⁻ [M = Tc, Re; X = F, Cl, Br, I]. The fluoro complexes are obtained by the reaction of HF on one of the other halogeno complexes and these in turn are obtained by reducing [MO₄]|⁻ (commonly by using I⁻) in aqueous HX. The corresponding Tc and Re complexes are closely similar, but an interesting difference between Tc⁴⁺ and Re⁴⁺ is found in their behaviour with CN⁻. The reaction

of KCN and K₂ReI₆ in methanol yields a mixture of K₄[Re⁶⁺(CN)₇].2H₂O and K₃[Re⁵⁺O₂(CN)₄] whereas the analogous reaction of KCN and K₂TcI₆ produces a reddish-brown, paramagnetic precipitate, thought to be K₂[Tc(CN)₆].

**Oxidation state III (d⁴)**

Nearly all manganese(III) complexes are octahedral and high-spin with magnetic moments close to the spin-only value of 4.90 BM expected for 4 unpaired electrons. The d⁴ configuration is also expected to be subject to Jahn–Teller distortions (p. 1021). For reasons which are not obvious, the [Mn(H₂O)₆]³⁺ ion in the alum CsMn(SO₄)₂·12H₂O does not display the appreciable distortion from octahedral symmetry (elongation of two trans bonds) found, for instance, in solid MnF₃, the octahedral Mn⁴⁺ sites of Mn₃O₄, [Mn(acac)₃] and in tris(tropolonato)manganese(III). Manganese(III) is strongly oxidizing in aqueous solution with a marked tendency to disproportionate into Mn⁴⁺ (i.e. MnO₂) and Mn⁶⁺ (see Fig. 24.1). It is, however, stabilized by O-donor ligands, as evidenced by the way in which the virtually white Mn(OH)₂ rapidly darkens in air as it oxidizes to hydrous Mn₂O₃ or MnO(OH), and by the preparation of [Mn(acac)₃] via the aerial oxidation of aqueous Mn²⁺ in the presence of acetylacetonate. K₃[Mn(C₂O₄)₃]·3H₂O is also known, while the complexing oxoanions, phosphate and sulfate, have a stabilizing effect on aqueous solutions. The main preparative routes to Mn³⁺ are by reduction of KMnO₄ or oxidation of Mn⁴⁺. The latter may be effected electrolytically but a common method is by way of the red-brown acetate. This is similar to the “basic” acetate of chromium(III) and so involves the [Mn₃O(MeCOO)₆]⁴⁻ unit (see Fig. 23.9, p. 1030). The hydrate is prepared by oxidation of manganese(II) acetate with KMnO₄ in glacial acetic acid, and the anhydrous salt by the action of acetic hydride on hydrated manganese(II) nitrate.

The field of oxo-bridged polynuclear complexes of manganese, much of it involving mixed oxidation states and facile redox behaviour, is expanding rapidly. Oxidation of an ethanolic solution of Mn⁴⁺ acetate by (Bu₄N)MnO₄ in the presence of acetic acid and pyridine can yield either the Mn⁴⁺ compound, [Mn₃O(MeCOO)₆py₂]⁺ or the Mn⁶⁺Mn⁴⁺ compound, [Mn₃O(MeCOO)₆py₂]. Addition of bipyridyl to solutions of these in MeCN gives the tetraneutral, [Mn₄O₂(MeCOO)₇(bipy)₂]⁺ and [Mn₄O₂(MeCOO)₆(bipy)₂] respectively. The structures of the cores of these and other Mn₄ complexes are given in Fig. 24.5.

Still higher nuclearities, up to 12 in [Mn₁₂O₁₂(RCOO)₁₆(H₂O)₄] (R = Me, Ph), have been reported. The cores of these two compounds, which are of interest as potential building blocks in the preparation of molecular ferromagnets, consist of a central [Mn⁴⁺(μ-O)₄] cubane linked by O-bridges to eight Mn atoms.

The most important low-spin octahedral complex of Mn³⁺ is the dark-red cyano complex, [Mn(CN)₆]³⁻, which is produced when air is bubbled through an aqueous solution of Mn²⁺ and CN⁻. [MnX₅I²⁻ (X = F, Cl) are also known; the chloro ion, at least when combined with the cation [bipyH₂]²⁺, is notable as an example of a square pyramidal manganese complex.

Technetium(III) complexes are accessible especially if stabilized by back-bonding ligands, and are most commonly 6-coordinate. [TcCl₂(diars)₂]ClO₄, prepared by the reaction of o-phenylenebisdimethylarsine and HCl with HTcO₄ in aqueous alcohol, is probably the best known. The rhenium(III) analogue is isomorphous but requires the help of a reducing agent such as H₃PO₂ to effect the reduction from [ReO₄]⁻. Other examples are [Tc(NCS)₆]³⁻ and [Tc(thiourea)₆]³⁺. However, 7-coordinate compounds such as [M(CN)₇]⁴⁻ are also known and, more recently, it has been reported that the}

---

reaction of $[\text{MOCl}_4^-]$ with excess arylhydrazine and $\text{PPh}_3$ in ethanol gives 5-coordinate, diamagnetic, $[\text{MCl}(_2\text{Ar}_2)(\text{PPh}_3)_2]$. In general $\text{Re}^{\text{III}}$ is readily oxidized to $\text{Re}^{\text{IV}}$ or $\text{Re}^{\text{VII}}$ unless it is stabilized by metal–metal bonding$^{(20)}$ as in the case of the trihalides already discussed. Rhenium(III) complexes with Cl$^-$ and Br$^-$ have been characterized and are of two types, $[\text{Re}_2\text{X}_{12}]^{3^-}$ and $[\text{Re}_2\text{X}_8]^{2^-}$, both of which involve multiple Re–Re bonds. If $\text{Re}_3\text{Cl}_9$ or $\text{Re}_3\text{Br}_9$ are dissolved in conc HCl or conc HBr respectively, stable, red, diamagnetic salts may be precipitated by adding a suitable monovalent cation. Their stoichiometry is $M\text{ReX}_4$ and they were formerly thought to be unique examples of low-spin, tetrahedral complexes. X-ray analysis, however, showed that the anions are trimeric with the same structure as the halides (Fig. 24.3) and likewise incorporating Re=Re double bonds. Their chemistry reflects their structure since 3 halide ions per trimeric unit can be replaced by ligands such as MeCN, $\text{Me}_2\text{SO}$, $\text{Ph}_3\text{PO}$ and $\text{PET}_2\text{Ph}$ yielding neutral complexes $[\text{Re}_3\text{X}_9\text{L}_3]$. The blue diamagnetic complexes $[\text{Re}_2\text{X}_8]^{2^-}$ are produced when $[\text{ReO}_4^-]$ in aqueous HCl or HBr is reduced by $\text{H}_3\text{PO}_2$ and they can then be precipitated by the addition of a suitable cation. A more efficient method, which also yields a product soluble in polar organic solvents, is the reaction of (NBu$_4$)$_2\text{ReO}_4$ with refluxing benzoyl chloride followed by the addition of a solution of (NBu$_4$)$_2\text{Cl}$ in ethanol saturated with HCl. Salts of $[\text{Re}_2\text{X}_8]^{2^-}$ are the starting points for almost all dirhenium(III) compounds and the ion provided one of the first examples of a quadruple bond in a stable compound (see pp. 1032, 1034). The structure of $[\text{Re}_2\text{Cl}_8]^{2^-}$ is shown in Fig. 24.6 and, as in $[\text{Mo}_2\text{Cl}_8]^{4^-}$ (Fig. 23.11, p. 1033), the chlorine atoms are eclipsed. In both ions the metal has a d$^4$ configuration which is to be expected if a $\delta$-bond is present. $[\text{Re}_2\text{Cl}_8]^{2^-}$ can be reduced polarographically to unstable $[\text{Re}_2\text{Cl}_8]^{3^-}$ and $[\text{Re}_2\text{Cl}_8]^{4^-}$, and also undergoes a variety of substitution reactions (Fig. 24.6b,c,d).

One Cl on each Re may be replaced by phosphines, while MeSCH$_2$CH$_2$SMe (dth) takes up 4 coordination positions on 1 Re to give $[\text{Re}_2\text{Cl}_5\text{(dth)}_2]$. In this case the average oxidation state of the rhenium has been reduced to $+2.5$. The reduction in bond order from 4 to 3.5, which the addition of a $\delta^*$ electron implies, causes some lengthening of the Re–Re distance and the configuration is staggered. Carboxylates are able to bridge the metal atoms forming complexes of the type $[\text{Re}_2\text{Cl}_2\text{(O}_2\text{C}_3\text{R})_4]$ which are clearly analogous to the dimeric carboxylates found in the previous group.

In the octachloro technetium system, by contrast, the paramagnetic $[\text{TeCl}_6]^{3^-}$ is the most readily obtained species. The Tc has a formal oxidation state of $+2.5$ with a $d(\text{Tc–Tc})$ 210.5 pm and the configuration is eclipsed. The pale green $[\text{NBu}_4]^+_2[\text{Te}^{\text{III}}\text{Cl}_8]^{2-}$ can be isolated from the products of reduction of $[\text{TcCl}_6]^{2-}$ with Zn/HCl(aq). The compound is strictly isomorphous with $[\text{NBu}_4]^+_2[\text{Re}_2\text{Cl}_8]$ and has $d(\text{Tc–Tc})$ 214.7 pm. The reason for the increase in Tc–Tc distance on removal of the $\delta^*$ electron, and the consequent increase in the presumed bond order from 3.5 to 4, is not clear, but has been ascribed to a decrease in the strength of $\sigma$ and $\pi$ bonding caused by orbital contraction occurring as the charge on the metal core (and hence the bond order) increases.$^{(21)}$  

### Oxidation state II (d$^5$)

The chemistry of technetium(II) and rhenium(II) is meagre and mainly confined to arsine and phosphine complexes. The best known of these are $[\text{MCl}_2(\text{diars})_2]$, obtained by reduction with hypophosphite and $\text{Sn}^{\text{II}}$ respectively from the corresponding Tc$^{\text{III}}$ and Re$^{\text{III}}$ complexes, and in which the low oxidation state is presumably stabilized by $\pi$ donation to the ligands. This oxidation state, however, is really best typified by manganese for which it is the most thoroughly studied and, in aqueous solution, by far the most

---

$^{21}$ p. 123 of ref. 20.
stable; accordingly it provides the most extensive cationic chemistry in this group.

Salts of manganese(II) are formed with all the common anions and most are water-soluble hydrates. The most important of these commercially and hence the most widely produced is the sulfate, which forms several hydrates of which $\text{MnSO}_4 \cdot 5\text{H}_2\text{O}$ is the one commonly formed. It is manufactured either by treating pyrolusite with sulfuric acid and a reducing agent, or as a byproduct in the production of hydroquinone ($\text{MnO}_2$ is used in the conversion of aniline to quinone):

$$\text{PhNH}_2 + 2\text{MnO}_2 + 2\frac{1}{2}\text{H}_2\text{SO}_4 \rightarrow \text{OC}_6\text{H}_4\text{O}$$

$$+ 2\text{MnSO}_4 + \frac{1}{2}(\text{NH}_4)_2\text{SO}_4 + 2\text{H}_2\text{O}$$

It is the starting material for the preparation of nearly all manganese chemicals and is used in fertilizers in areas of the world where there is a deficiency of Mn in the soil, since Mn is an essential trace element in plant growth. The anhydrous salt has a surprising thermal stability; it remains unchanged even at red heat, whereas the sulfates of Fe$^{II}$, Co$^{II}$ and Ni$^{II}$ all decompose under these conditions.
Aqueous solutions of salts with non-coordinating anions contain the pale-pink, \([\text{Mn(H}_2\text{O)}_6]^{2+}\), ion which is one of a variety of high-spin octahedral complexes (\(t^3_{2g}e^3_g\)) which have been prepared more especially with chelating ligands such as en, edta, and oxalate. As is expected, most of these have magnetic moments close to the spin-only value of 5.92 BM, and are very pale in colour. This is a consequence of the fact that all electronic d-d transitions from a high-spin \(d^5\) configuration must, of necessity, involve the pairing of some electrons and are therefore spin-forbidden. This is embodied in the interpretation\(^{(22)}\) of the rather complex absorption spectrum of \([\text{Mn(H}_2\text{O)}_6]^{2+}\).

The resistance of Mn\(^{II}\) to both oxidation and reduction is generally attributed to the effect of the symmetrical \(d^5\) configuration, and there is no doubt that the steady increase in resistance of M\(^{II}\) ions to oxidation found with increasing atomic number across the first transition series suffers a discontinuity at Mn\(^{II}\), which is more resistant to oxidation than either Cr\(^{II}\) to the left or Fe\(^{II}\) to the right. However, the high-spin configuration of the Mn\(^{II}\) ion provides no CFSE (p. 1131) and the stability constants of its high-spin complexes are consequently lower than those of corresponding complexes of neighbouring M\(^{II}\) ions and are kinetically labile. In addition, a zero CFSE confers no advantage on any particular stereochemistry which must be one of the reasons for the occurrence of a wider range of stereochemistries for Mn\(^{II}\) than is normally found for M\(^{II}\) ions.

Green-yellow salts of the tetrahedral \([\text{MX}_4]^{2-}\) (\(X = \text{Cl}, \text{Br}, \text{I}\)) ions can be obtained from ethanolic solutions and are well characterized. Furthermore, a whole series of adducts \([\text{MnX}_2\text{L}_2]\) (\(X = \text{Cl}, \text{Br}, \text{I}\)) are known where \(L\) is an \(N\)-, \(P\)- or \(As\)-donor ligand, and both octahedral and tetrahedral stereochemistries are found. Of interest because of the possible role of manganese porphyrins in photosynthesis is \([\text{Mn}^{II}(\text{phthalocyamine})]\) which is square planar. The reaction of aqueous edta with MnCO\(_3\) yields a number of complex species, amongst them the 7-coordinate \([\text{Mn(edta)}(\text{H}_2\text{O})]^{2-}\) which has a capped trigonal prismatic structure. The highest coordination number, 8, is found in the anion \([\text{Mn}(\eta^2-\text{NO}_3)_4]^{2-}\) which, like other such ions, is approximately dodecahedral (p. 916).

A varied chemistry, centred on the phosphines \([\text{MnX}_2(\text{PR}_3)_2]\), is also developing. These are moisture sensitive and, frequently, air-sensitive, polymeric solids which can be obtained not only by the reaction of the phosphine with MnX\(_2\) (\(X = \text{Cl}, \text{Br, I}\)), but also by the reaction of the phosphorane, \(R_3\text{PX}_2\), with powdered metal.\(^{(23)}\) In the case of \([\text{Mn}_2(\text{PPhMe}_2)_2]\) two isomers have been characterised. Both consist of chains of \([\text{Mn}(\mu-\text{I})_2]\) units but whereas, in the one prepared from MnX\(_2\) two phosphines are coordinated to alternate metals (4,6,4,6 coordination), in the one prepared from Mn metal, a single phosphine is coordinated to each metal (uniform 5,5,5,5,5 coordination).\(^{(23)}\) \([\text{MnX}_2(\text{PR}_3)_2]\) have also been found to react reversibly with a variety of small molecules such as CO, NO, C\(_2\)H\(_4\) and SO\(_2\) (see for instance ref. 24). O\(_2\) will also react reversibly in some cases but its controlled addition to the pale-pink \([\text{Mn}_2(\text{PMe}_3)_2]\) (obtained from \(\text{PMe}_3\) and Mn powder in dry ethyl ether as a 4,6,4,6 coordination polymer) yields successively\(^{(25)}\) the dark-red dimer, \([\text{Mn}^{II}(\text{PMe}_3)_2(\mu-\text{I})\text{Mn}^{II}(\text{PMe}_3)_2\text{I}_2]\) (involving approximately tetrahedral Mn\(^{III}\) and trigonal bipyramidal Mn\(^{II}\)) and finally the dark-green, trigonal bipyramidal \([\text{Mn}^{III}(\text{PMe}_3)_2\text{I}_3]\).

Spin-pairing in manganese(II) requires a good deal of energy and is achieved only by ligands such as CN\(^-\) and CNR which are high in the spectrochemical series. The low-spin complexes, \([\text{Mn(CN)}_6]^{4-}\) and \([\text{Mn(CNR)}_6]^{2+}\) are presumed

24.3.5 The biochemistry of manganese

Traces of manganese are found in many plants and bacteria, and a healthy human adult contains about 10–20 mg of Mn.

In many manganoproteins the manganese is in the II oxidation state and can often be replaced by magnesium(II) without loss of function. In other cases, where redox activity is involved, some naturally occurring forms containing either manganese or iron are known. The most important natural role of manganese, however, is in the oxidation of water in green plant photosynthesis (p. 125) where its presence in photosystem II (PSII) is essential. Here, absorbed radiation provides the energy for the oxidation

---

26 pp. 559–63 of ref. 20.

---

of water, dioxygen being evolved and electrons transferred to photosystem I (PSI) where NADP is reduced. The oxidation proceeds by four 1-photon, 1-electron steps and it appears that it is the redox properties of a group of Mn atoms which provide stable stages for this stepwise oxidation. Manganese probably has two further functions:

(a) to act as a template holding two molecules of water close enough to facilitate O–O bond formation;
(b) to make the bound water more acidic, so facilitating loss of H⁺

It is no doubt significant that the equilibrium constant for the reaction

\[ \text{H}_2\text{O} + \text{Mn}^{III} + \text{H}_2\text{O} \rightleftharpoons \text{HO-Mn}^{III} + \text{H}_3\text{O}^+ \]

is larger for Mn^{III} than for any other trivalent, first row transition metal ion.

Although definitive crystallographic data are lacking it seems clear that the “water oxidizing centre” (WOC) or “oxygen evolving complex” (OEC) of PSII contains four Mn atoms and it is believed that these are arranged in one of the cluster forms shown in Fig. 24.5. Physical techniques which have been used to study these proteins include esr, uv-visible spectroscopy, magnetic measurements and EXAFS. Two Mn–Mn distances, 270 and 330 pm are indicated, with O-, N- and possible Cl-donor atoms, giving a core of fairly low symmetry. A plausible sequence of oxidation state changes for the four Mn atoms consistent with, but by no means defined by, the available data would be:

\[ (\text{II})(\text{III})_3 \rightarrow (\text{III})_4 \rightarrow (\text{III})_3(\text{IV}) \]

\[ \rightarrow (\text{III})_2(\text{IV})_2 \rightarrow (\text{III})(\text{IV})_3 \]

Efforts have been made to reproduce these characteristics in model systems, and molecules with the core structures already described have been prepared. Though none as yet has shown any photoredox activity the 270 pm distance has been shown to be consistent with (µ-oxo)₂ bridges and 330 pm with µ-oxo or µ-oxo-µ-carboxylate bridges. Several mechanistic proposals have been made incorporating these features.

### 24.3.6 Organometallic compounds

Carbonyls, cyclopentadienyls and their derivatives occupy a central position in the chemistry of this as of preceding groups, the bonding involved and even their stoichiometries having in some cases posed difficult problems. Increasingly, however, interest has focused on the chemistry of compounds involving M–C σ bonds, of which rhenium provides as rich a variety as any transition metal. It is also notable that, whereas the organometallic chemistry of manganese is largely limited to oxidation states 0, I and II, that of rhenium extends to VII.(²⁸,²⁹)

Only one well-characterized binary carbonyl is formed by each of the elements of this group. That of manganese is best prepared by reducing Mn₂ (e.g. with LiAlH₄) in the presence of CO under pressure. Those of technetium and rhenium are made by heating their heptoxides with CO under pressure. They are sublimable, isomorphous, crystalline solids: golden-yellow for [Mn₂(CO)₁₀], mp 154°, and colourless for [Tc₂(CO)₁₀], mp 160° and [Re₂(CO)₁₀], mp 177°. Their stabilities in air show a regular gradation: manganese carbonyl is quite stable below 110°C, technetium carbonyl decomposes slowly and rhenium carbonyl may ignite spontaneously. The empirical stoichiometry M(CO)₅ would imply a paramagnetic molecule with 17 valence electrons, but the observed diamagnetism (for Mn and Re) suggests at least a dimeric structure. In fact, X-ray analysis reveals the structure shown in Fig. 24.8(a) in which two M(CO)₅ groups in staggered configuration are held together by an M–M bond, unsupported by bridging ligands (cf. S₂F₁₀, p. 684).

Very many derivatives of the carbonyls of Mn,(³⁰) Tc and Re have been prepared since the parent carbonyls were first synthesized in 1949, 1961 and 1941 respectively; among the more important are the carbonylate anions,

---

SCHEME A  Some reactions of \([\text{Mn}_2(\text{CO})_{10}]\) and its derivatives.\(^{(31)}\)

SCHEME B  Some reactions of \([\text{Tc}_2(\text{CO})_{10}]\) and its derivatives.\(^{(32)}\)

\(^{32}\)R. D. PEACOCK, ibid, p. 899 for Scheme B, p. 953 for Scheme C and p. 954 for Scheme D.
the carbonyl cations, and the carbonyl hydrides. Typical reactions are summarized in schemes A, B, C and D (this last on p. 1067).

Sodium amalgam reductions of \( \text{M}_2(\text{CO})_{10} \) give \( \text{Na}^+ [\text{M}(\text{CO})_5]^\text{−} \) and, indeed, further reduction\(^{33} \) leads to the “super reduced” species \( [\text{M}(\text{CO})_4]^3\text{−} \) in which the metals exhibit their lowest known formal oxidation state of \( −3 \). On the other hand, treatment of \( [\text{M}(\text{CO})_5\text{Cl}] \) with \( \text{AlCl}_3 \) and \( \text{CO} \) under pressure produces \( [\text{M}(\text{CO})_6]^+ \text{AlCl}_4\text{−} \) from which other salts of the cation can be obtained.

Acidification of \( [\text{M}(\text{CO})_5]^− \) produces the octahedral and monomeric, \( [\text{MH}(\text{CO})_5] \), and a number of polymeric carbonyls have been obtained by reduction of \( [\text{M}_2(\text{CO})_{10}] \), including interesting hydrogen-bridged complexes such as \( [\text{H}_3\text{Mn}_3(\text{CO})_{12}] \) (the first transition metal cluster in which the \( \text{H} \) atoms were located), \( [\text{H}_4\text{Re}_4(\text{CO})_{12}] \) and \( [\text{H}_6\text{Re}_4(\text{CO})_{12}]^2\text{−} \) (Fig. 24.8). The tendency to form high nuclearity carbonyl clusters is, however, much less evident for Mn than for Re. The largest so far obtained for Mn is the heptanuclear, \( [\text{Mn}_7(\mu_3-\text{OH})_6(\text{CO})_8]^3\text{4} \) but this is exceptional, there being very few others with nuclearities higher than four.\(^{30} \)

By contrast, the stronger M–M bonds characteristic of Re, help to provide a wider

---

Some carbonyls and carbonyl hydrides of Group 7 metals.

(a) $[\text{Mn}_2(\text{CO})_6]$, $\text{M} = \text{Mn}$, Tc, Re (Mn–Mn 293 pm, Tc–Tc 304 pm, Re–Re 302 pm).
(b) $[\text{H}_3\text{Mn}_3(\text{CO})_{12}]$. Mn–Mn 311 pm. (c) $[\text{H}_4\text{Re}_4(\text{CO})_{12}]$, Re–Re 289.6–294.5 pm. (In this structure the 4 Re atoms lie at the corners of a tetrahedron, the faces of which are bridged by 4 H atoms; the molecule is viewed from above one Re which obscures the fourth H. For clarity the CO groups are not shown but 3 are attached to each Re so as to “eclipse” the edges of the tetrahedron.)
(c) $[\text{H}_6\text{Re}_4(\text{CO})_{12}]^{-2}$, Re–Re 314.2–317.2 pm. (As in (c) the 4 Re atoms lie at the corners of a tetrahedron and the CO groups have been omitted for clarity. The 3 CO groups attached to each Re are now “staggered” with respect to the edges of the tetrahedron, whilst the H atoms (6) are presumed to bridge these edges.)

variety\(^{(35)}\) of which the carbon-centred clusters $[\text{H}_2\text{Re}_6\text{C}(\text{CO})_{18}]^{2-}$, $[\text{Re}_7\text{C}(\text{CO})_{21}]^{3-}$ and $[\text{Re}_8\text{C}(\text{CO})_{24}]^{2-}$ (Fig. 24.9), obtained by the pyrolytic reduction of $\text{Re}_2(\text{CO})_{10}$ with varying proportions of Na in thf, may be mentioned. The H atoms in the first of these clusters, though not positively located, were thought to be face-capping (i.e. $\mu_3$). On the other hand $[\text{Re}_7\text{HC}(\text{CO})_{21}]^{2-}$, which is obtained by treating a salt of $[\text{Re}_7\text{C}(\text{CO})_{21}]^{3-}$ in acetone or thf with a strong acid such as HBF$_4$ or H$_2$SO$_4$, exists in two isomeric forms and potential energy computations suggest that both contain a $\mu$-H atom and differ in the cluster edge which this bridges\(^{(36)}\) (Fig. 24.9d and e).

When MnCl$_2$ in thf is treated with C$_3$H$_5$Na, amber-coloured crystals of manganocene, $[\text{Mn}(\eta^5\text{C}_3\text{H}_5)]_2$, mp 172°, are produced. It is very sensitive to both air and water and is a most unusual compound. At room temperature it is polymeric with Mn($\eta^5\text{C}_3\text{H}_5$) units linked by bridging C$_3$H$_5$ groups in a zig-zag arrangement.

At about 159°C it turns pink and adopts the “sandwich” structure, expected for [M(C₅H₅)₂] compounds, and this is retained in the gaseous phase and in hydrocarbon solutions. Using substituted cyclopentadienyls a variety of analogous sandwich compounds have been prepared(37) and their magnetic properties indicate that the high-spin (5 unpaired electrons) and low-spin (1 unpaired electron) configurations are sufficiently close together to produce an equilibrium between the two in many cases (Fig. 24.10). The spin state depends on the nature and number of substituents in the C₅ ring and also on solvent and temperature. Electron donating substituents, such as methyl, enhance the covalent character of the Mn–C bonding and favour the low-spin configuration. Thus [Mn(η⁵-C₅Me₅)₂]
SCHEME D Some reactions of rhenium carbonyl chloride.

Figure 24.10 Spin equilibrium in $[\text{Mn}(\eta^5-\text{C}_5\text{H}_4\text{Me})_2]$: the orbitals shown here are the mainly metal-based orbitals in the centre of the MO diagram for metallocenes (see Fig. B, p. 939).

is exclusively low-spin, $[\text{Mn}(\eta^5-\text{C}_5\text{H}_4\text{Me})_2]$ and other monoalkyl substituted ring systems exhibit spin-equilibria, while manganocene itself with a magnetic moment of 5.86 BM in hydrocarbon solvents at room temperature, is almost (but not entirely) high-spin.

Apart from the formation of $[\text{Re}(\eta^5-\text{C}_5\text{H}_5)_2]$ on N$_2$ matrices at 20 K, Tc and Re analogues of manganocene have not been prepared. Instead, when TcCl$_4$ or ReCl$_5$ are treated with NaC$_5$H$_5$ in thf, the diamagnetic, yellow crystalline hydrides, $[\text{M(Re}(\eta^5-\text{C}_5\text{H}_5)_2]\text{H}]$ are obtained (Fig. 24.11a). The protons on the cyclopentadienyl rings give rise to only one nmr signal, presumably because of rapid rotation of the rings about the metal-ring axis making the protons indistinguishable. As with Mn, however, methyl substitution has a stabilizing effect and purple $[\text{Re}(\eta^5-\text{C}_5\text{Me}_5)_2]$
Manganese, Technetium and Rhenium Ch. 24

with Tc–Tc distances respectively of 407.7(4) and the unusually short 186.7(4) pm.

Manganese(II) forms alkyls with a distinct tendency to polymerize. Thus the bright orange Mn(CH₂SiMe₃)₂ is a polymer in which each Mn attains tetrahedral coordination, being doubly bridged to each adjacent metal by two CH₂SiMe₃ groups (each Mn–C–Mn bridge is best regarded as a three-centre, two-electron bond). Red-brown Mn(CH₂CMe₃)₂ is similarly bridged but, for no obvious reason, is only tetrameric, a terminal ligand being attached to each of the two outer Mn atoms which are therefore only 3-coordinate.

Figure 24.11 (a) [M(η⁵-C₅H₅)₂H] (M = Tc, Re) (b) [Re(η⁵-C₅Me₅Et)O₃] (The structure of [Re(η⁵-C₅Me₅)O₃] is presumed to be identical but was not determined because of the lack of suitable single crystals). (c) Section of the linear chain [Tc₂(C₅Me₅)O₃]ₙ.

is readily obtained by photolysis of a solution of [Re(η⁵-C₅Me₅)₂H] in pentane. It is low-spin at low temperatures but has a minor contribution from the high-spin configuration at room temperature.

Pentamethylcyclopentadienyl compounds also provide a convenient route into high-valent organorhenium chemistry.⁴⁹ Oxidation of [Re⁴(η⁵-C₅Me₅)(CO)₃] by H₂O₂ in a two-phase water–benzene system gives high yields of lemon yellow [Re(η⁵-C₅Me₅)O₃] (Fig. 24.11b) which, being stable in air even up to 140°C, demonstrates the remarkable stabilizing effect of oxygen on Re in high oxidation states. The same procedure in the case of technetium raises its oxidation state only to 3.5, forming yellow [Tc₂(C₅Me₅)O₃]ₙ (Fig. 24.11c) in which linear chains of Tc atoms are bridged alternately by (μ-C₅Me₅) and (μ-O₃).

Figure 24.12 Rhenium clusters: [Re₃Cl₆R₆]; arrows indicate vacant coordination sites where further ligands can be attached.

The simplest of the σ-bonded Re–C compounds is the green, paramagnetic, crystalline, thermally unstable ReMe₆, which, after WMe₆, was only the second hexamethyl transition metal compound to be synthesized (1976). It reacts with LiMe to give the unstable, pyrophoric, Li₂[ReMe₆], which has a square-antiprismatic structure, and incorporation of oxygen into the coordination sphere greatly increases the stability, witness Re⁶⁺O₃Me₄, which is thermally stable up to 200°C, and Re⁶⁺O₃Me, which is stable in air. The interaction of [ReCl₄(thf)₂]
with (α-tolyl)MgBr in thf yields the dark red, paramagnetic tetraaryl, \([\text{Re}(2-\text{MeC}_6\text{H}_4)_4]\)\(^{40}\). This highly air-sensitive compound, if treated with PMe\(_2\)R (R = Me, Ph), is converted into the thermally stable and rather inert benzyne, \([\text{Re}(\eta^2-\text{C}_6\text{H}_3\text{Me})(\text{PMe}_2\text{R})_2(2-\text{MeC}_6\text{H}_4)_2]\)\(^{41}\).

A whole series of alkyl cluster compounds \(\text{Re}_3\text{Cl}_3\text{R}_6\) has been prepared by reacting \(\text{Re}_3\text{Cl}_9\) with a large excess of RMgCl in thf. The blue diamagnetic trimethylsilylmethyl complex (Fig. 24.12) is best known. A red isomer has been obtained in which the Cl bridges have exchanged positions with three of the terminal alkyls, and it is also possible to replace the Cl bridges by CH\(_3\) to produce, \([\text{Re}_3(\mu-\text{CH}_3)_3(\text{CH}_2\text{SiMe}_3)_6]\). Adducts, \([\text{Re}_3\text{Cl}_3(\text{CH}_2\text{SiMe}_3)_6\text{L}_3]\) (L = CO, H\(_2\)O) can be obtained, but phosphines tend to cause cleavage of the Re\(_3\) ring instead of forming adducts.

25

Iron, Ruthenium and Osmium

25.1 Introduction

The nine elements, Fe, Ru, Os; Co, Rh, Ir; Ni, Pd and Pt, together formed Group VIII of Mendeleev’s periodic table. They will be treated here, like the other transition elements, in “vertical” triads, but because of the marked “horizontal” similarities it is not uncommon for Fe, Co and Ni to be distinguished from the other six elements (known collectively as the “platinum” metals) and the two sets of elements considered separately.

The triad Fe, Ru and Os is dominated, as indeed is the whole block of transition elements, by the immense importance of iron. This element has been known since prehistoric times and no other metal has played a more important role in man’s material progress. Iron beads dating from around 4000 BC were no doubt of meteoric origin, and later samples, produced by reducing iron ore with charcoal, were not cast because adequate temperatures were not attainable without the use of some form of bellows. Instead, the spongy material produced by low-temperature reduction would have had to be shaped by prolonged hammering. It seems that iron was first smelted by the Hittites in Asia Minor sometime in the third millennium BC, but the value of the process was so great that its secret was carefully guarded and it was only with the eventual fall of the Hittite empire around 1200 BC that the knowledge was dispersed and the “Iron Age” began. In more recent times the introduction of coke as the reductant had far-reaching effects, and was one of the major factors in the initiation of the Industrial Revolution. The name “iron” is Anglo-Saxon in origin (iren, cf. German Eisen). The symbol Fe and words such as “ferrous” derive from the Latin ferrum, iron.

Biologically, iron plays crucial roles in the transport and storage of oxygen and also in electron transport, and it is safe to say that, with only a few possible exceptions in the bacterial world, there would be no life without iron. Again, within the last forty years or so, the already rich organometallic chemistry of iron has been enormously expanded, and work in the whole field given an added impetus by the discovery and characterization of ferrocene.

---

§25.2.2 Preparation and uses of the elements

Ruthenium and osmium, though interesting and useful, are in no way comparable with iron and are relative newcomers. They were discovered independently in the residues left after crude platinum had been dissolved in aqua regia; ruthenium in 1844 from ores from the Urals by K. Klaus(2a) who named it after Ruthenia, the Latin name for Russia; and osmium in 1803 by S. Tennant who named it from the Greek word for odour (ὀσμή, osme) because of the characteristic and pungent smell of the volatile oxide, OsO₄. (CAUTION: OsO₄ is very toxic.)

25.2 The Elements Iron, Ruthenium and Osmium

25.2.1 Terrestrial abundance and distribution

Ruthenium and osmium are generally found in the metallic state along with the other “platinum” metals and the “coinage” metals. The major source of the platinum metals are the nickel–copper sulfide ores found in South Africa and Sudbury (Canada), and in the river sands of the Urals in Russia. They are rare elements, ruthenium particularly so, their estimated abundances in the earth’s crustal rocks being but 0.0001 (Ru) and 0.005 (Os) ppm. However, as in Group 7, there is a marked contrast between the abundances of the two heavier elements and that of the first.

The nuclei of iron are especially stable, giving it a comparatively high cosmic abundance (Chap. 1, p. 11), and it is thought to be the main constituent of the earth’s core (which has a radius of approximately 3500 km, i.e. 2150 miles) as well as being the major component of “siderite” meteorites. About 0.5% of the lunar soil is now known to be metallic iron and, since on average this soil is 10 m deep, there must be $\sim 10^{12}$ tonnes of iron on the moon’s surface. In the earth’s crustal rocks (6.2%, i.e. 62 000 ppm) it is the fourth most abundant element (after oxygen, silicon and aluminium) and the second most abundant metal. It is also widely distributed, as oxides and carbonates, of which the chief ones are: haematite (Fe₂O₃), magnetite (Fe₃O₄), limonite ($\sim 2$Fe₂O₃·$3$H₂O) and siderite (FeCO₃). Iron pyrite (FeS₂) is also common but is not used as a source of iron because of the difficulty in eliminating the sulfur. The distribution of iron has been considerably influenced by weathering. Leaching from sulfide and silicate deposits occurs readily as FeSO₄ and Fe(HCO₃)₂ respectively. In solution, these are quickly oxidized, and even mildly alkaline conditions cause the precipitation of iron(III) oxide. Because of their availability, production of iron ores can be confined to those of the highest grade in gigantic operations.

25.2.2 Preparation and uses of the elements

Pure iron, when needed, is produced on a relatively small scale by the reduction of the pure oxide or hydroxide with hydrogen, or by the carbonyl process in which iron is heated with carbon monoxide under pressure and the Fe(CO)₅ so formed decomposed at 250°C to give the powdered metal. However, it is not in the pure state but in the form of an enormous variety of steels that iron finds its most widespread uses, the world’s annual production being over 700 million tonnes.

The first stage in the conversion of iron ore to steel is the blast furnace (see Panel), which accounts for the largest tonnage of any metal produced by man. In it the iron ore is reduced by coke,† while limestone removes any sand or clay as a slag. The molten iron is run off to be cast into moulds of the required shape or into ingots (“pigs”) for further processing — hence the names “cast-iron” or “pig-iron”. This is an

---

† The actual reducing agent is, in the main, CO. Direct reduction of the ore using $\text{H}_2$, CO or CO + $\text{H}_2$ gas (produced from natural gas or fossil fuels) now accounts for about 4% of the world’s total production of iron. With a much lower operating temperature than that of the blast furnace, reduction is confined to the ore, producing a “sponge” iron and leaving the gangue relatively unchanged. This offers a potential economy in fuel providing that the quantity and composition of the gangue do not adversely affect the subsequent conversion to steel — which is most commonly by the electric arc furnace.
Iron$^{(3,4)}$ and Steel$^{(5)}$

About 1773, in order to overcome a shortage of timber for the production of charcoal, Abraham Darby developed a process for producing carbon (coke) from coal and used this instead of charcoal in his blast furnace at Coalbrookdale in Shropshire. The impact was dramatic. It so cheapened and increased the scale of ironmaking that in the succeeding decades Shropshire iron was used to produce for the first time: iron cylinders for steam-engines, iron rails, iron boats and ships, iron aqueducts, and iron-framed buildings. The iron bridge erected nearby over the River Severn in 1779, gave its name to the small town which grew around it and still stands, a monument to the process which “opened up” the iron industry to the Industrial Revolution.

The blast furnace (Fig. A, opposite) remains the basis of ironmaking though the scale, if not the principle, has changed considerably since the eighteenth century: the largest modern blast furnaces have hearths 14 m in diameter and produce up to 10 000 tonnes of iron daily.

The furnace is charged with a mixture of the ore (usually haematite), coke and limestone, then a blast of hot air, or air with fuel oil, is blown in at the bottom. The coke burns and such intense heat is generated that temperatures approaching $2000^\circ$C are reached near the base of the furnace and perhaps $200^\circ$C at the top. The net result is that the ore is reduced to iron, and silicaceous gangue forms a slag (mainly $\text{CaSiO}_3$) with the limestone:

$$2\text{Fe}_2\text{O}_3 + 3\text{C} \rightarrow 4\text{Fe} + 3\text{CO}_2$$

$$\text{SiO}_2 + \text{CaCO}_3 \rightarrow \text{CaSiO}_3 + \text{CO}_2$$

The molten iron, and the molten slag which floats on the iron, collect at the bottom of the furnace and are tapped off separately. As the charge moves down, the furnace is recharged at the top, making the process continuous. Of course the actual reactions taking place are far more numerous than this and only the more important ones are summarized in Fig. A. The details are exceedingly complex and still not fully understood. At least part of the reason for this complexity is the rapidity with which the blast passes through the furnace ($\sim 10$ s) which does not allow the gas-solid reactions to reach equilibrium. The main reduction occurs near the top, as the hot rising gases meet the descending charge. Here too the limestone is converted to CaO. Reduction to the metal is completed at somewhat higher temperatures, after which fusion occurs and the iron takes up Si and P in addition to C. The deleterious uptake of S is considerably reduced if manganese is present, because of the formation of MnS which passes into the slag. For this the slag must be adequately fluid and to this end the ratio of base (CaO):acid (SiO$_2$, Al$_2$O$_3$) is maintained by the addition, if necessary, of gravel (SiO$_2$). The slag is subsequently used as a building material (breeze blocks, wall insulation) and in the manufacture of some types of cement.

Traditionally, pig-iron was converted to wrought-iron by the “puddling” process in which the molten iron was manually mixed with haematite and excess carbon and other impurities burnt out. Some wrought-iron was then converted to steel by cementation process (prolonged heating of wrought-iron bars with charcoal) and the crucible process (fusion of wrought-iron with the correct amount of charcoal). In the mid-nineteenth century, production was enormously increased by the introduction of the Bessemer process in which the carbon content of molten pig-iron in a “converter” was lowered by blasting compressed air through it. The converter was lined with silica or limestone in order to form a molten slag with the basic or acidic impurities present in the pig-iron. Air and appropriate linings were also employed in the Open-hearth process which allowed better control of the steel’s composition, but both processes have now been supplanted by the Basic oxygen and Electric arc processes.

Basic oxygen process (BOP). This process, of which there are several modifications, originated in Austria in 1952, and because of its greater speed has since become by far the most common means of producing steel. A jet of pure oxygen is blown through a retractable steel “lance” into, or over the surface of, the molten pig-iron which is contained in a basic-lined furnace. Impurities form a slag which is usually removed by tilting the converter.

Electric arc process. Patented by Siemens in 1878, this uses an electric current through the metal (direct-arc), or an arc just above the metal (indirect-arc), as a means of heating. It is widely used in the manufacture of alloy- and other high-quality steels.

World production of iron ore in 1995 was 1020 million tonnes (Mt) (China 25%, Brazil 18%, former USSR 14%, Australia 12.9%, India and USA 6% each). In the same year world production of raw steel was 748 Mt (Western Europe 22.7%, N. America 16.2%, Japan 13.6%, China 12.4%, former USSR 10.6% and S. America 4.7%).

---

impure form of iron, containing about 4% of carbon along with variable amounts of Si, Mn, P and S. It is hard but notoriously brittle. To eradicate this disadvantage the non-metallic impurities must be removed. This can be done by oxidizing them with haematite in the now obsolete “puddling process”, producing the much purer “wrought-iron”, which is tough and malleable and ideal for mechanical working. Nowadays, however, the bulk of pig-iron is converted into steel containing 0.5–1.5% C but very little S or P. The oxidation in this case is most commonly effected in one of a number of related processes by pure oxygen (basic oxygen process, or BOP), but open-hearth and electric arc furnaces are also used, while the Bessemer Converter (see Panel) was of great historical importance. This “mild steel” is cheaper than wrought-iron and stronger and more workable than cast-iron; it also has the advantage over both that it can be hardened by heating to redness and then cooling rapidly (quenching) in water or mineral oil, and “tempered” by re-heating to 200–300°C and cooling more slowly. The hardness, resilience and ductility can be controlled by varying the temperature and the rate of cooling as well as the precise composition of the steel (see below). Alloy steels, with their enormous variety of physical properties, are prepared by the addition of the appropriate alloying metal or metals.

All the platinum group metals are isolated from “platinum concentrates” which are commonly obtained either from “anode slimes” in the electrolytic refining of nickel and copper, or as “converter matte” from the smelting of sulfide ores.\(^{(6)}\) The details of the procedure used differ from location to location and depend on the composition of the concentrate. Classical methods of separation, relying on selective precipitation, are still widely employed but solvent extraction and ion exchange techniques are increasingly being introduced to effect the primary separations (p. 1147).

Ru and Os are usually removed by distillation of their tetroxides immediately after the initial dissolution with hydrochloric acid and chlorine. Collection of the tetroxides in alcoholic NaOH and aqueous HCl respectively yields OsO\(_2\)(NH\(_3\))\(_4\)-Cl\(_2\) and (NH\(_4\))\(_3\)RuCl\(_6\) from which the metals are

obtained by ignition in H₂. The metals are in the form of powder or sponge and are usually consolidated by powder-metallurgical techniques. Major uses of ruthenium are as a coating for titanium anodes in the electrolytic production of Cl₂ and, more recently, as a catalyst in the production of ammonia (p. 421). Osmium is used in dentistry as a hardening agent in gold alloys. However, Ru and Os, along with Ir, are regarded as the minor platinum metals, being obtained largely as byproducts in the production of Pt, Pd and Rh, and their annual world production is only of the order of tonnes. (Weights of Ru and Os, as of most precious metals, are generally quoted in troy ounces: 1 troy ounce = 1.097 avoirdupois ounce = 31.103 g.)

25.2.3 Properties of the elements

Table 25.1 summarizes some of the important properties of Fe, Ru and Os. The two heavier elements in particular have several naturally occurring isotopes, and difficulties in obtaining calibrated measurements of their relative abundances limit the precision with which their atomic weights can be determined. Osmium is the densest of all elements, surpassing iridium by the tiniest of margins.⁷

All three elements are lustrous and silvery in colour. Iron when pure is fairly soft and readily worked, but ruthenium and osmium are less tractable in this respect. The structures of the solids are typically metallic, being hcp for the heavier elements and bcc for iron at room temperature (α-iron). However, the behaviour of iron is complicated by the existence of a fcc form (γ-iron) at higher temperatures (above 910⁰), reverting to bcc again (δ-iron) at about 1390⁰, some 145⁰ below its mp. Technologically, the carbon content is crucial, as can be seen from the Fe/C phase diagram (Fig. 25.1), which also throws light on the hardening and tempering

⁷Densities are calculated from crystallographic data and depend on a knowledge of the wavelength of the X-rays, Avogadro’s constant and the atomic weight of the element. Using the best available data the densities of Os and Ir are calculated to be 22.587 ± 0.009 and 22.562 ± 0.009 g cm⁻³ respectively at 20°C. J. W. ARBLASTER, *Platinum Metals Rev.* 33, 14–16 (1989). *Ibid.*, 39, 164 (1995).
Figure 25.1 The iron-carbon phase diagram for low concentrations of carbon.

processes already referred to. The lowering of the mp from 1535°C to 1015°C when the C content reaches 4.3%, facilitates the fusion of iron in the blast furnace, and the lower solubility of Fe3C ("cementite") in α-iron as compared to δ- and γ-iron leads to the possibility of producing metastable forms by varying the rate of cooling of hot steels. At elevated temperatures a solid solution of Fe3C in γ-iron, known as "austenite", prevails. If 0.8% C is present, slow cooling below 723°C causes Fe3C to separate forming alternate layers with the α-iron. Because of its appearance when polished, this is known as "pearlite" and is rather soft and malleable. If, however, the cooling is rapid (quenching) the separation is suppressed and the extremely hard and brittle “martensite” is produced. Reheating to an intermediate temperature tempers the steel by modifying the proportions of hard and malleable forms. If the C content of the steel is below 0.8% then slow cooling gives a mixture of pearlite and α-iron and, if higher than 0.8% a mixture of pearlite and Fe3C. Varying the proportion of carbon in the steel thereby further extends the range of physical properties which can be attained by appropriate heat treatment.

The magnetic properties of iron are also dependent on purity and heat treatment. Up to 768°C (the Curie point) pure iron is ferromagnetic as a result of extensive magnetic interactions between unpaired electrons on adjacent atoms, which cause the electron spins to be aligned in the same direction, so producing exceedingly high magnetic susceptibilities and the characteristic ferromagnetic properties of “saturation” and “hysteresis”. The existence of unpaired electrons on the individual atoms, as opposed to being delocalized in bands permeating the lattice, can be rationalized at least partly by supposing that in the bcc lattice the metal d2 and d3-y2 orbitals, which are not directed towards nearest neighbours, are therefore nonbonding and so can retain 2 unpaired electrons on the atom. On the other hand, electrons in the remaining three d orbitals participate in the formation of a conduction band of predominantly paired electrons. At temperatures above the Curie temperature, thermal energy overcomes the interaction between the electrons localized on individual atoms; their mutual alignment is broken, and normal paramagnetic behaviour ensues. This is sometimes referred to as β-iron (768–910°C) though the crystal structure remains bcc as in ferromagnetic α-iron. For the construction of permanent magnets, cobalt steels are particularly useful, whereas for the “soft” irons used in electric motors and transformer cores (where the magnetization undergoes rapid reversal) silicon steels are preferred.

The mps and bps and enthalpies of atomization indicate that the (n-1)d electrons are contributing to metal bonding less than in earlier groups although, possibly due to an enhanced tendency for metals with a d5 configuration to resist delocalization of their d electrons, Mn and to a lesser extent Tc occupy “anomalous” positions so that for Fe and Ru the values of these quantities are actually higher than for the elements immediately preceding them. In the third transition series Re appears to be “well-behaved” and the changes from W → Re → Os are consequently smooth.

25.2.4 Chemical reactivity and trends

As expected, contrasts between the first element and the two heavier congeners are noticeable,
Rusting of Iron

The economic importance of rusting can scarcely be overestimated. Although precision is impossible, it is likely that the cost of corrosion is over 1% of the world’s economy.

Rusting of iron consists of the formation of hydrated oxide, Fe(OH)$_3$ or FeO(OH), and is evidently an electrochemical process which requires the presence of water, oxygen and an electrolyte — in the absence of any one of these rusting does not occur to any significant extent. In air, a relative humidity of over 50% provides the necessary amount of water. The mechanism is complex and will depend in detail on the prevailing conditions, but may be summarized as:

\[
\text{the cathodic reduction: } 3\text{O}_2 + 6\text{H}_2\text{O} + 12e^- \rightarrow 12\text{(OH)}^- \\
\text{and the anodic oxidations: } 4\text{Fe} \rightarrow 4\text{Fe}^{2+} + 8e^- \\
\text{and } 4\text{Fe}^{2+} \rightarrow 4\text{Fe}^{3+} + 4e^- \\
i.e. overall: } 4\text{Fe} + 3\text{O}_2 + 6\text{H}_2\text{O} \rightarrow 4\text{Fe}^{3+} + 12\text{(OH)}^- \\
4\text{Fe(OH)}_3 \text{ or } 4\text{FeO(OH)} + 4\text{H}_2\text{O}
\]

The presence of the electrolyte is required to provide a pathway for the current and, in urban areas, this is commonly iron(II) sulfate formed as a result of attack by atmospheric SO$_2$ but, in seaside areas, airborne particles of salt are important. Because of its electrochemical nature, rusting may continue for long periods at a more or less constant rate, in contrast to the formation of an anhydrous oxide coating which under dry conditions slows down rapidly as the coating thickens.

The anodic oxidation of the iron is usually localized in surface pits and crevices which allow the formation of adherent rust over the remaining surface area. Eventually the lateral extension of the anodic area undermines the rust to produce loose flakes. Moreover, once an adherent film of rust has formed, simply painting over gives but poor protection. This is due to the presence of electrolytes such as iron(II) sulfate in the film so that painting merely seals in the ingredients for anodic oxidation. It then only requires the exposure of some other portion of the surface, where cathodic reduction can take place, for rusting beneath the paint to occur.

The protection of iron and steel against rusting takes many forms, including: simple covering with paint; coating with another metal such as zinc (galvanizing) or tin; treating with “inhibitors” such as chromate(VI) or (in the presence of air) phosphate or hydroxide, all of which produce a coherent protective film of Fe$_2$O$_3$. Another method uses sacrificial anodes, most usually Mg or Zn which, being higher than Fe in the electrochemical series, are attacked preferentially. In fact, the Zn coating on galvanized iron is actually a sacrificial anode.

Both in the reactivity of the elements and in their chemistry. Iron is much the most reactive metal of the triad, being pyrophoric if finely divided and dissolving readily in dilute acids to give Fe$^{II}$ salts; however, it is rendered passive by oxidizing acids such as concentrated nitric and chromic, due to the formation of an impervious oxide film which protects it from further reaction but which is immediately removed by acids such as hydrochloric. Ruthenium and osmium, on the other hand, are virtually unaffected by non-oxidizing acids, or even aqua regia. Iron also reacts fairly easily with most non-metals whereas ruthenium and osmium do so only with difficulty at high temperatures, except in the case of oxidizing agents such as F$_2$ and Cl$_2$. Indeed, it is with oxidizing agents generally that Ru and Os metals are most reactive. Thus Os is converted to OsO$_4$ by conc nitric acid and both metals can be dissolved in molten alkali in the presence of air or, better still, in oxidizing flux such as Na$_2$O$_2$ or KClO$_3$ to give the ruthenates and osmates [RuO$_4$]$^{2-}$ and [OsO$_2$(OH)$_4$]$^{2-}$ respectively. If the aqueous extracts from these fusions are treated with Cl$_2$ and heated, the tetroxides distill off, providing convenient preparative starting materials as well as the means of recovering the elements.

Ruthenium and Os are stable to atmospheric attack though if Os is very finely divided it gives off the characteristic smell of OsO$_4$. By contrast, iron is subject to corrosion in the form of rusting which, because of its great economic importance, has received much attention (see Panel above).

Figure 25.2  Plot of volt-equivalent against oxidation state for Fe, Ru and Os in acidic aqueous solution.

In moving across the transition series, iron is the first element which fails to attain its group oxidation state (+8). The highest oxidation state known (so far) is +6 in $[\text{FeO}_4]^2-$ and even this is extremely easily reduced. On the other hand, ruthenium and osmium do attain the group oxidation state of +8, though they are the last elements to do so in the second and third transition series, and this is consequently the highest oxidation state for any element (see also
Ruthenium(VII) is significantly less stable than Os(VIII) and it is clear that the second- and third-row elements, though similar, are by no means as alike as for earlier element-pairs in the transition series. The same gradation within the triad is well illustrated by the reactions of the metals with oxygen. All react on heating, but their products are, respectively, \( \text{Fe}_2\text{O}_3 \) and \( \text{Fe}_3\text{O}_4 \), \( \text{Ru}^{IV}\text{O}_2 \) and \( \text{Os}^{VIII}\text{O}_4 \). In general terms it can be said that the most common oxidation states for the three elements are \(+2\) and \(+3\) for \( \text{Fe} \), \(+3\) for \( \text{Ru} \), and \(+4\) for \( \text{Os} \). And, while \( \text{Fe} \) (and to a lesser extent \( \text{Ru} \)) has an extensive aqueous cationic chemistry in its lower oxidation states, \( \text{Os} \) has none. Table 25.2 and Fig. 25.2 summarize the relative stabilities of the various oxidation states in acidic aqueous solution.

A selection of representative examples of compounds of the three elements is given in Table 25.3. As in the preceding group there is

Three oxides of iron may be distinguished, but are all subject to nonstoichiometry. The lowest is FeO which is obtained by heating iron in a low partial pressure of O\(_2\) or as a fine, black pyrophoric powder by heating iron(II) oxide in vacuo. Below about 575°C it is unstable towards disproportionation into Fe and Fe\(_3\)O\(_4\) but can be obtained as a metastable phase if cooled rapidly. It has a rock-salt structure but is always deficient in iron, with a homogeneity range of Fe\(_{0.84}\)O to Fe\(_{0.95}\)O. Treatment of any aqueous solution of Fe\(^{II}\) with alkali produces a flocculent precipitate. If air is rigorously excluded this is the virtually white Fe(OH)\(_2\) which is almost entirely basic in character, dissolving readily in non-oxidizing acids to give Fe\(^{III}\) salts but

---

showing only slight reactivity towards alkali. It gradually decomposes, however, to Fe$_3$O$_4$ with evolution of hydrogen and in the presence of oxygen darkens rapidly and eventually forms the reddish-brown hydrated iron(III) oxide. Fe$_3$O$_4$ is a mixed Fe$^{II}$/Fe$^{III}$ oxide which can be obtained by partial oxidation of FeO or, more conveniently, by heating Fe$_2$O$_3$ above about 1400°C. It has the inverse spinel structure. Spinels are of the form M$^{III}$M$^{II}_3$O$_4$ and in the normal spinel (p. 247) the oxide ions form a ccp lattice with M$^{III}$ ions occupying tetrahedral sites and M$^{II}$ ions octahedral sites. In the inverse structure half the M$^{III}$ ions occupy tetrahedral sites, with the M$^{II}$ and the other half of the M$^{III}$ occupying octahedral sites.† Fe$_3$O$_4$ occurs naturally as the mineral magnetite or lodestone. It is a black, strongly ferromagnetic substance (or, more strictly, “ferrimagnetic” — see p. 1081), insoluble in water and acids. Its electrical properties are not simple, but its rather high conductivity may be ascribed to electron transfer between Fe$^{II}$ and Fe$^{III}$.

Fe$_2$O$_3$ is known in a variety of modifications of which the more important are the $\alpha$- and $\gamma$-forms. When aqueous solutions of iron(III) are treated with alkali, a gelatinous reddish-brown precipitate of hydrated oxide is produced (this is amorphous to X-rays and is not simple Fe(OH)$_3$, but probably Fe(OH)$_2$); when heated to 200°C, this gives the red-brown $\alpha$-Fe$_2$O$_3$. Like V$_2$O$_3$ and Cr$_2$O$_3$ this has the corundum structure (p. 243) in which the oxide ions are hcp and the metal ions occupy octahedral sites. It occurs naturally as the mineral haematite and, besides its overriding importance as a source of the metal (p. 1072), it is used (a) as a pigment, (b) in the preparation of rare earth/iron garnets and other ferrites (p. 1081), and (c) as a polishing agent — jewellers’ rouge. The second variety $\gamma$-Fe$_3$O$_4$ is metastable and is obtained by careful oxidation of Fe$_3$O$_4$, like which it is cubic and ferrimagnetic. If heated in vacuo it reverts to Fe$_3$O$_4$ but heating in air converts it to $\alpha$-Fe$_2$O$_3$. It is the most widely used magnetic material in the production of magnetic recording tapes.

The interconvertibility of FeO, Fe$_3$O$_4$ and $\gamma$-Fe$_3$O$_4$ arises because of their structural similarity. Unlike $\alpha$-Fe$_2$O$_3$, which is based on a hcp lattice of oxygen atoms, these three compounds are all based on ccp lattices of oxygen atoms. In FeO, Fe$^{II}$ ions occupy the octahedral sites and nonstoichiometry arises by oxidation, when some Fe$^{II}$ ions are replaced by two-thirds their number of Fe$^{III}$ ions. Continued oxidation produces Fe$_3$O$_4$ in which the Fe$^{II}$ ions are in octahedral sites, but the Fe$^{III}$ ions are distributed between both octahedral and tetrahedral sites. Eventually, oxidation leads to $\gamma$-Fe$_3$O$_4$ in which all the cations are Fe$^{III}$ which are randomly distributed between octahedral and tetrahedral sites. The oxygen lattice remains intact throughout but contracts somewhat as the number of iron atoms which it accommodates diminishes.

Ruthenium and osmium have no oxides comparable to those of iron and, indeed, the lowest oxidation state in which they form oxides is $\text{Ru}^{IV}$. RuO$_2$ is a blue to black solid, obtained by direct action of the elements at 1000°C, and has the rutile (p. 961) structure. The intense colour has been suggested as arising from the presence of small amounts of Ru in another oxidation state, possibly $\text{Ru}^{III}$. OsO$_2$ is a yellowish-brown solid, usually prepared by heating the metal at 650°C in NO. It, too, has the rutile structure.

The most interesting oxides of Ru and Os, however, are the volatile, yellow tetroxides, RuO$_4$ (mp 25°C, bp 130°C$^{13}$) and OsO$_4$ (mp 40°C, bp 130°C). They are tetrahedral molecules and the latter is perhaps the best-known compound of osmium. It is produced by aerial oxidation of the heated metal or by oxidizing other compounds of osmium with

---

† Although Fe$_3$O$_4$ is an inverse spinel it will be recalled that Mn$_3$O$_4$ (pp. 1048–9) is normal. This contrast can be explained on the basis of crystal field stabilization. Manganese(II) and Fe$^{III}$ are both $d^5$ ions and, when high-spin, have zero CFSE whether octahedral or tetrahedral. On the other hand, Mn$^{III}$ is a $d^4$ and Fe$^{II}$ a $d^6$ ion, both of which have greater CFSEs in the octahedral rather than the tetrahedral case. The preference of Mn$^{III}$ for the octahedral sites therefore favours the spinel structure, whereas the preference of Fe$^{II}$ for these octahedral sites favours the inverse structure.

nitric acid. It dissolves in aqueous alkali to give \([\text{Os}^{\text{VIII}}\text{O}_4(\text{OH})_2]^{2-}\) and oxidizes conc (but not dil) hydrochloric acid to \(\text{Cl}_2\), being itself reduced to \(\text{H}_2\text{OsCl}_6\). It is used in organic chemistry to oxidize \(\text{C} = \text{C}\) bonds to cis-diols and is also employed as a biological stain. Unfortunately, it is extremely toxic and its volatility renders it particularly dangerous. \(\text{RuO}_4\) is, appreciably less stable and will oxidize dil as well as conc \(\text{HCl}\), while in aqueous alkali it is reduced to \([\text{Ru}^{\text{VI}}\text{O}_4]^{2-}\). If heated above 100°C it decomposes explosively to \(\text{RuO}_2\) and is liable to do the same at room temperature if brought into contact with oxidizable organic solvents such as ethanol. Its preparation obviously requires stronger oxidizing agents than that of \(\text{OsO}_4\); nitric acid alone will not suffice and instead the action of \(\text{KMnO}_4\), \(\text{KIO}_4\) or \(\text{Cl}_2\) on acidified solutions of a convenient \(\text{Ru}\) compound is used.

The sulfides are fewer in number than the oxides and favour lower metal oxidation states. Iron forms 3 sulfides (p. 680). \(\text{FeS}\) is a grey, nonstoichiometric material, obtained by direct action of the elements or by treating aqueous \(\text{Fe}^{\text{II}}\) with alkali metal sulfide. It has a \(\text{NiAs}\) structure (p. 679) in which each metal atom is octahedrally surrounded by anions but is also quite close to 2 other metal atoms. It oxidizes readily in air and dissolves in aqueous acids with evolution of \(\text{H}_2\text{S}\). \(\text{FeS}_2\) can be prepared by heating \(\text{Fe}_2\text{O}_3\) in \(\text{H}_2\text{S}\) but is most commonly encountered as the yellow mineral pyrites. This does not contain \(\text{Fe}^{\text{IV}}\) but is composed of \(\text{Fe}^{\text{II}}\) and \(\text{S}_2^{2-}\) ions in a distorted rock-salt arrangement, its diamagnetism indicating low-spin \(\text{Fe}^{\text{II}}(d^6)\). It is very unreactive unless heated, when it gives \(\text{Fe}_2\text{O}_3 + \text{SO}_2\) in air, or \(\text{FeS} + \text{S}\) in a vacuum. \(\text{Fe}_2\text{S}_3\) is the unstable black precipitate resulting when aqueous \(\text{Fe}^{\text{III}}\) is treated with \(\text{S}^{2-}\), and is rapidly oxidized in moist air to \(\text{Fe}_2\text{O}_3\) and \(\text{S}\).

Ruthenium and osmium form only disulfides. These have the pyrite structure and are diamagnetic semiconductors; this implies that they contain \(\text{M}^{\text{II}}\). \(\text{RuSe}_2\), \(\text{RuTe}_2\), \(\text{OsSe}_2\) and \(\text{OsTe}_2\) are very similar. All 6 dichalcogenides are obtained directly from the elements.

### 25.3.2 Mixed metal oxides and oxoanions

The "ferrites" and "garnets" of iron are mixed metal oxides of considerable technological importance. They are obtained by heating \(\text{Fe}_2\text{O}_3\) with the carbonate of the appropriate metal. The ferrites have the general form \(\text{M}^{\text{II}}\text{Fe}^{\text{III}}\text{O}_4\). Some adopt the normal spinel structure and others the inverse spinel structure (p. 248) as just described for \(\text{Fe}_3\text{O}_4\) (which can itself be regarded as the ferrite \(\text{Fe}^{\text{II}}\text{Fe}^{\text{III}}\text{O}_4\)). In inverse spinels the unpaired electrons of all the cations in octahedral sites (\(\text{M}^{\text{II}}\) and half the \(\text{M}^{\text{III}}\)) are magnetically coupled parallel to give a ferromagnetic sublattice, while the unpaired electrons of all the cations in tetrahedral sites (the remaining \(\text{M}^{\text{III}}\)) are similarly but independently coupled parallel to give a second ferromagnetic sublattice. The spins of one sublattice, however, are antiparallel to those of the other. If the cations in the octahedral sites have the same total number of unpaired electrons as those in the tetrahedral sites, then the effects of 2 ferromagnetic sublattices are mutually compensating and "antiferromagnetism" results; but where the sublattices are not balanced then a type of ferromagnetism known as ferrimagnetism results, the explanation of which was first given by L. Néel in 1948 (Nobel Prize for Physics, 1970). Important applications of inverse spinel ferrites are as cores in high-frequency transformers (where they have the advantage over metals of being free from eddy-current losses), and in computer memory systems.

So-called “hexagonal ferrites” such as \(\text{BaFe}_{12-}\text{O}_{19}\) are ferrimagnetic and are used to construct permanent magnets. A third type of ferrimagnetic mixed oxides are the garnets, \(\text{M}^{\text{II}}\text{Fe}_5\text{O}_{12}\), of which the best known is yttrium iron garnet (YIG) used as a microwave filter in radar.

Mixed oxides of \(\text{Fe}^{\text{IV}}\) such as \(\text{M}_3\text{Fe}_2\text{O}_4\) and \(\text{M}_2\text{Fe}_2\text{O}_4\) can be prepared by heating \(\text{Fe}_2\text{O}_3\) with the appropriate oxide or hydroxide in

---

oxygen. These do not contain discrete $[\text{FeO}_4]^{4-}$ anions and, as was seen above, mixed oxides of Fe$^{III}$ are generally based on close-packed oxide lattices with no iron-containing anions. However, oxoanions of iron are known and are usually based on the Fe$O_4$ tetrahedron. Thus for iron(III), Na$_3$Fe$O_4$, K$_6[\text{Fe}_2O_6]$ (2 edge-sharing tetrahedra), and Na$_{14}[\text{Fe}_6O_{18}]$ (rings of 6 corner-sharing tetrahedra), have been prepared and more recently, for iron(V), K$_3[\text{FeO}_4]$.$^{15}$ But the best-known oxoanion of iron is the ferrate(VI) prepared by oxidizing a suspension of hydrous Fe$_2O_3$ in conc alkali with chlorine, or by the anodic oxidation of iron in conc alkali. The tetrahedral $[\text{FeO}_4]^{2-}$ ion is red-purple and is an extremely strong oxidizing agent. It oxidizes NH$_3$ to N$_2$ even at room temperature and, although it can be kept for a period of hours in alkaline solution, in acid or neutral solutions it rapidly oxidizes the water, so liberating oxygen:

$$2[\text{FeO}_4]^{2-} + 5\text{H}_2\text{O} \rightarrow 2\text{Fe}^{3+} + 10\text{OH}^- + \frac{3}{2}\text{O}_2$$

The distinction between the first member of the group and the two heavier members, which was seen to be so sharp in the early groups of transition metals, is much less obvious here. The only unsubstituted, discrete oxoanions of the heavier pair of metals are the tetrahedral $[\text{RuVII}O_4]^{-}$ and $[\text{RuVIIO}_4]^{2-}$. This behaviour is akin to that of iron or, even more, to that of manganese, whereas in the osmium analogues the metal always increases its coordination number by the attachment of extra OH$^-$ ions. If RuO$_4$ is dissolved in cold dilute KOH, or aqueous K$_2$RuO$_4$ is oxidized by chlorine, virtually black crystals of K[Ru$VII$O$_4$] ("perruthenate") are deposited. These are unstable unless dried and are reduced by water, especially if alkaline, to the orange $[\text{RuVIIO}_4]^{2-}$ ("ruthenate") by a mechanism which is thought to involve octahedral intermediates of the type $[\text{RuO}_4(\text{OH})_2]^{3-}$ and $[\text{RuO}_4(\text{OH})_2]^{2-}$ K$_2[\text{RuO}_4]$ is obtained by fusing Ru metal with KOH and KNO$_3$.

By contrast, dissolution of OsO$_4$ in cold aqueous KOH produces deep-red crystals of K$_2[\text{OsVIII}O_4(\text{OH})_2]$ ("perosmate"), which is easily reduced to the purple "osmate", K$_2[\text{OsVIIO}_2(\text{OH})_4]$. The anions in both cases are octahedral with, respectively, trans OH and trans O groups.

By heating the metal with appropriate oxides or carbonates of alkali or alkaline earth metals, a number of mixed oxides of Ru and Os have been made. They include Na$_3$Os$VII$O$_6$, Li$_6$Os$VII$O$_6$ and the "ruthenites", M$_6$Ru$V$O$_9$, in all of which the metal is situated in octahedral sites of an oxide lattice. Ru$V$ (octahedral) has now also been established by $^{99}$Ru Mössbauer spectroscopy as a common stable oxidation state in mixed oxides such as Na$_3$Ru$V$O$_4$, Na$_4$Ru$V$O$_7$, and the ordered perovskite-type phases M$_2$Ln$^{III}$Ru$V$O$_6$.

### 25.3.3 Halides and oxohalides

The known halides of this group are listed in Table 25.6. As in the preceding group the highest halide is a heptafluoride, but OsF$_7$ (unlike ReF$_7$) is thermally unstable. It was for many years thought that OsF$_8$ existed but the yellow crystalline material to which the formula had been ascribed turned out to be OsF$_6$, the least unstable of the platinum metal hexafluorides. (In view of the propensity of higher fluorides to attack the vessels containing them, to disproportionate and to hydrolyse, it is not surprising that early reports on them sometimes proved to be erroneous.) The highest chloride is OsCl$_5$ and, rather unexpectedly perhaps, neither ruthenium nor iron form a chloride in an oxidation state higher than +3. Iron in fact does not form even a fluoride in an oxidation state higher than +3. OsF$_7$ has been obtained as a yellow solid by direct action of the elements at 600°C.
and a pressure of 400 atm, but under less drastic conditions OsF₆ is produced, as is RuF₆. This latter pair are low-melting, yellow and brown solids, respectively, hydrolysing violently with water and with a strong tendency to disproportionate into F₂ and lower halides. The pentafluorides are both polymeric, easily hydrolysed solids obtained by specific oxidations or reduction of other fluorides, and their structures involve [MF₅]₄ units in which 4 corner-sharing MF₆ octahedra form a ring (Fig. 25.3).

The tetrafluorides are yellow solids, probably polymeric, and are obtained by reducing RuF₅ with I₂, and OsF₅ with W(CO)₆. The tetrachloride and tetrabromide of osmium require pressure as well as heat in their preparations from the elements and are black solids, the bromide consisting of OsBr₆ octahedra connected by shared edges.

![Figure 25.3](image-url) Tetrameric pentafluorides of Ru and Os, [M₄F₂₀]. Their structures are similar to, but more distorted than, those of the pentafluorides of Nb and Ta (see Fig. 22.4).
In the +3 and +2 oxidation states those halides of osmium which have been reported are poorly characterized, grey or black solids. The compound obtained by thermal decomposition of OsBr\(_4\) and previously thought to be OsBr\(_3\) has since been shown\(^\text{16}\) to be Os\(_2\)OBr\(_6\), the chloride analogue of which is also known. For ruthenium, RuCl\(_3\) is well known and, as the anhydrous compound, exists in two forms: heating Ru metal at 330°C in CO and Cl\(_2\) produces the dark-brown \(\alpha\)-form which if heated above 450°C in Cl\(_2\) is converted to the black \(\alpha\)-form which is isomorphous with CrCl\(_3\) (p. 1020). Evaporation of a solution of RuO\(_4\) in hydrochloric acid in a stream of HCl gas produces red RuCl\(_3\).3H\(_2\)O; aqueous solutions contain both [Ru(H\(_2\)O)\(_6\)]\(^{3+}\) and chloro-substituted species and are easily hydrolysed and oxidized to Ru\(^{IV}\). Where impurities due to such reactions are suspected, conversion back to Ru\(^{III}\) chloride can be effected by repeated evaporation to dryness with conc HCl. This gives a uniform though rather poorly characterized product that is widely used as the starting material in ruthenium chemistry.

All the anhydrous +3 and +2 halides of iron are readily obtained, except for iron(II1) iodide, where the oxidizing properties of Fe\(^{III}\) and the reducing properties of I\(^-\) lead to thermodynamic instability. It has, however, been prepared\(^\text{17}\) in mg quantities by the following reaction, with air and moisture rigorously excluded,

\[
\text{Fe(CO)}_3 + \text{I}_2 \xrightarrow{\text{hexane}} \text{Fe(CO)}_3\text{I}_2 + \text{CO} \xrightarrow{1/2 \text{I}_2 + \text{hv}} \xrightarrow{-20^\circ\text{C}} \text{FeI}_3 + 4\text{CO}
\]

The other anhydrous FeX\(_3\) can be prepared by heating the elements (though in the case of FeBr\(_3\) the temperature must not rise above 200°C otherwise FeBr\(_2\) is formed). The fluoride, chloride and bromide are respectively white, dark brown and reddish-brown. The crystalline solids contain Fe\(^{III}\) ions octahedrally surrounded by halide ions and decompose to FeX\(_2\) + \(\frac{1}{2}\)X\(_2\) if heated strongly under vacuum. FeCl\(_3\) sublimes above 300°C and vapour pressure measurements show the vapour to contain dimeric Fe\(_2\)Cl\(_6\), like Al\(_2\)Cl\(_6\) consisting of 2 edge-sharing tetrahedra. The trifluoride is sparingly soluble, and the chloride and bromide very soluble in water and they crystallize as white FeF\(_3\).4H\(_2\)O (converting above 50°C to the pink trihydrate),\(^\text{18}\) yellow-brown FeCl\(_3\).6H\(_2\)O and dark-green FeBr\(_3\).6H\(_2\)O. The chloride is probably the most widely used etching material, being particularly important for etching copper in the production of electrical printed circuits. It is also used in water treatment as a coagulant (by producing a “ferric hydroxide” floc which removes organic matter and suspended solids) in cases where the SO\(_4^{2-}\) of the more widely used iron(II1) sulfate is undesirable.

Of the anhydrous dihalides of iron the iodide is easily prepared from the elements but the others are best obtained by passing HX over heated iron. The white (or pale-green) difluoride has the rutile structure the pale-yellow dichloride the CdCl\(_2\) structure (based on ccp anions, p. 1212) and the yellow-green dibromide and grey diiodide the CdI\(_2\) structure (based on hcp anions, p. 1212), in all of which the metal occupies octahedral sites. All these iron dihalides dissolve in water and form crystalline hydrates which may alternatively be obtained by dissolving metallic iron in the aqueous acid.

Apart from the pale green RuOF\(_4\) and the oxochlorides already referred to, oxohalides are largely confined to the oxofluorides of osmium,\(^\text{19}\) Os\(_2\)OF\(_2\), Os\(_2\)OF\(_3\), OsOF\(_5\), OsOF\(_4\) and the recently confirmed\(^\text{20}\) Os\(_2\)OF\(_4\), previously thought to be OsOF\(_6\). The compounds of Os\(^{VIII}\) are orange and red solids and those of the lower oxidation states are yellow to green. Typical preparations involve

---

§25.3.4 Complexes

25.3.4 Complexes

Oxidation state VIII (d⁰)

Iron forms barely any complexes in oxidation states above +3, and in the +8, +7 and +6 states those of ruthenium are less numerous than those of osmium. RuVIII complexes are confined to a few unstable (sometimes explosive) amine adducts of RuO₄. The “perosmates” (p. 1082) are, of course, adducts of OsO₄, but the most stable OsVIII complexes are the “osmiamates”, [OsO₃N]⁻ (p. 419). Pale-yellow crystals of K[OsO₃N] are obtained when solutions of OsO₄ in aqueous KOH (i.e. the perosmate) are treated with ammonia: the compound has been known since 1847 and A. W. Werner formulated it correctly in 1901. The anion is isoelectronic with OsO₄ and has a distorted tetrahedral structure (C₃v), while its infrared spectrum shows ν₆ = 1023 cm⁻¹, consistent with an Os=N triple bond. Hydrochloric and hydrobromic acids reduce K[OsO₃N] to red, K₂[OsV¹NCl₅].

Oxidation state VII (d¹)

Fluorides and oxo compounds of RuVII and OsVII have already been mentioned, and salts such as (R₄N)[RuO₄], (R = n-propyl, n-butyl) are useful reagents to oxidize a variety of organic materials without attacking double or allylic bonds.²²

---

Oxidation state VI (d²)

The most important members of this class are the osmium nitrido, and the “osmyl” complexes. The reddish-purple K₂[OsNCI₅] mentioned above is the result of reducing the osmiamate. The anion has a distorted octahedral structure with a formal triple bond Os=N (161 pm) and a pronounced “trans-influence” (pp. 1163–4), i.e. the Os–Cl distance trans to Os=N is much longer than the Os–Cl distances cis to Os=N (261 and 236 pm respectively). The anion [OsNCI₅]²⁻ also shows a “trans-effect” in that the CI opposite the N is more labile than the others, leading, for instance, to the formation of [OsV¹NCI₄]⁻, which has a square-pyramidal structure with the N occupying the apical position.

The osmyl complexes, of which the osmate ion [OsV⁰O₂(OH)₄]²⁻ may be regarded as the precursor, are a series of diamagnetic complexes containing the linear O=Os=O group together with 4 other, more remote, donor atoms which occupy the equatorial plane. That the Os–O bonds are double (i.e. 1σ and 1τ) is evident from the bond lengths of 175 pm — very close to those of 172 pm in OsO₄. The diamagnetism can then be explained using the MO approach outlined in Chapter 19, but modified to allow for the tetragonal compression along the axis of the osmyl group (taken to define the z-axis). On this model, the effect of 6 σ interactions produces the molecular orbitals shown in Fig. 19.14 (p. 922). The tetragonal compression then splits the essentially metallic t₂g and e'_g sets, as shown to the left of Fig. 25.4b. Two 3-centre π bonds are then formed, one by overlap of the metal dₓz orbital with the pₓ orbitals of the 2 oxygen atoms (Fig. 25.4a), the second similarly by dₓz and pᵧ overlap. Each 3-centre interaction produces 1 bonding, 1 virtually nonbonding, and 1 antibonding MO, as shown. The metal dₓz orbital remains unchanged and, in effect, the two d electrons of the Os are obliged to pair-up in it since other empty orbitals are inaccessible to them.

The [OsV⁰O₂]²⁺ group has a formal similarity to the more familiar uranyl ion [UO₂]²⁺ and is present in a variety of octahedral complexes.
Figure 25.4 Proposed π bonding in osmyl complexes: (a) 3-centre π bond formed by overlap of ligand π\textsubscript{z} and metal d\textsubscript{xz} orbitals (a similar bond is produced by p\textsubscript{z} and d\textsubscript{yz} overlap), and (b) MO diagram (see text).

in which the 4 equatorial sites are occupied by ligands such as OH\textsuperscript{−}, halides, CN\textsuperscript{−}, (C\textsubscript{2}O\textsubscript{4})\textsuperscript{2−}, NO\textsubscript{2}−, NH\textsubscript{3} and phthalocyanine. These are obtained from OsO\textsubscript{4} or potassium osmate.

A few analogous but less stable trans-dioxoruthenium(VI) compounds such as the bright yellow [RuO\textsubscript{2}(O\textsubscript{2}CCH\textsubscript{3})\textsubscript{2}py\textsubscript{2}] (Ru−O = 172.6 pm) are also known.(25)

Oxidation state V (d\textsuperscript{3})

This is not a very stable state for this group of metals in solution, [MF\textsubscript{6}]\textsuperscript{−} and [OsCl\textsubscript{6}]\textsuperscript{−} being amongst the few established examples. It is, however, well-characterized and stable in numerous solid-state oxide systems (p. 1082).

Oxidation state IV (d\textsuperscript{4})

Under normal circumstances this is the most stable oxidation state for osmium and the [OsX\textsubscript{6}]\textsuperscript{2−} complexes (X = F, Cl, Br, I) are particularly well known. [RuX\textsubscript{6}]\textsuperscript{2−} (X = F, Cl, Br) are also familiar but can more readily be reduced to Ru\textsuperscript{III}. All these [MX\textsubscript{6}]\textsuperscript{2−} ions are octahedral and low-spin, with 2 unpaired electrons. Their magnetic properties are interesting and highlight the limitations of using “spin-only” values of magnetic moments in assessing the number of unpaired electrons (see Panel).

The action of hydrochloric acid on RuO\textsubscript{4} in the presence of KCl produces a deep-red crystalline material, of stoichiometry K\textsubscript{2}[RuCl\textsubscript{5}(OH)], but its diamagnetism precludes this simple formulation. The compound is in fact K\textsubscript{4}[Cl\textsubscript{3}Ru−O−RuCl\textsubscript{5}] and is of interest as providing an early application of simple MO theory to a linear M−O−M system (not unlike the later treatment of the osmyl group). If the Ru−O−Ru axis is taken as the z-axis and each Ru\textsuperscript{IV} is regarded as being octahedrally coordinated, then the low-spin configuration of each Ru\textsuperscript{IV} ion is d\textsubscript{xy} d\textsubscript{yz} d\textsubscript{zx}. The diamagnetism is accounted for on the basis of two 3-centre π bonds, one arising from overlap.

That halide ligands should cause spin-pairing may in itself seem surprising, but this is not all. The regular, octahedral complexes of OsIV have magnetic moments at room temperature in the region of 1.48 BM and these decrease rapidly as the temperature is reduced. Even the moments of similar complexes of RuIV (which at around 2.9 BM are close to the “spin-only moment” expected solely from the angular momentum of 2 unpaired electrons) fall sharply with temperature. In the first place, low-spin configurations are much more common for the second- and third-row than for first-row transition elements and this is due to (a) the higher nuclear charges of the heavier elements which exert stronger attractions on the ligands so that a given set of ligands produces a greater splitting of the metal d orbitals, and (b) the larger sizes of 4d and 5d orbitals compared to 3d orbitals, with the result that interelectronic repulsions, which tend to oppose spin-pairing, are lower in the former cases. These factors explain why the halide complexes of OsIV and RuIV are low-spin but what of the temperature dependence and their magnetic behaviour? This arises from the effect of “spin–orbit coupling” which can be summarized in a plot of $\mu_e$ versus $kT/|\lambda|$ (Fig. A). $\lambda$ is the spin–orbit coupling constant for a particular ion and is indicative of the strength of the coupling between the angular momentum vectors associated with $S$ and $L$, and also of the magnitude of the splitting of the ground term of the ion ($^1T$, in the case of low-spin $d^4$). When $|\lambda|$ is of comparable magnitude to $kT$, $\mu_e \sim 3.6$ BM, which is the spin-only moment (2.83 BM) plus a contribution from the orbital angular momentum. Thus, CuII ($\lambda = -115$ cm$^{-1}$) and MnIII ($\lambda = -178$ cm$^{-1}$) at room temperature ($kT \sim 200$ cm$^{-1}$), lie on the flat portion of the curve and so have magnetic moments of about 3.6 BM which only begin to fall at appreciably lower temperatures. On the other hand, RuIV ($\lambda = -700$ cm$^{-1}$) and OsIV ($\lambda = -2000$ cm$^{-1}$) have moments which at room temperature are already on the steep portion of the curve and so are extremely dependent on temperature. In each case, as the temperature approaches 0 K so also $\mu_e \rightarrow 0$, corresponding to a coupling of $L$ and $S$ vectors in opposition and their associated magnetic moments therefore cancelling each other.

![Figure A](image_url)

**Figure A** The variation with temperature and spin-orbit coupling constant, of the magnetic moments of octahedral, low-spin, $d^4$ ions. (The values of $\mu_e$ at 300 K are marked for individual ions).

All $d^9$ configurations with $T$ ground terms give rise to magnetic moments which are lower for second- and third-row than for first-row transition elements and are temperature dependent, but in no case so dramatically as for low-spin $d^4$.

of the oxygen $p_x$ orbital and the two $d_{xz}$ orbitals of the Ru ions, and the other similarly from $p_y$ and $d_{yz}$ overlap (Fig. 25.5). The bromo analogue apparently does not exist.\(^{(26)}\)

Ruthenium(IV) produces few other complexes of interest but osmium(IV) yields several sulfito complexes (e.g. [Os(SO$_3$)$_6$]$^{8-}$ and substituted derivatives) as well as a number of complexes, such as [Os(bipy)Cl$_4$] and [Os(diars)$_2$X$_2$]$^{2+}$ (X = Cl, Br, I), with mixed halide and Group 15 donor atoms. The iron analogues of the latter complexes (with X = Cl, Br), are obtained by oxidation of

---

Figure 25.5  π bonding in [Ru₂OCl₁₀]²⁻: (a) 3-centre π bond formed by overlap of an oxygen px and ruthenium dₓz orbitals (another similar bond is produced by px and dₓz overlap), and (b) MO diagram.

[Fe(diars)₂X₂]⁺ with conc HNO₃ and provide rare examples of complexes containing iron in an oxidation state higher than +3. The halide ions are trans to each other and a reduction in the magnetic moment at 293 K from a value of ~3.6 BM (which might have been expected, since λ = -260 cm⁻¹ for Fe⁴⁺ — see Panel) to 2.98 BM is explained by a large tetragonal distortion.

Oxidation state III (d⁵)

Ruthenium(III) and osmium(III) complexes are all octahedral and low-spin with 1 unpaired electron. Iron(III) complexes, on the other hand, may be high or low spin, and even though an octahedral stereochemistry is the most common, a number of other geometries are also found. In other respects, however there is a gradation down the triad, with RuIII occupying an intermediate position between FeIII and OsIII. For iron the oxidation state +3 is one of its two most common and for it there is an extensive, simple, cationic chemistry (though the aquo ion, [Fe(H₂O)₆]³⁺, is too readily hydrolysed to be really common). For ruthenium it is the best-known oxidation state and [Ru(H₂O)₆]³⁺, which can be obtained by oxidation of the divalent ion (p. 1095), has been characterized in the toluene sulfonate, [Ru(H₂O)₆](tos)₃ and the caesium alum (see below). For osmium, however, OsIII is a distinctly less-common oxidation state, being readily oxidized to OsIV or even, in the presence of π-acceptor ligands such as CN⁻, reduced to OsII. There is no evidence of a simple aquo ion of osmium in this or indeed in any other oxidation state.

Except with anions such as iodide (but see p. 1084) which have reducing tendencies, iron(III) forms salts with all the common anions, and these may be crystallized in pale-pink or pale-violet hydrated forms. These presumably contain the [Fe(H₂O)₆]³⁺ cation, and the iron alums certainly do. These alums have the composition Fe₂(SO₄)₃Mₓ(SO₄).2₄H₂O and can be formulated [M⁺(H₂O)₆][FeIII(H₂O)₆][SO₄]₂.

Like the analogous chrome alums they find use as mordants in dying processes. The sulfate is the cheapest salt of Fe$^{III}$ and forms no less than 6 different hydrates (12, 10, 9, 7, 6 and 3 mols of H$_2$O of which 9H$_2$O is the most common); it is widely used as a coagulant in the treatment not only of potable water but also of sewage and industrial effluents.

In the crystallization of these hydrated salts from aqueous solutions it is essential that a low pH (high level of acidity) is maintained, otherwise hydrolysis occurs and yellow impurities contaminate the products. Similarly, if the salts are redissolved in water, the solutions turn yellow-brown. The hydrolytic processes are complicated, and, in the presence of anions with appreciable coordinating tendencies, are further confused by displacement of water from the coordination sphere of the iron.

However, in aqueous solutions of salts such as the perchlorate the following equilibria are important:

\[
[\text{Fe(H}_2\text{O)}_6]^{3+} \rightleftharpoons [\text{Fe(H}_2\text{O)}_4(\text{OH})]^2+ + \text{H}^+; \quad K = 10^{-3.05} \text{ mol dm}^{-3}
\]

\[
[\text{Fe(H}_2\text{O)}_5(\text{OH})]^2+ \rightleftharpoons [\text{Fe(H}_2\text{O)}_4(\text{OH})_2]^+ + \text{H}^+; \quad K = 10^{-3.26} \text{ mol dm}^{-3}
\]

and also \[2[\text{Fe(H}_2\text{O)}_6]^{3+} \rightleftharpoons [\text{Fe(H}_2\text{O)}_4(\text{OH})]^4+ + 2\text{H}^+ + 2\text{H}_2\text{O}; \quad K = 10^{-2.91} \text{ mol dm}^{-3}\]

(The dimer in the third equation is actually \[(\text{H}_2\text{O})_4\text{Fe}<\neg \to \neg \to \text{Fe(H}_2\text{O)}_4]^{4+}\) and weakly coupled electron spins on the 2 metal ions reduce the magnetic moment per iron below the spin-only value for 5 unpaired electrons.)

It is evident therefore that Fe$^{III}$ salts dissolved in water produce highly acidic solutions and the simple, pale-violet, hexaaquo ion only predominates if further acid is added to give pH $\sim$ 0. At somewhat higher values of pH the solution becomes yellow due to the appearance of the above hydrolysed species and if the pH is raised above 2–3, further condensation occurs, colloidal gels begin to form, and eventually a reddish-brown precipitate of hydrous iron(III) oxide is formed (see p. 1080).

The colours of these solutions are of interest. Iron(III) like manganese(II), has a d$^5$ configuration and its absorption spectrum might therefore be expected to consist similarly of weak spin-forbidden bands. However, a crucial difference between the ions is that Fe$^{III}$ carries an additional positive charge, and its correspondingly greater ability to polarize coordinated ligands produces intense, charge-transfer absorptions at much lower energies than those of Mn$^{II}$ compounds. As a result, only the hexaaquo ion has the pale colouring associated with spin-forbidden bands in the visible region of the spectrum, while the various hydrolysed species have charge transfer bands, the edges of which tail from the ultraviolet into the visible region producing the yellow colour and obscuring weak d–d bands. Even the hexaquo ion’s spectrum is dominated in the near ultraviolet by charge transfer, and a full analysis of the d–d spectrum of this and of other Fe$^{III}$ complexes is consequently not possible.

Iron(III) forms a variety of cationic, neutral and anionic complexes, but an interesting feature of its coordination chemistry is a marked preference (not shown by Cr$^{III}$ with which in many other respects it is similar) for O-donor as opposed to N-donor ligands. Ammines of Fe$^{III}$ are unstable and dissociate in water; chelating ligands such as bipy and phen which induce spin-pairing produce more stable complexes, but even these are less stable than their Fe$^{II}$ analogues. Thus, whereas deep-red aqueous solutions of [Fe(phen)$_3$]$^{2+}$ are indefinitely stable, the deep-blue solutions of [Fe(phen)$_3$]$^{3+}$ slowly turn khaki-coloured as polymeric hydroxo species form. By contrast, the intense colours produced when phenols or enols are treated with Fe$^{III}$, and which are used as characteristic tests for these organic materials, are due to the formation of Fe–O complexes. Again, the addition of phosphoric acid to yellow, aqueous solutions of FeCl$_3$, for instance, decolourizes them because

of the formation of phosphato complexes such as \([\text{Fe}(\text{PO}_4)_3]^{3-}\) and \([\text{Fe}(\text{HPO}_4)_3]^{3-}\). The deep-red \([\text{Fe}(\text{acac})_3]\) and the green \([\text{Fe}(\text{C}_2\text{O}_4)_3]^{3-}\) are other examples of complexes with oxygen-bonded ligands although the latter, whilst very stable towards dissociation, is photosensitive due to oxidation of the oxalate ion by \(\text{Fe}^{III}\) and so decomposes to \(\text{Fe}(\text{C}_2\text{O}_4)\) and \(\text{CO}_2\).

Complexes with mixed \(O\)-and \(N\)-donor ligands such as edta and Schiff bases are well known and \([\text{Fe}((\text{edta})(\text{H}_2\text{O}))^2-\) and \([\text{Fe}((\text{salen})\text{Cl})]^-\) are examples of 7-coordinate (pentagonal bipyramidal) and 5-coordinate (square-pyramidal) stereochemistries respectively.

As in the case of \(\text{Cr}^{III}\), oxo-bridged species with magnetic moments reduced below the spin-only value (5.9 BM in the case of high-spin \(\text{Fe}^{III}\)) are known. \([\text{Fe}((\text{salen})\text{Cl})]_2\text{O}\), for instance, has a moment of 1.9 BM at 298 K which falls to 0.6 BM at 80 K and the interaction between the electron spins on the 2 metal ions is transmitted across an Fe–O–Fe bridge, bent at an angle of 140°. Trinuclear, basic carboxylates, \([\text{Fe}_3\text{O}(\text{O}_2\text{CR})_6\text{L}_3])^+\), are, however, entirely analogous to their \(\text{Cr}^{III}\) counterparts (p. 1030).\(^{29}\)

Halide complexes decrease markedly in stability from \(\text{F}^-\) to \(\text{I}^-\). Fluoro complexes are quite stable and in aqueous solutions the predominant species is \([\text{Fe}_5\text{F}_2(\text{H}_2\text{O})]\)^2- while isolation of the solid and fusion with \(\text{KH}_2\text{F}\) yields \([\text{Fe}_5\text{F}_6]\)^3-. Chloro complexes are appreciably less stable, and tetrahedral rather than octahedral coordination is favoured.\(^{\dagger}\) \([\text{FeCl}_4]^-\) can be isolated in yellow salts with large cations such as \([\text{RN}_4]^+\) from ethanolic solutions or conc HCl. \([\text{FeBr}_4]^-\) and \([\text{FeI}_4]^-\) are also known but are readily reduced to \(\text{Fe}^{II}\) either by internal oxidation–reduction or by the action of excess ligand.\(^{30}\)

The blood-red colour produced by mixing aqueous solutions of \(\text{Fe}^{III}\) and \(\text{SCN}^-\) (and which provides a well-known test for \(\text{Fe}^{III}\)) is largely due to \([\text{Fe}((\text{SCN})(\text{H}_2\text{O})_3]^2+\) but, in addition to this, the simple salt \(\text{Fe}((\text{SCN})_3)\) and salts of complexes such as \([\text{Fe}((\text{SCN})_4)]^-\) and \([\text{Fe}((\text{SCN})_6)]^{3-}\) can also be isolated.

The high-spin \(d^5\) configuration of \(\text{Fe}^{III}\), like that of \(\text{Mn}^{II}\), confers no advantage by virtue of CFSE (p. 1131) on any particular stereochemistry. Some examples of its consequent ability to adopt stereochemistries other than octahedral have just been mentioned and further examples are given in Table 25.3 (p. 1078). These cover the range of coordination numbers from 3 to 8.

Further similarity with \(\text{Mn}^{II}\) may be seen in the fact that the vast majority of the compounds of \(\text{Fe}^{III}\) are high-spin. Only ligands such as bipy and phen (already mentioned) and \(\text{CN}^-\), which are high in the spectrochemical series, can induce spin-pairing. The low-spin \([\text{Fe}((\text{CN})_6)]^{3-}\), which is best known as its red, crystalline potassium salt, is usually prepared by oxidation of \([\text{Fe}((\text{CN})_6)]^{4-}\) with, for instance, \(\text{Cl}_2\). It should be noted that in \([\text{Fe}((\text{CN})_6)]^{3-}\) the \(\text{CN}^-\) ligands are sufficiently labile to render it poisonous, in apparent contrast to \([\text{Fe}((\text{CN})_6)]^{4-}\), which is kinetically more inert. Dilute acids produce \([\text{Fe}((\text{CN})_5(\text{H}_2\text{O}))]^2-\), and other pentacyano complexes are known.

\(\text{Fe}^{III}\) complexes in general have magnetic moments at room temperature which are close to 5.92 BM if they are high-spin and somewhat in excess of 2 BM (due to orbital contribution) if they are low-spin. A number of complexes, however, were prepared in 1931 by L. Cambi and found to have moments intermediate between these extremes. They are the iron(III)-\(N,N\)-dialkylthiocarbamates, \([\text{Fe}(\text{S}_2\text{CNR}_2)_3]\), in which the ligands are:

\[
\begin{align*}
\text{R} & \quad \text{C} & \quad \text{N} \\
\text{S} & \quad \text{S} & \quad \text{R}
\end{align*}
\]

\(\text{R}\) and \(\text{S}\) can be either identical or different.

\(^{\dagger}\) In the compound, previously assumed to be \((\text{pyH})_3[\text{Fe}_2\text{Cl}_5]\) with the anion composed of a pair of face-sharing octahedra, the iron is in fact coordinated tetrahedrally and the correct formulation is, \((\text{pyH})_3\text{Cl}[\text{FeCl}_4]_2\); see R. SHAVIV, C. B. LOWE, J. A. ZORA, C. B. AAKEROY, P. B. HITCHCOCK, K. R. SEDDON and R. L. CARLIN, \textit{Inorg. Chim. Acta} \textbf{198–200}, 613–21 (1992).

so that the Fe$^{III}$ is surrounded octahedrally by 6 sulfur atoms. They provide well documented examples of high-spin/low-spin crossover (i.e., spin equilibria) (see Panel p. 1096).

Ruthenium(III) forms extensive series of halide complexes, the aquo-chloro series being probably the best characterized of all its complexes. The Ru$^{II}$/Cl$^-$/H$_2$O system has received extensive study, especially by ion-exchange techniques. The ions [RuCl$_n$(H$_2$O)$_6-n$]$^{(n-3)}$ from $n = 6$ to $n = 0$ have all been identified in solution and a number also isolated as solids. K$_3$[RuF$_6$] can be obtained from molten RuCl$_3$/KHF$_2$. Several bromo complexes have been reported amongst them the dimeric anion [Ru$_2$Br$_9$]$^{3-}$ which, like its choloro analogue, is composed of a pair of face-sharing octahedra. There are, however, no iodo complexes and, whilst [Os(CN)$_6$]$^{3-}$ as well as the Fe$^{III}$ analogue are known and some substituted cyano complexes of Ru$^{III}$ have been prepared, the parent [Ru(CN)$_6$]$^{3-}$ has only recently been isolated as the brilliant yellow (Ru$_n^+$(CN)$_6$)$^+$ salt by aerial oxidation of dmf solution of [Ru(CN)$_6$]$^{2+}$.(31) Ru$^{III}$ is much more amenable to coordination with N-donor ligands than is Fe$^{III}$, and forms ammines with from 3 to 6 NH$_3$ ligands (the extra ligands making up octahedral coordination are commonly H$_2$O or halides) as well as complexes with bipy and phen. Treatment of “RuCl$_3$” with aqueous ammonia in air slowly yields an extremely intense red solution (ruthenium red) from which a diamagnetic solid can be isolated, apparently of the form:

$$[(\text{NH}_3)_2\text{Ru}^{II}-\text{O}-\text{Ru}^{IV}(\text{NH}_3)_4-\text{O}-\text{Ru}^{III}(\text{NH}_3)_5]^6^+$$

Its diamagnetism can be explained on the basis of $\pi$ overlap, producing polycentre molecular orbitals essentially the same as used for [Ru$_2$OCl$_1$O]$^{4-}$ (see Fig. 25.5). It is stable in either acid or alkali and its acid solution can be used as an extremely sensitive test for oxidizing agents since even such a mild reagent as iron(III) chloride oxidizes the red, 6+ cation to a yellow, paramagnetic, 7+ cation of the same constitution (a change which is detectable in solutions containing less than 1 ppm Ru).

Trinuclear basic acetates [Ru$_3$(O$_2$CMe)$_6$L$_3$]$^+$ have also been prepared apparently with the same constitution as the analogous Fe$^{III}$ and Cr$^{III}$ compounds (p. 1030).

For osmium, halogeno complexes are less diverse but the reaction of acetic acid/acetic anhydride with [OsCl$_6$]$^{2-}$ yields brown Os$_2$(O$_2$CMe)$_4$-Cl$_2$ which, if treated as a suspension in anhydrous ethanol with gaseous HX (X = Cl, Br), yields [Os$_2$X$_4$]$^{2-}$. These diamagnetic ions are notable for the presence of the Os≡Os triple bond unsupported by bridging ligands. The triply bridged [Os$_2$Br$_9$]$^{3-}$ is also known.(32)

**Oxidation state II (d$^6$)**

This is the second of the common oxidation states for iron and is familiar for ruthenium, particularly with Group 15-donor ligands (Ru$^{II}$ probably forms more nitrosyl complexes than any other metal). Osmium(II) also produces a considerable number of complexes but is usually more strongly reducing than Ru$^{II}$.

Iron(II) forms salts with nearly all the common anions.† These are usually prepared in aqueous solution either from the metal or by reduction of the corresponding Fe$^{III}$ salt. In the absence of other coordinating groups these solutions contain the pale-green [Fe(H$_2$O)$_6$]$^{2+}$ ion which is also present in solids such as Fe(ClO$_4$)$_2$.6H$_2$O, FeSO$_4$.7H$_2$O and the well-known “Mohr’s salt”, (NH$_4$)$_2$SO$_4$.FeSO$_4$.6H$_2$O introduced into volumetric analysis by K. F. Mohr in the 1850s.‡

---

† An exception is NO$_2^-$ which instantly oxidizes Fe$^{II}$ to Fe$^{III}$ and liberates NO. Fe(BrO$_3$)$_2$ and Fe(IO$_3$)$_2$ also are unstable.
‡ K. F. Mohr (1806–79) was Professor of Pharmacy at the University of Bonn. Among his many inventions were the specific gravity balance, the burette, the pinch clamp, the cork borer, and the use of the so-called Liebig condenser for refluxing. In addition to his introduction of iron(II) ammonium sulfate as a standard reducing agent he devised Mohr’s method for titrating halide solutions with silver ions.
The hydrolysis (which in the case of Fe" produces acidic solutions) is virtually absent, and in aqueous solution the addition of CO₃²⁻ does not result in the evolution of CO₂ but simply in the precipitation of white FeCO₃. The moist precipitate oxidizes rapidly on exposure to air but in the presence of excess CO₂ the slightly soluble Fe(HCO₃)₂ is formed. It is the presence of this in natural underground water systems, leading to the production of FeCO₃ on exposure to air, followed by oxidation to iron(III) oxide, which leads to the characteristic brown deposits found in many streams.

The possibility of oxidation to Fe" is a crucial theme in the chemistry of Fe" and most of its salts are unstable with respect to aerial oxidation, though double sulfates are much less so (e.g. Mohr’s salt above). However, the susceptibility of Fe" to oxidation is dependent on the nature of the ligands attached to it and, in aqueous solution, on the pH. Thus the solid hydroxide and alkaline solutions are very readily oxidized whereas acid solutions are much more stable (see Panel opposite).

Iron(II) forms complexes with a variety of ligands. As is to be expected, in view of its smaller cationic charge, these are usually less stable than those of Fe" but the antipathy to N-donor ligands is less marked. Thus [Fe(NH₃)₆]²⁺ is known whereas the Fe" analogue is not; also there are fewer Fe" complexes with O-donor ligands such as acac and oxalate, and they are less stable than those of Fe". High-spin octahedral complexes of Fe" have a free-ion ⁵D ground term, split by the crystal field into a ground ⁵T₂₈ and an excited ⁵E₉ term. A magnetic moment of around 5.5 BM (i.e. 4.90 BM + orbital contribution) is expected for pure octahedral symmetry but, in practice, distortions produce values in the range 5.0–5.4 BM, and the higher values are difficult to explain.

Low-spin, octahedral complexes are formed by ligands such as bipy, phen and CN⁻, and their stability is presumably enhanced by the symmetrical t⁴₈ configuration. [Fe(bipy)₃]²⁺ and [Fe(phen)₃]²⁺ are stable, intensely red complexes, the latter being employed as the redox indicator, “ferroin”, due to the sharp colour change which occurs when strong oxidizing agents are added to it:

\[
[\text{Fe(phen)}_3^{2-}] \rightleftharpoons [\text{Fe(phen)}_3^{3+} + e^-]
\]

Mono- and bis-phenanthroline complexes can be prepared but these are both high-spin and, because of the increase in CFSE (p. 1131) accompanying spin pairing (\(\frac{5}{2} \Delta_0 \rightarrow \frac{15}{2} \Delta_0\)), addition of phenanthroline to aqueous Fe" leads almost entirely to the formation of the tris complex rather than mono or bis, even though the Fe" is initially in great excess. Pale-yellow K₄[Fe(CN)₆]·3H₂O can be crystallized from aqueous solutions of iron(II) sulfate and an excess of KCN: this is clearly more convenient than the traditional method of fusing nitrogenous animal residues (hides, horn, etc.) with iron and K₂CO₃. The hexacyanoferrate(II) anion (ferrocyanide) is kinetically inert and is said to be non-toxic, but HCN is liberated by the addition of dilute acids.
The Fe$^{\text{III}}$/Fe$^{\text{II}}$ Couples

A selection of the standard reduction potentials for some iron couples is given in Table A, from which the importance of the participating ligand can be judged (see also Table 25.8 for biologically important iron proteins). Thus Fe$^{\text{III}}$, being more highly charged than Fe$^{\text{II}}$ is stabilized (relatively) by negatively charged ligands such as the anions of edta and derivatives of 8-hydroxyquinoline, whereas Fe$^{\text{II}}$ is favoured by neutral ligands which permit some charge delocalization in $\pi$-orbitals (e.g. bipy and phen).

$^a$quin$^-$ = 5-methyl-8-hydroxyquinoline.

The value of $E^\circ$ for the couple involving the simple aquated ions, shows that Fe$^{\text{II}}$(aq) is thermodynamically stable with respect to hydrogen; which is to say that Fe$^{\text{III}}$(aq) is spontaneously reduced by hydrogen gas (see p. 435). However, under normal circumstances, it is not hydrogen but atmospheric oxygen which is important and, for the process $\frac{1}{2}\text{O}_2 + 2\text{H}^+ + 2e^- \rightarrow \text{H}_2\text{O}, E^\circ = 1.229 \text{V}$, i.e. oxygen gas is sufficiently strong an oxidizing agent to render [Fe(H$_2$O)$_6$]$^{2+}$ (and, indeed, all other Fe$^{\text{II}}$ species in Table A) unstable wrt atmospheric oxidation. In practice the oxidation in acidic solutions is slow and, if the pH is increased, the potential for the Fe$^{\text{III}}$/Fe$^{\text{II}}$ couple remains fairly constant until the solution becomes alkaline and hydrous Fe$_2$O$_3$ (considered here for convenience to be Fe(OH)$_3$) is precipitated. But here the change is dramatic, as explained below.

The actual potential $E$ of the couple is given by the Nernst equation,

$$E = E^\circ - \frac{RT}{nF} \ln \frac{[\text{Fe}^{\text{II}}]}{[\text{Fe}^{\text{III}}]}$$

where $E = E^\circ$ when all activities are unity. However, once precipitation occurs, the activities of the iron species are far from unity; they are determined by the solubility products of the 2 hydroxides. These are:

$$[\text{Fe}^{\text{II}}][\text{OH}^-]^2 \sim 10^{-14} (\text{mol dm}^{-3})^2 \text{ and } [\text{Fe}^{\text{III}}][\text{OH}^-]^3 \sim 10^{-26} (\text{mol dm}^{-3})^4$$

Therefore when [OH$^-$] = 1 mol dm$^{-3}$, $\frac{[\text{Fe}^{\text{II}}]}{[\text{Fe}^{\text{III}}]} \sim 10^{22}$

Hence $E \sim 0.771 - 0.05916 \log_{10}(10^{22}) = 0.771 - 1.301 = -0.530 \text{ V}$

Thus by making the solution alkaline the sign of $E$ has been reversed and the susceptibility of Fe$^{\text{II}}$ (aq) to oxidation (i.e. its reducing power) enormously increased. This is why white, precipitated Fe(OH)$_2$ and FeCO$_3$ are rapidly darkened by aerial oxidation and why Fe$^{\text{II}}$ in alkaline solution will reduce nitrates to ammonia and copper(II) salts to metallic copper.
Addition of $K_4[Fe^{II}(CN)_6]$ to aqueous $Fe^{III}$ produces the intensely blue precipitate, Prussian blue. The X-ray powder pattern and Mössbauer spectrum of this are the same as those of Turnbull’s blue which is produced by the converse addition of $K_3[Fe^{III}(CN)_6]$ to aqueous $Fe^{II}$. By varying the conditions and proportions of the reactants, a whole range of these blue materials can be produced of varying composition with some, which are actually colloidal, described as soluble Prussian blue. They have found application as pigments in the manufacture of inks and paints since their discovery in 1704 and, in 1840, their formation on sensitized paper was utilized in the production of blueprints. It appears that all these materials have the same basic structure. This consists of a cubic lattice of low-spin $Fe^{II}$ and high-spin $Fe^{III}$ ions with cyanide ions lying linearly along the cube edges, and water molecules situated inside the cubes. The intense colour is due to charge-transfer from $Fe^{II}$ to $Fe^{III}$. Unfortunately, detailed characterizations are bedevilled by difficulties in obtaining satisfactory single crystals and reproducible compositions. Good quality single crystals formulated as $Fe_4[Fe(CN)_6]_3 \cdot xH_2O (x = 14–16)$ can be produced by the slow diffusion of $H_2O$ vapour into a solution of $Fe^{III}$ and $[Fe(CN)_6]^{4-}$ in conc $HCl$. This has the same basic lattice but with some of the $Fe^{II}$ and $CN^-$ sites occupied by water. Less delicate methods lead to the absorption of alkali metal ions (particularly $K^+$) and to formulations such as $M^+Fe^{II}Fe^{III}(CN)_6 \cdot xH_2O$. The same structure motif is found in $Fe^{III}Fe^{III}(CN)_6$ and in the virtually white, readily oxidizable $K_2Fe^{II}Fe^{II}(CN)_6$, the former having no counter cations while the $K^+$ ions of the latter fill all the lattice cubes. Having all their iron atoms in a uniform oxidation state, however, these two compounds lack the intense colour of the Prussian blues.

It is possible to replace 1 $CN^-$ in the hexacyanoferrate(II) ion with $H_2O$, $CO$, $NO_2^-$, and, most importantly, with $NO^+$. The “nitroprusside” ion $[Fe(CN)_5NO]^{2-}$ can be produced by the action of 30% nitric acid on either $[Fe(CN)_6]^{4-}$ or $[Fe(CN)_6]^{3-}$. That it formally contains $Fe^{II}$ and $NO^+$ (rather than $Fe^{III}$ and NO) is evident from its diamagnetism, although Mössbauer studies indicate that there is appreciable π delocalization of charge from the $t_2g$ orbitals of the $Fe^{II}$ to the nitrosyl and cyanide groups. The red color of $[Fe(CN)_5(NOS)]^{4-}$, formed by the addition of sulfide ion, is used in a common qualitative test for sulfur. Another qualitative test involving an iron nitrosyl is the “brown ring” test for $NO_3^-$, using iron(II) sulfate and conc $H_2SO_4$ in which NO is produced. The brown colour, which appears to be due to charge-transfer, evidently arises from a cationic iron nitrosyl complex which has a magnetic moment $\sim 3.9\,\mu_B$; it is therefore formulated as $[Fe(NO)(H_2O)_5]^{2+}$ in which the iron can be considered formally to be in the $+1$ oxidation state.

Roussin’s “red” and “black” salts, formulated respectively as $K_2[Fe_2(NO)_4S_2]$ and $K[Fe_4(NO)_7S_3]$, are obtained by the action of NO on $Fe^{II}$ in the presence of $S_2^-$ and are structurally interesting. In both cases the iron atoms are pseudo-tetrahedrally coordinated (Fig. 25.6) and, though the assignment of formal oxidation states has only doubtful significance, their diamagnetism and the presence of rather short Fe–Fe distances are indicative of some direct metal–metal interaction. The $[NeL_4]^+$ black salt in acetonitrile solution has been reversibly reduced electrochemically to $[Fe_4(NO)_7S_3]^-$ ($n = 1–4$), the $n = 2$ and 3 compounds being isolated and shown to retain essentially the same structure, though somewhat expanded, as expected with the extra charge.

These, and related, iron nitrosyl compounds have excited considerable interest because of their biological activity. Nitroprusside induces muscle relaxation and is therefore used to control high blood pressure. Roussin’s black salt has antibacterial activity under conditions relevant to

food-processing, while some of the red esters promote the activity of certain environmental carcinogens.

In addition to high-spin octahedral complexes with magnetic moments in excess of 5 BM, and diamagnetic, low-spin octahedral complexes, Fe\(^{II}\) affords further examples of high-spin/low-spin transitions within a given compound (see Panel, p. 1096). It has already been noted that a change from high-spin to low-spin accompanies the change,

\[
[\text{Fe(phen)}_2(H_2O)_2]^{2+} \rightarrow [\text{Fe(phen)}_3]^{2+}
\]

so it is no great surprise that spin transitions have been found in [Fe(phen)_2X_2] \((X = \text{NCS}, \text{NCSe})\) complexes and their bipy analogues. These evidently lie just to the high-field side of the crossover since at temperatures below \(-125^\circ\text{C}\) the compounds are almost diamagnetic (what paramagnetism there is is probably due to impurity), while at some temperature between \(-125^\circ\text{C}\) and \(-75^\circ\text{C}\) depending on the compound, the moment quite suddenly rises to over 5 BM. Confirmation of the transition in these and other Fe\(^{II}\) complexes has been provided by electronic and Mössbauer spectroscopy.

Apart from compounds such as \([\text{RuCl}_2(P\text{Ph}_3)_3]\), which is square pyramidal because the sixth coordinating position is stereochemically blocked, Ru\(^{II}\) compounds (and also Os\(^{II}\) compounds) are octahedral and diamagnetic. \([\text{Ru(H}_2\text{O})_6]^{2+}\) can be prepared in aqueous solution by electrolytic reduction of \([\text{RuCl}_5(H_2O)]^{2-}\) using Pt/H\(_2\) and, though readily oxidized to Ru\(^{III}\) (p. 1088), has been isolated and characterized\(^{27}\) in the pink \([\text{Ru(H}_2\text{O})_6](\text{tos})_2\) and the sulfates \(\text{M}_2[\text{Ru(H}_2\text{O})_6](\text{SO}_4)_2\) \((\text{M} = \text{Rb, NH}_4)\). The cyanato complexes \([\text{Ru(CN)}_6]^{4-}\) and \([\text{Ru(CN)}_3\text{NO}]^{2-}\), analogous to their iron counterparts, are also known but the most notable compounds of Ru\(^{II}\) are undoubtedly its complexes with Group 15 donor ligands, such as the ammines and nitrosyls.

\([\text{Ru(NH}_3)_6]^{2+}\) and corresponding tris chelates with en, bipy and phen, etc., are obtained from \(\text{"RuCl}_3\) with Zn powder as a reducing agent. The hexaamine is a strongly reducing substance and \([\text{Ru(bipy)}_3]^{2+}\), although thermally very stable, is capable of photochemical excitation involving the promotion of an electron from a molecular orbital of essentially metal character to one of an essentially ligand character, after which its oxidation is possible. A number of similar
Spin Equilibria

Because the d-orbitals of a metal in an octahedral complex split into \( t_{2g} \) and \( e_g \) sets (p. 922), each of the \( d^4-d^7 \) configurations can exist in either high-spin or low-spin configurations, depending on whether the energy \( \Delta E \) required to force spin-pairing is greater or smaller than the orbital splitting \( \Delta_0 \) (or \( 10Dq \)). This is illustrated in the energy level diagrams (Figs. A and B) for \( d^5 \) and \( d^6 \) ions where in each case at a critical value of \( \Delta_0 \) (the crossover point), the ground terms of the high- and low-spin configurations \( ^6A_{1g} \) and \( ^2T_{2g} \) respectively for \( d^5 \), \( ^5T_{2g} \) and \( ^1A_{1g} \) for \( d^6 \) are equal. Close to the crossover point both terms are thermally accessible and a Boltzmann distribution of molecules between the two states can be envisaged.

Energy level diagrams for, A \( d^5 \) ions and B \( d^6 \) ions.

This simple explanation accounts quite well for a variety of dithiocarbamato complexes of iron(III) whose magnetic moments rise gradually from about 2.3 BM (corresponding to low-spin \( d^5 \)) at very low temperatures to > 4 BM (corresponding to roughly equal populations in the two states) above room temperature.

However, the emptying of the \( e_g \) orbitals in changing from high- to low-spin allows a shortening of metal-ligand distances with a corresponding increase in \( \Delta_0 \). Such a situation does not correspond to the crossover point since the two isomers occupy different positions on the \( \Delta_0 \) axis. In solutions, conversion of one isomer to the other is usually facile and equilibrium readily established. In solids, on the other hand, molecules are coupled by lattice vibrations and the conversion is often accompanied by a change of phase. The iron(II) compound [Fe(phen)₂(NCS)₂] is a good example of this, the change in magnetic moment being far too abrupt to be accounted for by a simple Boltzmann distribution between thermally accessible spin states.

Spin equilibria have been investigated by bulk magnetic measurements, X-ray crystallography, vibrational, electronic, Mössbauer, esr and nmr spectroscopy and also at high pressures. Besides their obvious intrinsic interest, they have biological relevance because of the change in spin when haemoglobin is oxygenated (p. 1099). Geologically, the high-spin iron(II) in minerals such as olivine (p. 347) becomes low-spin under high pressure in the earth’s mantle. Since some spin-transitions can be induced optically, there are also possible light storage applications.

Complexes with substituted bipyridyl ligands luminesce in visible light (39) and considerable effort is being devoted to preparing suitable derivatives which could be used to catalyze the photolytic decomposition of water, with a view to the conversion of solar energy into hydrogen fuel.

\[
2[\text{Ru}(L-L)_3]^{2+} + 2\text{H}^+ \longrightarrow 2[\text{Ru}(L-L)_3]^{3+} + \text{H}_2
\]

then

\[
2[\text{Ru}(L-L)_3]^{3+} + 2\text{OH}^- \longrightarrow 2[\text{Ru}(L-L)_3]^{2+} + \text{H}_2\text{O} + \frac{1}{2}\text{O}_2
\]

i.e.

\[
\text{H}_2\text{O} \rightleftharpoons \text{H}^+ + \text{OH}^- \longrightarrow \text{H}_2 + \frac{1}{2}\text{O}_2
\]

\[\text{References:}\]
The pentaammine derivative, \([\text{Ru(NH}_3\text{)}_5\text{N}_2\text{I}_2^+]\), when prepared in 1965 by the reduction of aqueous \(\text{RuCl}_3\) with \(\text{N}_2\text{H}_4\), was the first dinitrogen complex to be produced (p. 414). It contains the linear \(\text{Ru}–\text{N}–\text{N}\) group \((v(\text{N–N}) = 2140 \text{ cm}^{-1}\)). The dinuclear derivative \([\text{NH}_3\text{)}_5\text{Ru}–\text{N}–\text{N}–\text{Ru(NH}_3\text{)}_5\text{I}_4^+]\) with a linear \(\text{Ru}–\text{N}–\text{N}–\text{Ru}\) bridge \((v(\text{N–N}) = 2100 \text{ cm}^{-1}\) compared to 2331 cm\(^{-1}\) for \(\text{N}_2\) itself) is also known (see pp. 414 and 1035 for a fuller discussion of the significance of \(\text{N}_2\) complexes).

The nitrosyl complex \([\text{Ru(NH}_3\text{)}_5\text{N}=\text{O}^+\), which is obtained by the action of \(\text{HNO}_2\) on \([\text{Ru(NH}_3\text{)}_6\text{I}_2^+\), is isoelectronic with \([\text{Ru(NH}_3\text{)}_5\text{N}_2\text{I}_2^+]\) and is typical of a whole series of \(\text{Ru}^\text{II}\) nitrosyls.\(^{11,21}\) They are prepared using reagents such as \(\text{HNO}_3\) and \(\text{NO}_2^-\) and are invariably mononitrosyls, \(1 \text{ NO}\) apparently sufficing to satisfy the \(\pi\)-donor potential of \(\text{Ru}^\text{II}\). The \(\text{RuNO}\) group is characterized by a short \(\text{Ru}–\text{N}\) distance in the range 171–176 pm, and a stretching mode \(v(\text{N–O})\) in the range 1930–1845 cm\(^{-1}\), consistent with the formulation \(\text{Ru}^\text{II}–\text{N}=\text{O}\). The other ligands making up the octahedral coordination include halides, \(\sigma\)-donor anions, and neutral, mainly Group 15 donor ligands.

The stability of ruthenium nitrosyl complexes poses a practical problem in the processing of wastes from nuclear power stations. \(^{106}\text{Ru}\) is a major fission product of uranium and plutonium and is a \(\beta^-\) and \(\gamma\) emitter with a half-life of 1 year (374 d). The processing of nuclear wastes depends largely on the solvent extraction of nitric acid media, using tri-\(\text{n-buty}l\) phosphate (TBP) as the solvent (p. 1261). In the main, the uranium and plutonium enter the organic phase while fission products such as Cs, Sr and lanthanides remain in the aqueous phase. Unfortunately, by this procedure \(\text{Ru}\) is less effectively removed from the U and Pu than any other contaminant. The reason for this problem is the coordination of TBP to stable ruthenium nitrosyl complexes which are formed under these conditions. This confers on the ruthenium an appreciable solubility in the organic phase, thereby necessitating several extraction cycles for its removal.

Osmium(II) forms no hexaaquo complex and \([\text{Os(NH}_3\text{)}_6\text{I}_2^+]\), which may possibly be present in potassium/liquid \(\text{NH}_3\) solutions, is also unstable. \([\text{Os(NH}_3\text{)}_5\text{N}_2\text{I}_2^+]\) and other dinitrogen complexes are known but only ligands with good \(\pi\)-acceptor properties, such as \(\text{CN}^–\), bipy, phen, phosphines and arsines, really stabilize \(\text{Os}^\text{II}\), and these form complexes similar to their \(\text{Ru}^\text{II}\) analogues.

### Mixed Valence Compounds of Ruthenium\(^{40}\)

Ruthenium provides more examples of dinuclear compounds in which the metal is present in a mixture of oxidation states (or in a non-integral oxidation state) than any other element.

Heating \(\text{RuCl}_3.3\text{H}_2\text{O}\) in acetic acid/acetic anhydride under reflux yields brown \([\text{Ru}_2(\text{O}_2\text{CCl}_3\text{)}_4]\)–\(\text{Cl}\) (cf Os p. 1091) in which the metals are linked by four acetate bridges in the manner of \(\text{Cr}^\text{II}\) and \(\text{Mo}^\text{II}\) carboxylates (p. 1033). In this and analogous carboxylates, \(\text{Ru} = \text{Ru} 224–230 \text{ pm}\) with magnetic moments indicative of three unpaired electrons; this can be explained by the assumption that the \(\pi^*\) and \(\delta^*\) orbitals (see Fig. 23.14) are close enough in energy to afford the \(\pi^*\delta^*\) configuration.\(^{41}\) Treatment of \([\text{Ru(NH}_3\text{)}_6\text{I}_2^+]\) in conc. \(\text{HCl}\) produces the intensely coloured ruthenium blue, \([(\text{NH}_3\text{)}_5\text{Ru(\mu-Cl)}\text{Ru(NH}_3\text{)}_5\text{I}_2^+]\) (\(\text{Ru}–\text{Ru} 275.3 \text{ pm}\)). In all these cases the metal atoms are indistinguishable and are assigned an oxidation state of 2.5.

The “Creutz-Taube” anion, \([(\text{NH}_3\text{)}_5\text{Ru}-\text{N(CH=CH)}\text{N}\text{Ru(NH}_3\text{)}_5\text{I}_5^+]\) displays more obvious redox properties, yielding both 4+ and 6+ species, and much interest has focused on the extent to which the pyrazine bridge facilitates electron transfer. A variety of spectroscopic studies supports the view that low-energy electron tunnelling across the bridge delocalizes the charge, making the 5+ ion symmetrical. Other complexes, such as the anion \([(\text{CN})_5\text{Ru}^\text{II}(\mu-\text{CN})\text{Ru}^\text{III}(\text{CN})_5]^–\), are asymmetric.

---

and are thought to have potential use in laser technology.\(^{42}\)

**Lower oxidation states**

With rare exceptions, such as \([\text{Fe(bipy)}_3]^0\), oxidation states lower than +2 are represented only by carbonyls, phosphines, and their derivatives. These will be considered together with other organometallic compounds in Section 25.3.6.

### 25.3.5 The biochemistry of iron\(^{43-45}\)

Iron is the most important transition element involved in living systems, being vital to both plants and animals. The stunted growth of the former is well known on soils which are either themselves deficient in iron, or in which high alkalinity renders the iron too insoluble to be accessible to the plants. Very efficient biological mechanisms exist to control the uptake and transport of iron and to ensure its presence in required concentrations. The adult human body contains about 4 g of iron (i.e. \(~0.005\%\) of body weight), of which about 3 g are in the form of haemoglobin, and this level is maintained by absorbing a mere 1 mg of iron per day — a remarkably economical utilization.

Proteins involving iron have two major functions:

(a) oxygen transport and storage;

(b) electron transfer.

Ancillary to the proteins performing these functions are others which transport and store the iron itself. All these proteins are conveniently categorized according to whether or not they contain haem, and the more important classes found in nature are listed in Table 25.7.

---

Haemoglobin and myoglobin

Haemoglobin (see p. 126) is the oxygen-carrying protein in red blood-cells (erythrocytes) and is responsible for their colour. Its biological function is to carry \(O_2\) in arterial blood from the lungs to the muscles, where the oxygen is transferred to the immobile myoglobin, which stores it so that it is available as and when required for the generation of energy by the metabolic oxidation of glucose. At this point the haemoglobin picks up \(CO_2\), which is a product of the oxidation of glucose, and transports it in venous blood back to the lungs.

In haemoglobin which has no \(O_2\) attached (and is therefore known as deoxyhaemoglobin or reduced haemoglobin), the iron is present as high-spin \(Fe^{II}\) and the reversible attachment of \(O_2\) (giving oxyhaemoglobin) changes this to diamagnetic, low-spin \(Fe^{II}\) without affecting the metal’s oxidation state. This is remarkable, the more so because, if the globin is removed by treatment with HCl/acetone, the isolated haem in water entirely loses its \(O_2\)-carrying ability, being instead oxidized by air to haematin in which the iron is high-spin \(Fe^{III}\):

\[
\text{oxyhaemoglobin (low-spin \(Fe^{III}\))} + O_2 \Rightarrow \text{deoxyhaemoglobin (high-spin \(Fe^{III}\))} \quad \text{a variety of oxidizing agents} \quad \text{methaemoglobin (high-spin \(Fe^{III}\))}
\]

\[
\text{globin + haem (protein) (high-spin \(Fe^{III}\))} \quad O_2 \Rightarrow \text{haematin + globin (high-spin (protein) \(Fe^{III}\))}
\]

The key to the explanation lies in (a) the observation that in general the ionic radius of \(Fe^{II}\) (and also, for that matter, of \(Fe^{III}\)) decreases by roughly 20% when the configuration changes from high- to low-spin (see Table 25.1), and (b) the structure of haemoglobin.

As a result of intensive study, enough is known about the structure of haemoglobin to allow the broad principles of its operation to be explained. It is made up of 4 subunits, each of which consists of a protein (globin), in the form of a folded helix or spiral, attached to 1 iron-containing group (haem). The proteins are of two types, one denoted as \(\alpha\) consists of 141 amino acids, the other denoted as \(\beta\) consists of 146 amino acids. The polar groups of each protein are on the outside of the structure leaving a hydrophobic interior. The haem group, which is held in a protein “pocket” is therefore in a hydrophobic environment. Within the haem group the iron is coordinated to 4 nitrogen atoms of the planar group known as protoporphyrin IX (PIX). In the case of deoxyhaemoglobin the \(Fe^{II}\), being high-spin, is too large to fit easily inside the hole provided by the porphyrin ring and is situated 55 pm above the ring which, in turn, is slightly bent into a domed shape, the better to accommodate the \(Fe^{III}\). The fifth coordination site, away from the ring, is occupied by an imidazole nitrogen of a proximal histidine of the globin (Fig. 25.7). The vacant sixth site, below the ring, is essentially vacant, “reserved” for the \(O_2\) but with another (distal) histidine restricting access. This is the so-called “tense” (deoxyT) form in which the 4 subunits of deoxyhaemoglobin are held together in an approximately tetrahedral arrangement by electrostatic \(-\text{NH}_3^+ \cdots \text{OOC}^-\) “salt bridges.”

In order that \(O_2\) may bond to the haem, the distal histidine must swing away but, once the \(O_2\) is attached, it swings back to form a hydrogen bond with the \(O_2\). The \(Fe^{II}\) becomes low-spin and the oxyT form, which is still domed, “relaxes” to the planar oxyR form as the now smaller \(Fe^{II}\) slips into the ring which becomes planar again. When this occurs to one of the 4 subunits of deoxyhaemoglobin the movement of the Fe, and of the histidines attached to it, is communicated through the protein chains to the other subunits. This produces a rotation and linear movement of one \(\alpha\beta\) pair w.r.t. the other which, crucially,
converts the other 3 subunits to the deoxyR form, greatly increasing their affinity for O₂. The effect of attaching one O₂ to haemoglobin is therefore to greatly increase its affinity for more.

Conversely, as O₂ is removed from oxyhaemoglobin the reverse conformational changes occur and successively decrease its affinity for oxygen. This is the phenomenon of *cooperativity*, and its physiological importance lies in the fact that it allows the efficient transfer of oxygen from oxyhaemoglobin to myoglobin. This is because myoglobin contains only 1 haem group and can be regarded crudely as a single haemoglobin subunit. It therefore cannot display a cooperative effect and at lower partial pressures of oxygen it has a greater affinity than haemoglobin for oxygen. This can be seen in Fig. 25.8 which shows that, while haemoglobin is virtually saturated with O₂ in the lungs, when it experiences the lower partial pressures of oxygen in the muscle tissue its affinity for O₂ has fallen off so much more rapidly than that of myoglobin that oxygen transfer ensues. Indeed, the actual situation is even more effective than this, because the affinity of haemoglobin for oxygen decreases when the pH is lowered (this is called the Bohr effect and arises in a complicated manner from the effect of pH on the salt bridges holding the subunits together). Since the CO₂ released in the muscle lowers the pH, it thereby facilitates the transfer of oxygen from the oxyhaemoglobin, and the greater the muscular activity the more the release of CO₂ helps to meet the increased demand for oxygen. Excess CO₂ is then removed from the tissue,
predominantly in the form of soluble \( \text{HCO}_3^- \) ions whose formation is facilitated by the protein chains of deoxyhaemoglobin which act as a buffer by picking up the accompanying protons.

\[
\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{HCO}_3^- + \text{H}^+ 
\]

The mode of bonding of the \( \text{O}_2 \) to Fe is important. In oxyhaemoglobin the hydrogen bonding to the distal histidine tilts the \( \text{O}_2 \) and produces an Fe–O–O angle of about 120°. This geometry (which hinders the formation of the Fe–O–Fe or Fe–O\(_2–\)Fe bridge believed to be an intermediate in Fe\(^{\text{II}}\) to Fe\(^{\text{III}}\) oxidations) along with the hydrophobic environment which inhibits electron transfer, together prevent the oxidation of Fe\(^{\text{II}}\) which would destroy the haemoglobin.

The poisoning effect of molecules such as CO and PF\(_3\) (p. 495) arises simply from their ability to bond reversibly to haem in the same manner as \( \text{O}_2 \), but much more strongly, so that oxygen transport is prevented. The cyanide ion CN\(^{-}\) can also displace \( \text{O}_2 \) from oxyhaemoglobin but its very much greater toxicity at small concentrations stems not from this but from its interference with the action of cytochrome a.

**Cytochromes**

The haem unit was evidently a most effective evolutionary development since it is found not only in the oxygen-transporting substances but also in electron transporters such as the cytochromes which are scattered widely throughout nature. There are three main types of cytochromes, a, b and c, members of each type being distinguished by subscripts, and their role is as intermediates in the metabolic oxidation of glucose by molecular oxygen. The iron of the haem group is attached to an associated protein by an imidazole N just as in haemoglobin and myoglobin. In most a and b cytochromes the sixth coordination site of the iron is also occupied by an imidazole N but, in type c and some type b cytochromes, it is occupied by a tightly bound S from a methionine residue rendering these cytochromes inert not only to oxygen but also to the poisons which affect oxygen carriers. Electron transfer is effected in a series of steps, in each of which the oxidation state of the iron is normally in a low-spin configuration oscillates between +2 and +3. Since the cytochromes are involved in the order b,c,a, the reduction potential of each step is successively increased (Table 25.8), so forming a “redox gradient”. This allows energy from the glucose oxidation to be released gradually and to be stored in the form of adenosine triphosphate (ATP) (see also p. 528).

The link with the final electron acceptor, \( \text{O}_2 \), is the enzyme cytochrome c oxidase which spans the inner membrane of the mitochondrion. It consists of cytochromes a and a\(_3\) along with two, or possibly three, Cu atoms. The details of its action are not fully established but the overall reaction catalysed by the enzyme is:

\[
4\text{Cytc}^{2+} + \text{O}_2 + 8\text{H}^+_{\text{inside}} \rightarrow 4\text{Cytc}^{3+} + 2\text{H}_2\text{O} + 4\text{H}^+_{\text{outside}}
\]

indicating the transport not only of electrons but also of protons across the mitochondrial membrane. As the end member of the redox gradient it differs from the other members in bonding \( \text{O}_2 \) directly and so being extremely susceptible to poisoning by CN\(^{-}\).

Another important group of cytochromes, found in plants, bacteria and animals is cytochrome P-450, so-called because of the absorption at 450 nm characteristic of their complexes with CO. Their function is to activate

O₂ sufficiently to facilitate its cleavage and so catalyse the reaction,

\[ R-H + O_2 + 2H^+ + 2e^- \rightarrow R-OH + H_2O \]

thus making R–H water soluble and aiding its elimination. They have molecular weights in the region of 50,000 and O₂ bonds to the haem in a manner similar to that in haemoglobin but with cysteine instead of histidine in the proximal position. The S donor atom of the cysteine is helpful in stabilizing an Fe⁴⁺=O group the oxygen of which is then inserted into the R–H bond.

Iron-sulfur proteins (⁴⁷,⁴⁸)

In spite of the obvious importance and diversity of haem proteins, comparable functions, especially that of electron transfer, are performed by non-haem iron proteins (NHIP).⁴ These too are widely distributed (well over 100 are now known), different types being involved in nitrogen fixation (p. 1035) and photosynthesis as well as in the metabolic oxidation of sugars prior to the involvement of the cytochromes mentioned above. The NHIP responsible for electron transfer are the iron–sulfur proteins which are of relatively low molecular weight (6000–12,000) and contain 1, 2, 4 or 8 Fe atoms which, in all the structures which have been definitely established, are each coordinated to 4 S atoms in an approximately tetrahedral manner. As a consequence of the small ligand fields associated in the tetrahedral coordination, these all contain iron in the high-spin configuration. Nearly all NHIP are notable for reduction potentials in the unusually low range -0.05 to -0.49 V (Table 25.8), indicating their ability to act as reducing agents at the low-potential end of biochemical processes.

The simplest NHIP is rubredoxin, in which the single iron atom is coordinated (Fig. 25.9a) to 4 S atoms belonging to cysteine residues in the protein chain. It differs from the other Fe–S proteins in having no labile sulfur (i.e. inorganic sulfur which can be liberated as H₂S by treatment with mineral acid; sulfur atoms of this type are not part of the protein, but form bridges between Fe atoms.)

NHIP with more than one Fe are conveniently classified as [2Fe–2S], [3Fe–4S] and [4Fe–4S] types. The first of these, the so-called plant ferredoxins act as 1-electron transfer agents and contain 2 Fe atoms joined by S bridges with terminal cysteine groups (Fig. 25.9b). The 2 Fe atoms in the oxidized form are high-spin Fe(II) but very low magnetic moments are observed because of strong spin–spin interaction via the bridging atoms. The iron centres are not equivalent however, and esr evidence suggests that in the reduced form they exist as Fe(II) and Fe(I) rather than both having a fractional oxidation state of +2.5.

The existence of [3Fe–4S] ferredoxins has been established by Mössbauer spectroscopy only comparatively recently. The cluster consists essentially of the cubane [4Fe–4S] with one corner removed, the irons being high-spin Fe(III) in the oxidized form and Fe(II) + 2Fe(III) in the reduced. The most common and most stable of the ferredoxins, however, are the [4F–4S] type (Fig. 25.9c). In these clusters the 4 × Fe and 4 × S atoms form 2 interpenetrating tetrahedra which together make up a distorted cube in which each Fe atom is additionally coordinated to a cysteine sulfur to give it an approximately tetrahedral coordination sphere. The cluster, like the 2-Fe dimer, acts as a 1-electron transfer agent so that an 8-Fe protein, in which there are two [4Fe–4S] units with centres about 1200 pm apart can effect a 2-electron transfer. Why 4 Fe atoms are required to transfer 1 electron is not obvious. Synthetic analogues, prepared by reacting FeCl₃, NaHS and an appropriate thiol (or still better FeCl₃, elemental sulfur and the Li salt of a thiol), have properties similar to those of the natural proteins and have been used

---

† The oxygen-carrying function is performed in some invertebrates by haemerythrin which, in spite of its name, does not contain haem. It is a diron–oxygen protein. See K. K. ANDERSON and A. GRALUND, Adv. Inorg. Chem. 43, 359–408 (1995).
extensively in attempts to solve this problem.\(^{(43)}\)

The esr, electronic, and Mössbauer spectra, as well as the magnetic properties of the synthetic \([\text{Fe}_4\text{S}_4\text{SR}_4]^{3-}\) anions, are similar to those of the reduced ferredoxins, whose redox reaction is therefore mirrored by:

\[
\text{[Fe}_4\text{S}_4\text{SR}_4]^{3-} \rightleftharpoons \text{[Fe}_4\text{S}_4\text{SR}_4]^{2-}
\]

\[
\text{reduced ferredoxin} \rightleftharpoons \text{oxidized ferredoxin}
\]

This indicates a change in the formal oxidation state of the iron from +2.25 to +2.5, and mixed \(\text{Fe}^{\text{III}}/\text{Fe}^{\text{II}}\) species have been postulated. However, it appears likely that these clusters are best regarded as electronically delocalized systems in which all the Fe atoms are equivalent.

4-Fe proteins are also known in which the diamagnetic, oxidized \([\text{Fe}_4\text{S}_4\text{SR}_4]^{2-}\) can be further oxidized at high potentials of about +0.35 V (hence "high potential iron sulfur proteins", HIPIP) to paramagnetic \((S = 1/2), [\text{Fe}_4\text{S}_4\text{SR}_4]^{-}\) species. Structural details and, indeed, biological function are still unclear.

Other non-haem proteins, distinct from the above iron-sulfur proteins are involved in the roles of iron transport and storage. Iron is absorbed as \(\text{Fe}^{\text{II}}\) in the human duodenum and passes into the blood as the \(\text{Fe}^{\text{III}}\) protein, transferrin.\(^{(49)}\) The \(\text{Fe}^{\text{III}}\) is in a distorted octahedral environment consisting of 1 × N, 3 × O and a chelating carbonate ion which

apparently “locks” the iron into the binding site. This has a stability constant sufficiently high for the uncombined protein to strip Fe$^{III}$ from such stable complexes as those with phosphate and citrate ions, and so it very efficiently scavenges iron from the blood plasma. The iron is then transported to the bone marrow where it is released from the transferrin (presumably after the temporary reduction of Fe$^{III}$ to Fe$^{II}$ since the latter’s is a much less-stable complex), to be stored as ferritin, prior to its incorporation into haemoglobin. Ferritin is a water-soluble material consisting of a layer of protein encapsulating iron(III) hydroxyphosphate to give an overall iron content of about 20%.

### 25.3.6 Organometallic compounds

Within the field of organometallic chemistry, iron has long held a dominant position, and the last decade has seen explosive growth in the organic chemistry of ruthenium and osmium, particularly in the cluster chemistry of osmium carbonyls. Carbonyls and metallocenes occupy dominant positions in this diverse field. Thus, although alkyls and aryls are known, they are only obtained with bulky groups which cannot undergo β-elimination (p. 925) or if the M–C σ bonds are stabilized by π-bonding ligands such as CO and P-donors.

**Carbonyls (see p. 926)**

Having the d$^6$s$^2$ configuration, the elements of this triad are able to conform with the 18-electron rule by forming mononuclear carbonyls of the type M(CO)$_5$. These are volatile liquids which can be prepared by the direct action of CO on the powdered metal (Fe$^+$ and Ru) or by the action of CO on the tetroxide (Os), in each case at elevated temperatures and pressures.

Fe(CO)$_5$ is a highly toxic substance discovered in 1891, the only previously known metal carbonyl being Ni(CO)$_4$. Like its thermally unstable Ru and Os analogues, its structure is trigonal bipyramidal (Fig. 25.10a) but its $^{13}$C nmr spectrum indicates that all 5 carbon atoms are equivalent and this is explained by the molecules’ fluxional behaviour (p. 914).

![Some carbonyls of Fe, Ru and Os](image)

**Figure 25.10** Some carbonyls of Fe, Ru and Os: (a) M(CO)$_5$; M = Fe, Ru, Os. (b) Fe$_3$(CO)$_9$; Fe–Fe = 252.3 pm. (c) Fe$_3$(CO)$_{12}$; 1 Fe–Fe = 256 pm, 2 Fe–Fe = 268 pm. (d) M$_3$(CO)$_{12}$; M = Ru, Os, Ru–Ru = 285 pm, Os–Os = 288 pm. (e) and (f) are alternative representations of (c) and (d) emphasizing respectively the icosahedral and anti-cubeoctahedral arrangements of the CO ligands.

Exposure of Fe(CO)₅ in organic solvents to ultraviolet light produces volatile orange crystals of the enneacarbonyl, Fe₂(CO)₉. Its structure consists of two face-sharing octahedra (Fig. 25.10b). An electron count shows that the dimer has a total of 34 valence electrons, i.e. 17 per iron atom. The observed diamagnetism is therefore explained by the presence of an Fe–Fe bond which is consistent with an interatomic separation virtually the same as in the metal itself. It is of interest that Ru and Os counterparts of Fe₂(CO)₉ are not only thermally less stable (the former especially so) but apparently are also structurally different, having an M–M bond supported by only 1 CO bridge. The carbonyls, which are produced along with the pentacarbonyls of Ru and Os and were initially thought to be enneacarbonyls, are in fact trimers, M₃(CO)₁₂, which also differ structurally from Fe₃(CO)₁₂ (Fig. 25.10c to f). This dark-green solid, which is best obtained by oxidation of [FeH(CO)₄]⁻ (see below), has a triangular structure in which two of the iron atoms are bridged by a pair of carbonyl groups, and can be regarded as being derived from Fe₂(CO)₉ by replacing a bridging CO with Fe(CO)₄. The Ru and Os compounds (orange and yellow respectively), on the other hand, have a more symmetrical structure in which all the metal atoms are equivalent and are held together solely by M–M bonds. It has been suggested (Johnson's Ligand Polyhedral Model)⁵²) that the structure of the iron compound is determined not by the major bonding forces but by the interactions between the 12 CO ligands which in fact form an icosahedral array. This accommodates an Fe₃ triangle with Fe–Fe distances similar to those in the metal, but not the larger Ru₃ and Os₃ triangles which force the ligands to adopt the less dense anticeuboctahedral form. As with the mononuclear carbonyl, the ¹³C nmr spectrum of the iron compound indicates C atom equivalence but this can be accounted for by oscillation of the Fe₃ triangle without disruption of the icosahedral array of CO ligands.⁵² In solution, a non-bridged isomer is formed, different from the Ru₃ and Os₃ carbonyls and again probably retaining the icosahedral arrangement of ligands.

The chemistry of these carbonyls, especially those of Os, is extensive and displays an astonishing structural diversity which has been exploited particularly by the Cambridge group of J. Lewis.⁵³ Os₃(CO)₁₂ is the starting material for the preparation of other Os₃ species and for clusters of higher nuclearity.⁵⁴ It is itself prepared by the reaction of OsO₄ and CO under high pressure and is more stable than its Ru counterpart, which has a weaker M–M bond enthalpy (76 kJ mol⁻¹ compared to 94 kJ mol⁻¹ in Os₈(CO)₁₂) and fragments rather easily. Thermolysis of Os₃(CO)₁₂ at 200°C yields mainly Os₆(CO)₁₈ along with smaller quantities of Os₅(CO)₁₆, Os₇(CO)₂₁ (Fig. 25.11) and Os₈(CO)₂₃. By careful adjustment of conditions, thermal and photochemical methods can give good yields of selected products but more rational methods have also been developed. Nucleophilic attack, by amine oxides for instance, removes CO (as CO₂) allowing a vacant site to be filled by a donor solvent such as MeCN. The products may themselves be pyrolysed or the solvent molecules replaced by metal nucleophiles such as H₂Os(CO)₄:

\[
\text{Os₃(CO)₁₂} + \text{R₃NO} \xrightarrow{\text{MeCN}} \text{Os₃(CO)₁₁(MeCN)}
\]

\[
\text{H₂Os(CO)₄} \xrightarrow{\text{H₂Os(CO)₄}} \text{H₂Os₄(CO)₁₃}
\]

**Carbonyl hydrides and carbonylate anions**

The treatment of iron carbonyls with aqueous or alcoholic alkali can, by varying the conditions, be used to produce a series of interconvertible carbonate anions: [HFe(CO)₄]⁻, [Fe(CO)₄]²⁻, [Fe₂(CO)₈]²⁻, [HFe₂(CO)₁₁]⁻ and [Fe₄(CO)₁₃]²⁻. Of these the first has a distorted trigonal bipyramidal structure with axial H, the second

---

is isoelectronic and isostructural with Ni(CO)₄ and the third is isoelectronic with Co₂(CO)₈ and isostructural with the isomer containing no CO bridges, while the trimeric and tetrameric anions have the cluster structures shown in Fig. 25.11. The related ruthenium complexes [HRu₃(CO)₁₁]⁻ and [H₃Ru₄(CO)₁₂]⁻, are of interest as possible catalysts for the "water-gas shift reaction".†

† Water-gas is produced by the high-temperature reaction of water and C:

\[ C + H₂O \rightarrow CO + H₂ \]

and is therefore a mixture of H₂O, CO and H₂. By suitably adjusting the relative proportions of CO and H₂, "synthesis gas" is obtained which can be used for the synthesis of methanol and hydrocarbons (the Fischer–Tropsch process). It is this catalytically controlled adjustment:

\[ H₂O + CO \leftrightarrow H₂ + CO₂ \]

which is the water-gas shift reaction (WGSR) (see p. 421).

Reduction of the pH of solutions of carbonylate anions yields a variety of protonated species and, from acid solutions, carbonyl hydrides such as the unstable, gaseous H₂Fe(CO)₄ and the polymeric liquids H₂Fe₂(CO)₈ and H₂Fe₃(CO)₁₁ are liberated. The use of ligand-replacement reactions to yield hydrides of higher nuclearity has already been noted.

Thermolysis of binary carbonyls or of their partially substituted derivatives, either under vacuum or in solutions, has been used to produce carbonyls and carbonylate anions with an unparalleled range of structures (Fig. 25.11). The Ru chemistry, though less well developed, mostly parallels that of Os.⁵⁵ These compounds are interesting not only for their catalytic potential but also for the preparative and theoretical problems they pose. Almost all these

---

polyhedral clusters are networks of triangular faces, are diamagnetic and have structures which can be rationalized by electron-counting arguments. However, in applying these rules it has to be noted that where an \( \text{M(CO)}_3 \) group "caps" a triangular face it has no effect on the skeletal electron count of the central polyhedron. Nor do such rules predict structures precisely. The \([\text{H}_2\text{M}_6(\text{CO})_{18}], [\text{HM}_6(\text{CO})_{18}]^{-}\) and \([\text{M}_6(\text{CO})_{18}]^{2-}\) clusters, for instance, while being stoichiometrically the same for \( \text{M} = \text{Ru} \) and \( \text{M} = \text{Os} \), and having the same essentially octahedral skeletons, nevertheless differ appreciably in the disposition of the attached carbonyl groups. The incorporation of interstitial (encapsulated) atoms such as \( \text{C}, \text{H}, \text{S}, \text{N}, \text{P} \) and, more recently, \( \text{B}^{36} \) is a widespread and frequently stabilizing feature of these clusters. Carbido clusters are the most common the \( \text{C} \) contributing 4 electrons

---

to the formal electron count and originating possibly from the solvent or, more often, from cleavage of a CO ligand. This is especially true for Ru where the formation of carbido clusters is a general consequence of thermolysis. Some illustrative examples of these compounds are listed in Table 25.9.

The encapsulated atom usually occupies the centre of the polyhedron of metals (or its base in the case of square pyramids). Its position can be located with precision by X-ray crystallography except for H, when it is possible only under the most favourable conditions, or by neutron diffraction.

A general property of these carbonyl clusters is their tendency to behave as electron “sinks”, and their redox chemistry is extensive.\(^{57}\) [Ru\(_6\)(H)\(_2\)(CO)\(_{17}\)]\(^{-}\) has been characterized in no less than five oxidation states \((n = 0–4)\); though admittedly this is exceptional.

**Carbonyl halides and other substituted carbonyls**

Numerous carbonyl halides, of which the best known are octahedral compounds of the type [M(CO)\(_4\)X\(_2\)] are obtained by the action of halogen on Fe(CO)\(_5\), or CO on MX\(_3\) (M = Ru, Os). Stepwise substitution of the remaining CO groups is possible by X\(^-\) or other ligands such as N, P and As donors.

Direct substitution of the carbonyls themselves is of course possible. Besides Group 15 donor ligands, unsaturated hydrocarbons give especially interesting products. The iron carbonyl acetylenes provided early examples of the use of carbonyls in organic synthesis. From them a wide variety

---

of cyclic compounds can be obtained as a result of condensation of coordinated acetylenes with themselves and/or CO. The complexes involving the acetylenes alone are usually unstable intermediates which are only separable when bulky substituents are incorporated on the acetylene. More usually, complexes of the condensed cyclic products are isolated. These ring systems include quinones, hydroquinones, cyclobutadienes and cyclopentadienones, the specific product depending on the particular iron carbonyl used and the precise conditions of the reaction.

Ferrocene and other cyclopentadienyls

Bis(cyclopentadienyl)iron, [Fe($\eta^5$-C$_5$H$_5$)$_2$], or, to give it the more familiar name coined by M. C. Whiting, "ferrocene", is the compound whose discovery in the early 1950s utterly transformed the study of organometallic chemistry. Yet the two groups of organic chemists who independently made the discovery, did so accidentally. P. L. Pauson and T. J. Kealy (Nature 168, 1039 (1951)) were attempting to synthesize fulvalene, $\text{C}_{10}H_{10}$, by reacting the Grignard reagent cyclopentadienyl magnesium bromide with FeCl$_3$, but instead obtained orange crystals (mp 173°C) containing Fe$^{II}$ and analysing for C$_{10}$H$_{10}$Fe. In a paper submitted simultaneously (J. Chem. Soc. 632 (1952)), S. A. Miller, T. A. Tebbott and J. F. Tremaine reported passing cyclopentadiene and N$_2$ over a reduced iron catalyst as part of a programme to prepare amines and they too obtained C$_{10}$H$_{10}$Fe.†

The initial structural formulation was $\text{Fe} \text{C}_5\text{H}_5\text{Fe}$, but the correct formulation, an unprecedented "sandwich" compound, was soon to follow. For this and for subsequent independent work in this field, G. Wilkinson and E. O. Fischer shared the 1973 Nobel Prize for Chemistry.

The structure of ferrocene and an MO description of its bonding have already been given (p. 937). The rings are virtually eclipsed as they are in the analogous ruthenocene (light-yellow, mp 199°C) and osmocene (white, mp 229°C).

This is also the case in the decamethylmetallocenes of Ru and Os but not in the iron analogue which has a staggered conformation, presumably due to steric crowding around the smaller metal. [M($\eta^5$-C$_5$H$_5$)$_2$] satisfy the 18-electron rule (p. 1134) and are stable to air and water but are readily oxidized. From ferrocene the blue-green, paramagnetic ferricinium ion, [Fe$^{III}$($\eta^5$-C$_5$H$_5$)$_2$]$^+$, is produced whereas the Ru and Os monocations are unstable, oxidizing further to [M$^{IV}$($\eta^5$-C$_5$H$_5$)$_2$]$^{2+}$ or dimerizing to [(M$^{IV}$-Cy)$_2$M$^{III}$-M$^{III}$($\eta^5$-C$_5$H$_5$)$_2$]$^{2+}$. The decamethylferricinium salt, [Fe($\eta^5$-C$_5$Me$_5$)$_2$][tcmpn], (tcmpn = tetracyanoethylene) is a dark green crystalline material consisting of linear chains of alternating anions and cations. It has the astonishing property of being a 1D molecular ferromagnet (with a saturation magnetisation greater than that of metallic iron itself on a molar basis), although the mechanism by which this originates is not yet settled.

The most notable chemistry of the bis(cyclopentadienyls results from the aromaticity of the cyclopentadienyl rings. This is now far too extensively documented to be described in full but an outline of some of its manifestations is in Fig. 25.14. Ferrocene resists catalytic hydrogenation and does not undergo the typical reactions of conjugated dienes, such as the Diels–Alder reaction. Nor are direct nitration and halogenation possible because of oxidation to the ferricinium ion. However, Friedel–Crafts acylation as well as alkylation and metallation reactions, are readily effected. Indeed, electrophilic substitution of ferrocene occurs with such facility compared to, say, benzene ($3 \times 10^6$ faster) that some explanation is called for. It has been suggested that,

† In retrospect it seems likely that ferrocene was actually first prepared as volatile yellow crystals in the 1930s by chemists at Union Carbide who passed dicyclopentadiene through a heated iron tube, but the significance was not then realized.

Figure 25.14  Some reactions of ferrocene.
in general, electrophilic substituents \( (E^+) \) interact first with the metal atom and then transfer to the \( \text{C}_5\text{H}_5 \) ring with proton elimination. Similar reactions are possible for ruthenocene and osmocene but usually occur less readily, and it appears that reactivity decreases with increasing size of the metal (see adjacent Scheme).

Many interesting cyclopentadienyl iron carbonyls have been prepared, the best known being the purple dimer, \([\text{Fe}(\eta^5-\text{C}_5\text{H}_5)(\text{CO})_2]_2\) (Fig. 25.15a), prepared by reacting \( \text{Fe} (\text{CO})_5 \) and dicyclopentadienyl at 135°C in an autoclave. Diamagnetism and an Fe - Fe distance of only 249 pm indicate the presence of an Fe-Fe bond. Prolonged reaction of the same reactants produces the very dark green, tetrameric cluster compound, \([\text{Fe}(\eta^5-\text{C}_5\text{H}_5)(\text{CO})_4\] (Fig. 25.15b), which involves CO groups which are triply bridging and so give rise to an exceedingly low (1620 cm\(^{-1}\)) \( \nu_{\text{CO}} \) absorption. \([\text{Fe}(\eta^1-\text{C}_5\text{H}_5)(\eta^5-\text{C}_5\text{H}_5)(\text{CO})_2]\) (Fig. 25.15c) is also of note as an early example of a fluxional organometallic compound. The \(^1\text{H} \) nmr spectrum consists of only two sharp lines, one for each ring. A single line is expected for the pentahapto ring since all its protons are equivalent, but it is clear that some averaging process must be occurring for the

Figure 25.15 Some cyclopentadienyl iron carbonyls: (a) \([\eta^5-\text{C}_5\text{H}_5]\text{Fe} (\text{CO})_2\]_2, (b) \([\eta^5-\text{C}_5\text{H}_5]\text{Fe} (\text{CO})_4\] and (c) \([\eta^1-\text{C}_5\text{H}_5](\eta^5-\text{C}_5\text{H}_5)\text{Fe} (\text{CO})_2\].
non-equivalent protons of the monohapto ring to produce just one line. It is concluded that the point of attachment of the monohapto ring to the metal must change repeatedly and rapidly ("ring whizzling") thus averaging the protons.

Although the cyclopentadienyls dominate the "aromatic" chemistry of this group, bis(arene) compounds are also well established. They are able to satisfy the 18-electron rule as the dications, \([\text{M(arene)}_2]^{2+}\) or by the two rings adopting different bonding modes; one \(\eta^6\) the other \(\eta^4\).

Other aspects of the organometallic chemistry of this triad have been referred to in Chapter 19 but for fuller details more extensive reviews should be consulted.\(^{50,59}\)

Cobalt, Rhodium and Iridium

26.1 Introduction

Although hardly any metallic cobalt was used until the twentieth century, its ores have been used for thousands of years to impart a blue colour to glass and pottery. It is present in Egyptian pottery dated at around 2600 BC and Iranian glass beads of 2250 BC.† The source of the blue colour was recognized in 1735 by the Swedish chemist G. Brandt, who isolated a very impure metal, or “regulus”, which he named “cobalt rex”. In 1780 T. O. Bergman showed this to be a new element. Its name has some resemblance to the Greek word for “mine” but is almost certainly derived from the German word Kobold for “goblin” or “evil spirit”. The miners of northern European countries thought that the spitefulness of such spirits was responsible for ores which, on smelting, not only failed unexpectedly to yield the anticipated metal but also produced highly toxic fumes ($\text{As}_4\text{O}_6$).

In 1803 both rhodium and iridium were discovered, like their preceding neighbours in the periodic table, ruthenium and osmium, in the black residue left after crude platinum had been dissolved in aqua regia. W. H. Wollaston discovered rhodium, naming it after the Greek word ρόδον for “rose” because of the rose-colour commonly found in aqueous solutions of its salts. S. Tennant discovered iridium along with osmium, and named it after the Greek goddess Iris (ἱρίς, ἱρίς), whose sign was the rainbow, because of the variety of colours of its compounds.

26.2 The Elements

26.2.1 Terrestrial abundance and distribution

Rhodium and iridium are exceedingly rare elements, comprising only 0.0001 and 0.001 ppm of the earth’s crust respectively, and even

† “Smalt”, produced by fusing potash, silica and cobalt oxide, can be used for colouring glass or for glazing pottery. The secret of making this brilliant blue pigment was apparently lost, to be rediscovered in the fifteenth century. Leonardo da Vinci was one of the first to use powdered smalt as a “new” pigment when painting his famous “The Madonna of the Rocks”.

cobalt (29 ppm, i.e. 0.0029%), though widely distributed, stands only thirtieth in order of abundance and is less common than all other elements of the first transition series except scandium (25 ppm).

More than 200 ores are known to contain cobalt but only a few are of commercial value. The more important are arsenides and sulfides such as smaltite, CoAs₂, cobaltite (or cobalt glance), CoAsS, and linnaeite, Co₃S₄. These are invariably associated with nickel, and often also with copper and lead, and it is usually obtained as a byproduct or coproduct in the recovery of these metals. The world’s major sources of cobalt are the African continent and Canada with smaller reserves in Australia and the former USSR. All the platinum metals are generally associated with each other and rhodium and iridium therefore occur wherever the other platinum metals are found. However, the relative proportions of the individual metals are by no means constant and the more important sources of rhodium are the nickel–copper–sulfide ores found in South Africa and in Sudbury, Canada, which contain about 0.1% Rh. Iridium is usually obtained from native osmiridium (Ir ~ 50%) or iridiosmium (Ir ~ 70%) found chiefly in Alaska as well as South Africa.

26.2.2 Preparation and uses of the elements

The production of cobalt is usually subsidiary to that of copper or nickel and the methods employed differ widely, depending on which of these it is associated with. In general the ore is subjected to appropriate roasting treatment so as to remove gangue material as a slag and produce a “speiss” of mixed metal and oxides. In the case of arsenical ores, As₂O₅ is condensed and provides a valuable byproduct. In the case of copper ores, the primary process leaves a spent electrolyte from which iron is precipitated as the hydroxide by lime and the cobalt then separated by further electrolysis. Nickel ores yield acidic sulfate or chloride solutions and the methods used to separate the nickel and cobalt include: (a) precipitation of cobalt as the sulfide; (b) oxidation of cobalt and precipitation of Co(OH)₃; (c) making the solution alkaline with NH₃ and removal of nickel either as the sparingly soluble (NH₄)₂Ni(SO₄)₂.6H₂O or by selective reduction to the metal by H₂ under pressure; (d) anion exchange, utilizing the preferential formation of [CoCl₄]²⁻.

World production of cobalt in 1995 was about 20 000 tonnes, considerably below capacity. The major producing countries are Zaire, Zambia, Canada, Finland and the former Soviet Union.

The largest use of cobalt is in the production of chemicals for the ceramic and paint industries. In ceramics the main use now is not to provide a blue colour, but rather white by counterbalancing the yellow tint arising from iron impurities. Blue pigments are, however, used in paints and inks, and cobalt compounds are used to hasten the oxidation and hence the drying of oil-based paints. Cobalt compounds are also employed as catalysts in a range of organic reactions of which the “OXO” (or hydroformylation) reaction and hydrogenation and dehydrogenation reactions are the most important (pp. 1134–6).

Other uses include the manufacture of magnetic alloys. Of these the best known is “Alnico”, a steel containing, as its name implies, aluminium and nickel, as well as cobalt. It is used for permanent magnets which are up to 25 times more powerful than ordinary steel magnets.

As already noted (p. 1073), the platinum metals are all isolated from concentrates obtained as “anode slimes” or “converter matte.” In the classical process, after ruthenium and osmium have been removed, excess oxidants are removed by boiling, iridium is precipitated as (NH₄)₂IrCl₆ and rhodium as [Rh(NH₃)₅Cl]Cl₂. In alternative solvent extraction processes (p. 1147) [IrCl₆]²⁻ is extracted in organic amines leaving rhodium in the aqueous phase to be precipitated, again, as [Rh(NH₃)₅Cl]Cl₂. In all cases ignition in H₂

---

§26.2.3 Properties of the elements

Yields the metals as powders or sponges which can be consolidated by the techniques of powder metallurgy.

In 1996, consumption in the western world was 14.2 tonnes of rhodium and 3.8 tonnes of iridium. Unquestionably the main uses of rhodium (over 90%) are now catalytic, e.g. for the control of exhaust emissions in the car (automobile) industry and, in the form of phosphine complexes, in hydrogenation and hydroformylation reactions where it is frequently more efficient than the more commonly used cobalt catalysts. Iridium is used in the coating of anodes in chloralkali plant and as a catalyst in the production of acetic acid. It also finds small-scale applications in specialist hard alloys.

26.2.3 Properties of the elements

Some of the important properties of these three elements are summarized in Table 26.1.

The metals are lustrous and silvery with, in the case of cobalt, a bluish tinge. Rhodium and iridium are both hard, cobalt less so but still appreciably harder than iron. Rhodium and Ir have fcc structures, the first elements in the transition series to do so; this is in keeping with the view, based on band-theory calculations, that the fcc structure is more stable than either bcc or hcp when the outer d orbitals are nearly full. Cobalt, too, has an allotrope (the β-form) with this structure but this is only stable above 417°C; below this temperature the hcp α-form is the more stable. However, the transformation between these allotropes is generally slow and the β-form, which can be stabilized by the addition of a few per cent of iron, is often present at room temperature. This, of course, has an effect on physical properties and is no doubt responsible for variations in reported values for some properties even in the case of very pure cobalt. By contrast the atomic weights of cobalt and rhodium at least are known with considerable precision, since these elements each have but one naturally occurring isotope. In the case of cobalt this is 59Co, but bombardment by thermal neutrons converts this to the radioactive 60Co. The latter has a half-life of 5.271 y and decays by means of β− and γ emission to non-radioactive 60Ni. It is used in many fields of research as a concentrated source of γ-radiation, and also medically in the treatment of malignant growths. Iridium has two stable isotopes: 191Ir 37.3% and 193Ir 62.7%.

The mps, bps and enthalpies of atomization are lower than for the preceding elements in the periodic tables, presumably because the \((n-1)d\) electrons are being drawn increasingly into the inert electron cores of the atoms. In the first series Co, like its neighbours Fe and Ni, is ferromagnetic (in both allotropic forms); while it does not attain the high saturation magnetization of iron, its Curie point (>1100°C) is much higher than that for Fe (768°C).

### 26.2.4 Chemical reactivity and trends

Cobalt is appreciably less reactive than iron, and so contrasts less markedly with the two heavier members of its triad. It is stable to atmospheric oxygen unless heated, when it is oxidized first to \(\text{Co}_2\text{O}_4\); above 900°C the product is CoO which is also produced by the action of steam on the red-hot metal. It dissolves rather slowly in dil mineral acids giving salts of \(\text{Co}^{2+}\), and reacts on heating with the halogens and other non-metals such as B, C, P, As and S, but is unreactive to \(\text{H}_2\) and \(\text{N}_2\).

Rhodium and iridium will also react with oxygen and halogens at red-heat, but only slowly, and these metals are especially notable for their extreme inertness to acids, even aqua regia. Dissolution of rhodium metal is best effected by fusion with \(\text{NaHSO}_4\), a process used in its commercial separation. In the case of iridium, oxidizing molten alkalis such as \(\text{Na}_2\text{O}_2\) or \(\text{KOH} + \text{KNO}_3\) will produce \(\text{Ir}_2\text{O}_3\) which can then be dissolved in aqua regia. Alternatively, a rather extreme measure which is efficacious with both metals, is to heat them with conc HCl + \(\text{NaClO}_3\) in a sealed tube at 125–150°C.

Table 26.2 is a list of examples of compounds of these elements in various oxidation states. The most striking feature of this, as compared to the corresponding lists for preceding triads, is that for the first time the range of oxidation states has diminished. This is a manifestation of the increasing stability of the \((n-1)d\) electrons, whose attraction to the atomic nucleus is now sufficient to prevent the elements attaining the highest oxidation states and so to render irrelevant the concept of a “group” oxidation state. No oxidation states are found above +6 for Rh and Ir, or above +5 for Co. Indeed, examples of cobalt in +4 and +5 and of rhodium or iridium in +5 and +6 oxidation states are rare and sometimes poorly characterized.

The most common oxidation states of cobalt are +2 and +3. \([\text{Co(H}_2\text{O})_6]^{2+}\) and \([\text{Co(H}_2\text{O})_6]^{3+}\) are both known but the latter is a strong oxidizing agent and in aqueous solution, unless it is acidic, it decomposes rapidly as the \(\text{Co}^{3+}\) oxidizes the water with evolution of oxygen. Consequently, in contrast to \(\text{Co}^{2+}\), \(\text{Co}^{3+}\) provides few simple salts, and those which do occur are unstable. However, \(\text{Co}^{3+}\) is unsurpassed in the number of coordination complexes which it forms, especially with \(N\)-donor ligands. Virtually all of these complexes are low-spin, the \(t^6\) configuration producing a particularly high CFSE (p. 1131).

The effect of the CFSE is expected to be even more marked in the case of the heavier elements because for them the crystal field splittings are much greater. As a result the +3 state is the most important one for both Rh and Ir and \([\text{M(H}_2\text{O})_6]^{3+}\) are the only simple aquo ions formed by these elements. With \(\pi\)-acceptor ligands the +1 oxidation state is also well known for Rh and Ir. It is noticeable, however, that the similarity of these two heavier elements is less than is the case earlier in the transition series and, although rhodium resembles iridium more than cobalt, nevertheless there are significant differences. One example is provided by the +4 oxidation state which occurs to an appreciable extent in iridium but not in rhodium. (The ease with which \(\text{Ir}^{IV} \rightarrow \text{Ir}^{III}\) sometimes occurs can be a source of annoyance to preparative chemists.)

Table 26.2 also reveals a diminished tendency on the part of these elements to form compounds of high coordination number when compared with the iron group and, apart from \([\text{Co(NO}_3)_4]^{2-}\), a coordination number of 6 is rarely exceeded. There is also a marked reluctance to form oxoanions (p. 1118). This is presumably because their formation requires the donation of \(\pi\) electrons from the oxygen atoms to the metal and the metals become progressively

less able to act as π acceptors as their d orbitals are filled.

Hydrido complexes of all three elements, and covering a range of formal oxidation states, are important because of their roles in homogeneous catalysis either as the catalysts themselves or as intermediates in the catalytic cycles.

26.3 Compounds of Cobalt, Rhodium and Iridium

Binary borides (p. 147) and carbides (p. 297) have been discussed already.

### 26.3.1 Oxides and sulfides

As a result of the diminution in the range of oxidation states which has already been mentioned, the number of oxides formed by these elements is less than in the preceding groups, being confined to two each for cobalt (COO, Co\(_3\)O\(_4\)) and rhodium (Rh\(_2\)O\(_3\), RhO\(_2\)) and to just one for iridium (IrO\(_2\)) (though an impure sesquioxide Ir\(_2\)O\(_3\) has been reported — see below). No trioxides are known.

The only oxide formed by any of these metals in the divalent state is CoO; this is prepared as an olive-green powder by strongly heating the metal in air or steam, or alternatively by heating
the hydroxide, carbonate or nitrate in the absence of air. It has the rock-salt structure and is antiferromagnetic below 289 K. By reacting it with silica and alumina, pigments are produced which are used in the ceramics industry. CoO is stable in air at ambient temperatures and above 900°C but if heated at, say, 600–700°C, it is converted into the black Co₃O₄. This is Co⁰Co²⁺O₄ and has the normal spinel structure with Co²⁺ ions in tetrahedral and Co³⁺ in octahedral sites within the ccp lattice of oxide ions. This is to be expected (p. 1080) because of the dominating advantage of placing the d⁶ ions in octahedral sites, where adoption of the low-spin configuration gives it a decisively favourable CFSE. The ability of Co₃O₄ to absorb oxygen, and possibly also the retention of water in preparations from the hydroxide, have led to claims for the existence of Co₂O₃, but it is doubtful if these claims are valid. Oxidation of Co(OH)₂, or addition of aqueous alkali to a cobalt(III) complex, produces a dark-brown material which on drying at 150°C in fact gives cobalt(III) oxide hydroxide, CoO(OH).

Heating rhodium metal or the trichloride in oxygen at 600°C, or simply heating the trinitrate, produces dark-grey Rh₂O₃ which has the corundum structure (p. 242); it is the only stable oxide formed by this metal. The yellow precipitate formed by the addition of alkali to aqueous solutions of rhodium(III) is actually Rh₂O₃·5H₂O rather than a genuine hydroxide. Electrolytic oxidation of Rh³⁺ solutions and addition of alkali gives a yellow precipitate of RhO₂·2H₂O, but attempts to dehydrate this produce Rh₂O₃. Black anhydrous RhO₂ is best obtained by heating Rh₂O₃ in oxygen under pressure; it has the rutile structure, but it is not well characterized.

For iridium the position is reversed. This time it is the black dioxide, IrO₂, with the rutile structure (p. 961), which is the only definitely established oxide. It is obtained by heating the metal in oxygen or by dehydrating the precipitate produced when alkali is added to an aqueous solution of [IrCl₆]²⁻. Contamination either by unreacted metal or by alkali is, however, difficult to avoid. The other oxide, Ir₂O₃, is said to be obtained by igniting K₂IrCl₆ with NaCO₃ or, as its hydrate, by adding KOH to aqueous K₃[IrCl₆] under CO₂. However, even if it is a true compound, it is always impure and is readily oxidized to IrO₂.

Oxoanions are rare in this group; exceptions include the unstable [CoV⁰O₄]³⁻ and [CoIV⁰O₃]⁴⁻. Heating mixtures of the appropriate oxides in oxygen, or under pressure, produces materials with the stoichiometry, M₃CoO₄, which, together with their oxidizing properties, suggests the presence of Co⁵⁺. When CoO is heated with 2.2 moles of Na₂O at 550°C in a sealed tube under argon, bright-red crystals of Na₄CoO₃ are formed. The compound hydrolyses immediately on contact with atmospheric moisture and is notable in containing discrete planar [CoO₃]⁴⁻ ions reminiscent of the carbonate ion (Co–O 186 ± 6 pm) and is similar to the red oxoferrate(II), Na₄[FeO₃]. The lustrous red tetracobaltate(II) Na₁₀[Co₂O₃]₉, with an anion analogous to the catena-tetracarbonate [C₄O₈]²⁻, is also known. For iridium, prolonged heating of IrO₂ and Li₂O produces Li₂IrO₃ which, when heated with 2.2 moles of Na₂O at 800°C for 71 days, gives transparent red crystals of Na₄IrO₄ in which the Ir(IV) is surrounded by four O' in a square (Ir–O = 190.2 pm).⁴

A larger number of sulfides have been reported but not all of them have been fully characterized. Cobalt gives rise to CoS₂ with the pyrites structure (p. 680), Co₃S₄ with the spinel structure (p. 247), and Co₁₋ₓS which has the NiAs structure (p. 555) and is cobalt-deficient. All are metallic, as is Co₉S₈ and the corresponding selenides and tellurides. The sulfides of rhodium and iridium are notable mainly for their inertness especially towards acids, and most of them are semiconductors. They are the disulfides MS₂, obtained from the elements; the “sesquisulfides” M₂S₃, obtained by passing H₂S through aqueous solutions of M₃⁺, and Rh₂S₄ and IrS₃, obtained by heating MCl₅ + S at 600°C. Numerous nonstoichiometric selenides and tellurides are also known.

Because of possible catalytic and biological relevance of metal–sulfur clusters, several such compounds of cobalt have been prepared. The action of H₂S or M₂S (M = alkali metal) on a non-aqueous solution of a convenient cobalt compound (often containing, or in the presence of, a phosphine) is a typical route. Diamagnetic [Co₆S₈(PR₃)₆] (R = Et, Ph) comprise an octahedral array of metal atoms (Co–Co in the range 281.7 to 289.4 pm), all faces capped by μ₃-S atoms, and show facile redox behaviour

\[
[\text{Co₆S₈(PR₃)₆}] \rightleftharpoons [\text{Co₆S₈(PR₃)₆}]^+ 
\]

An indication of the range of such clusters which might possibly be synthesized is given by the observation that mass spectroscopic analysis of the products of laser-ablation of CoS₅ show no less than 83 gaseous ions ranging from [CoS₂]⁻ to [Co₃S₂₄]⁻.

### 26.3.2 Halides

The known halides of this triad are listed in Table 26.3. It can be seen that, apart from CoF₃, CoF₄ and the doubtful iridium tetrahalides, they fall into three categories:

- (a) higher fluorides of Ir and Rh;
- (b) a full complement of trihalides of Ir and Rh;
- (c) dihalides of cobalt

The octahedral hexafluorides are obtained directly from the elements and both are volatile, extremely reactive and corrosive solids, RhF₆ being the least stable of the platinum metal hexafluorides and reacting with glass even when carefully dried. They are thermally unstable and must be frozen out from the hot gaseous reaction mixtures, otherwise they dissociate.

---

The pentafluorides of Rh and Ir may be prepared by the deliberate thermal dissociation of the hexafluorides. They also are highly reactive and are respectively dark-red and yellow solids, with the same tetrameric structure as [RuF₅]₄ and [OsF₅]₄ (p. 1083).

RhF₅ is a purple-red solid, usually prepared by the reaction of the strong fluorinating agent BrF₃ on RhBr₃. The corresponding compound IrF₄ has had an intriguing and instructive history. It was first claimed in 1929 and again in 1956 but this material was shown in 1965 to be, in reality, the previously unknown IrF₅. IrF₄ can now be made (1974) by reducing IrF₅ with the stoichiometric amount of iridium-black:

\[ 4\text{IrF}_5 + \text{Ir} \xrightarrow{400^\circ} 5\text{IrF}_4 \]

The dark-brown product disproportionates above 400° into IrF₃ and the volatile IrF₅. The structure features \{IrF₆\} octahedra which share 4 F atoms, each with one other \{IrF₆\} group, leaving a pair of cis vertices unshared; this is essentially a rutile type structure (p. 961) from which alternate metal atoms have been removed from each edge-sharing chain. It was the first 3D structure to have been found for a tetrafluoride.

Claims have been made for the isolation of all the other iridium tetrahalides, but there is some doubt as to whether these can be substantiated. This is an unexpected situation since +4 is one of iridium's common oxidation states and, indeed, the derived anions [IrX₆]²⁻ (X = F, Cl, Br) are well known.

The most familiar and most stable of the halides of Rh and Ir, however, are the trihalides. Those of Rh range in colour from the red RhF₃ to black RhI₃ and, apart from the latter, which is obtained by the action of aqueous KI on the tribromide, they may be obtained in the anhydrous state directly from the elements. RhF₃ has a structure similar to that of ReO₃ (p. 1047), while RhCl₃ is isomorphous with AlCl₃ (p. 234). The anhydrous trihalides are generally unreactive and insoluble in water but, excepting the triiodide which is only known in this form, water-soluble hydrates can be produced by wet methods. RhF₃·6H₂O and RhF₃·9H₂O can be isolated from aqueous solutions of Rh³⁺ acidified with HF. Their aqueous solutions are yellow, possibly due to the presence of [Rh(H₂O)_6]³⁺. The dark-red deliquescent RhCl₃·3H₂O is the most common compound of rhodium and the usual starting point for the preparation of other rhodium compounds, and is itself best prepared from the metal sponge. This is heated with KCl in a stream of Cl₂ and the product extracted with water. The solution contains K₂[Rh(H₂O)Cl₅] and treatment with KOH precipitates the hydrous Rh₂O₃ which can be dissolved in hydrochloric acid and the solution evaporated to dryness. RhBr₃·2H₂O also is formed from the metal by treating it with hydrochloric acid and bromine.

The iridium trihalides are rather similar to those of rhodium. Anhydrous IrF₃ is obtained by reducing IrF₅ with the metal, IrCl₃ and IrBr₃ by heating the elements, and IrI₃ by heating its hydrate in vacuo. Water-soluble hydrates of the tri-chloride, -bromide, and -iodide are produced by dissolving hydrous Ir₂O₃ in the appropriate acid and, like its rhodium analogue, IrCl₃·3H₂O provides a convenient starting point in iridium chemistry.

Lower halides of Rh and Ir have been reported and, whilst their existence cannot be denied with certainty, further substantiation is needed. Unquestionably, the divalent state is the preserve of cobalt. Apart from the strongly oxidizing CoF₃ (a light-brown powder isomorphous with FeCl₃ and the product of the action of F₂ on CoCl₂ at 250°C) and CoF₄ (identified in the gaseous phase by mass spectometry, as the singly charged cation, when CoF₃ and TbF₄ are heated to 600–680 K), the only known halides of cobalt are the dihalides. In all of these the cobalt is octahedrally coordinated. The anhydrous compounds are prepared by dry methods: CoF₂ (pink) by heating CoCl₂ in HF; CoCl₂ (blue) and CoBr₂ (green) by the action of the halogens on the heated metal; Co₂ (blue-black) by the action

---

of HI on the heated metal. The fluoride is only slightly soluble in water but the others dissolve readily to give solutions from which pink or red hexahydrates can be crystallized. These solutions can alternatively and more conveniently be made by dissolving the metal, oxide or carbonate in the appropriate hydrohalic acid. The chloride is widely used as an indicator in the desiccant, silica gel, since its blue anhydrous form turns pink as it hydrates (see p. 1131).

The disinclination of these metals to form o xoanions has already been remarked and the same is evidently true of oxohalides: none have been authenticated.

26.3.3 Complexes

The chemistry of oxidation states above IV is sparse. Apart from RhF₆ and IrF₆, such chemistry as there is, is mainly confined to salts of [RhF₆]⁻ and [IrF₆]⁻. These are prepared respectively by the action of F₂ on RhCl₃ and KF under pressure, and by fluorinating a lower halide of iridium with BrF₃ in the presence of a halide of the counter cation. Hydrido complexes of iridium in the formal oxidation state V are obtained by the action of LiAlH₄ or LiBH₄ on IrIII compounds in the presence of a halide of the counter cation. Hydrido complexes of iridium in the formal oxidation state VI are obtained by the action of LiAlH₄ or LiBH₄ on IrIII compounds in the presence of phosphine or cyclopentadienyl ligands. [IrH₅(PR₃)₂], in which the five hydrogens lie equatorially in a pentagonal bipyramid, and the "half sandwich", [(η⁵-C₅Me₅)IrH₄], are examples.

Oxidation state IV (d⁵)

Cobalt provides only a few examples of this oxidation state, namely some fluoro compounds and mixed metal oxides, whose purity is questionable and, most notably, the thermally stable, brown, tetraalkyl, [Co(1-norbornyl)₄]. Prepared by the reaction of CoCl₂ and Li(1-norbornyl), it is the only one of a series of such compounds obtained for the first row transition metals Ti to Co which has been structurally characterized. It is tetrahedral and, with a d⁵ configuration, its room-temperature magnetic moment of 1.89 BM indicates that it is low-spin; the first example to be authenticated for a tetrahedral complex of a first row transition metal. Rhodium(IV) complexes are confined to salts of the oxidizing and readily hydrolysed [RhX₆]²⁻ (X = F, Cl), the green solid Cs₂[RhCl₆] being one of the few to be confirmed. Only iridium(IV) shows appreciable stability.

The salts of [IrX₆]²⁻ (X = F, Cl, Br) are comparatively stable and their colour deepens from red, through reddish-black to bluish-black with increasing atomic weight of the halogen. [IrF₆]²⁻ is obtained by reduction of [IrF₆]⁻, [IrCl₆]²⁻ by oxidation of [IrCl₆]³⁻ with chlorine, and [IrBr₆]²⁻ by Br⁻ substitution of [IrCl₆]²⁻ in aqueous solution. The hexachloroiridates in particular have been the subject of many magnetic investigations. They have magnetic moments at room temperature somewhat below the spin-only value for the t₂g configuration (1.73 BM), and this falls with temperature. This has been interpreted as the result of antiferromagnetic interaction operating by a superexchange mechanism between adjacent IrIV ions via intervening chlorine atoms. More importantly, in 1953 in a short but classic paper, J. Owen and K. W. H. Stevens reported the observation of hyperfine structure in the esr signal obtained from solid solutions of (NH₄)₂[IrCl₆] in the isomorphous, but diamagnetic, (NH₄)₂[PtCl₆]. This arises from the influence of the chlorine nuclei and, from the magnitude of the splitting, it was inferred that the single unpaired electron, which is ostensibly one of the metal d⁵ electrons, in fact spends only 80% of its time on the metal, the rest of the time being divided equally between the 6 chlorine ligands. This was the first unambiguous evidence that metal d electrons are able to move in molecular

---

orbitals over the whole complex, and implies the presence of \( \pi \) as well as \( \sigma \) bonding.

In aqueous solution, the halide ions of \([\text{IrX}_6]^{2-}\) may be replaced by solvent and a number of aquo substituted derivatives have been reported. Other \( \text{Ir}^{IV} \) complexes with \( O \)-donor ligands are \([\text{IrCl}_4(\text{C}_2\text{O}_4)]^{2-}\), obtained by oxidizing \( \text{Ir}^{III} \) oxalato complexes with chlorine, and \( \text{Na}_2\text{IrO}_3 \), obtained by fusing \( \text{Ir} \) and \( \text{Na}_2\text{CO}_3 \).

Two interesting trinuclear complexes must also be mentioned. They are \( \text{K}_{10}[\text{Ir}_3\text{O}(\text{SO}_4)_9] \cdot 3\text{H}_2\text{O} \), obtained by boiling \( \text{Na}_2\text{IrCl}_6 \) and \( \text{K}_2\text{SO}_4 \) in conc sulfuric acid, and \( \text{K}_4[\text{Ir}_3\text{N}(\text{SO}_4)_6(\text{H}_2\text{O})_3] \), obtained by boiling \( \text{Na}_3\text{IrCl}_6 \) and \( (\text{NH}_4)_2\text{SO}_4 \) in conc sulfuric acid. They have the structure shown in Fig. 26.1, analogous to that of the basic carboxylates, \([\text{M}^{III}(\text{O}_2\text{CR})_6\text{L}_3]^+ \) (see Fig. 23.9). The oxo species formally contains 1 \( \text{Ir}^{IV} \) and 2 \( \text{Ir}^{III} \) ions and the nitride species 2 \( \text{Ir}^{IV} \) ions and 1 \( \text{Ir}^{III} \) ion, but in each case the charges are probably delocalized over the whole complex.

**Oxidation state III (d\( ^6 \))**

For all three elements this is the most prolific oxidation state, providing a wide variety of kinetically inert complexes. As has already been pointed out, these are virtually all low-spin and octahedral, a major stabilizing influence being the high CFSE associated with the \( t_{2g}^6 \) configuration (\( \frac{12}{5} \Delta_0 \), the maximum possible for any \( d^6 \) configuration). Even \([\text{Co}(\text{H}_2\text{O})_6]^{3+}\) is low-spin but it is such a powerful oxidizing agent that it is unstable in aqueous solutions and only a few simple salts of cobalt(II) may be replaced by solvent and a number of

---

changes in $E^\circ$ are even greater than those noted for the Fe$^{III}$/Fe$^{II}$ couple (p. 1093), though if the two systems are compared it must be remembered that the oxidation state which can be stabilized by adoption of the low-spin $t^6_{2g}$ configuration is +3 for cobalt but only +2 for iron. Nevertheless, the effect of increasing pH is closely similar, the M$^{III}$ “hydroxide” of both metals being far less soluble than the M$^{II}$ “hydroxide”. In the case of cobalt this reduces $E^\circ$ from 1.83 to 0.17 V:

$$\text{Co}^{III} \text{O(OH)} + \text{H}_2\text{O} + \text{e}^- \rightleftharpoons \text{Co}^{II} \text{(OH)}_2 + \text{OH}^-; \quad E^\circ = 0.17 \text{ V}$$

thereby facilitating oxidation to the +3 state.

Complexes of cobalt(III), like those of chromium(III) (p. 1027), are kinetically inert and so, again, indirect methods of preparation are to be preferred. Most commonly the ligand is added to an aqueous solution of an appropriate salt of cobalt(II), and the cobalt(II) complex thereby formed is oxidized by some convenient oxidant, frequently (if an N-donor ligand is involved) in the presence of a catalyst such as active charcoal. Molecular oxygen is often used as the oxidant simply by drawing a stream of air through the solution for a few hours, but the same result can, in many cases, be obtained more quickly by using aqueous solutions of H$_2$O$_2$.

The cobaltammines, whose number is legion, were amongst the first coordination compounds to be systematically studied and are undoubtedly the most extensively investigated class of cobalt(III) complex. Oxidation of aqueous mixtures of CoX$_2$, NH$_4$X and NH$_3$ (X = Cl, Br, NO$_3$, etc.) can, by varying the conditions and particularly the relative proportions of the reactants, be used to prepare complexes of types such as [Co(NH$_3$)$_6$]$^{3+}$, [Co(NH$_3$)$_3$X]$^{2+}$ and [Co(NH$_3$)$_4$X$_2$]$^{+}$. The range of these compounds is further extended by the replacement of X by other anionic or neutral ligands. The inertness of the compounds makes such substitution reactions slow (taking hours or days to attain equilibrium) and, being therefore amenable to examination by conventional analytical techniques, they have provided a continuing focus for kinetic studies. The forward (aquation) and backward (anation) reactions of the pentaammines:

$$[\text{Co(NH}_3)_5\text{X}]^{2+} + \text{H}_2\text{O} \rightleftharpoons [\text{Co(NH}_3)_5(\text{H}_2\text{O})]^3+ + \text{X}^-$$

must be the most thoroughly studied substitution reactions, certainly of octahedral compounds. Furthermore, the isolation of cis and trans isomers of the tetraammines (p. 914) was an important part of Werner’s classical proof of the octahedral structure of 6-coordinate complexes. The kinetic inertness of cobalt(III) was also exploited by H. Taube to demonstrate the inner-sphere mechanism of electron transfer (see Panel on p. 1124).

Compounds analogous to the cobaltammines may be similarly obtained using chelating amines such as ethylenediamine or bipyridyl, and these too have played an important role in stereochemical studies. Thus cis-[Co(en)$_2$(NH$_3$)$_2$Cl]$^{2+}$ was resolved into d(+)- and l(-)- optical isomers by Werner in 1911 thereby demonstrating, to all but the most determined doubters, its octahedral stereochemistry. More recently, the absolute configuration of one of the optical isomers of [Co(en)$_3$]$^{3+}$ was determined (see Panel on p. 1125).

Another N-donor ligand, which forms extremely stable complexes, is the NO$_2^-$ ion: its best-known complex is the orange “sodium cobaltinitrite”, Na$_3$[Co(NO$_2$)$_6$], aqueous solutions of which were used for the quantitative precipitation of K$^+$ as K$_3$[Co(NO$_2$)$_6$] in classical analysis. Treatment of this with fluorine yields

---

$^1$ The observation by B. M. Tassaert in 1798 that solutions of cobalt(II) chloride in aqueous ammonia gradually turn brown in air, and then wine-red on being boiled, is generally accepted as the first preparation of a cobalt(III) complex. It was realized later that more than one complex was involved and that, by varying the relative concentrations of ammonia and chloride ion, the complexes CoCl$_3$ xNH$_3$ (x = 6, 5 and 4) could be separated.

$^2$ So deep-seated at that time was the conviction that optical activity could arise only from carbon atoms that it was argued that the ethylenediamine must be responsible, even though it is itself optically inactive. The opposition was only finally assuaged by Werner’s subsequent resolution of an entirely inorganic material (p. 913).
Electron Transfer (Redox) Reactions

Two mechanisms exist for the transfer of charge from one species to another:

1. Outer-sphere. Here, electron transfer from one reactant to the other is effected without changing the coordination sphere of either. This is likely to be the case if both reactants are coordinatively saturated and can safely be assumed to be so if the rate of the redox process is faster than the rates observed for substitution (ligand transfer) reactions of the species in question. A good example is the reaction:

\[
[\text{Fe}^{II}(\text{CN})_6]^{2-} + [\text{I}^{IV}\text{Cl}_6]^{2-} \rightleftharpoons [\text{Fe}^{III}(\text{CN})_6]^{3-} + [\text{I}^{III}\text{Cl}_6]^{3-}
\]

The observed rate law for this type of reaction is usually first order in each reactant. Extensive theoretical treatments have been performed, most notably by R. A. Marcus and N. S. Hush, details of which can be found in more specialized sources.\(^{(14)}\)

2. Inner-sphere. Here, the two reactants first form a bridged complex (precursor); intramolecular electron transfer then yields the successor which in turn dissociates to give the products. The first demonstration of this was provided by H. Taube. He examined the oxidation of \([\text{Cr}(\text{H}_2\text{O})_6]^{3+}\) by \([\text{CoCl}(\text{NH}_3)_5]^{2+}\) and postulated that it occurs as follows:

\[
[\text{Cr}^{III}(\text{H}_2\text{O})_6]^{2+} + [\text{Co}^{II}\text{Cl}(\text{NH}_3)_5]^{2+} \xrightarrow{\text{electron transfer}} [\text{Co}^{II}(\text{H}_2\text{O})_5\text{Cl}]^{2+} + [\text{Co}^{III}(\text{NH}_3)_5]^{3+}
\]

The superb elegance of this demonstration lies in the choice of reactants which permits no alternative mechanism. \(\text{Cr}^{II}\) (d\(^4\)) and \(\text{Co}^{II}\) (d\(^7\)) species are known to be substitutionally labile whereas \(\text{Cr}^{III}\) (d\(^3\)) and \(\text{Co}^{III}\) (low-spin d\(^6\)) are substitutionally inert. Only if electron transfer is preceded by the formation of a bridged intermediate can the inert cobalt reactant be persuaded to release a Cl\(^-\) ligand and so allow the quantitative formation of the (then inert) chromium product. Corroboration that electron transfer does not occur by an outer-sphere mechanism followed by loss of Cl\(^-\) from the chromium is provided by the fact that, if \(^{35}\text{Cl}^-\) is added to the solution, none of it finds its way into the chromium product.

Demonstration of ligand transfer is crucial to the proof that this particular reaction proceeds via an inner-sphere mechanism, and ligand transfer is indeed a usual feature of inner-sphere redox reactions, but it is not an essential feature of all such reactions. The observed rate law for inner-sphere, as for outer-sphere, reactions is commonly first order in each reactant but this does not indicate which step is rate-determining. Again, details should be obtained from more extensive accounts.\(^{(14)}\)

For their work in this field, Taube and Marcus were awarded Nobel Prizes for Chemistry in 1983 and 1992 respectively.

K\(_3\)[CoF\(_6\)], whose anion is notable not only as the only hexahalogeno complex of cobalt(III) but also for being high-spin and hence paramagnetic with a magnetic moment at room temperature of nearly 5.8 BM.

[Co(CN)\(_6\)]\(^{3-}\) has already been mentioned and is extremely stable, being inert to alkalis and, like [Fe(CN)\(_6\)]\(^{4-}\), which likewise involves the \(t_2^g\) configuration, it is reportedly nontoxic.

Complexes of cobalt(III) with \(O\)-donor ligands are generally less stable than those with \(N\)-donors although the dark-green [Co(acac)\(_3\)] and M\(_2^+\)[Co-(C\(_2\)O\(_4\))\(_3\)] complexes, formed from the chelating ligands acetylacetonate and oxalate, are stable. Other carboxylato complexes such as those of
Determination of Absolute Configuration

Because they rotate the plane of polarized light in opposite directions (p. 919) it is a relatively simple matter to distinguish an optical isomer from its mirror image. But to establish their absolute configurations is a problem which for long defeated the ingenuity of chemists. Normal X-ray diffraction techniques do not distinguish between them, but J. M. Bijvoet developed the absorption edge, or anomalous, diffraction technique which does. In this method the wavelength of the X-rays is chosen so as to correspond to an electronic transition of the central metal atom, and under these circumstances phase changes are introduced into the diffracted radiation which are different for the two isomers. An understanding of the phenomenon not only allows the isomers to be distinguished but also their configurations to be identified. Once the absolute configuration of one complex has been determined in this way, it can then be used as a standard to determine the absolute configuration of other, similar, complexes by the relatively simpler method of comparing their optical rotary dispersion (ORD) and circular dichroism (CD) curves.15

Normal measurements of optical activity are concerned with the ability of the optically active substance to rotate the plane of polarization of plane polarized light, its specific optical rotary power ($\alpha_m$) being given by

$$\alpha_m = \frac{\alpha V}{m l} \text{ rad m}^2 \text{ kg}^{-1}$$

where $\alpha$ is the observed angle of rotation, $V$ is the volume, $m$ is the mass, and $l$ is the path length.

The reason why this phenomenon occurs is that plane polarized light can be considered to be made up of left- and of right-circularly polarized components, and the nature of an optically active substance is such that, in passing through it, one component passes through greater electron density than does the other. As a result, that component is slowed down relative to the other and the two components emerge somewhat out-of-phase, i.e. the plane of polarization of the light has been rotated. If the wavelength of the polarized light is varied, and $\alpha_m$ then plotted against wavelength, the result is known as an optical rotary dispersion curve. For those wavelengths at which the substance is transparent, $\alpha_m$ is virtually constant, which is to say the ORD curve is flat. But what happens when the wavelength of the light is such that it is absorbed by the substance in question?

In absorbing light the molecules of a substance undergo electronic excitations which involve displacement of electron charge. Because of their differing routes through the molecules, the two circularly polarized components of the light produce these excitations to different extents and are consequently absorbed to different extents. The difference in extinction coefficients, $\epsilon_{\text{left}} - \epsilon_{\text{right}}$, can be measured and is known as the circular dichroism. If the CD is plotted against wavelength it is therefore zero at wavelengths where there is no absorption but passes through a maximum, or a minimum, where absorption occurs. Accompanying these changes in CD it is found that the ORD curve is like a first derivative, passing through zero at the absorption maximum (Fig. A). Such a change in sign of $\alpha_m$ highlights the importance of quoting the wavelength of the light used when classifying optical isomers as (+) or (−), since the classification could be reversed by simply using light of a different wavelength.‡

**Figure A** Diagrammatic representation of the Cotton effect (actually “positive” Cotton effect. The “negative” effect occurs when the CD curve shows a minimum and the ORD curve is the reverse of the above).

Panel continues

‡The situation is perhaps not quite so bad as is implied here, since single measurements of $\alpha_m$ are usually made at the sodium D line, 589.6 nm. Nevertheless, it is clearly better to state the wavelength than to assume that this will be understood.

The behaviours of CD and ORD curves in the vicinity of an absorption band are collectively known as the Cotton effect after the French physicist A. Cotton who discovered them in 1895. Their importance in the present context is that molecules with the same absolute configuration will exhibit the same Cotton effect for the same d-d absorption and, if the configuration of one compound is known, that of closely similar ones can be established by comparison.

The optical isomer of \([\text{Co(en)}_3]^3+\) referred to in the main text is the (+)N~D isomer, which has a left-handed (laevo) screw axis as shown in Fig. Ba, and according to the convention recommended by IUPAC is given the symbol \(\Lambda\). This is in contrast to its mirror image (Fig. Bb) which has a right-handed (dextro) screw axis and is given the symbol \(\Delta\).

**Figure B** The absolute configuration of the optical isomers of a metal tris-chelates complex such as \([\text{Co(en)}_3]^3+\). (a) \(\Lambda\) configuration and (b) \(\Delta\) configuration.

The acetate are, however, less stable but are involved in the catalysis of a number of oxidation reactions by \(\text{Co}^{II}\) carboxylates.

A noticeable difference between the chemistries of complexes of chromium(III) and cobalt(III) is the smaller susceptibility of the latter to hydrolysis, though limited hydrolysis, leading to polynuclear cobaltammines with bridging \(\text{OH}^-\) groups, is well known. Other commonly occurring bridging groups are \(\text{NH}_2\), \(\text{NH}_2^\text{II}\) and \(\text{NO}_2^-\), and singly, doubly and triply bridged species are known such as

the bright-blue \([\text{Co}^\text{II}-\text{OH}-\text{Co}^\text{II}-\text{NH}_2-\text{Co}^\text{II}-\text{NH}_3]_5^5+,\)

\(\text{garnet-red} \quad [\text{NH}_3]_3\text{Co}^\text{II}-\text{OH}-\text{Co}^\text{II}-\text{Co}^\text{II}-\text{NH}_3]_4^4+,\)

and \(\text{red} \quad [\text{NH}_3]_3\text{Co}^\text{II}-\text{OH}-\text{Co}^\text{II}-\text{NH}_3]_3^3+\).

But probably the most interesting of the polynuclear complexes are those containing -O-O-bridges (see also p. 616).

In the preparation of cobalt(III) hexaammine salts by the aerial oxidation of cobalt(II) in aqueous ammonia it is possible, in the absence of a catalyst, to isolate a brown intermediate, \([\text{Co}^\text{II}-\text{O}_2-\text{Co}^\text{II}-\text{NH}_3]_5^4+\). This is moderately stable in aqueous ammonia and in the solid, but decomposes readily in acid solutions to \(\text{Co}^{III}\) and \(\text{O}_2\), while oxidizing agents such as \((\text{S}_2\text{O}_8)^2-\) convert it to the green, paramagnetic \([\text{Co}^\text{II}-\text{O}_2-\text{Co}^\text{II}-\text{NH}_3]_3^3+(\mu_{390} \sim 1.7\text{BM})\). The formulation of the brown compound poses no problems. The 2 cobalt atoms are in the +3 oxidation state and are joined by a peroxy group, \(\text{O}_2^2-\), all of which accords with the observed diamagnetism; moreover, the stereochemistry of the central Co–O–O–Co group (Fig. 26.2a) is akin to that of \(\text{H}_2\text{O}_2\) (p. 634). The green compound is less straightforward. Werner thought that it too involved a peroxy group but in this instance bridging \(\text{Co}^{III}\) and \(\text{Co}^{IV}\) atoms.

**Figure 26.2** \(\text{O}_2\) bridges in dinuclear cobalt complexes: (a) peroxy \((\text{O}_2^2-)\) bridge, and (b) superoxo \((\text{O}_2^-)\) bridge.
This could account for the paramagnetism, but esr evidence shows that the 2 cobalt atoms are actually equivalent, and X-ray evidence shows the central Co–O–O–Co group to be planar with an O–O distance of 131 pm, which is very close to the 128 pm of the superoxide, O$_2^-$, ion. A more satisfactory formulation therefore is that of 2 Co$^{III}$ atoms joined by a superoxide bridge. Molecular orbital theory predicts that the unpaired electron is situated in a π orbital extending over all 4 atoms. If this is the case, then the π orbital is evidently concentrated very largely on the bridging oxygen atoms.

If [(NH$_3$)$_5$Co–O$_2$–Co(NH$_3$)$_5$]$^{4+}$ is treated with aqueous KOH another brown complex, [(NH$_3$)$_4$Co(μ-NH$_2$)(μ-O$_2$)Co(NH$_3$)$_4$]$^{3+}$ is obtained and, again, a 1-electron oxidation yields a green superoxo species, [(NH$_3$)$_4$Co(μ-NH$_2$)-(μ-O$_2$)Co(NH$_3$)$_4$]$^{4+}$. The sulfite of this latter is actually one component of Vortmann’s sulfite — the other is the red [(NH$_3$)$_4$Co(μ-NH$_2$)-(μ-OH)Co(NH$_3$)$_4$](SO$_4$)$_2$. They are obtained by aerial oxidation of ammoniacal solutions of cobalt(II) nitrate followed by neutralization with H$_2$SO$_4$.

Apart from the above green superoxo-bridged complexes and the blue fluoro complexes, [CoFsI$_3$] and [CoF$_3$(H$_2$O)$_3$], octahedral complexes of cobalt(III) (being low-spin) are diamagnetic. Their magnetic properties are therefore of little interest but, somewhat unusually for low-spin compounds, their electronic spectra have received a good deal of attention$^{16}$ (see Panel on p. 1128). Data for a representative sample of complexes are given in Table 26.5

Complexes of rhodium(II) are usually derived, directly or indirectly, from RhCl$_3$.3H$_2$O and those of iridium(III) from (NH$_4$)$_3$[IrCl$_6$]. All the compounds of Rh$^{III}$ and Ir$^{III}$ are diamagnetic and low-spin, the vast majority of them being octahedral with the $t_{2g}$ configuration. Their electronic spectra can be interpreted in the same way as the spectra of Co$^{III}$ complexes, though the second d–d band, especially in the case of Ir$^{III}$, is frequently obscured by charge-transfer absorption. The d–d absorptions at the blue end of the visible region are responsible for the yellow to red colours which characterize Rh$^{III}$ complexes.

Similarity with cobalt is also apparent in the affinity of Rh$^{III}$ and Ir$^{III}$ for ammonia and amines. The kinetic inertness of the ammines of Rh$^{III}$ has led to the use of several of them in studies of the trans effect (p. 1163) in octahedral complexes, while the ammines of Ir$^{III}$ are so stable as to withstand boiling in aqueous alkali. Stable complexes such as [M(C$_2$O$_4$)$_3$]$^{3-}$, [M(acac)$_3$] and [M(CN)$_6$]$^{3-}$ are formed by all three metals. Force constants obtained from the infrared spectra of the hexacyano complexes indicate that the M–C bond strength increases in the order Co < Rh < Ir. Like cobalt, rhodium too forms bridged superoxides such as the blue, paramagnetic, [Cl(py)$_4$Rh–O$_2$–Rh(py)$_4$Cl]$^{5+}$ produced by aerial oxidation of aqueous ethanolic solutions of RhCl$_3$ and pyridine.$^{17}$ In fact it seems likely that many of the species produced by oxidation of aqueous solutions of Rh$^{III}$ and presumed to contain the metal in higher oxidation states, are actually superoxides of Rh$^{III}$.$^{18}$

---

Electronic Spectra of Octahedral Low-spin Complexes of Co(II)

It is possible to observe spin-allowed, d–d bands in the visible region of the spectra of low-spin cobalt(III) complexes because of the small value of $10D_q$, $\Delta$, which is required to induce spin-pairing in the cobalt(III) ion. This means that the low-spin configuration occurs in complexes with ligands which do not cause the low-energy charge transfer bands which so often dominate the spectra of low-spin complexes.

In practice two bands are generally observed and are assigned to the transitions: $v_1 = {}^1T_{1g} \leftarrow {}^1A_{1g}$ and $v_2 = {}^1T_{2g} \leftarrow {}^1A_{1g}$ (see Fig. A)

![Figure A](image)

These transitions correspond to the electronic promotion $t_{2g}^5 \rightarrow t_{2g}^4e_g^1$ with the promoted electron maintaining its spin unaltered. The orbital multiplicity of the $t_{2g}^5e_g^1$ configuration is 6 and so corresponds to two orbital triplet terms ${}^1T_{1g}$ and ${}^1T_{2g}$. If, on the other hand, the promoted electron changes its spin, the orbital multiplicity is again 6 but the two $T$ terms are now spin triplets, $^3T_{1g}$ and $^3T_{2g}$. A weak band attributable to the spin-forbidden $^3T_{1g} \leftarrow {}^1A_{1g}$ transition is indeed observed in some cases in the region of 11000–14000 cm$^{-1}$.

Data for some typical complexes are given in Table 26.5. The assignments are made, producing values of the inter-electronic repulsion parameter $B$ as well as of the crystal-field splitting, $10D_q$.

The colours of cis and trans isomers of complexes [CoL$_4$X$_2$] or [Co(L-L)$_2$X$_2$] frequently differ and, although simple observation of colour will not alone suffice to establish a cis or trans geometry, an examination of the electronic spectra does have diagnostic value. Calculations of the effect of low-symmetry components in the crystal field show that the trans isomer will split the excited terms appreciably more than the cis, and the effect is most marked for ${}^1T_{1g}$, the lowest of the excited terms. In practice, if L-L and X are sufficiently far apart in the spectrochemical series (e.g. L-L = en and X = F which has been thoroughly examined), the $v_1$ band splits completely, giving rise to three separate bands for the trans complex whereas the cis merely shows slight asymmetry in the lower energy band. Furthermore, because (like tetrahedral complexes) a cis isomer lacks a centre of symmetry, its spectrum is more intense than that of the centrosymmetric trans isomer.

It is relevant to note at this point that, because the metal ions are isoelectronic, the spectra of low-spin Fe(II) complexes might be expected to be similar to those of low-spin Co(III). However, Fe(II) requires a much stronger crystal field to effect spin-pairing and the ligands which provide such a field also give rise to low-energy charge-transfer bands which almost always obscure the d–d bands. Nevertheless, the spectrum of the pale-yellow [Fe(CN)$_6$]$^{3-}$ shows a shoulder at 31 000 cm$^{-1}$ on the side of a charge transfer absorption and this is attributed to the ${}^1T_{1g} \leftarrow {}^1A_{1g}$ transition.
Despite the above similarities, many differences between the members of this triad are also to be noted. Reduction of a trivalent compound, which yields a divalent compound in the case of cobalt, rarely does so for the heavier elements where the metal, univalent compounds, or $M^{III}$ hydrido complexes are the more usual products. Rhodium forms the quite stable, yellow $[\text{Rh(H}_2\text{O)}_6]^{3+}$ ion when hydrous Rh$_2$O$_3$ is dissolved in mineral acid, and it occurs in the solid state in salts such as the perchlorate, sulfate and alums. $[\text{Ir(H}_2\text{O)}_6]^{3+}$ is less readily obtained but has been shown to occur in solutions of $L^{III}$ in conc HClO$_4$.

There is also clear evidence of a change from predominantly class-a to class-b metal characteristics (p. 909) in passing down this group. Whereas cobalt(II) forms few complexes with the heavier donor atoms of Groups 15 and 16, rhodium(III), and more especially indium (II), coordinate readily with $P-$, $As-$, and $S-$ donor ligands. Compounds with $Se-$ and even $Te-$ are also known. Thus infrared, X-ray and $^{14}$N nmr studies show that, in complexes such as $[\text{Co(NH}_3)_4(\text{NCS})_2]^+$, the NCS$^-$ acts as an N-donor ligand, whereas in $[\text{M(SCN)}_6]^{3-}$ (M = Rh, Ir) it is an S-donor. Likewise in the hexahalogeno complex anions, $[\text{MX}_6]^{3-}$, cobalt forms only that with fluoride, whereas rhodium forms them with all the halides except iodide, and iridium forms them with all except fluoride.

Besides the thiocyanates, just mentioned, other S-donor complexes which are of interest are the dialkyl sulfides, $[\text{MC}_2(\text{SR}_2)_3]$, produced by the action of SR$_2$ on ethanolic RhCl$_3$ or on $[\text{IrCl}_6]^{3-}$. Phosphorus and arsenic compounds are obtained in a similar fashion, and the best known are the yellow to orange complexes, $[\text{ML}_3\text{X}_3]$ (M = Rh, Ir; X = Cl, Br, I; L = trialkyl or triaryl phosphine or arsine). These compounds may exist as either mer or fac isomers, and these are normally distinguished by their proton nmr spectra (a distinction previously made by the measurement of dipole moments). An especially interesting feature of their chemistry is the ease with which they afford hydride and carbonyl derivatives. For instance, the colourless, air-stable $[\text{RhH(NH}_3)_4]\text{SO}_4$ is produced by the action of Zn powder on ammoniacal RhCl$_3$ in the presence of $(\text{NH}_4)_2\text{SO}_4$:

$$\text{Zn} + [\text{RhCl(NH}_3)_4]\text{Cl}_2 \rightarrow [\text{RhH(NH}_3)_4]\text{SO}_4$$

Ternary hydrides of Rh and Ir containing the octahedral $[\text{MH}_6]^{3-}$ anions have been prepared by the reaction of LiH and the metal under a high pressure of H$_2$. It is however unusual for hydrides of metals in such a high formal oxidation state as +3 to be stable in the absence of $\pi$-acceptor ligands and, indeed, in the presence of $\pi$-acceptor ligands such as tertiary phosphines and arsines, the stability of rhodium(III) hydrides is enhanced. Thus H$_3$PO$_2$ reduces $[\text{RhCl}_3\text{L}_3]$ to either $[\text{RhHCl}_2\text{L}_3]$ or $[\text{Rh}_2\text{Cl}_3\text{L}_3]$, depending on L; and the action of H$_2$ on $[\text{Rh}_{2}\text{P(Ph}_3)_3\text{X}]$ (X = Cl, Br, I) yields $[\text{RhH}_2\text{P(Ph}_3)_3\text{X}]$ which is, formally at least, an oxidation by molecular hydrogen. However, it is iridium(III) that forms more hydrido-phosphine and hydrido-arsine complexes than any other platinum metal. Using NaBH$_4$, LiAlH$_4$, EtOH or even SnCl$_2$ + H$^+$ to provide the hydride ligand, complexes of the type $[\text{MH}_n\text{L}_3\text{X}_3-n]$ can be formed for very many of the permutations which are possible from L = trialkyl or triaryl phosphine or arsine; X = Cl, Br or I. Many polynuclear hydride complexes are also known.

**Oxidation state II (d$^7$)**

There is a very marked contrast in this oxidation state between cobalt on the one hand, and the two heavier members of the group on the other. For cobalt it is one of the two most stable oxidation states, whereas for the others it is of only minor importance.

---

Many early reports of Rh$^{II}$ and Ir$^{II}$ complexes have not been verified and in some cases may have involved M$^{III}$ hydrides. Monomeric compounds require stabilization by ligands such as phosphines or C$_6$C$_15$-. Thus, the action of LiCsC$_15$ on [L$_2$M$^{-}$C$_1$-ML$_2$], where L$_2$ = [P(OPh)$_3$], cyclooctene or cycloocta-1,5-diene, affords trans square planar products of the type [M$^I$(η$^1$-C$_6$C$_15$)$_2$(L$_2$)]$^-$, oxidation of which yield monomeric paramagnetic compounds such as [M$^I$(η$^1$-C$_6$C$_15$)$_2$(L$_2$)]$^-$ and, in the case of iridium, square planar [Ir$^II$(η$^1$-C$_6$C$_15$)$_4$]$^{2-}$ isolated as its (NBu$_4$)$^+$ salt.($^{22}$) Rhodium($^{II}$) is somewhat more common than iridium($^{II}$). Paramagnetic, trans square planar phosphines [RhCl$_2$L$_2$] and the alkyl (RhR$_2$(tht)$_2$), (R = 2,4,6-Pr$_3$C$_6$H$_2$; tht = tetrahydrothiophene) have been characterized.($^{23}$) Also, depending on temperature and relative concentrations, the reaction of Rh(NO)$_2$Cl$_2$(PPh$_3$)$_2$ and Na(S$_2$CNR$_2$)$_2$ in benzene yields either Rh(S$_2$CNR$_2$)$_2$ or Rh(S$_2$CNR$_2$)(PPh$_3$), characterized by spectroscopic methods as square planar and square pyramidal respectively.($^{24}$)

Rhodium($^{II}$), however, is most familiar in a series of green dimeric diamagnetic compounds.($^{25}$) If hydrous Rh$_2$O$_3$, or better still RhCl$_3$.3H$_2$O and sodium carboxylate, is refluxed with the appropriate acid and alcohol, green or blue solvated [Rh(O$_2$CR)$_2$(PPh$_3$)$_2$] is formed. Compounds of this type are generally air-stable and have the same bridged structure as the carboxylates of Cr$^{II}$, Mo$^{II}$ and Cu$^{II}$; in the case of the acetate this involves a Rh–Rh distance of 239 pm which is consistent with a Rh–Rh bond. If rhodium acetate is treated with a strong acid such as HBF$_4$, whose anion has little tendency to coordinate, green solutions apparently containing the diamagnetic Rh$_2$$^{4+}$ ion are obtained but no solid salt of this has been isolated. Why no comparable Ir$^{II}$ carboxylates, and very few other dimeric species stabilized by metal–metal bonding, have yet been prepared is not clear.

By contrast, Co$^{II}$ carboxylates such as the red acetate, Co(O$_2$CMe)$_2$.4H$_2$O, are monomeric and in some cases the carboxylate ligands are undentate. The acetate is employed in the production of catalysts used in certain organic oxidations, and also as a drying agent in oil-based paints and varnishes. Cobalt($^{II}$) gives rise to simple salts with all the common anions and they are readily obtained as hydrates from aqueous solutions. The parent hydroxide, Co(OH)$_2$, can be precipitated from the aqueous solutions by the addition of alkali and is somewhat amphoteric, not only dissolving in acid but also redissolving in excess of conc alkali, in which case it gives a deep-blue solution containing [Co(OH)$_4$]$^{2-}$ ions. It is obtainable in both blue and pink varieties: the former is precipitated by slow addition of alkali at 0°C, but it is unstable and, in the absence of air, becomes pink on warming (cf. p. 1131).

Complexes of cobalt($^{II}$) are less numerous than those of cobalt($^{III}$) but, lacking any configuration comparable in stability with the $t^5_{2e}$ of Co$^{III}$, they show a greater diversity of types and are more labile. The redox properties have already been referred to and the possibility of oxidation must always be considered when preparing Co$^{II}$ complexes. However, providing solutions are not alkaline and the ligands not too high in the spectrochemical series, a large number of complexes can be isolated without special precautions. The most common type is high-spin octahedral, though spin-pairing can be achieved by ligands such as CN$^-$ (p. 1133) which also favour the higher oxidation state. Appropriate choice of ligands can however lead to high-spin–low-spin equilibria as in [Co(terpy)$_2$]X$_2$.nH$_2$O and some 5- and 6-coordinated complexes of Schiff bases and pyridines.($^{26}$)

Many of the hydrated salts and their aqueous solutions contain the octahedral, pink

†The Crystal Field Stabilization Energy (CFSE) is the additional stability which accrues to an ion in a complex, as compared to the free ion, because its d orbitals are split. In an octahedral complex a $t_2$ electron increases the stability by $2/5Δ_o$ and an $e_g$ electron decreases it by $3/5Δ_o$. In a tetrahedral complex the orbital splitting is reversed and an $e_g$ electron therefore increases the stability by $3/5Δ_t$ whereas a $t_2$ electron decreases it by $2/5Δ_t$.

The tetrameric structure of $[\text{Co(acac)}_2]_4$. $\text{Co(H}_2\text{O)}_6]^{2+}$, and bidentate $N$-donor ligands such as en, bipy and phen form octahedral cationic complexes $[\text{Co(L-L)}_3]^{3+}$, which are much more stable to oxidation than is the hexaammine $[\text{Co(NH}_3)_6]^{2-}$. Acac yields the orange $[\text{Co(acac)}_2(\text{H}_2\text{O})_2]$ which has the trans octahedral structure and can be dehydrated to $[\text{Co(acac)}_2]$ which attains octahedral coordination by forming the tetrameric species shown in Fig. 26.3. This is comparable with the trimeric $[\text{Ni(acac)}_2]_3$ (p. 1157), like which it shows evidence of weak ferromagnetic interactions at very low temperatures. $[\text{Co(edta)}(\text{H}_2\text{O})]^{2+}$ is ostensibly analogous to the 7-coordinate Mn$^{II}$ and Fe$^{II}$ complexes with the same stoichiometry, but in fact the cobalt is only 6-coordinate, 1 of the oxygen atoms of the edta being too far away from the cobalt (272 compared to 223 pm for the other edta donor atoms) to be considered as coordinated.

Tetrahedral complexes are also common, being formed more readily with cobalt(II) than with the cation of any other truly transitional element (i.e. excluding Zn$^{II}$). This is consistent with the CFSEs of the two stereochemistries (Table 26.6). Quantitative comparisons between the values given for CFSE(oct) and CFSE(tet) are not possible because of course the crystal field splittings, $Δ_o$ and $Δ_t$, differ. Nor is the CFSE by any means the most important factor in determining the stability of a complex. Nevertheless, where other factors are comparable, it can have a decisive effect and it is apparent that no configuration is more favourable than d$^7$ to the adoption of a tetrahedral as opposed to an octahedral stereochemistry. Thus, in aqueous solutions containing $[\text{Co(H}_2\text{O)}_6]^{2+}$ there are also present in equilibrium, small amounts of tetrahedral $[\text{Co(H}_2\text{O)}_4]^{2+}$, and in acetic acid the tetrahedral $[\text{Co(O}_2\text{CMe)}_4]^{2-}$ occurs. The anionic complexes $[\text{CoX}_4]^{2-}$ are formed with the unidentate ligands, $X = \text{Cl, Br, I, SCN and OH}$, and a whole series of complexes, $[\text{CoL}_2X_2]$ ($L = \text{ligand with group 15 donor atom; } X = \text{halide, NCS}$), has been prepared in which both stereochemistries are found. $[\text{CoCl}_2\text{py}_2]$ exists in two isomeric forms: a blue metastable variety which is monomeric and tetrahedral, and a violet, stable form which is polymeric and achieves octahedral coordination by means of chloride bridges. Ligand polarizability is an important factor determining which stereochemistry is adopted, the more polarizable ligands favouring the tetrahedral form since fewer of them are required to neutralize the metal's cationic charge. Thus, if $L = \text{py}$, replacement of $\text{Cl}^-$ by $\text{I}^-$ makes the stable form tetrahedral and if $L = \text{phosphine or arsine}$ the tetrahedral form is favoured irrespective of $X$.

The most obvious distinction between the octahedral and tetrahedral compounds is that in general the former are pink to violet in colour whereas the latter are blue, as exemplified by the well-known equilibrium:

$[\text{Co(H}_2\text{O)}_6]^{2+} + 4\text{Cl}^- \rightleftharpoons [\text{CoCl}_4]^{2-} + 6\text{H}_2\text{O}$

pink blue

This is not an infallible distinction (as the blue but octahedral $\text{CoCl}_2$ demonstrates) but is a useful...
Electronic Spectra and Magnetic Properties of High-spin Octahedral and Tetrahedral Complexes of Cobalt(II)

Cobalt(II) is the only common $d^7$ ion and because of its stereochemical diversity its spectra have been widely studied. In a cubic field, three spin-allowed transitions are anticipated because of the splitting of the free-ion, ground $^4F$ term, and the accompanying $^4P$ term. In the octahedral case the splitting is the same as for the octahedral $d^2$ ion and the spectra can therefore be interpreted in a semi-quantitative manner using the same energy level diagram as was used for V$^{3+}$ (Fig. 22.9, p. 997). In the present case the spectra usually consist of a band in the near infrared, which may be assigned as $v_1 = ^4T_{2g}(F) \leftrightarrow ^4T_{1g}(F)$, and another in the visible, often with a shoulder on the low energy side. Since the transition $^4A_{2g}(F) \leftrightarrow ^4T_{1g}(F)$ is essentially a 2-electron transition from $t^2_{2g}$ to $t^2_{2g}$ it is expected to be weak, and the usual assignment is

$$v_2(\text{shoulder}) = ^4A_{2g}(F) \leftrightarrow ^4T_{1g}(F)$$

$$v_1 = ^4T_{1g}(P) \leftrightarrow ^4T_{1g}(F)$$

Indeed, in some cases it is probable that $v_2$ is not observed at all, but that the fine structure arises from term splitting due to spin-orbit coupling or to distortions from regular octahedral symmetry.

In tetrahedral fields the splitting of the free ion ground term is the reverse of that in octahedral fields so that, for $d^7$ ions in tetrahedral fields $^4A_{2g}(F)$ lies lowest but three spin-allowed bands are still anticipated. In fact, the observed spectra usually consist of a broad, intense band in the visible region (responsible for the colour and often about 10 times as intense as in octahedral compounds) with a weaker one in the infrared. The only satisfactory interpretation is to assign these, respectively, as, $v_3 = ^4T_{1g}(P) \leftrightarrow ^4A_{2g}(F)$ and $v_2 = ^4T_{1g}(F) \leftrightarrow ^4A_{2g}(F)$ in which case $v_1 = ^4T_{2g}(F) \leftrightarrow ^4A_{2g}(F)$ should be in the region 3000–5000 cm$^{-1}$. Examination of this part of the infrared has sometimes indicated the presence of a band, although overlying vibrational bands make interpretation difficult.

Table 26.7 gives data for a number of octahedral and tetrahedral complexes, the values of $10Dq$ and $B$ having been derived by analysis of the spectra.$^{27}$ It is clear from these data that the “anomalous” blue colour of octahedral CoCl$_2$ arises because 6 Cl$^-$ ions generate such a weak crystal field that the main band in its spectrum is at an unusually low energy, extending into the red region (hence giving a blue colour) rather than the green-blue region (which would give a red colour) more commonly observed for octahedral Co$^{3+}$ compounds.

Magnetic properties provide a complementary means of distinguishing stereochemistry. The $T^2$ ground term of the octahedral ion is expected to give rise to a temperature-dependent orbital contribution to the magnetic moment whereas the $A^2$ ground term of the tetrahedral ion is not. As a matter of fact, in a tetrahedral field the excited $^4T_{2g}(F)$ term is “mixed into” the ground $^4A_{2g}$ term because of spin–orbit coupling and tetrahedral complexes of Co$^{3+}$ are expected to have magnetic moments given by $\mu_e = \mu_{\text{spin-only}}(1 - 4x/10Dq)$, where $\lambda = -170$ cm$^{-1}$ and $\mu_{\text{spin-only}} = 3.87$ BM.

Thus the magnetic moments of tetrahedral complexes lie in the range 4.4–4.8 BM, whereas those of octahedral complexes are around 4.8–5.2 BM at room temperature, falling off appreciably as the temperature is reduced.

empirical guide whose reliability is improved by a more careful analysis of the electronic spectra$^{27}$ (see Panel). Data for some octahedral and tetrahedral complexes are given in Table 26.7.

Square planar complexes are also well authenticated if not particularly numerous and include [Co(phthalocyanine)] and [Co(CN)$_3$]$^-$ as well as [Co(salen)] and complexes with other Schiff bases. These are invariably low-spin with magnetic moments at room temperature in the range 2.1–2.9 BM, indicating 1 unpaired electron. They are primarily of interest because of their oxygen-carrying properties, discussed already in Chapter 14 where numerous reviews on the subject are cited. The uptake of dioxygen, which bonds in the bent configuration,

$$\text{Co} - \overset{\text{O}}{\text{O}} - \overset{\text{O}}{\text{O}}$$

is accompanied by the attachment of a solvent molecule trans to the O$_2$ and the retention of the single unpaired electron. There is fairly general agreement, based on esr evidence, that electron transfer from metal to O$_2$ occurs just as in the bridged complexes referred to on

$^{27}$ pp. 480-504 of ref. 16.

p. 1126, producing a situation close to the extreme represented by low-spin Co\textsuperscript{III} attached to a superoxide ion, O\textsubscript{2}-. (The opposite extreme, represented by Co\textsuperscript{II}–O\textsubscript{2}, implies that the unpaired electron resides on the metal with the dioxygen being rendered diamagnetic by the loss of the degeneracy of its \(\pi^*\) orbitals with consequent spin pairing.) However, the precise extent of the electron transfer is probably determined by the nature of the ligand \textit{trans} to the O\textsubscript{2}.

The difficulty of assigning a formal oxidation state is more acutely seen in the case of 5-coordinate NO adducts of the type \([\text{Co(NO)}(\text{salen})]\). These are effectively diamagnetic and so have no unpaired electrons. They may therefore be formulated either as Co\textsuperscript{III}–NO\textsuperscript{−} or Co\textsuperscript{I}–NO\textsuperscript{+}. The infrared absorptions ascribed to the N–O stretch lie in the range 1624–1724 \(\text{cm}^{-1}\), which is at the lower end of the range said to be characteristic of NO\textsuperscript{+}. But, as in all such cases which are really concerned with the differing polarities of covalent bonds, such formalism should not be taken literally.

Other 5-coordinate Co\textsuperscript{II} compounds which have been characterized include \([\text{CoBr}_3(\text{N}(\text{C}_2\text{H}_4\text{NMe}_2)_3)]^+\), which is high-spin with 3 unpaired electrons and is trigonal bipyramidal (imposed by the "tripod" ligand), and \([\text{Co(CN)}_5]^3-\), which is low-spin with 1 unpaired electron and is square pyramidal. The latter complex is isolated from solutions of Co(CN)\textsubscript{2} and KCN as the yellow \([\text{NEt}_2\text{Pr}]^+\) salt, an extremely oxygen-sensitive and hygroscopic material. A further difficulty which hindered its isolation is its tendency to dimerize to the more familiar deep-violet, \([\text{CN}_5\text{Co}–\text{Co(CN)}_5]^6-\). The absence of a simple hexacyano complex is significant as it seems to be generally the case that ligands such as CN\textsuperscript{−}, which are expected to induce spin-pairing, favour a coordination number for Co\textsuperscript{II} of 4 or 5 rather than 6; the planar \([\text{Co(diars)}_2]\)\textsubscript{(ClO}_4\) is a further illustration of this. Presumably the Jahn–Teller distortion, which is anticipated for the low-spin \(t^2_g e^1_g\) configuration is largely responsible.

Oxidation state I (d\textsuperscript{8})

Oxidation states lower than +2 normally require the stabilizing effect of \(\pi\)-acceptor ligands and some of these are appropriately considered along with organometallic compounds in Section 26.3.5. Exceptions are the square pyramidal anion of the black, Mg\textsubscript{2}[CoH\textsubscript{3}] (obtained by prolonged heating of the powdered metals under high
pressure of H₂) and the linear anion of the garnet red Cs₂K₂[CoO₂]⁺(27a) (see p. 1166). However, although +1 is not a common oxidation state for cobalt, it is one of the two most common states for both rhodium and iridium and as such merits separate consideration.

Simple ligand-field arguments, which will be elaborated when M⁺ ions of the Ni, Pd, Pt triad are discussed on p. 1157, indicate that the d⁸ configuration favours a 4-coordinate, square-planar stereochemistry. In the present group, however, the configuration is associated with a lower oxidation state and the requirements of the 18-electron rule,¹ which favour 5-coordination, are also to be considered. The upshot is that most Co⁺ complexes are 5-coordinate, like [Co(CNR)₅]⁺, and square-planar Co⁺ is apparently unknown. On the other hand, complexes of Rh⁺ and Ir⁺ are predominantly square planar, although 5-coordination does also occur.

These complexes are usually prepared by the reduction of compounds such as RhCl₃-3H₂O and K₂IrCl₆ in the presence of the desired ligand. It is often unnecessary to use a specific reductant, the ligand itself or alcoholic solvent being adequate, and not infrequently leading to the presence of CO or H in the product. A considerable proportion of the complexes of Rh⁺ and Ir⁺ are phosphines and of these, two in particular demand attention. They are Wilkinson’s catalyst, [RhCl(PPh₃)₃], and Vaska’s compound, trans-[IrCl(CO)(PPh₃)₂], both essentially square planar.

Wilkinson’s catalyst, [RhCl(PPh₃)₃]. This red-violet compound(28), which is readily obtained by refluxing ethanolic RhCl₃·3H₂O with an excess of PPh₃, was discovered(29) in 1965. It undergoes a variety of reactions, most of which involve either replacement of a phosphine ligand (e.g. with CO, CS, C₂H₄, O₂ giving trans products) or oxidative addition (e.g. with H₂, MeI) to form Rh⁺⁺, but its importance arises from its effectiveness as a catalyst(30) for highly selective hydrogenations of complicated organic molecules which are of great importance in the pharmaceutical industry. Its use allowed, for the first time, rapid homogeneous hydrogenation at ambient temperatures and pressures:

\[
\begin{align*}
\text{C} &= \text{C} \\
\text{C} &= \text{C} \\
\text{H} &= \text{H} \\
\text{Catalyst} &\rightarrow \\
\text{H} &= \text{H}
\end{align*}
\]

The precise mechanism is complicated and has been the subject of much speculation and controversy, but Fig. 26.4 shows a simplified but reasonable scheme. The essential steps in this are the oxidative addition of H₂ (if the hydrogen atoms are regarded as “hydridic”, i.e. as H⁻, the metal’s oxidation state increases from +1 to +3); the formation of an alkene complex; alkene insertion and, finally, the reductive elimination of the alkane (i.e. the metal’s oxidation state reverting to +1). The rhodium catalyst is able to fulfil its role because the metal is capable of changing its coordination number (loss of phosphine from the dihydro complex being encouraged by the large size of the ligand) and it possesses oxidation states (+1 and +3) which differ by 2 and are of comparable stability.

The discovery of the catalytic properties of [RhCl(PPh₃)₃] naturally brought about a widespread search for other rhodium phosphines with catalytic activity. One of those which was found, also in Wilkinson’s laboratory, was trans-[Rh(CO)H(PPh₃)₃] which can conveniently be

¹ The filling-up of the bonding MOs of the molecule may be regarded, more simply, as the filling of the outer 9 orbitals of the metal ion with its own d electrons plus a pair of σ electrons from each ligand. A 4-coordinate d⁸ ion is thus a “16-electron” species and is “ coordinatively unsaturated”. Saturation in this sense requires the addition of 10 electrons, i.e. 5 ligands, to the metal ion. By contrast rhodium(III) is a d⁶ ion and so can expand its coordination sphere to accommodate 6 ligands with important consequences in catalysis which will be seen below.

²²b The paramagnetic impurity which invariably accompanies Wilkinson’s catalyst has proved difficult to identify. It is probably the air-stable, green, trans-[RhCl(CO)(PPh₃)₂], see K. R. Dunbar and S. C. Haefner, Inorg. Chem. 31, 3676-9 (1992).

Figure 26.4 The catalytic cycle for the hydrogenation of an alkene, catalysed by \([\text{RhCl}(\text{PPh}_3)_3]\) in benzene; possible coordination of solvent molecules has been ignored and the ligand \text{PPh}_3 has been represented as \text{P} throughout, for clarity.

dealt with here. It was found that, for steric reasons, it selectively catalyses the hydrogenation of alk-1-enes (i.e. terminal olefins) rather than alk-2-enes and it has been used in the hydroformylation of alkenes, (i.e. the addition of H and the formyl group, \text{CHO}) also known as the OXO process because it introduces oxygen into the hydrocarbon. This is a process of enormous industrial importance, being used to convert alk-1-enes into aldehydes which can then be converted to alcohols for the production of polyvinylchloride (PVC) and polyalkenes and, in the case of the long-chain alcohols, in the production of detergents:

\[
\text{RCH=CH}_2 + \text{H}_2 + \text{CO} \xrightarrow{\text{catalyst}} \text{RCH}_2\text{CH}_2\text{CHO}
\]

A simplified reaction scheme is shown in Fig. 26.5. Again, the ability of rhodium to change its coordination number and oxidation state is crucial, and this catalyst has the great advantage over the conventional cobalt carbonyl catalyst that it operates efficiently at much lower temperatures and pressures and produces straight-chain as opposed to branched-chain products.

The reason for its selectivity lies in the insertion step of the cycle. In the presence of the two bulky PPh\(_3\) groups, the attachment to the metal of \(-\text{CH}_2\text{CH}_2\text{R}\) (anti-Markovnikov addition, leading to a straight chain product) is easier than the attachment of \(-\text{CH}(\text{CH}_3)\text{R}\) (Markovnikov addition, leading to a branched-chain product).

Vaska’s compound, \text{trans-[IrCl(CO)(PPh}_3)_2]}. This yellow compound can be prepared by the reaction of triphenylphosphine and IrCl\(_3\) in a solvent such as 2-methoxyethanol which acts both as reducing agent and supplier of CO. It was discovered in 1961 by L. Vaska and J. W. di Luzio\(^{31}\) and recognized as an ideal material for the study of oxidative addition reactions, since its products are generally stable and readily characterized. It is certainly the most thoroughly investigated compound of Ir\(^{31}\). It forms octahedral Ir\(^{11}\) complexes in oxidative addition reactions with \text{H}_2, \text{Cl}_2, \text{HX}, \text{MeI} and \text{RCO}_2\text{H}, and \text{^1H nmr} shows that in all cases the phosphine ligands are \text{trans} to each other. The 4 remaining ligands (Cl, Cl, Cl, Cl).

Figure 26.5 The catalytic cycle for the hydroformylation of an alkene catalysed by trans-\([\text{RhH(CO)(PPh}_3]_2\). The tertiary phosphine ligand has been represented as P throughout.

CO and two components of the reactant) therefore lie in a plane and 3 isomers are possible:

There is apparently no simple way of predicting which of these will be formed and each case must be examined individually. The situation is further complicated by the fact that, when the Cl of Vaska’s compound is replaced by H, Me or Ph, addition of H₂ gives products in which the phosphines are now cis. Various theoretical models have been suggested to account for this.\(^{(32)}\)

Addition reactions with ligands such as CO and SO₂ (the addition of which as an uncharged ligand is unusual) differ in that no oxidation occurs and 5-coordinate 18-electron Ir\(^{IV}\) products are formed.

The facile absorption of O₂ by a solution of Vaska’s compound is accompanied by a change in colour from yellow to orange which may be reversed by flushing with N₂. This

is one of the most widely studied synthetic oxygen-carrying systems and has been discussed earlier (p. 615). The O–O distance of 130 pm in the oxygenated product (see Fig. 14.5b, p. 617) is rather close to the 128 pm of the superoxide ion, O$_2^-$, but this would imply Ir$^{II}$ which is paramagnetic whereas the compound is actually diamagnetic. The oxygenation is instead normally treated as an oxidative addition with the O$_2$ acting as a bidentate peroxy ion, O$_2^{2-}$, to give a 6-coordinate Ir$^{III}$ product. However, in view of the small “bite” of this ligand the alternative formulation in which the O$_2$ acts as a neutral unidentate ligand giving a 5-coordinate Ir$^1$ product has also been proposed.

Oxygen-carrying properties are evidently critically dependent on the precise charge distribution and steric factors within the molecule. Replacement of the Cl in Vaska’s compound with I causes loss of oxygen-carrying ability, the oxygenation being irreversible. This can be rationalized by noting that the lower electronegativity of the iodine would allow a greater electron density on the metal, thus facilitating M → O$_2$ $\pi$ donation: this increases the strength of the M–O$_2$ bond and, by placing charge in antibonding orbitals of the O$_2$, causes an increase in the O–O distance from 130 to 151 pm.

**Lower oxidation states**

Numerous complexes of Co, Rh and Ir are known in which the formal oxidation state of the metal is zero, −1, or even lower. Many of these compounds contain CO, CN$^-$ or RNC as ligands and so are more conveniently discussed under organometallic compounds (Section 26.3.5). However, other ligands such as tertiary phosphines also stabilize the lower oxidation states, as exemplified by the brown, tetrahedral, paramagnetic complex [Co$^0$(PMe$_3$)$_4$]: this is made by reducing an ethereal solution of CoCl$_2$ with Mg or Na amalgam in the presence of PMe$_3$. Further treatment of the product with Mg/thf in the presence of N$_2$ gives [Mg(thf)$_4$][Co$^{-II}$(N$_2$)(PMe$_3$)$_4$]. Similar reactions with P(OMe)$_3$ and P(OEt)$_3$ give both paramagnetic monomers [Co$^0$(P(OR)$_3$)$_4$], and diamagnetic dimers [Co$^0$_2(P(OR)$_3$)$_8$], whereas the more bulky P(OPr$^i$)$_3$ yields only the orange-red monomeric product. With an excess of sodium amalgam as reducing agent the product with this latter ligand is the white-crystalline Na[Co$^{-I}$(P(OPr$^i$)$_3$)$_5$]. In view of the ready solubility of this compound in pentane and the d$^{10}$ configuration of Co$^{-I}$ it may be that only 4 of the phosphite ligands are directly coordinated to the metal centre: one possible formulation would be

![Diagram](https://example.com/diagram.png)

With the terdentate $P$-donor ligand, MeC-(CH$_2$PPh$_2$)$_3$, (tppme) excess sodium amalgam and an atmosphere of N$_2$ yields the deep-brown [(tppme)Co–N–N–Co(tppme)] which, unusually for a dimer, is paramagnetic.$^{33}$ The N–N distance in the linear bridge is 118 pm compared with 109.8 pm in N$_2$ (p. 412).

Another technique for obtaining low oxidation states is by electrolytic reduction using cyclic voltametry. Some spectacular series can be achieved of which, perhaps, the most notable is based on [Ir$^{III}$(bipy)$_3$]$^{3+}$: this, when dissolved in MeCN, can be oxidized to [Ir$^{IV}$(bipy)$_3$]$^{4+}$ and reduced in successive 1-electron steps to give every oxidation state down to [Ir$^{-IV}$(bipy)$_3$]$^{3-}$, a total of 8 interconnected redox complexes. However, by no means all have been isolated as solid products from solution. Many other

---

Next Page
such redox series are known for these and other elements.

### 26.3.4 The biochemistry of cobalt

The wasting disease in sheep and cattle known variously as "pine" (Britain), "bush sickness" (New Zealand), "coast disease" (Australia), and "salt sick" (Florida) has been recognized since the late eighteenth century. When it was realized to be an anaemic condition it was thought to be due to iron deficiency and was therefore treated, with mixed success, by administering iron salts. Then, in the 1930s, it was found by workers in Australia and New Zealand that the efficacious principle in the iron treatment was actually an impurity (cobalt) but its role was not understood. This became more evident when vitamin B₁₂ was extracted from raw liver and shown to be responsible for the latter's well-known effectiveness in treating pernicious anaemia. It is now known that vitamin B₁₂ is a coenzyme† in a number of biochemical processes, the most important of which is the formation of erythrocytes (red blood-cells). It obviously functions extremely effectively, the human body for instance containing a mere 2–5 mg, concentrated in the liver.

The structure of the diamagnetic, cherry-red vitamin B₁₂ is shown in Fig. 26.6 and it can be seen that the coordination sphere of the cobalt has many similarities with that of iron in haem (see Fig. 25.7). In both cases the metal is coordinated to 4 nitrogen atoms of an unsaturated macrocycle (in this case part of a "corrin" ring which is less symmetrical and not so unsaturated as the porphyrin in haem) with an imidazole nitrogen in the fifth position. A major difference is apparent, however, in the sixth coordination position which, in haemoglobin, is either vacant or occupied by O₂. Here it is filled by a σ-bonded carbon, making vitamin B₁₂ the first, and so far the only, fully established naturally occurring organometallic compound. The usual methods of isolation lead to a product known as cyanocobalamin, which is the same as vitamin B₁₂ itself but with CN⁻ instead of deoxyadenosine in the sixth coordination position. This is a labile site, and other derivatives such as aquocobalamin can be prepared.

Enzymes are proteins which act as very specific catalysts in biological systems. Their activity may depend on the presence of substances, often metal complexes, of much lower molecular weight. These activators are known as "coenzymes".

---

† Enzymes are proteins which act as very specific catalysts in biological systems. Their activity may depend on the presence of substances, often metal complexes, of much lower molecular weight. These activators are known as "coenzymes".

The reductions are effected in nature by ferredoxin (p. 1102). This behaviour can be reproduced surprisingly well by simpler, model compounds. Some of the best known of these are obtained by the addition of axial groups to the square-planar complexes of CoII with Schiff bases, or substituted glyoximes (giving cobaloximes) as illustrated in Fig. 26.7. The reduced CoI species of these, along with vitamin B_{12s}, are amongst the most powerful nucleophiles known (hence, “supernucleophiles”), liberating H\textsubscript{2} from water.

Virtually all the biological processes, in which vitamin B\textsubscript{12} is active, involve substituent exchange of the type:

\[
\begin{array}{c}
\text{H} \\
\text{R} \\
\text{C} \\
\text{C} \\
\end{array} \quad \leftrightarrow \quad \begin{array}{c}
\text{R} \\
\text{H} \\
\text{C} \\
\text{C} \\
\end{array}
\]

which, significantly, does not involve solvent protons. The precise mechanism of these reactions is not settled but all involve cleavage of the Co–C bond and it is evident from the study of model systems that the lack of complete planarity of the corrin ring is an important factor in controlling this.\(^{36}\)

\section*{26.3.5 Organometallic compounds\(^{37}\)}

Many of the organometallic compounds of the elements of this group show valuable catalytic activity and, as discussed above, much of the chemistry of vitamin B\textsubscript{12} is the chemistry of the Co–C\textsubscript{\sigma} bond. Simple homoleptic alkyls and aryls of cobalt, [CoR\textsubscript{\textit{n}}], have not in fact been prepared, but this is evidently not due to thermodynamic instability of the Co–C bond. Compounds containing such bonds can be prepared in abundance, not only with (\(\sigma + \pi\))-bonding ligands such as phosphines and CO but also with non-\(\pi\)-bonding ligands such as Schiff bases and glyoximes. These latter presumably owe their existence not to electronic but rather to steric factors, the additional ligands blocking what might otherwise be energetically favourable decomposition paths.

Carbonyls (see p. 926)

Because they possess an odd number of valence electrons the elements of this group can only satisfy the 18-electron rule in their carbonyls if M–M bonds are present. In accord with this, mononuclear carbonyls are not formed. Instead \([\text{M}_2(\text{CO})_8], [\text{M}_4(\text{CO})_{12}]\) and \([\text{M}_6(\text{CO})_{16}]\) are the principal binary carbonyls of these elements. But reduction of \([\text{Co}_2(\text{CO})_8]\) with, for instance, sodium amalgam in benzene yields the monomeric and tetrahedral, 18-electron ion, \([\text{Co}(\text{CO})_4]^-\), acidification of which gives the pale yellow hydride, \([\text{HCo}(\text{CO})_4]\). Reductions employing Na metal in liquid NH\(_3\) yield the “super-reduced” \([\text{M}(\text{CO})_3]^3^-\) (M = Co, Rh, Ir) containing these elements in their lowest formal oxidation state.\(^{(38)}\)

The importance of cobalt carbonyls lies in their involvement in hydroformylation reactions discussed above. The original, and still widely used, process depends on the use of cobalt salts rather than the newer rhodium catalysts (pp. 1134–5). The mechanism of the cobalt cycle is more difficult to ascertain but it seems clear that the active agent is the hydride, \([\text{HCo}(\text{CO})_4]^-\). It is, moreover, plausible that the cycle is basically the same as that outlined in Fig. 26.5 but starting with loss of CO from \([\text{HCo}(\text{CO})_4]^-\) rather than loss of phosphine from \([\text{Rh}(\text{CO})_2(\text{PPh}_3)_3]\), so producing a comparable coordinatively unsaturated intermediate to which the alkene can attach itself. The disadvantages of the system, as already mentioned, are its lack of specificity, leading to branched-chain products, and the necessity of high temperatures (>150°C) and pressure (~200 atm). In addition the volatility of \([\text{HCo}(\text{CO})_4]\) poses recovery problems.

The dinuclear octacarbonyls are obtained by heating the metal (or in the case of iridium, IrCl\(_3\) + copper metal) under a high pressure of CO (200–300 atm). \([\text{Co}_2(\text{CO})_8]\) is by far the best known, the other two being poorly characterized; it is an air-sensitive, orange-red solid melting at 51°C. The structure, which involves two bridging carbonyl groups as shown in Fig. 26.8a, can perhaps be most easily rationalized on the basis of a “bent” Co–Co bond arising from overlap of angled metal orbitals (d\(^2\)sp\(^3\) hybrids). However, in solution this structure is in equilibrium with a second form (Fig. 26.8b) which has no bridging carbonyls and is held together solely by a Co–Co bond.

The most stable carbonyls of rhodium and iridium are respectively red and yellow solids of the form \([\text{M}_4(\text{CO})_{12}]\) which are obtained by heating MCl\(_3\) with copper metal under about 200 atm of CO. The black cobalt analogue is more simply obtained by heating \([\text{Co}_2(\text{CO})_8]\) in an inert atmosphere

\[
2[\text{Co}_2(\text{CO})_8] \xrightarrow{50^\circ\text{C}} [\text{Co}_4(\text{CO})_{12}] + 4\text{CO}
\]

The structures are shown in Fig. 26.8c and d and differ in that, whereas the Ir compound consists of a tetrahedron of metal atoms held together solely by M–M bonds, the Rh and Co compounds each incorporate 3 bridging carbonyls. A similar difference was noted in the case of the trinuclear carbonyls of Fe, Ru and Os (p. 1104) and can be explained in a similar way.\(^{(39)}\) The M\(_4\) tetrahedra of Co and Rh are small enough to be accommodated in an icosahedral array of CO ligands whereas the larger Ir\(_4\) tetrahedron forces the adoption of the less dense cube octahedral array of ligands.

Of the \([\text{M}_6(\text{CO})_{16}]\) carbonyls the very dark-brown Rh compound prepared simultaneously with and separated from \([\text{Rh}_4(\text{CO})_{12}]\) is the best known. In the solid its structure consists of an octahedral array of Rh(CO)\(_2\) units with the remaining 4 CO's bridging 4 faces of the octahedron (Fig. 26.8e). A black isomorphous, and presumably isostructural, Co analogue and an isostructural red Ir analogue are known. A second, black Ir isomer occurs which differs only in that it has 4 edge-bridging rather than face-bridging CO groups. Again rationalization is possible on the basis of the ligand polyhedral

\[^{39}\text{B. F. G. Johnson and Y. V. Roberts, Polyhedron, 12, 977–90 (1993).}\]
Figure 26.8 Molecular structures of some binary carbonyls of Co, Rh, and Ir. (a) Co$_2$(CO)$_8$ in solid state, showing the formation of a “bent” Co–Co bond. (b) Co$_2$(CO)$_8$ in solution. (c) Ir$_4$(CO)$_{12}$. (d) M$_4$(CO)$_{12}$, M = Co, Rh. (e) M$_6$(CO)$_{16}$ M = Co, Rh and Ir (for its red isomer). (f) black isomer of Ir$_6$(CO)$_{16}$.

model. In both structures the ligands occupy the 16 vertices of a tetracapped truncated tetrahedron. In one case the 4 caps are the face-bridging ligands, in the other the edge-bridging ligands. The two structures are related by a simple rotation of the M$_6$ octahedron about a C$_4$ axis.\(^{(39)}\)

Carbonyl hydrides and carbonylate anions are obtained by reducing neutral carbonyls, as mentioned above, and in addition to mononuclear metal anions, anionic species of very high nuclearity have been obtained, often by thermolysis. These are especially numerous for Rh and in certain Rh$_{13}$, Rh$_{14}$ and Rh$_{15}$ anions have structures conveniently visualized either as polyhedra encapsulating further metal atoms, or alternatively as arrays of metal atoms forming portions of hexagonal close packed or body centred cubic lattices stabilized by CO ligands. [Rh$_{13}$H$_3$(CO)$_{24}$]$^{2-}$ (Fig 26.9a) is typical.

The anionic cluster [Ir$_6$(CO)$_{15}$]$^{2-}$ is octahedral and an increasing number of Ir clusters have been reported recently though their preparations are more difficult and yields usually smaller than for rhodium. [Ir$_{14}$(CO)$_{27}$]$^-\,$ has the highest nuclearity so far and is obtained as black crystals by oxidizing [Ir$_6$(CO)$_{15}$]$^{2-}$ with ferricinium ion\(^{(40)}\) (Fig 26.9b).

The incorporation of interstitial or encapsulated heteroatoms is a common and stabilizing feature. Carbon is the most common and, as is the case in

Figure 26.9 Schematic representations of the metal cores of some clusters of group 9 metals.

(a) \([\text{Rh}_{13}\text{H}_3(\text{CO})_{24}]^{2-}\); the H atoms migrate within the cluster.
(b) \([\text{Ir}_{14}(\text{CO})_{27}]^-\).
(c) \([\text{Rh}_6(\text{CO})_{15}]^2^-\).
(d) \([\text{Rh}_8(\text{CO})_{19}]^-\); a trigonal prism of 6 Rh atoms has one face capped by a seventh Rh atom and one edge bridged by the eighth Rh atom. 
(e) \([\text{Co}_8(\text{CO})_{18}]^2^-\); the 8 Co atoms define a distorted bicapped trigonal prism which, alternatively, can be viewed as a distorted square antiprism.
(f) \([\text{Rh}_{12}(\text{C}_2)(\text{CO})_{25}]^-\).

group 8 (p. 1107), may originate from the solvent or from cleavage of a CO ligand. The carbido C contributes 4 electrons to the cluster bonding and in the 90-electron species \([\text{Rh}_6(\text{CO})_{15}]^2^-\) features trigonal prismatic coordination of Rh6 about the central C (Fig. 26.9c). More complex geometries are found for \([\text{Rh}_8(\text{CO})_{19}]^-\) (Fig. 26.9d) and \([\text{Co}_9(\text{CO})_{18}]^2^-\) (Fig. 26.9e): these two iso-electronic clusters are not isostructural though a slight distortion would (hypothetically) transform one into the other. The central carbido C in the square antiprismatic \([\text{Co}_9(\text{CO})_{18}]^2^-\) is formally 8-coordinate, the Co–C distances being in the range 195–220 pm with a mean value of 207 pm. Even more complicated structures are found for the large Rh clusters containing 2 carbido C atoms: \([\text{Rh}_{12}(\text{C}_2)(\text{CO})_{25}]^-\) (Fig. 26.9f has no symmetry elements but it is clear that the Rh12 cluster surrounds an ethanide unit C2 in which the C–C distance is only 147 pm); the cluster also has 14 pendant terminal CO groups, 10 μ-CO groups and one μ3-CO. In contrast, \([\text{Rh}_{15}(\text{C}_2)(\text{CO})_{28}]^-\) has individual 6-coordinate (octahedral) carbido C atoms symmetrically placed on each side of a central Rh which itself has 12 Rh nearest neighbours in addition to the 2 C atoms. Again, the approach to metal structures is notable and is one of the main interests in constructing large clusters and studying their chemical and catalytic activity.

H, P, As, S have also been encapsulated in ions such as \([\text{Rh}_{13}(\text{H}_3)(\text{CO})_{24}]^{2-}\), \([\text{Rh}_6(\text{P}(\text{CO})_{21})^2^-\), \([\text{Rh}_{10}(\text{As}(\text{CO})_{22})]^3^-\) and \([\text{Rh}_{17}(\text{S})_2(\text{CO})_{32}]^3^-\).
More recently N has been encapsulated\(^{(41)}\) in [Rh\(_{14}\)(N\(_2\))(CO)\(_{25}\)]\(^{2-}\) and [Rh\(_{23}\)(N\(_4\))(CO)\(_{38}\)]\(^{3-}\). The latter is the largest Rh cluster so far characterized. It consists of an irregular polyhedron of 21 Rh atoms encapsulating a pair of particularly close (257.1 pm) Rh atoms as well as 4 N atoms each of which is located in a semi octahedral site.

Other derivatives of the carbonyls are of course numerous; Ir forms many carbonyl halides of the types [Ir\(^{1}\)(CO)\(_3\)X], [Ir\(^{2}\)(CO)\(_2\)X\(_2\)]\(^{-}\), [Ir\(^{III}\)(CO)\(_2\)X\(_4\)]\(^{-}\) and [Ir\(^{III}\)(CO)X\(_5\)]\(^{3-}\), but the stability of carbonyl halides falls off in the sequence Ir > Rh > Co and those of Co are only of the type [Co(CO)\(_4\)X] and are very unstable.

The bulk of derivatives are obtained by the displacement of CO by other ligands. These include phosphines and other group 15 donors, NO, mercaptans and unsaturated organic molecules such as alkenes, alkynes and cyclopentadienyls.

**Cyclopentadienyls**

Cobaltocene, [Co\(^{III}\)(η\(^5\)-C\(_5\)H\(_5\))\(_2\)], is a dark-purple air-sensitive material, prepared by the reactions of sodium cyclopentadiene and anhydrous CoCl\(_2\) in thf. Having 1 more electron than ferrocene, it is paramagnetic with a magnetic moment of 1.76 BM and, while it is thermally stable up to 250°C, its most obvious characteristic is its ready loss of this electron to form the yellow-green cobalticenium ion, [Co\(^{III}\)(η\(^5\)-C\(_5\)H\(_5\))\(_2\)]\(^{+}\). This resists further oxidation, being stable even in conc HNO\(_3\) but, like the isoelectronic ferrocene, is susceptible to nucleophilic attack on its rings.

Rhodocene, [Rh(η\(^5\)-C\(_5\)H\(_5\))\(_2\)], is also known but is unstable to oxidation and has a tendency to form dimeric species. Claims for the existence of iridocene probably refer to Ir\(^{III}\) complexes. However, the yellow rhodocenium and iridocenium cations are certainly known and are entirely analogous to the cobalticenium cation in their resistance to oxidation and susceptibility to nucleophilic attack.

Numerous “half-sandwich” compounds of the type [M(η\(^5\)-C\(_5\)R\(_5\))L\(_2\)], M = Rh, Ir; R = H, Me; L = CO, phosphine etc.) are known and are useful reagents. [Ir(η\(^5\)-C\(_5\)Me\(_5\))(CO)\(_2\)] for instance is an excellent nucleophile and is also used in the photochemical activation of C–H in alkanes. It is particularly effective in the latter role when supercritical CO\(_2\) is the solvent.\(^{(42)}\)

---

27.1 Introduction

An alloy of nickel was known in China over 2000 years ago, and Saxon miners were familiar with the reddish-coloured ore, NiAs, which superficially resembles Cu$_2$O. These miners attributed their inability to extract copper from this source to the work of the devil and named the ore “Kupfernickel” (Old Nick’s copper). In 1751 A. F. Cronstedt isolated an impure metal from some Swedish ores and, identifying it with the metallic component of Kupfernickel, named the new metal “nickel”. In 1804 J. B. Richter produced a much purer sample and so was able to determine its physical properties more accurately.

Impure, native platinum seems to have been used unwittingly by ancient Egyptian craftsmen in place of silver, and was certainly used to make small items of jewellery by the Indians of Ecuador before the Spanish conquest. The introduction of the metal to Europe is a complex and intriguing story.\(^1\) In 1736 A. de Ulloa, a Spanish astronomer and naval officer, observed an unworkable metal, platina (Spanish, little silver), in the gold mines of what is now Colombia. Returning home in 1745 his ship was attacked by privateers and finally captured by the British navy. He was brought to London and his papers confiscated, but was fortunately befriended by members of the Royal Society and was indeed elected to that body in 1746 when his papers were returned. Meanwhile, in 1741, C. Wood brought to England the first samples of the metal and, following the eventual publication of de Ulloa’s report in 1748, investigation of its properties began in England and Sweden. It became known as “white gold” (a term now used to describe an Au/Pd alloy) and the “eighth metal” (the seven metals Au, Ag, Hg, Cu, Fe, Sn and Pb having been known since ancient times). Great difficulty was experienced in working it because of its high mp and brittle nature (due to impurities of Fe and Cu). Powder metallurgical techniques of fabrication were developed\(^\dagger\) in great secrecy in Spain by the Indians to whom platinum was available only in the form of fine, hand-separated grains which must have been fabricated by ingenious, if crude, powder metallurgy.

\(^\dagger\) Precedence must in fact be given to the South American Indians to whom platinum was available only in the form of fine, hand-separated grains which must have been fabricated by ingenious, if crude, powder metallurgy.
Frenchman P. F. Chabeneau, and subsequently in London by W. H. Wollaston, who in the years 1800–21 produced well over 1 tonne of malleable platinum. These techniques were developed because the chemical methods used to isolate the metal produced an easily powdered spongy precipitate. Not until the availability, half a century later, of furnaces capable of sustaining sufficiently high temperatures was easily workable, fused platinum commercially available.

In 1803, in the course of his study of platinum, Wollaston isolated and identified palladium from the mother liquor remaining after platinum had been precipitated as \(\text{(NH}_4\text{)}_2\text{PtCl}_6\) from its solution in aqua regia. He named it after the newly discovered asteroid, Pallas, itself named after the Greek goddess of wisdom (παλλάς, palladion, of Pallas).

### 27.2 The Elements

#### 27.2.1 Terrestrial abundance and distribution

Nickel is the seventh most abundant transition metal and the twenty-second most abundant element in the earth’s crust (99 ppm). Its commercially important ores are of two types:

1. **Laterites**, which are oxide/silicate ores such as garnierite, \((\text{Ni,Mg})_6\text{Si}_2\text{O}_10(\text{OH})_8\), and nickeliferous limonite, \((\text{Fe, Ni})\text{O(OH)}_n\text{H}_2\text{O}\), which have been concentrated by weathering in tropical rainbelt areas such as New Caledonia, Cuba and Queensland.

2. **Sulfides** such as pentlandite, \((\text{Ni, Fe})_9\text{S}_8\), associated with copper, cobalt and precious metals so that the ores typically contain about 1\% Ni. These are found in more temperate regions such as Canada, the former Soviet Union and South Africa.

Arsenide ores such as niccolite (Kupfernickel (NiAs), smaltite ((Ni, Co, Fe)As\(_2\)) and nickel glance (NiAsS) are no longer of importance.

The most important single deposit of nickel is at Sudbury Basin, Canada. It was discovered in 1883 during the building of the Canadian Pacific Railway and consists of sulfide outcrops situated around the rim of a huge basin 17 miles wide and 37 miles long (possibly a meteoritic crater). Fifteen elements are currently extracted from this region (Ni, Cu, Co, Fe, S, Te, Se, Au, Ag and the six platinum metals).

Although estimates of their abundances vary considerably, Pd and Pt (approximately 0.015 and 0.01 ppm respectively) are much rarer than Ni. They are generally associated with the other platinum metals and occur either native in placer (i.e. alluvial) deposits or as sulfides or arsenides in Ni, Cu and Fe sulfide ores. Until the 1820s all platinum metals came from South America, but in 1819 the first of a series of rich placer deposits which were to make Russia the chief source of the metals for the next century, was discovered in the Urals. More recently however, the copper-nickel ores in South Africa and Russia (where the Noril’sk-Talnakh deposits are well inside the Arctic Circle) have become the major sources, supplemented by supplies from Sudbury.

#### 27.2.2 Preparation and uses of the elements

Production methods for all three elements are complicated and dependent on the particular ore involved; they will therefore only be sketched in outline. In the case of nickel the oxide ores are not generally amenable to concentration by normal physical separations and so the whole ore has to be treated. By contrast the sulfide ores

---

can be concentrated by flotation and magnetic separations, and for this reason they provide the major part of the world’s nickel, though the use of laterite ores is appreciable.

A quarter of the world’s nickel comes from Sudbury and there silica is added to the nickel/copper concentrates which are then subjected to a series of roasting and smelting operations. This reduces the sulfide and iron contents by converting the iron sulfide first to the oxide and then to the silicate which is removed as a slag. The resulting “matte” of nickel and copper sulfides is allowed to cool over a period of days, when Ni$_3$S$_2$, Cu$_2$S and Ni/Cu metal$^\dagger$ form distinct phases which can be mechanically separated. (In the older, Orford, process the matte was heated with NaHSO$_4$ and coke, producing molten Na$_2$S which dissolved the copper sulfide and formed an upper layer, leaving the nickel sulfide below; on solidification the silvery upper layer was cut from the black lower layer — hence the process was commonly called the “tops and bottoms” process.) The matte may be cast directly as anode with pure nickel sheet as cathode and electrolysed using an aqueous NiSO$_4$, NiCl$_2$ electrolyte. Alternatively, the matte may be leached with hydrochloric acid, nickel chloride crystallized and converted to the oxide by high temperature oxidation with air, and finally the oxide reduced to the metal by H$_2$ at 600°C.

The carbonyl process developed in 1899 by L. Mond is still used, though it is mainly of historic interest. In this the heated oxide is first reduced by the hydrogen in water gas (H$_2$ + CO). At atmospheric pressure and a temperature around 50°C, the impure nickel is then reacted with the residual CO to give the volatile Ni(CO)$_4$. This is passed over nucleating pellets of pure nickel at a temperature of 230°C when it decomposes, depositing nickel of 99.95% purity and leaving CO to be recycled.

$$\begin{align*}
\text{ nickel} + 4\text{ carbon monoxide} & \rightarrow \text{ nickel carbonyl} \\
50°C & \rightarrow 230°C
\end{align*}$$

Somewhat higher pressures and temperatures (e.g. 20 atm and 150°C) are used to form the carbonyl in modern Canadian plant, but the essential principle of the Mond process is retained.

Total world production of nickel is in the region of 1.0 million tonnes pa of which (1995) 25% comes from the former Soviet Union, 18% from Canada, 12% from New Caledonia and 10% from Australia. The bulk of this is used in the production of alloys both ferrous and non-ferrous. In 1889 J. Riley of Glasgow published a report on the effect of adding nickel to steel. This was noticed by the US Navy who initiated the use of nickel steels in armour plating. Stainless steels contain up to 8% Ni and the use of “Alnico” steel for permanent magnets has already been mentioned (p. 1114).

The non-ferrous alloys include the misleadingly named nickel silver (or German silver) which contains 10–30% Ni, 55–65% Cu and the rest Zn; when electroplated with silver (electroplated nickel silver) it is familiar as EPNS tableware. Monel (68% Ni, 32% Cu, traces of Mn and Fe) is used in apparatus for handling corrosive materials such as F$_2$; cupro-nickels (up to 80% Cu) are used for “silver” coinage; Nichrome (60% Ni, 40% Cr), which has a very small temperature coefficient of electrical resistance, and Invar, which has a very small coefficient of expansion are other well-known Ni alloys. Electroplated nickel is an ideal undercoat for electroplated chromium, and smaller amounts of nickel are used as catalysts in the hydrogenation of unsaturated vegetable oils and in storage batteries such as the Ni/Fe batteries.

Ninety-eight per cent of the world’s supply of platinum metals comes from three countries — the former Soviet Union (49%), the Republic of South Africa (43%), and Canada (6%). Because of the different proportions of Pt and Pd in their deposits, the Republic of South Africa is the major source of Pt and the former USSR of Pd. Only in the RSA (where the Bushveld complex contains over 70% of the world’s reserves of the platinum metals at concentrations of 8–9 grams per tonne) are the

$^\dagger$ This metallic phase is worked for precious metals which are preferentially dissolved in it.
327.2.2 Preparation and uses of the elements

platinum metals the primary products. Elsewhere, with concentrations of a mere fraction of a gramme per tonne, millions of tonnes of ore must be mined, milled and smelted each year. Precious metal concentrates are obtained either from the metallic phase of the sulfide matte (see above) or as anode slimes in the electrolytic refinement of the base metals. From these, all six platinum metals as well as Ag and Au are obtained by a composite process. Traditional methods were based on selective precipitation and developed to suit the composition of the concentrate. Although these methods are still in use the efficiency of the separations is not high and costly recycling is required. Solvent extraction and ion exchange techniques offer superior efficiency and are increasingly replacing the classical processes. Fig. 27.1 outlines a typical solvent extraction process (see also p. 1073 and p. 1114).

Current annual world production of all platinum metals is around 380 tonnes of which perhaps 150 tonnes is platinum and 210 tonnes is palladium. 35-40% of Pt and about half as

(a) All have zero nuclear spin except ¹⁹⁵Pt (33.8% abundance) which has a nuclear spin quantum number ½; this isotope finds much use in nmr spectroscopy both via direct observation of the ¹⁹⁵Pt resonance and even more by the observation of ¹⁹⁵Pt "satellites". Thus, a given nucleus coupled to ¹⁹⁵Pt will be split into a doublet symmetrically placed about the central unsplit resonance arising from those species containing any of the other 5 isotopes of Pt. The relative intensity of the three resonances will be (½ × 33.8):66.2:(½ × 33.8), i.e. 1:4:1.

27.2.3 Properties of the elements

Table 27.1 lists some of the important atomic and physical properties of these three elements. The prevalence of naturally occurring isotopes in this triad limits the precision of their quoted atomic weights, though the value for Ni was improved by more than two orders of magnitude in 1989 and that for Pt fifteen fold in 1995. Difficulties in attaining high purities have also frequently led to disparate values for some physical properties, while mechanical history has considerable effect on such properties as hardness. The metals are silvery-white and lustrous, and are both malleable and ductile so that they are readily worked. They are also readily obtained in finely divided forms which are catalytically very active. Platinum black, for instance, is a velvety-black powder obtained by adding ethanol to a solution of PtCl₂ in aqueous KOH and warming. Another property of platinum which has led to numerous laboratory applications is its coefficient of expansion which is virtually the same as that of soda glass into which it can therefore be fused to give a permanent seal.

Like Rh and Ir, all three members of this triad have the fcc structure predicted by band theory calculations for elements with nearly filled d shells. Also in this region of the periodic table, densities and mps are decreasing with increase in Z across the table: thus, although by comparison...
with the generality of members of the d block these elements are in each case to be considered as dense refractory metals, they are somewhat less so than their immediate predecessors, and palladium has the lowest density and melting point of any platinum metal.

Nickel is ferromagnetic, but less markedly so that either iron or cobalt and its Curie point (375°C) is also lower.

### 27.2.4 Chemical reactivity and trends

In the massive state none of these elements is particularly reactive and they are indeed very resistant to atmospheric corrosion at normal temperatures. However, nickel tarnishes when heated in air and is actually pyrophoric if very finely divided (finely divided Ni catalysts should therefore be handled with care). Palladium will also form a film of oxide if heated in air.

Nickel reacts on heating with B, Si, P, S and the halogens, though more slowly with F₂ than most metals do. It is oxidized at red heat by steam, and will dissolve in dilute mineral acids: slowly in most but quite rapidly in dil HNO₃. Conc HNO₃, on the other hand, renders it passive and dry hydrogen halides have little effect. It has a notable resistance to attack by aqueous caustic alkalis and therefore finds used in apparatus for producing NaOH.

Palladium is oxidized by O₂, F₂ and Cl₂ at red heat and dissolves slowly in oxidizing acids. Platinum is generally more resistant to attack than Pd and is, for instance, barely affected by mineral acids except aqua regia. However, both metals dissolve in fused alkali metal oxides and peroxides. It is also wise to avoid heating compounds containing B, Si, Pb, P, As, Sb or Bi in platinum crucibles under reducing conditions (e.g. the blue flame of a bunsen burner) since these elements form low-melting eutectics with Pt which cause the metal to collapse. All three elements absorb molecular hydrogen to an extent which depends on their physical state, but palladium does so to an extent which is unequalled by any other metal (section 27.3.1).

A list of typical compounds of these elements is given in Table 27.2 and it is noticeable that the reduction in the range of oxidation states compared to that in previous groups is continuing and differences between the two heavier elements are becoming increasingly evident. The maximum oxidation state is +6 but this is attained only by the heaviest element, platinum, in PtF₆; nickel and palladium only reach +4. At the other extreme, palladium and platinum provide no oxidation state below zero. The changes down the triad implied by these facts are also evidenced by those oxidation states which are the most stable for each element. For nickel, +2 is undoubtedly the most common and provides that element's most extensive aqueous chemistry. For palladium, +2 is again the most common, and [Pd(H₂O)₄]²⁺ like [Pt(H₂O)₄]²⁺ occurs in aqueous solutions from which potential ligands are excluded. For platinum, however, both +2 and +4 are prolific and form a vital part of early as well as more recent coordination chemistry.

Table 27.2 also reveals the reluctance of these elements to form compounds with high coordination numbers, a coordination number of 6 being rarely exceeded. In the divalent state nickel exhibits a wide and interesting variety of coordination numbers and stereochemistries which often exist simultaneously in equilibrium with each other, whereas palladium and platinum have a strong preference for the square planar geometry. The kinetic inertness of Pt⁺⁺ complexes has led to their extensive use in studies of geometrical isomerism and reaction mechanisms. As will be seen presently, these differences between the lightest and heaviest members of the triad can be largely rationalized by reference to their CFSEs.

Also in the divalent state, Pd and Pt show the class-b characteristic of preferring CN⁻ and ligands with nitrogen or heavy donor atoms rather than oxygen or fluorine. Platinum(IV) by contrast is more nearly class-a in character and is frequently reduced to Pt⁺⁺ by P- and As-donor ligands. The organometallic chemistry of these metals is rich and varied and that involving unsaturated hydrocarbons is the most familiar of its type.

### 27.3 Compounds of Nickel, Palladium and Platinum

Such binary borides (p. 145), carbides (p. 297) and nitrides (p. 417) as are formed have been referred to already. The ability of the metals to absorb molecular hydrogen has also been alluded to above. While the existence of definite hydrides of nickel and platinum is in doubt the existence of definite palladium hydride phases is not.

#### 27.3.1 The Pd/H\(_2\) system

The absorption of molecular hydrogen by metallic palladium has been the subject of theoretical and practical interest ever since 1866 when T. Graham reported that, on being cooled from red heat, Pd can absorb (or “occlude” as
he called it) up to 935 times its own volume of H₂. The gas is given off again on heating and this provides a convenient means of weighing H₂ — a fact utilized by E. W. Morley in his classic work on the composition of water (1895).

As hydrogen is absorbed, the metallic conductivity falls until the material becomes a semiconductor at a composition of about PdH₀.₅. Palladium is unique in that it does not lose its ductility until large amounts of H₂ have been absorbed. The hydrogen is first chemisorbed at the surface of the metal but at increased pressures it enters the metal lattice and the so-called α- and β-phase hydrides are formed (Fig. 27.2). The basic lattice structure is not altered but, whereas the α-phase causes only a slight expansion, the β-phase causes an expansion of up to 10% by volume. The precise nature of the metal–hydrogen interaction is still unclear but the hydrogen has a high mobility within the lattice and diffuses rapidly through the metal. This process is highly specific to H₂ and D₂, palladium being virtually impervious to all other gases, even He, a fact which is utilized in the separation of hydrogen from mixed gases. Industrial installations with outputs of up to 9 million ft³/day (255 million litres/day) are operated and it is of great importance in these that formation of the β-phase hydride is avoided, since the gross distortions and hardening which accompany it may result in splitting of the diffusion membrane. This can be done by maintaining the temperature above 300°C (Fig. 27.2), or alternatively by alloying the Pd with about 20% Ag which has the additional advantage of actually increasing the permeability of the Pd to hydrogen (p. 39).

27.3.2 Oxides and chalcogenides

The elements of this group form only one reasonably well-characterized oxide each, namely NiO, PdO and PtO₂, although claims for the existence of many others have been made. Formation of NiO by heating the metal in oxygen excess heat is associated with very heavy deuterium loading of Pd in the β-phase. Reproducibility is, however, poor and it seems probable that more than one effect is involved. The current consensus is against a “cold-fusion” explanation of the effects.
is difficult to achieve and incomplete conversion may well account for some of the claims for other nickel oxides, while grey to black colours probably arise from slight nonstoichiometry. It is best prepared as a green powder with the rock-salt structure (p. 242) by heating the hydroxide, carbonate or nitrate. Ni(OH)₂ is a green precipitate obtained by adding alkali to aqueous solutions of Ni²⁺ salts and, like NiO, is entirely basic, dissolving easily in acids.

Black PdO can be produced by heating the metal in oxygen but it dissociates above about 900°C. It is insoluble in acids. However, addition of alkali to aqueous solutions of Pd(NO₃)₂ produces a gelatinous dark-yellow precipitate of the hydrous oxide which is soluble in acids but cannot be fully dehydrated without loss of oxygen. No other palladium oxide has been characterized although the addition of alkali to aqueous solutions of Pd⁺⁺ produces a strongly oxidizing, dark-red precipitate which slowly loses oxygen and, at 200°C, forms PdO.

Addition of alkali to aqueous solutions of [Pt(H₂O)₄][ClO₄]₂ under an atmosphere of argon gives a white amphoteric hydroxide of Pt²⁺ at pH 4 which redissolves at pH 10. The precipitate slowly turns black at room temperature (more rapidly when dried at 100°C) and has been formulated as PtO₄·H₂O, but it is too unstable to be properly characterized. The stable oxide of platinum is found, instead, in the higher oxidation state. Addition of alkali to aqueous solutions of PtCl₄ yields a yellow amphoteric precipitate of the hydrated dioxide which redissolves on being boiled with an excess of strong alkali to give solutions of [Pt(OH)₆]²⁻; it also dissolves in acids. Dehydration by heating produces almost black PtO₂ but this decomposes to the elements above 650°C and cannot be completely dehydrated without some loss of oxygen.

Nickel sulfides are very similar to those of cobalt, consisting of NiS₂ (pyrites structure, p. 680), Ni₃S₄ (spinel structure, p. 247), and the black, nickel-deficient Ni₁₋ₓS (NiAs structure, p. 555), which is precipitated from aqueous solutions of Ni²⁺ by passing H₂S. There are also numerous metallic phases having compositions between NiS and Ni₃S₂.

Palladium and platinum both form a mono- and a di-sulfide. Brown PdS and black PtS₂ are obtained when H₂S is passed through aqueous solutions of Pd⁰ and Pt¹⁺⁺ respectively. Grey PdS₂ and green PtS are best obtained by respectively heating PdS with excess S and by heating PtCl₂, Na₂CO₃ and S. The crystal chemistry and electrical (and magnetic) properties of these phases and the many selenides and tellurides of Ni, Pd and Pt are complex.

27.3.3 Halides

The known halides of this group are listed in Table 27.3. This list differs from that of the halides of Co, Rh and Ir (Table 26.3) most obviously in that the +2 rather than the +3 oxidation state is now well represented for the heavier elements as well as for the lightest. The only hexa- and penta-halides are the dark-red PtF₆ and (PtF₅)₄ which are both obtained by controlled heating of Pt and F₂. The former is a volatile solid and, after RhF₆, is the least-stable platinum-metal hexafluoride. It is one of the strongest oxidizing agents known, oxidizing both O₂ (to O₃⁺[PtF₆]⁻) and Xe (to XePtF₆) (p. 892). The pentafluoride is also very reactive and has the same tetrameric structure as the pentafluorides of Ru, Os, Rh and Ir (Fig. 25.3). It readily disproportionates into the hexa- and tetra-fluorides.

Platinum alone forms all 4 tetrahalides and these vary in colour from the light-brown PtF₄ to the very dark-brown PtI₄. PtF₄ is obtained by the action of BrF₃ on PtCl₂ at 200°C and is violently hydrolysed by water. The others are obtained directly from the elements, the chloride being recrystallizable from water but the bromide and iodide being more soluble in alcohol and in ether. The only other tetrahalide is the red PdF₄ which is similar to its platinum analogue.

The most stable product of the action of fluorine on metallic palladium is actually Pd⁰[Pd¹⁺F₆]₂, and true trihalides of Pd do not occur. Similarly, the diamagnetic “trichloride” and “tribromide” of Pt

\(^{(a)}\) PtF$_6$ boils at 69.1°C. \(^{(b)}\) β-PdCl$_2$ and β-PtCl$_2$ (reddish-black) contain M$_6$Cl$_{12}$ clusters (Fig. 27.3b).

contain Pt$^\text{III}$ and Pt$^\text{IV}$ and the triiodide probably does also. Trihalides of nickel are confined to impure specimens of NiF$_3$.

All the dihalides, except PtF$_2$, are known, fluorine perhaps being too strongly oxidizing to be readily compatible with the metal in the lower of its two major oxidation states. Except for NiF$_2$, the yellow to dark-brown dihalides of nickel can be obtained directly from the elements; they dissolve in water from which hexahydrates containing the [Ni(H$_2$O)$_6$]$_2^+$ ion can be crystallized. These solutions may also be prepared more conveniently by dissolving Ni(OH)$_2$ in the appropriate hydrohalic acid. NiF$_2$ is best formed by the reaction of F$_2$ on NiCl$_2$ at 350°C and is only slightly soluble in water, from which the trihydrate crystallizes.

Violet, easily hydrolysed, PdF$_2$ is produced when Pd$^{11}$[Pd$^{14}$F$_6$] is refluxed with SeF$_4$ and is notable as one of the very few paramagnetic compounds of Pd$^{11}$. The paramagnetism arises from the $t_{2g}^2e_g^2$ configuration of Pd$^{11}$ which is consequent on its octahedral coordination in the rutile-type structure (p. 961). The dichlorides of both Pd and Pt are obtained from the elements and exist in two isomeric forms: which form is produced depends on the exact experimental conditions used. The more usual α-form of PdCl$_2$ is a red material with

\[\text{Figure 27.3} \hspace{1cm} (a) \text{The chain structure of } \alpha-\text{PdCl}_2, \text{ and (b) the } M_6\text{Cl}_{12} \text{ structural unit of } \beta-\text{PdCl}_2 \text{ and } \beta-\text{PtCl}_2. \text{ (Note its broad similarity with the } [M_6\text{X}_{12}]^{1+} \text{ unit of the lower halides of Nb and Ta shown in Fig. 22.6 and to the unit cell of the three-dimensional structure of NbO.)} \]
Fluorination of NiCl₂ + KCl produces red K₂NiF₆ which is strongly oxidizing and will liberate O₂ from water. Dark red complexes of the type [NiIV(L)](ClO₄)₂ (H₂L is a seixidentate oxime) have been obtained by the action of conc HNO₃ on [NiII(H₂L)](ClO₄)₂ and are stable indefinitely under vacuum but are reduced in moist air.

Palladium(IV) complexes are rather sparse and much less stable than those of PtIV. The best known are the hexahalogeno complexes [PdX₆]²⁻ (X = F, Cl, Br) of which [PdCl₆]²⁻, formed when the metal is dissolved in aqua regia, is the most familiar. In all of these the PdIV is readily reducible to PdII. In water, [PdF₆]²⁻ hydrolyses immediately to PdO₂.xH₂O while the chloro and bromo complexes give [PdCl₄]²⁻ plus X₂. An organometallic chemistry of PdIV is developing (p. 1167).

By contrast PtIV complexes rival those of PtII in number, and are both thermodynamically stable and kinetically inert. Those with halides, pseudo-halides, and N-donor ligands are especially numerous. Of the multitude of conceivable compounds ranging from [PtX₆]²⁻ through [PtX₄L₂] to [PtL₆]₄⁺, (X = F, Cl, Br, I, CN, SCN, SeCN; L = NH₃, amines) a large number have been prepared and characterized though, curiously, they do not include the [Pt(CN)₆]²⁻ ion. K₂PtCl₆ is commercially the most common compound of platinum and the brownish-red, “chloroplatinic acid”, H₂[PtCl₆](aq), is the usual starting material in PtIV chemistry. It is prepared by dissolving platinum metal sponge in aqua regia, followed by one or more evaporations with hydrochloric acid. A route to PtII chemistry also is provided by precipitation of the sparingly soluble K₂PtCl₆ followed by its reduction with hydrazine to K₂PtCl₄. The chloroaminines were extensively used by Werner and other early coordination chemists in their studies on the nature of the coordinate bond in general and on the octahedral geometry of PtIV in particular.

O-donor ligands such as OH⁻ and acac also coordinate to PtIV, but S- and Se-, and more especially P- and As-donor ligands, tend to reduce it to PtII.
Oxidation state III (d^7)

Perhaps surprisingly, mononuclear M^{III} compounds are rather better represented by nickel than by either palladium or platinum. K$_2$NiF$_6$ has been prepared by fluorinating KCl + NiCl$_2$ at high temperatures and pressures. It is a violet crystalline material which is reduced by water with evolution of oxygen. The observed elongation of the [NiF$_6$]$^{3-}$ octahedron has been ascribed to the Jahn–Teller effect (p. 1021) to be expected for a $t^6_{2g}e^1_g$ configuration although the reported magnetic moment of 2.5 BM at room temperature seems rather high for this configuration. Other examples include [Ni(bipy)$_3$]$^{3+}$, the black trigonal pyramidal [NiBr$_3$(PET$_3$)$_2$] and a number of compounds with N-donor macrocyclic ligands. Among the very few monomeric trivalent compounds of Pd and Pt, the blue (NBu$_4$)[Pt(C$_6$Cl$_5$)$_4$] (obtained by oxidizing the Pt$^{II}$ salt) and the red [Pd(1,4,7-trithiaclononane)$_2$](ClO$_4$)$_2$.H$_2$O.3H$_2$O (obtained$^9$) by cyclovoltammetric oxidation in 70% aqueous HClO$_4$ should be mentioned.

The most abundant examples of this oxidation state, however, are the dinuclear Pt compounds$^{10}$ of the type, [Pt$_2$(L-L)$_4$L$_2$]$^{4-}$ with single Pt–Pt bonds and the same tetrabridged structure of Mo$^{III}$ and Cr$^{III}$ (p. 1032). The first of these was K$_2$[Pt$_2$(SO$_4$)$_4$(H$_2$O)$_2$], prepared from [Pt(NO)$_2$]$_2$(NH$_3$)$_2$ and sulfuric acid, but those with phosphate or P-donor, pyrophosphito, (P$_2$O$_5$H$_2$)$_2^2-$, bridges are more numerous. Pt–Pt distances range from 278.2(1) pm, found with pyrophosphito bridges, down to 245.1(1) pm in Cs$_3$[Pt$_2$(μ-O$_2$CMe)$_2$(μ-O$_2$CCH$_2$)$_2$]. This yellow complex is obtained by a complex procedure$^{11}$ from K$_2$PtCl$_4$ and MeCOOAg and, besides a pair of O,O-donor acetate bridges, contains a pair of unique C,O-donor, –O.CO.CH$_2$–, bridges. Stable tetraacetato bridged dimers are not found.

A number of compounds which have in the past been claimed to contain the trivalent metals have later turned out to contain them in more than one oxidation state. One such is H. Wolfram’s red salt, Pt(EtNH$_2$)$_4$Cl$_3$.2H$_2$O, which has a structure (Fig. 27.4a) consisting of alternate octahedral Pt$^{IV}$ and square-planar Pt$^{II}$ linked by Cl bridges, i.e. [Pt$^{II}$(EtNH$_2$)$_4$]$^{2+}$[trans-(μ-Cl)$_2$-Pt$^{IV}$(EtNH$_2$)$_4$]$^{2+}$Cl$^{-}$.4H$_2$O. Other examples are

Development of Ideas on the Stereochemistry of Nickel(II)

The way in which our present understanding of the stereochemical intricacies of Ni\textsuperscript{II} has evolved illustrates rather well the interplay of theory and experiment. On the basis of valence-bond theory, three types of complex of d\textsuperscript{8} ions were anticipated. These were:

(i) octahedral, involving sp\textsuperscript{3}d\textsubscript{2} hybridization and paramagnetism from 2 unpaired electrons;
(ii) tetrahedral, involving sp\textsuperscript{3} hybridization and, again, paramagnetism from 2 unpaired electrons;
(iii) square planar, involving d\textsuperscript{2}sp\textsubscript{3}p\textsubscript{3} hybridization which implies the confinement of all 8 electrons in four d orbitals, so producing diamagnetism.

Since X-ray determinations of structure were too time-consuming to be widely used in the 1930s and 1940s and, in addition, square-planar geometry was a comparative rarity, any paramagnetic compound, which on the basis of stoichiometry appeared to be 4-coordinate, was presumed to be tetrahedral.

However, with the application in the 1950s of crystal field theory to transition-metal chemistry it was realized that CFSEs were unfavourable to the formation of tetrahedral d\textsuperscript{8} complexes, and previous assignments were re-examined. A typical case was [Ni(acac)]\textsubscript{2}, which had often been cited as an example of a tetrahedral nickel complex, but which was shown\textsuperscript{12} in 1956 to be trimeric and octahedral. The over-realism were then inclined to regard tetrahedral d\textsuperscript{8} as non-existent until first L. M. Venanzi\textsuperscript{13} and then N. S. Gill and R. S. Nyholm\textsuperscript{14} demonstrated the existence of discrete tetrahedral species which in some cases were also rather easily prepared.

More comprehensive examination of spectroscopic and magnetic properties of d\textsuperscript{8} ions followed which provided an explanation for the different types of Lifschitz salts (p. 1160) and led to studies of systems exhibiting anomalous properties. Rational explanations of these properties were eventually forthcoming.

provided by the one-dimensional conductors of platinum,\textsuperscript{14a} of which the cyan complexes are the best known. Thus K\textsubscript{2}[Pt(CN)\textsubscript{4}].3H\textsubscript{2}O is a very stable colourless solid, but by appropriate partial oxidation it is possible to obtain bronze-coloured, “cation deficient”, K\textsubscript{1.75}[Pt(CN)\textsubscript{4}].1.5H\textsubscript{2}O, and other partially oxidized compounds such as K\textsubscript{2}Pt(CN)\textsubscript{3}Cl\textsubscript{3}.3H\textsubscript{2}O. In these, square-planar [Pt(CN)\textsubscript{4}]\textsuperscript{2}\textsuperscript{-} ions are stacked (Fig. 27.4b) to give a linear chain of Pt atoms in which the Pt–Pt distances of 280–300 pm (compared to 348 pm in the original K\textsubscript{2}[Pt(CN)\textsubscript{4}].3H\textsubscript{2}O and 278 pm in the metal itself) allow strong overlap of the d\textsubscript{z2} orbitals. This accounts for the metallic conductance of these materials along the crystal axis. Indeed, there is considerable current interest in such “one-dimensional” electrical conductors.

Oxalato complexes [e.g. K\textsubscript{1.6}Pt(C\textsubscript{2}O\textsubscript{4})\textsubscript{2}.1.2-H\textsubscript{2}O] originally prepared as long ago as 1888 by the German chemist H. G. Söderbaum, are also one-dimensional conductors with analogous structures.

**Oxidation state II (d\textsuperscript{8})**

This is undoubtedly the most prolific oxidation state for this group of elements. The stereochemistry of Ni\textsuperscript{II} has been a topic of continuing interest (see Panel), and kinetic and mechanistic studies on complexes of Pd\textsuperscript{II} and Pt\textsuperscript{II} have likewise been of major importance. It will be convenient to treat Ni\textsuperscript{II} complexes first and then those of Pd\textsuperscript{II} and Pt\textsuperscript{II} (p. 1161).

**Complexes of Ni\textsuperscript{II}**. The absence of any other oxidation state of comparable stability for nickel implies that compounds of Ni\textsuperscript{II} are largely immune to normal redox reactions. Ni\textsuperscript{II} forms salts with virtually every anion and has an extensive aqueous chemistry based on the green\textsuperscript{1} [Ni(H\textsubscript{2}O)\textsubscript{6}]\textsuperscript{2}\textsuperscript{+} ion which is always present in the absence of strongly complexing ligands.

\textsuperscript{12} G. J. BULLEN, Nature 177, 537–8 (1956).

\textsuperscript{1} It was work on the absorption of light by solutions of nickel(II) which led A. Beer in 1852 to formulate the law which bears his name.
The coordination number of NiII rarely exceeds 6 and its principal stereochemistries are octahedral and square planar (4-coordinate) with rather fewer examples of trigonal bipyramidal (5), square pyramidal (5), and tetrahedral (4). Octahedral complexes of NiII are obtained (often from aqueous solution by replacement of coordinated water) especially with neutral N-donor ligands such as NH₃, en, bipy and phen, but also with NCS⁻, NO₂⁻ and the O-donor dimethylsulfoxide, dmso (Me₂SO).

The green trimer, [Ni(acac)₃], (Fig 27.5), prepared by dehydrating the monomeric octahedral trans-dihydrate, [Ni(acac)₂(H₂O)₂] and mentioned in the Panel opposite, has interesting magnetic properties. Down to about 80 K it behaves as a normal paramagnet but below that the magnetic moment per nickel atom rises from about 3.2 BM (as expected for 2 unpaired electrons, i.e. \( S = 1 \)) to 4.1 BM at 4.3 K. This corresponds to the ferromagnetic coupling of all 6 unpaired electrons in the trimer (i.e. \( S' = 3 \)). Replacement of the –CH₃ groups of acetylacetone by the bulkier C(CH₃)₃ apparently prevents the formation of the trimer and leads instead to the red square-planar monomer (Fig. 27.6a).

Of the four-coordinate complexes of NiII, those with the square planar stereochemistry are the most numerous. They include the yellow \([\text{Ni(CN)}₃]^{2-}\), the red \(\text{bis(N-methylsalicylaldiminato)nickel(II)}\) and the well-known \(\text{bis(dimethylglyoximato)nickel(II)}\) (Fig. 27.6b and c) obtained as a flocculent red precipitate in gravimetric determinations of nickel. Actually, in the solid state, this last compound consists of planar molecules stacked above each other so that Ni–Ni interactions occur (Ni–Ni 325 pm), and the nickel atoms should therefore be described as octahedrally coordinated. However, in non-coordinating solvents it dissociates into the square-planar monomer, while in bis(ethylmethylglyoximato)nickel(II) a much longer Ni–Ni separation (475 pm) indicates that even in the solid it must be regarded as square planar.

Although less numerous than the square-planar complexes, tetrahedral complexes of nickel(II) also occur. The simplest of these are the blue \([\text{NiX₄}]^{2-}\) (X = Cl, Br, I) ions, precipitated from ethanolic solutions by large cations such as \([\text{NR₃}]^{+}\), \([\text{PR₃}]^{−}\) and \([\text{AsR₃}]^{+}\). Other examples include a number of those of the type \([\text{NiL}_2\text{X}_2]\) (L = PR₃, AsR₃, OPR₃, OAsR₃) amongst which were the first authenticated examples of tetrahedral nickel (II).

A partial explanation, at least, can be provided for the relative abundances and ease of formation of the above stereochemical varieties of NiII complexes. It can be seen from Table 26.6 that the CFSEs of the d⁸ configuration, unlike those of the d⁷ configuration (e.g. CoII), favour an...
Electronic Spectra and Magnetic Properties of Complexes of Nickel(II)\(^{(15)}\)

Nickel(II) is the only common d\(^8\) ion and its spectroscopic and magnetic properties have accordingly been extensively studied.

In a cubic field three spin-allowed transitions are expected because of the splitting of the free-ion, ground 3\(^F\) term and the presence of the 3\(^P\) term. In an octahedral field the splitting is the same as for the octahedral d\(^3\) ion and the same energy level diagram (p. 1029) can be used to interpret the spectra as was used for octahedral Cr\(^{III}\). Spectra of octahedral Ni\(^{II}\) usually do consist of three bands which are accordingly assigned as:

\[
\begin{align*}
v_1 &= 3T_2(F) \leftrightarrow 3\Delta_2(F) = 9Dq; \\
v_2 &= 3T_1(F) \leftrightarrow 3\Delta_2(F); \\
v_3 &= 3T_1(F) \leftrightarrow 3\Delta_2(F)
\end{align*}
\]

with \(v_1\) giving the value of \(\Delta\), or 10\(Dq\), directly. Quite often there is also evidence of weak spin-forbidden (i.e. spin triplet \(\rightarrow\) singlet) absorptions and, in [Ni(H\(_2\)O)\(_6\)]\(^{2+}\) and [Ni(dms0)\(_6\)]\(^{2+}\), for instance, the \(v_2\) absorption has a strong shoulder on it. This is ascribed to a transition to the spin singlet \(1E_g\) which occurs when the \(1E_g\) and \(3T_1(F)\) terms are in close proximity.

For d\(^8\) ions in tetrahedral fields the splitting of the free-ion ground term is the inverse of its splitting in an octahedral field, so that \(3T_1(F)\) lies lowest. In this case three relatively intense bands are to be expected, arising from the transitions:

\[
\begin{align*}
v_1 &= 3T_2(F) \leftrightarrow 3T_1(F); \\
v_2 &= 3A_2(F) \leftrightarrow 3T_1(F); \\
v_3 &= 3T_1(F) \leftrightarrow 3T_1(F)
\end{align*}
\]

Table A gives data for a number of octahedral and tetrahedral complexes.

\(^{(a)}\)Obscured by intense charge-transfer absorptions.

The \(T\) ground term of the tetrahedral ion is expected to lead to a temperature-dependent orbital contribution to the magnetic moment, whereas the \(A\) ground term of the octahedral ion is not, though “mixing” of the excited \(3T_2(F)\) term into the \(3\Delta_2(F)\) ground term is expected to raise its moment to:

\[
\mu_\tau = \mu_{\text{spin-only}} (1 - \frac{4\lambda}{10Dq})
\]

where \(\lambda = -315\) cm\(^{-1}\) and \(\mu_{\text{spin-only}} = 2.83\) BM. (This is the exact reverse of the situations found for Co\(^{II}\); p. 1132.)

The upshot is that the magnetic moments of tetrahedral compounds are found to lie in the range 3.2–4.1 BM (and are dependent on temperature, and are reduced towards \(\mu_{\text{spin-only}}\) by electron delocalization on to the ligands and by distortions from ideal tetrahedral symmetry) whereas those of octahedral compounds lie in the range 2.9–3.3 BM.

The spectra of square-planar d\(^8\) complexes are usually characterized by a fairly strong band in the yellow to blue region (i.e. about 17 000–22 000 cm\(^{-1}\) or 600–450 nm) which is responsible for the reddish colour, and another band near the ultraviolet. The likelihood of \(\pi\)-bonding and attendant charge transfer makes a simple crystal-field treatment inappropriate, and unambiguous assignments are difficult.

Figure 27.7 The splitting of d orbitals in fields of different symmetries, and the resulting electronic configurations of the Ni^{II} d^8 ion.

This balance, which apparently involves both steric and electronic factors, is well illustrated by the series of complexes [Ni(PR3)2X2] (X = Cl, Br, I). The diamagnetic, planar forms are favoured by R = alkyl, X = I, and the paramagnetic tetrahedral forms by R = aryl, X = Cl. When mixed alkylarylphosphines are involved, conformational isomerism may occur. For example, [NiBr2(PEtPh2)2] has been isolated in both a green, paramagnetic (\(\mu_{300} = 3.20\) BM), tetrahedral form and a brown, diamagnetic, planar form.

These various stereochemistries are characterized by differing spectroscopic and magnetic properties (see Panel opposite). However, the crude traditional guidelines of colour and magnetism, namely that square planar compounds are red to yellow and diamagnetic whereas tetrahedral ones are green to blue and paramagnetic (due to the \(t^6_e^2t^2_g^2\) and \(e^4t^2_g\) configurations respectively), cannot be regarded as rigorously diagnostic. The octahedral [Ni(NO2)5]^{4-} and square planar [NiL2(quinoline)2] for instance, are respectively paramagnetic and diamagnetic (expected) but are

---

octahedral as opposed to a tetrahedral stereochemistry. It is also evident from Fig 27.7 that the square-planar geometry offers the possibility, not available in either the octahedral or tetrahedral cases, of accommodating all 8d electrons in 4 lower orbitals, thus leaving the uppermost (\(d_{z^2}\)) orbital empty. Providing therefore that the ligand field is of sufficiently low symmetry (or is sufficiently strong) to split the d orbitals enough to offset the energy required to pair-up 2 electrons, then the 4-coordinate, square-planar extreme can be energetically preferable not only to the tetrahedral but also to the 6-coordinate octahedral extreme. Thus, with the CN⁻ ligand which produces an exceptionally strong field, the square-planar [Ni(CN)4]^{2-} is formed rather than the tetrahedral isomer or the octahedral [Ni(CN)6]^{4-}. Also, many compounds of the type [NiL2X2], in which low-symmetry crystal fields are clearly possible, are planar. However, this selfsame formulation was mentioned above as including examples of tetrahedral complexes: evidently the factors which determine the geometry of a particular complex are finely balanced.
also brown-red and green (unexpected). Furthermore, the compounds, \([\text{Bu}^t\text{P}(\mu-O,\mu-\text{NR})\text{Ni}(\mu-O,\mu-\text{NR})\text{PBu}^t]\) (\(R = \text{Pr}^t, \text{cyclohexyl}\)) exist as both tetrahedral and square planar isomers of which not only the former but, uniquely, the latter also are paramagnetic.\(^\text{(16)}\) Presumably the separation of \(d_{x^2-y^2}\) and \(d_{xy}\) orbitals (Fig 27.7) is sufficiently small to allow both to be singly occupied.

Many compounds, of which \([\text{NiBr}_2(\text{PETPh}_2)_2]\) mentioned above is one, exist in solution as mixtures of isomers giving rise to intermediate values of \(\mu_e (0-3.2 \text{ BM})\). Such behaviour, previously regarded as "anomalous" is due to one of three possible types of equilibria:

1. **Planar–tetrahedral equilibria.** Compounds such as \([\text{NiBr}_2(\text{PETPh}_2)_2]\) mentioned above as well as a number of sec-alkylsalicylaldiminato derivatives (i.e. Me in Fig. 27.6b replaced by a sec-alkyl group) dissolve in non-coordinating solvents such as chloroform or toluene to give solutions whose spectra and magnetic properties are temperature-dependent and indicate the presence of an equilibrium mixture of diamagnetic planar and paramagnetic tetrahedral molecules.

2. **Planar–octahedral equilibria.** Dissolution of planar \(\text{Ni}^{II}\) compounds in coordinating solvents such as water or pyridine frequently leads to the formation of octahedral complexes by the coordination of 2 solvent molecules. This can, on occasions, lead to solutions in which the \(\text{Ni}^{II}\) has an intermediate value of \(\mu_e\) indicating the presence of comparable amounts of planar and octahedral molecules varying with temperature and concentration; more commonly the conversion is complete and octahedral solvates can be crystallized out. Well-known examples of this behaviour are provided by the complexes \([\text{Ni}(L-L)_2X_2]\) (\(L-L = \text{substituted ethylenediamine, } X = \text{variety of anions}\) generally known by the name of their discoverer I. Lifschitz. Some of these Lifschitz salts are yellow, diamagnetic and planar, \([\text{Ni}(L-L)_2]X_2\), others are blue, paramagnetic, and octahedral, \([\text{Ni}(L-L)_2]X_2\) or \([\text{Ni}(L-L)_2(\text{solvent})]X_2\). Which type is produced depends on the nature of \(L-L, X, \text{ and the solvent.}\)

3. **Monomer–oligomer equilibria.** \([\text{Ni(Mesal)}_2]\), mentioned above as a typical planar complex, is a much studied compound. In pyridine it is converted to the octahedral bispyridine adduct (\(\mu_{300} = 3.1 \text{ BM}\)), while in chloroform or benzene the value of \(\mu_e\) is intermediate but increases with concentration. This is ascribed to an equilibrium between the diamagnetic monomer and a paramagnetic dimer, which must involve a coordination number of the nickel of at least 5; a similar explanation is acceptable also for the paramagnetism of the solid when heated above 180°C. The trimerization of \(\text{Ni(acac)}_2\) to attain octahedral coordination has already been referred to but it may also be noted that it is reported to be monomeric and planar in dilute chloroform solutions.

Apart from the probably 5-coordinate \(\text{Ni}^{II}\) in the above oligomers, a number of well-characterized 5-coordinate complexes are known. These are either trigonal bipyramidal or square pyramidal, though the two forms are energetically similar and the stereochemistry is often imposed by the ligands. Thus the trigonal bipyramidal complexes, which are the more common, often involve tripod ligands (p. 907), while the quadridentate chain ligand,

\[\text{Me}_2\text{As(CH}_2)_3\text{As(Ph)}-\text{CH}_2-\text{As(Ph)(CH}_2)_3\text{AsMe}_2\]

(tetars) produces square pyramidal complexes of the type \([\text{Ni(tetars)}X]^+\). These 5-coordinate complexes can be of either high-spin or low-spin type. The former is found in \([\text{NiBr}[\text{Ni}^{(C}_2\text{H}_4\text{NMe}_2)_3]]^+\) but with \(P-\) or \(As\)-donor ligands low-spin configurations are found.

The \(\text{Ni}^{II}/\text{CN}^-\) system illustrates nicely the ease of conversion of the two stereochemistries. Although, as already pointed out, there is no evidence of a hexacyano complex, a square pyramidal pentacyano complex is known:

\[
\begin{align*}
\text{Ni}^{\text{CN}^-} &\xrightarrow{\text{CN}^-} [\text{Ni(CN)}_2]_{\text{aq}} \xrightarrow{\text{CN}^-} [\text{Ni(CN)}_4]^{2-} &\text{green ppt} \\
&\quad\text{redissolves} &\text{yellow} \\
&\quad\text{excess} &\text{[Ni(CN)]}_5^{3-}
\end{align*}
\]
Figure 27.8  The structure of the distorted (a) square-pyramidal and (b) trigonal bipyramidal \( [\text{Ni(CN)}_3]^\text{3-} \) ions in \( [\text{Cr(en)}_3][\text{Ni(CN)}_3].1\frac{1}{2}\text{H}_2\text{O} \).

The fascinating crystalline compound \( [\text{Cr(en)}_3][\text{Ni(CN)}_3].1\frac{1}{2}\text{H}_2\text{O} \) contains both square pyramidal and trigonal bipyramidal anions though each is distorted from true \( C_{4v} \) or \( D_{3h} \) symmetry as shown in Fig. 27.8.

Another interesting cyano derivative of nickel(II)\(^{16a}\) which may conveniently be mentioned here is the clathrate compound, \( [\text{Ni(CN)}_2^-\text{(NH}_3\text{)}].x\text{C}_6\text{H}_6 \) \( (x \leq 1) \). If \( \text{CN}^- \) is added to the blue-violet solution obtained by mixing aqueous solutions of \( \text{Ni}^{\text{II}} \) and \( \text{NH}_3 \), and this is then shaken with benzene, a pale-violet precipitate is obtained. This precipitate is soluble in conc \( \text{NH}_3 \). The benzene and ammonia can be removed by heating it above 150°C but not by washing or by application of reduced pressure. The benzene molecule is, in fact, trapped inside a cage formed by the lattice in which the nickel ions are coordinated to 4 cyanides situated in a square plane, and half are additionally coordinated to 2 ammonias (Fig. 27.9). The observed magnetic moment per Ni atom of 2.2 BM is entirely consistent with this since this average moment arises solely from the octahedrally coordinated Ni atoms, the square-planar Ni being diamagnetic.

Complexes of \( \text{Pd}^{\text{II}} \) and \( \text{Pt}^{\text{II}} \). The effect of complexation on the splitting of d orbitals is much greater in the case of second- and third-row transition elements, and the associated effects already noted for \( \text{Ni}^{\text{II}} \) are even more marked for \( \text{Pd}^{\text{II}} \) and \( \text{Pt}^{\text{II}} \); as a result, their complexes are, with rare exceptions, diamagnetic and the vast majority are planar also. Not many complexes are formed with \( \text{O} \)-donor ligands but, of the few that are, \( [\text{M(H}_2\text{O)}_4]^\text{2+} \) ions, and the polymeric anhydrous acetates \( [\text{Pd(O}_2\text{CMe)}_2]_3 \) and \( [\text{Pt(O}_2\text{CMe)}_2]_4 \) (Fig. 27.10), are the most
Figure 27.10 Anhydrous acetates of Pd$^{II}$ and Pt$^{II}$: (a) trimeric [Pd(O$_2$CMe)$_3$]$_3$ involving square-planar coordinated Pd but no metal–metal bonding (average Pd–Pd = 315 pm), and (b) tetrameric [Pt(O$_2$CMe)$_4$]$_4$ involving octahedrally coordinated Pt and metal–metal bonds (average Pt–Pt = 249.5 pm). The four bridging ligands in the Pt$_4$ plane are much more labile than the others.

Important.\(^\text{(17,18)}\) Approximately square planar [M(NO$_3$)$_4$]$^{2-}$ anions containing the unusual unidentate nitrato ion are also known.\(^\text{(19)}\) Fluoro complexes are even less prevalent, the preference of these cations being for the other halides, cyanide, N- and heavy atom-donor ligands.

The complexes [MX$_4$]$^{2-}$ (M = Pd, Pt; X = Cl, Br, I, SCN, CN) are all easily obtained and may be crystallized as salts of [NH$_4$]$^+$ and the alkali metals. By using [NR$_4$]$^+$ cations it is possible to isolate binuclear halogen-bridged anions [M$_2$X$_6$]$^{2-}$ (X = Br, I) which retain the square-planar coordination of M. Aqueous solutions of yellowish-brown [PdCl$_4$]$^{2-}$ and red [PtCl$_4$]$^{2-}$ are common starting materials for the preparation of other Pd$^{II}$ and Pt$^{II}$ complexes by successive substitution of the chloride ligands. In both [M(SCN)$_4$]$^{2-}$ complexes the ligands bond through their $\pi$-acceptor (S) ends, though in the presence of stronger $\pi$-acceptor ligands such as PR$_3$ and AsR$_3$ they tend to bond through their N ends.\(^\dagger\) Not surprisingly, therefore, several instances of linkage isomerism (p. 920) have been established in compounds of the type $\text{trans-}[\text{M(PR)}_3)_2\text{(SCN)}_2]$.

Complexes with ammonia and amines, especially those of the types [ML$_4$]$^{2+}$ and [ML$_2$X$_2$], are numerous for Pd$^{II}$ and even more so for Pt$^{II}$. Many of them were amongst the first complexes of these metals to be prepared and interest in them has continued since. For example, the colourless [Pt(NH$_3$)$_4$]Cl$_2$.H$_2$O can be obtained by adding NH$_3$ to an aqueous solution of PtCl$_2$ and, in 1828, was the first of the platinum ammines to be discovered (by G. Magnus). Other salts of the [Pt(NH$_3$)$_4$]$^{2+}$ ion are easily derived, the best known being Magnus’s green salt [Pt(NH$_3$)$_4$][PtCl$_4$]. That a green salt should result from the union of a colourless cation and a red anion was unexpected and is a consequence of the crystal structure, which consists of the square-planar anions and cations stacked

---

alternately to produce a linear chain of Pt atoms only 325 pm apart. Interaction between these metal atoms shifts the d–d absorption of the [PtCl₄]²⁻ ion from the green region (whence the normal red colour) towards the red, so producing the green colour.

Magnus's salt is an electrolyte and can form and non-ionized polymerization isomers (p. 921) of the stoichiometry PtCl₂(NH₃)$_2$ are also known which can be prepared as monomeric cis and trans isomers:

$$[\text{PtCl}_4]^{2-} \xrightarrow{\text{NH}_3} \text{cis-}[\text{PtCl}_2(\text{NH}_3)_2]$$

$$[\text{Pt(NH}_3)_4]^{2+} \xrightarrow{\text{HCl}} \text{trans-}[\text{PtCl}_2(\text{NH}_3)_2]$$

Their existence led Werner to infer a square-planar geometry for Pt$^{II}$.

Many substitution reactions are possible with these ammines and were studied extensively in the 1920s by the Russian, I. I. Chernyaev (also transliterated from the Cyrillic as Tscherniaev, etc.). He noticed that when there are alternative positions at which an incoming ligand might effect a substitution; the position chosen depends not so much on the substituting or substituted ligand as on the nature of the ligand trans to that position. This became known as the “trans-effect” and has had a considerable influence on the synthetic coordination chemistry of Pt$^{II}$ (see Panel).

A resurgence of interest in these seemingly simple complexes of platinum started in 1969 when B. Rosenberg and co-workers discovered the anti-tumour activity of cis-[PtCl₂(NH₃)$_2$]⁻.

---

**The Trans Effect**

Because their rates of substitution are convenient for study, most work has been done with platinum complexes, and for these it is found that ligands can be arranged in a fairly consistent order indicating their relative abilities to labilize ligands trans to themselves:

$$\text{F}^- < \text{OH}^- < \text{H}_2\text{O}, \text{NH}_3, \text{py} < \text{Cl}^- < \text{Br}^- < \text{I}^-, -\text{SCN}^-, \text{NO}_2^-, \text{C}_6\text{H}_5^- < \text{S}=-\text{C(NH}_2)_2, \text{CH}_3^- < \text{H}^+, \text{PR}_3, \text{AsR}_3 < \text{CN}^-, \text{CO}, \text{C}_2\text{H}_4$$

The reason why the particular substitution reactions of [PtCl₄]²⁻ and [Pt(NH₃)$_4$]²⁺, mentioned above, produce respectively cis and trans isomers is now evident. It is because, in both cases, in the second of the stepwise substitutions there is a choice of positions for the substitution and in each case it is a ligand trans to a Cl⁻ which is replaced in preference to a ligand trans to an NH₃:

Similar considerations have been invaluable in devising synthetic routes to numerous other isomeric complexes of Pt$^{IV}$ but, as can be seen in Fig. A, other considerations such as the relative stabilities of the different Pt–ligand bonds are also involved.

---

Panel continues

---

Explanations for the trans-effect abound and it seems that either π or σ effects, or both, are involved. The ligands exerting the strongest trans-effects are just those (e.g. C2H4, CO, PR3, etc.) whose bonding to a metal is thought to have most π-acceptor character and which therefore remove most π-electron density from the metal. This reduces the electron density most at the coordination site directly opposite, i.e. trans, and it is there that nucleophilic attack is most likely. This interpretation is not directly concerned with labilizing a particular ligand but rather with encouraging the attachment of a further ligand. It has consequently been applied most successfully to explaining kinetic phenomena such as reaction rates and the proportions of different isomers formed in a reaction (which depend on the rates of reaction), due to the stabilization of 5-coordinate reaction intermediates.

![Image of three isomers of [PtCl(NH3)(NH2Me)(NO2)].](image)

**Figure A** Preparation of the three isomers of [PtCl(NH3)(NH2Me)(NO2)]. Where indicated these steps can be explained by the greater trans-effect of the NO2- ligand. Elsewhere the weakness of the Pt–Cl as compared to the Pt–N bond must be invoked.

On the other hand, a ligand which is a strong σ-donor is expected to produce an axial polarization of the metal, its lone-pair inducing a positive charge on the near side of the metal and a concomitant negative charge on the far side. This will weaken the attachment to the metal of the trans ligand. This interpretation has been most successfully used to explain thermodynamic, “ground state” properties such as the bond lengths and vibrational frequencies of the trans ligands and their nmr coupling constants with the metal.

In order to distinguish between kinetic and thermodynamic phenomena it is convenient to refer to the former as the “trans-effect” and the latter as the “trans-influence” or “static trans-effect”, though this nomenclature is by no means universally accepted. However, it appears that to account satisfactorily for the kinetic "trans-effect", both π (kinetic) and σ (thermodynamic) effects must be invoked to greater or lesser extents. Thus, for ligands which are low in the trans series (e.g. halides), the order can be explained on the basis of a π effect whereas for ligands which are high in the series the order is best interpreted on the basis of a σ effect. Even so, the relatively high position of H2O which can have no π-acceptor properties, seems to be a result of a σ mechanism or some other interaction.

("cisplatin"). Binding of cisplatin to DNA appeared to be the central feature of the action and, since the trans-isomer is inactive, it was evident that chelation (or at least coordination to donor atoms in close proximity) is an essential part of the activity. Extensive studies, involving in particular proton nmr, suggested that Pt loses the Cl- ligands and binds to N-7 atoms of a pair of guanine bases on adjacent strands of DNA. Recent X-ray work on a 12-base-pair fragment of double stranded DNA

confirms that the binding of Pt distorts the local DNA structure therefore inhibiting the cell division inherent in the proliferation of cancer cells.

In order to avoid serious side effects of cisplatin (kidney- and neuro-toxicity) alternative Pt compounds have been developed. The most important of these is “carboplatin” in which the cis-chlorides are replaced by the O-chelate, cyclobutanedicarboxylate but all of them have ligands with NH groups which facilitate the hydrogen bonding thought to stabilize the distortions of the DNA structure.

Treatment of aqueous solutions of cis-[PtCl₂(NH₃)₂] with a variety of pyrimidines yields blue, oligomeric (Pt₄) compounds of the type known since the early 20th century as “platinum blues.” They are mostly, mixed valence, paramagnetic compounds and although some have been characterized(23) others are less well-defined and include green and violet materials.

Stable complexes of Pd²⁺ and Pt²⁺ are formed with a variety of S-donor ligands which includes the inorganic sulfite (SO₃⁻) and thiosulfate (S₂O₃²⁻) apparently coordinating through 1 S and 1 O) but those with organo-sulfur ligands such as 1,2-dithiolenes are of more interest. The anions [M(mnt)₂]²⁻ (mnt = S₂C₂(CN)₂, M = Ni, Pd, Pt) have a facile redox chemistry yielding products with unusual electrical properties. Most salts of the square planar [M(mnt)₂]⁻ crystallize in stacks, in which the anions associate in pairs, and are semiconductors but the nonstoichiometric (H₂O)₀.₃₃Li₀.₈[Pt(mnt)₂]1.₆₇H₂O is a linear conductor and Cs₀.₈₂[Pd(mnt)₂]0.₅H₂O shows metallic conductance when subject to high pressure.(24)

The essentially class-b character of Pd²⁺ and Pt²⁺ is further indicated by the ready formation of complexes with phosphines and arsines. [M(PR₃)₂X₂] and the arsine analogues are particularly well known. Zero dipole moments indicate that the palladium complexes are invariably trans, whereas those of platinum may be either cis or trans the latter being much the more soluble and having lower mps. When these bisphosphines and bisarsines are boiled in alcohol, or alternatively when they are fused with MX₂, the dimeric complexes [MLX₂]₂ are frequently obtained. Again, zero dipole moments (in some cases confirmed by X-ray analysis) indicate that these are all of the symmetrical trans form (a).

By involving SCN⁻ a novel 8-membered ring system has been produced (b).

Nuclear magnetic resonance has proved to be a particularly useful tool in studying phosphines of platinum. The nuclear spins of ³¹P and ¹⁹⁵Pt (both equal to ½) couple, and the strength of this coupling (as measured by the “coupling constant” J) is affected much more by ligands trans to the phospine than by those which are cis. This has helped in determinations of structure and also in studies of the “trans influence”. Platinum(II) also forms a number of quite stable monohydrido (H⁻) phosphines which have proved similarly interesting, the ¹¹H⁻¹⁹⁵Pt coupling constants being likewise sensitive to the trans ligand.

It has already been pointed out that the overwhelming majority of complexes of Pd²⁺ and Pt²⁺ are square planar. However, 5-coordinate intermediates are almost certainly involved in many of the substitution reactions of these 4-coordinate complexes, and 5-coordinate trigonal

---

bipyramidal complexes with “tripod” ligands (p. 907) are well established. These ligands include the tetraarsine, As(\(\text{C}_6\text{H}_4\)−2−As\(\text{Ph}_2\)) \(_2\) (gas, p. 1150), its phosphine analogue and also \(\text{N}((\text{CH}_2\text{CH}_2\text{NMe}_2)_3\) i.e. \((\text{Me}_6\text{tren})\). The somewhat less-rigid tetraarsine, 1,2-\(\text{C}_6\text{H}_4\)\{\(\text{As} (\text{Me})\)-\(\text{C} \&\)-As\(\text{Me}_2\)}\(_2\) (tpas), however forms a red, square-pyramidal complex \([\text{Pd}(\text{tpas})\text{Cl}]\text{ClO}_4\) with palladium.

### Oxidation state I (\(\text{d}^9\))

Although nickel(I) is thought to be involved in some nickel-containing enzymes, this oxidation state is best represented by yellow to red, tetrahedral phosphines such as \([\text{Ni}(\text{PPPh}_3)_3\text{X}]\) \((\text{X} = \text{Cl}, \text{Br}, \text{I})\) which are paramagnetic, as expected for a \(\text{d}^9\) configuration, and relatively stable. \([\text{Ni}(\text{PMe}_3)_4]\text{[BPb]}\) has also been structurally characterized. A more recent\(^{25}\) example is \(\text{K}_3[\text{NiO}_2]\). This dark red, air- and water-sensitive compound, like the \(\text{Fe}^1\) (p. 1082 footnote) and \(\text{Co}^1\) (p. 1134) analogues, is prepared by heating \(\text{K}_6\text{CdO}_4\) in a closed Ni cylinder at 500°C for 49 days when it reacts with the cylinder walls:

\[
\text{K}_6\text{CdO}_4 + 2\text{Ni} \rightarrow 2\text{K}_3[\text{NiO}_2] + \text{Cd}
\]

These anions are remarkable not only for the low coordination number but also for the low oxidation state of the metals in combination with oxygen which is more commonly to be found stabilizing high oxidation states.

### Oxidation state 0 (\(\text{d}^{10}\))

Besides \([\text{Ni}(\text{CO})_4]\) and organometallic compounds discussed in the next section, nickel is found in the formally zero oxidation state with ligands such as \(\text{CN}^−\) and phosphines. Reduction of \(\text{K}_2[\text{Ni}^0(\text{CN})_4]\) with potassium in liquid ammonia precipitates yellow \(\text{K}_4[\text{Ni}^0(\text{CN})_4]\), which is sensitive to aerial oxidation. Being isoelectronic with \([\text{Ni}(\text{CO})_4]\) it is presumed to be tetrahedral. Similarity with the carbonyl is still more marked in the case of the gaseous and tetrahedral \([\text{Ni}(\text{PF}_3)_4]\), which also can be prepared directly from the metal and ligand:

\[
\text{Ni} + 4\text{PF}_3 \xrightarrow{1000° \text{C}} [\text{Ni}(\text{PF}_3)_4]
\]

The pale yellow \([\text{Ni}(\text{PF}_3)_4]\) is also tetrahedral but with some distortion.\(^{26}\) In sharp contrast to nickel, palladium forms no simple carbonyl, \(\text{Pt}(\text{CO})_4\) is prepared only by matrix isolation at very low temperatures and reports of \(\text{K}_4[\text{M}(\text{CN})_4]\) \((\text{M} = \text{Pd}, \text{Pt})\) may well refer to hydrido complexes; in any event they are very unstable. The chemistry of these two metals in the zero oxidation state is in fact essentially that of their phosphine and arsine complexes and was initiated by L. Malatesta and his school in the 1950s. Compounds of the type \([\text{M}(\text{PR}_3)_4]\), of which \([\text{Pt}(\text{PPPh}_3)_4]\) has been most thoroughly studied, are in general yellow, air-stable solids or liquids obtained by reducing \(\text{M}^\text{II}\) complexes in \(\text{H}_2\text{O}\) or \(\text{H}_2\text{O}/\text{EtOH}\) solutions with hydrazine or sodium borohydride. They are tetrahedral molecules whose most important property is their readiness to dissociate in solution to form 3-coordinate, planar \([\text{M}(\text{PR}_3)_3]\) and, in traces, probably also \([\text{M}(\text{PR}_3)_2]\) species. The latter are intermediates in an extensive range of addition reactions (many of which may properly be regarded as oxidative additions) giving such products as \([\text{Pt}^\text{III}(\text{PPPh}_3)_2\text{L}_2]\), \((\text{L} = \text{O}, \text{CN}, \text{N}_3)\) and \([\text{Pt}^\text{II}(\text{PPPh}_3)_2\text{LL}']\), \((\text{L'} = \text{H}, \text{Cl}; \text{R}, \text{I})\) as well as \([\text{Pt}^\text{III}(\text{C}_2\text{H}_4)(\text{PPPh}_3)_2]\) and \([\text{Pt}^\text{II}(\text{CO})_2(\text{PPPh}_3)_2]\).

The mechanism by which this low oxidation state is stabilized for this triad has been the subject of some debate. That it is not straightforward is clear from the fact that, in contrast to nickel, palladium and platinum require the presence of phosphines for the formation of stable carbonyls. For most transition metals the \(\pi\)-acceptor properties of the ligand are thought to be of considerable importance and there is

no reason to doubt that this is true for Ni\(^{0}\).
For Pd\(^{0}\) and Pt\(^{0}\), however, it appears that \(\sigma\)-bonding ability is also important, and the smaller importance of \(\pi\) backbonding which this implies is in accord with the higher ionization energies of Pd and Pt [804 and 865 kJ mol\(^{-1}\) respectively] compared with that for Ni [737 kJ mol\(^{-1}\)].

### 27.3.5 The biochemistry of nickel\(^{(27)}\)

Until the discovery in 1975 of nickel in jack bean urease (which, 50 years previously, had been the first enzyme to be isolated in crystalline form and was thought to be metal-free) no biological role for nickel was known. Ureases occur in a wide variety of bacteria and plants, catalyzing the hydrolysis of urea,

\[
\text{OC(NH}_2\text{)}_2 + \text{H}_2\text{O} \rightarrow \text{H}_2\text{NCOO}^- + \text{NH}_4^+ 
\]

Results from an array of methods, including X-ray absorption, EXAFS, esr and magnetic circular dichroism, suggest that in all ureases the active sites are a pair of Ni\(^{II}\) atoms. In at least one urease,\(^{(27a)}\) these are 350 pm apart and are bridged by a carboxylate group. One nickel is attached to 2 N atoms with a fourth site probably used for binding to urea. The second nickel has a trigonal bipyramidal coordination sphere.

Three other Ni-containing enzymes found in bacteria have now been identified: Hydrogenases, most of which also contain Fe and catalyse the reaction, \(2\text{H}_2 + \text{O}_2 \rightarrow 2\text{H}_2\text{O}\). The Ni has a coordination sphere of 5 or 6 mixed S-, N-, O-donors and is believed to undergo redox cycling between III, II and I oxidation states. CO Dehydrogenase, also incorporating Fe and catalysing the oxidation of CO to \(\text{CO}_2\). The attachment of CO to a nickel centre coordinated to perhaps four S-donors is postulated.

**Methyl-coenzyme M reductase** participates in the conversion of \(\text{CO}_2\) to \(\text{CH}_4\) and contains 6-coordinate nickel(II) in a highly hydrogenated and highly flexible porphyrin system. This flexibility is believed to allow sufficient distortion of the octahedral ligand field to produce low-spin Ni\(^{II}\) (Fig. 27.7) which facilitates the formation of a Ni\(^{I}\)–CH\(_3\) intermediate.

### 27.3.6 Organometallic compounds\(^{(19,28)}\)

All three of these metals have played major roles in the development of organometallic chemistry. The first compound containing an unsaturated hydrocarbon attached to a metal (and, indeed, the first organometallic compound if one excludes the cyanides) was \([\text{Pt(C}_2\text{H}_4]\text{Cl}_2]\), discovered by the Danish chemist W. C. Zeise as long ago as 1827 and followed 4 years later by the salt which bears his name, K[Pt(C\(_2\)H\(_4\))Cl\(_2\)]. \([\text{Ni(CO)}_4]\) was the first metal carbonyl to be prepared when L. Mond and his co-workers discovered it in 1888. The platinum methyls, prepared in 1907 by W. J. Pope, were amongst the first-known transition metal alkyls, and the discovery by W. Reppe in 1940 that Ni\(^{II}\) complexes catalyse the cyclic oligomerization of acetylenes produced a surge of interest which was reinforced by the discovery in 1960 of the \(\pi\)-allylic complexes of which those of Pd\(^{II}\) are by far the most numerous.

#### \(\sigma\)-Bonded compounds

These are of two main types: compounds of \(\text{M}^{IV}\), which for platinum have been known since the beginning of this century and commonly involve the stable \([\text{PtMe}_3]\) group; and compounds of the divalent metals, which were first studied by J. Chatt and co-workers in the late 1950's and are commonly of the type \([\text{MR}_2\text{L}_2]\) (L = phosphine). In the Pt\(^{IV}\) compounds the metal is always octahedrally coordinated and this is frequently achieved in interesting ways. Thus the trimethyl halides, conveniently obtained

§27.3.6 Organometallic compounds

no reason to doubt that this is true for Ni\(^{0}\). For Pd\(^0\) and Pt\(^0\), however, it appears that \(\sigma\)-bonding ability is also important, and the smaller importance of \(\pi\) backbonding which this implies is in accord with the higher ionization energies of Pd and Pt [804 and 865 kJ mol\(^{-1}\) respectively] compared with that for Ni [737 kJ mol\(^{-1}\)].

27.3.5 The biochemistry of nickel\(^{(27)}\)

Until the discovery in 1975 of nickel in jack bean urease (which, 50 years previously, had been the first enzyme to be isolated in crystalline form and was thought to be metal-free) no biological role for nickel was known. Ureases occur in a wide variety of bacteria and plants, catalyzing the hydrolysis of urea,

\[
\text{OC(NH}_2)_2 + \text{H}_2\text{O} \rightarrow \text{H}_2\text{NCOO}^- + \text{NH}_4^+
\]

Results from an array of methods, including X-ray absorption, EXAFS, esr and magnetic circular dichroism, suggest that in all ureases the active sites are a pair of Ni\(^{II}\) atoms. In at least one urease,\(^{(27a)}\) these are 350 pm apart and are bridged by a carboxylate group. One nickel is attached to 2 N atoms with a fourth site probably used for binding to urea. The second nickel has a trigonal bipyramidal coordination sphere.

Three other Ni-containing enzymes found in bacteria have now been identified:

*Hydrogenases*, most of which also contain Fe and catalyse the reaction, \(2\text{H}_2 + \text{O}_2 \rightarrow 2\text{H}_2\text{O}\). The Ni has a coordination sphere of 5 or 6 mixed S-, N-, O-donors and is believed to undergo redox cycling between III, II and I oxidation states.

*CO Dehydrogenase*, also incorporating Fe and the oxidation of CO to CO\(_2\). The attachment of CO to a nickel centre coordinated to perhaps four S-donors is postulated.

Methyl-coenzyme M reductase participates in the conversion of CO\(_2\) to CH\(_4\) and contains 6-coordinate nickel(II) in a highly hydrogenated and highly flexible porphyrin system. This flexibility is believed to allow sufficient distortion of the octahedral ligand field to produce low-spin Ni\(^{II}\) (Fig. 27.7) which facilitates the formation of a Ni\(^{I}\) – CH\(_3\) intermediate.

27.3.6 Organometallic compounds\(^{(4,28)}\)

All three of these metals have played major roles in the development of organometallic chemistry. The first compound containing an unsaturated hydrocarbon attached to a metal (and, indeed, the first organometallic compound if one excludes the cyanides) was [Pt(C\(_2\)H\(_4\))Cl\(_2\)], discovered by the Danish chemist W. C. Zeise as long ago as 1827 and followed 4 years later by the salt which bears his name, K[Pt(C\(_2\)H\(_4\))Cl\(_2\)].\(_2\). [Ni(CO)\(_4\)] was the first metal carbonyl to be prepared when L. Mond and his co-workers discovered it in 1888. The platinum methlys, prepared in 1907 by W. J. Pope, were amongst the first-known transition metal alkyls, and the discovery by W. Reppe in 1940 that Ni\(^{II}\) complexes catalyse the cyclic oligomerization of acetylenes produced a surge of interest which was reinforced by the discovery in 1960 of the \(\pi\)-allylic complexes of which those of Pd\(^{II}\) are by far the most numerous.

\(\sigma\)-Bonded compounds

These are of two main types: compounds of M\(^{IV}\), which for platinum have been known since the beginning of this century and commonly involve the stable \{PtMe\(_3\}\} group; and compounds of the divalent metals, which were first studied by J. Chatt and co-workers in the late 1950’s and are commonly of the type [MR\(_2\)L\(_2\)] (L = phosphine). In the Pt\(^{IV}\) compounds the metal is always octahedrally coordinated and this is frequently achieved in interesting ways. Thus the trimethyl halides, conveniently obtained

by treating PtCl$_4$ with MeMgX in benzene, are tetramers, [PtMe$_3$X]$_4$, in which the 4 Pt atoms form a cube involving triply-bridging halogen atoms (Fig. 27.11a). The dimeric [PtMe$_3$(acac)$_2$] is also unusual in that the acac is both O- and C-bonded (Fig. 27.11b), while in [PtMe$_3$(acac)(bipy)] 7-coordination is avoided because the acac coordinates merely as a unidentate C-donor. Pd$^{II}$ compounds such as [Pd(bipy)Me$_3$] are also octahedral but are limited in number and much less stable than those of Pt$^{IV}$, being susceptible to reductive elimination.\[29\]

The chequered history of compounds of this type makes salutory reading. H. Gilman and M. Lichtenwalter (1938, 1953) reported the synthesis of PtMe$_4$ in 46% yield by reacting Me$_3$PtI with NaMe in hexane. R. E. Rundle and J. H. Sturdivant determined the X-ray crystal structure of this product in 1947 and described it as a tetramer [(PtMe$_4$)$_4$]: this required the concept of a multicentred, 2-electron bond, and was one of the first attempts to interpret the bonding in a presumed electron-deficient cluster compound. In fact, tetramethylplatinum cannot be prepared in this way and is unknown; Gilman’s compound was actually a hydrolysis product [(PtMe$_3$(OH))$_4$] and the mistaken identity of the crystal went undetected by the X-ray work, because at that time, the scattering curves for the 9-electron groups CH$_3$ and OH were indistinguishable in the presence of Pt. Interestingly, the compound PtMes(OH) had, in reality, already been synthesized by W. J. Pope and S. J. Peachey as long ago as 1909, and its tetrameric structure was confirmed by subsequent X-ray work.\[30\] In a parallel study,\[31\] the transparent tan-coloured tetramer [(PtMe$_4$)$_4$] has now been shown to be the same compound as was previously erroneously reported in 1938 as hexamethylplatinum, [Me$_2$Pt—PtMe$_3$]. This was equally erroneously described in 1949 on the basis of an incomplete X-ray structural study as a methyl-bridged oligomer [(PtMe$_3$)$_2$] or an infinite chain of methyl-bridged 6-coordinate (PtMes)$_x$-groups. A qualitative test for iodine would have revealed the error 30 years earlier.

Although PtMe$_4$ remains unknown it has more recently been shown that reaction of [PtMe$_2$(PPh$_3$)$_2$] with LiMe yields the square-planar Pt$^{II}$ complex Li$_2$[PtMe$_4$], whereas reaction of [PtMe$_3$I]$_2$ with LiMe affords the octahedral Pt$^{IV}$ complex Li$_2$[PtMe$_6$].\[32\] The thermally stable, colourless, 8-coordinate complex [PtMe$_3$(η$_5$-C$_5$H$_5$)$_2$] is also known.\[33\]

The stabilities of the [ML$_2$R$_2$] phosphines increase from Ni$^{II}$ to Pt$^{IV}$ and for Ni$^{II}$ they are only isolable when R is an o-substituted aryl. Those of Pt$^{IV}$, on the other hand, are amongst the most stable σ-bonded organo-transition metal compounds while those of Pd$^{II}$ occupy an intermediate position.

**Carbonyls (see p. 926)**

On the basis of the 18-electron rule, the d$^8$s$^2$ configuration is expected to lead to carbonyls of formula [M(CO)$_4$] and this is found for nickel. [Ni(CO)$_4$], the first metal carbonyl to be discovered, is an extremely toxic, colourless liquid (mp -19.3°C, bp 42.2°C) which is tetrahedral in the vapour and in the solid (Ni-C 184 pm, C-O 115 pm). Its importance in the Mond process for manufacturing nickel metal has already been mentioned as has the absence of stable analogues of Pd and Pt. It may be germane to add that the introduction of halides (which are σ-bonded) reverses the situation: [NiX(CO)$_3$]$^-$ (X = Cl, Br, I) are very unstable, the yellow [Pd$^{II}$(CO)Cl$_2$]$_n$ is somewhat less so, whereas the colourless [Pt$^{IV}$(CO)$_2$Cl$_2$] and [PtX$_3$(CO)]$^-$ are quite stable. [Ni(CO)$_4$] is readily oxidized by air and can be reduced by alkali metals in liquid ammonia or thf to yield a series of polynuclear carbonylate anion.
clusters but consisting mainly of \([\text{Ni}_5(\text{CO})_{12}]^{2-}\) and \([\text{Ni}_6(\text{CO})_{12}]^{2-}\). The latter, being more stable and less toxic than the monomer, is a common starting material for the preparation of other clusters,\(^{34}\) many of which are stabilized by encapsulated atoms of which carbon is especially efficacious. These clusters, which in general are intensely coloured and air-sensitive, have structures\(^{35}\) based on the stacking of \(\text{Ni}_3\) triangles and \(\text{Ni}_4\) squares and, in carbon-centred clusters of higher nuclearities, based on \(\text{Ni}_7\)C and \(\text{Ni}_8\)C moieties (Fig. 27.12). Other clusters, derived from reactions of \([\text{Ni}_6(\text{CO})_{12}]^{2-}\) and main group reactants, have icosahedral frameworks\(^{36}\) such as \(\text{Ni}_{10}\)Se\(_2\), \(\text{Ni}_9\)Te\(_3\) and \(\text{Ni}_{10}\)Sb. Some of these are centred with Ni, some centred with the main group element and others uncentred.

Reductions of \([\text{PtCl}_6]^{2-}\) in an atmosphere of CO provide a series of clusters, \([\text{Pt}_3(\text{CO})_6]_n^{2-}\) \((n = 1–6, 10)\) consisting of stacks of \(\text{Pt}_3\) triangles in slightly twisted columns; Pt–Pt = 266 pm in triangles, 303–309 pm between triangular planes (Fig. 27.12). A feature of these and other Pt clusters is that they mostly have electron counts lower than predicted by the usual electron counting rules. In the series just mentioned for instance, \(n = 1\) and \(n = 2\) have electron counts of 44 and 86 whereas 48 and 90 would

be expected for a triangle and trigonal prism respectively. This is ascribed to the relatively large 6s–6p energy gap in this part of the periodic table and the consequently reduced involvement of p-orbitals in skeletal bonding. Heating salts of the \( n = 3 \) anion in acetonitrile under reflux produces \([Pt_{19}(CO)_{22}]^{3-}\) containing two encapsulated metal atoms (Fig. 27.12c). \([Pt_{26}(CO)_{32}]^{3-}\) and \([Pt_{38}(CO)_{44}H_4]^{2-}\), in which the metal atoms adopt a virtually cubic close packed arrangement, have also been characterized. In contrast to the Pt\( _6 \) cluster above, the brown-black \([Pt_6(CO)_{16}(\mu-\text{dppm})]^2+\) is the first octahedral platinum carbonyl cluster to be characterized. All its CO groups are terminal.\(^{(36a)}\)

Palladium forms clusters of these types far less readily than nickel and platinum, unless they are stabilized by \( \sigma \)-donor ligands such as phosphines. This may be due to the lower energy of Pd–Pd bonds as reflected in the sublimation energies, 427, 354 and 565 \( \text{kJ mol}^{-1} \) for Ni, Pd and Pt.

**Cyclopentadienyls**

Nickelocene, \([\text{Ni}^{11}(\eta^5-C_5H_5)_2]\), is a bright green, reactive solid, conveniently prepared by adding a solution of \( \text{NiCl}_2 \) in dimethylsulfoxide to a solution of \( \text{KC}_5\text{H}_5 \) in 1,2-dimethoxyethane. It has the sandwich structure of ferrocene, and is similarly susceptible to ring-addition reactions, but its 2 extra electrons (\( \mu_c = 2.86 \text{ BM} \)) must be accommodated in an antibonding orbital (p. 938). The orange-yellow, \([\text{Ni}(\eta^5-C_5\text{H}_5)_2]^+\), cation is therefore easily obtained by oxidation and the “triple-decker sandwich” cation, \([\text{Ni}_2(\eta^5-C_5\text{H}_5)_3]^+\) (Fig. 27.13), is produced by reacting nickelocene with a Lewis acid such as BF\(_3\). This latter cation is a 34 valence electron species [i.e. \((2 \times 8) + (3 \times 6)\) for \(2\text{Ni}^{11}\) and \(3C_5\text{H}_5^-\)] and there are theoretical grounds for supposing that this, and the 30-electron configuration, will offer the same sort of stability for binuclear sandwich compounds that the 18-electron configuration offers for mononuclear compounds. The cyclopentadienyls of palladium and platinum are less stable than those of nickel, and while the heavier pair of metals form some monocyclopentadienyl complexes, neither forms a metallocene.

**Alkene and alkyne complexes**\(^{(37)}\)

These are important not only for their part in stimulating the development of bonding theory (for a fuller discussion, see p. 931) but also for their catalytic role in some important industrial processes.

Apart from some Pd\(^0\) and Pt\(^0\) biphosphine complexes, the alkene and alkyne complexes involve the metals in the formally divalent state. Those of Ni\(^{11}\) are few in number compared to those of Pd\(^{11}\), but it is Pt\(^{11}\) which provides the most numerous and stable compounds of this type. These are of the forms \([\text{PtCl}_3\text{Alk}]^-\), \([\text{PtCl}_2\text{Alk}]_2\) and \([\text{PtCl}_2\text{Alk}_2]\). They are generally prepared by treating an M\(^{11}\) salt with the hydrocarbon when a less strongly bonded anion is displaced. Thus, Zeise’s salt (p. 930) may be obtained by prolonged shaking of a solution of \( \text{K}_2\text{PtCl}_4 \) in

dil HCl with C₂H₄, though the reaction can be speeded-up by the addition of a small amount of SnCl₂. Treatment of an ethanolic solution of the product with conc HCl then affords the orange dimer, [[PtCl₂(C₂H₄)]₂]. If this is then dissolved in acetone at -70°C and further treated with C₂H₄, yellow, unstable crystals of the trans-bis(ethene) are formed:

\[
\begin{align*}
&\text{cis-Substituted dichloro complexes are obtained if chelating dialkenes such as cis-cis-cycloocta-1,5-diene (cod) are used (p. 932).} \\
&\text{A common property of coordinated alkenes is their susceptibility to attack by nucleophiles such as OH}^-\text{, OMe}^-\text{, MeCO}₂^-\text{, and Cl}^-\text{, and it has long been known that Zeise’s salt is slowly attacked by non-acidic water to give MeCHO} \\
&\text{and Pt metal, while corresponding Pd complexes are even more reactive.}^{[38]}\text{ This forms the basis of the Wacker process (developed by J. Smidt and his colleagues at Wacker Chemie, 1959–60) for converting ethene (ethylene) into ethanal (acetaldehyde) — see Panel overleaf.} \\
&\text{Alkyne complexes are essentially similar to the alkenes (p. 932) and those of Pt}^{II}\text{, particularly when the alkyne incorporates the t-butyl group, are the most stable. Ni}^{III}\text{ alkyne complexes are less numerous and generally less stable but are of greater practical importance because of their role as intermediates in the cyclic oligomerization of alkenes, discovered by W. Reppe (see Panel).}
\end{align*}
\]

\[\text{\pi-Allylic complexes}\]

\text{The preparation and bonding of complexes of the \(\eta^3\)-allyl group, CH₂=CH–CH₂–, have already been discussed (p. 933). This group, and substituted derivatives of it, may act as \(\sigma\)-bonded ligands, but it is as 3-electron \(\pi\)-donor ligands that they are most important. Crudely:}

\[
\begin{align*}
&\text{The} \text{\pi-allyl complexes of Pd}^{II}, \text{ e.g.} \ [\text{Pd}(\eta^3\text{-}
\begin{align*}
&\text{The role of the Pd and Ni complexes as intermediates in the oligomerization of conjugated dienes (of which 1,3-butadiene, C₄H₆, is the most familiar) have been extensively studied, particularly by G. Wilke and his group. For instance in the presence of [Ni(\eta^3\text{-C}_3\text{H}_5)X]_2 (X = Cl, Br, I), are very stable and more numerous than for any other metal, and neither Ni nor Pt form as many of these complexes. Indeed, the contrast between Pd and Pt is such that in reactions with alkenes, where a particular compound of Pt is likely to form an alkene complex, the corresponding compound of Pd is more likely to form a \(\pi\)-allyl complex. The other isomers of cdt are also obtained and, if a coordination site on the nickel is blocked by the addition of a ligand such as a tertiary phosphine, dimerization of the butadiene, rather than trimerization, occurs.}
\]

\[\text{trans, trans, trans-cyclo-dodeca-1,5,9-triene (cdt)}\]
Catalytic Applications of Alkene and Alkyne Complexes

The Wacker process

Ethanal is produced by the aerial oxidation of ethene in the presence of PdCl₂/CuCl₂ in aqueous solution. The main reaction is the oxidative hydrolysis of ethene:

\[
\text{C}_2\text{H}_4 + \text{PdCl}_2 + \text{H}_2\text{O} \rightarrow \text{MeCHO} + \text{Pd} + 2\text{HCl}
\]

The mechanism of this reaction is not straightforward but the crucial step appears to be nucleophilic attack by water or OH⁻ on the coordinated ethene to give σ-bonded \(-\text{CH}_2\text{CH}_2\text{OH}\) which then rearranges and is eventually eliminated as MeCHO with loss of a proton.

The commercial viability of the reaction depends on the formation of a catalytic cycle by reoxidizing the palladium metal \textit{in situ}. This is achieved by the introduction of CuCl₂:

\[
\text{Pd} + \text{CuCl}_2 \rightarrow \text{PdCl}_2 + 2\text{CuCl}
\]

Because the solution is slightly acidic, the CuCl₂ itself can be regenerated by passing in oxygen:

\[
2\text{CuCl} + 2\text{HCl} + \frac{1}{2}\text{O}_2 \rightarrow 2\text{CuCl}_2 + \text{H}_2\text{O}
\]

The overall reaction is thus:

\[
\text{C}_2\text{H}_4 + \frac{1}{2}\text{O}_2 \rightarrow \text{MeCHO}
\]

The Reppe Synthesis

Polymerization of alkynes by Ni^{II} complexes produces a variety of products which depend on conditions and especially on the particular nickel complex used. If, for instance, O-donor ligands such as acetylacetone or salicaldehyde are employed in a solvent such as tetrahydrofuran or dioxan, 4 coordination sites are available and cyclotetramerization occurs to give mainly cyclo-octatetraene (cot). If a less-labile ligand such as PPh₃ is incorporated, the coordination sites required for tetramerization are not available and cyclic trimerization to benzene predominates (Fig. A). These syntheses are amenable to extensive variation and adaptation. Substituted ring systems can be obtained from the appropriately substituted alkynes while linear polymers can also be produced.

Figure A  Cyclic oligomerizations of acetylene: tetramerization producing cyclooctatetraene (cot) and trimerization producing benzene.
28 Copper, Silver and Gold

28.1 Introduction

Collectively known as the “coinage metals” because of their former usage, these elements were almost certainly the first three metals known to man. All of them occur in the elemental, or “native”, form and must have been used as primitive money long before the introduction of gold coins in Egypt around 3400 BC.

Cold-hammering was used in the late Stone Age to produce plates of gold for ornamental purposes, and this metal has always been synonymous with beauty, wealth and power. Considerable quantities were accumulated by ancient peoples. The coffin of Tutankhamun (a minor Pharaoh who was only 18 when he died) contained no less than 112 kg of gold, and the legendary Aztec and Inca hoards in Mexico and Peru were a major reason for the Spanish conquests of Central and South America in the early sixteenth century. Today, the greatest hoard of gold is the 30,000 tonnes of bullion (i.e. bars) lying in the vaults of the US Federal Reserve Bank in New York and belonging to eighty different nations.

Estimates of the earliest use of copper vary, but 5000 BC is not unreasonable. By about 3500 BC it was being obtained in the Middle East by charcoal reduction of its ores, and by 3000 BC the advantages of adding tin in order to produce the harder bronze was appreciated in India, Mesopotamia and Greece. This established the “Bronze Age”, and copper has continued to be one of man’s most important metals.

The monetary use of silver may well be as old as that of gold but the abundance of the native metal was probably far less, so that comparable supplies were not available until a method of winning the metal from its ores had been discovered. It appears, however, that by perhaps 3000 BC a form of cupellation was in operation in Asia Minor and its use gradually

\[ \text{Cupellation processes vary but consist essentially of heating a mixture of precious and base (usually lead) metals in a stream of air in a shallow hearth, when the base metal is oxidized and removed either by blowing away or by absorption into the furnace lining. In the early production of silver, the sulfide ores must have been used to give first a silver/lead alloy from which the lead was then removed.} \]

spread, so that silver coinage was of crucial economic importance to all subsequent classical Mediterranean civilizations.

The name copper and the symbol Cu are derived from aes cyprium (later Cuprum), since it was from Cyprus that the Romans first obtained their copper metal. The words silver and gold are Anglo-Saxon in origin but the chemical symbols for these elements (Ag and Au) are derived from the Latin argentum (itself derived from the Greek ἀργός, argos, shiny or white) and aurum, gold.

28.2 The Elements

28.2.1 Terrestrial abundance and distribution

The relative abundances of these three metals in the earth’s crust (Cu 68 ppm, Ag 0.08 ppm, Au 0.004 ppm) are comparable to those of the preceding triad — Ni, Pd and Pt. Copper is found mainly as the sulfide, oxide or carbonate, its major ores being copper pyrite (chalcopyrite), CuFeS₂, which is estimated to account for about 50% of all Cu deposits; copper glance (chalcolite), Cu₂S; cuprite, Cu₂O and malachite, Cu₂CO₃(OH)₂. Large deposits are found in various parts of North and South America, and in Africa and the former Soviet Union. The native copper found near Lake Superior is extremely pure but the vast majority of current supplies of copper are obtained from low-grade ores containing only about 1% Cu.

Silver is widely distributed in sulfide ores of which silver glance (argentite), Ag₂S, is the most important. Native silver is sometimes associated with these ores as a result of their chemical reduction, while the action of salt water is probably responsible for their conversion into “horn silver”, AgCl, which is found in Chile and New South Wales. The Spanish Americas provided most of the world’s silver for the three centuries after about 1520, to be succeeded in the nineteenth century by Russia. Appreciable quantities are now obtained as a byproduct in the production of other metals such as copper, and the main producers are Mexico, the former Soviet Union, Peru, the USA and Australia.

Gold, too, is widely, if sparsely, distributed both native† and in tellurides, and is almost invariably associated with quartz or pyrite, both in veins and in alluvial or placer deposits laid down after the weathering of gold-bearing rocks. It is also present in sea water to the extent of around 1 × 10⁻³ ppm, depending on location, but no economical means of recovery has yet been devised. Prior to about 1830 a large proportion of the world’s stock of gold was derived from ancient and South American civilizations (recycling is not a new idea), and the annual output of new gold was no more than 12 tonnes pa. This supply gradually increased with the discovery of gold in Siberia followed by “gold rushes” in 1849 (California: as a result of which the American West was settled), 1851 (New South Wales and Victoria: within 7 y the population of Australia doubled to 1 million), 1884 (Transvaal), 1896 (Klondike, North-west Canada) and, finally, 1900 (Nome area of Alaska) as a result of which by 1890 world production had risen to 150 tonnes pa. It is now 15 times that amount, ~2300 tonnes pa.

28.2.2 Preparation and uses of the elements

A few of the oxide ores of copper can be reduced directly to the metal by heating with coke, but the bulk of production is from sulfide ores containing iron, and they require more complicated treatment. These ores are comparatively lean (often ~0.5% Cu) and their exploitation requires economies of scale. They are therefore obtained in huge, open-pit operations employing shovels

† The “Welcome Stranger” nugget found in Victoria, Australia, in 1869 weighed over 71 kg and yielded nearly 65 kg of refined gold but was, unfortunately, exceptional.

of up to 25 m³ (900 ft³) and trucks of up to 250 tonnes capacity, followed by crushing and concentration (up to 15–20% Cu) by froth-flotation. (The environmentally acceptable disposal of the many millions of tonnes of finely ground waste poses serious problems.) Silica is added to the concentrate which is then heated in a reverberatory furnace (blast furnaces are unsuitable for finely powdered ores) to about 1400°C when it melts. FeS is more readily converted to the oxide than is Cu₂S and so, with the silica, forms an upper layer of iron silicate slag leaving a lower layer of copper matte which is largely Cu₂S and FeS. The liquid matte is then placed in a converter (similar to the Bessemer converter, p. 1072) with more silica and a blast of air forced through it. This transforms the remaining FeS first to FeO and then to slag, while the Cu₂S is partially converted to Cu₂O and then to metallic copper:

\[
\begin{align*}
2\text{FeS} + 3\text{O}_2 & \rightarrow 2\text{FeO} + 2\text{SO}_2 \\
2\text{Cu}_2\text{S} + 3\text{O}_2 & \rightarrow 2\text{Cu}_2\text{O} + 2\text{SO}_2 \\
2\text{Cu}_2\text{O} + \text{Cu}_2\text{S} & \rightarrow 6\text{Cu} + \text{SO}_2
\end{align*}
\]

The major part of this “blister” copper is further purified electrolytically by casting into anodes which are suspended in acidified CuSO₄ solution along with cathodes of purified copper sheet. As electrolysis proceeds the pure copper is deposited on the cathodes while impurities collect below the anodes as “anode slime” which is a valuable source of Ag, Au and other precious metals.

About one-third of the copper used is secondary copper (i.e. scrap) but the annual production of new metal is nearly 8 million tonnes, the chief sources (1993) being Chile (22%), the USA (20%), the former Soviet Union (9%), Canada and China (7.5% each) and Zambia (5%). The major use is as an electrical conductor but it is also widely employed in coinage alloys as well as the traditional bronze (Cu plus 7–10% Sn), brass (Cu–Zn), and special alloys such as Monel (Ni–Cu).

Most silver is nowadays produced as a byproduct in the manufacture of non-ferrous metals such as copper, lead and zinc, when the silver follows the base metal through the concentration and smelting processes. In the case of copper production, for instance, the anode slimes mentioned above are treated with hot, aerated dilute H₂SO₄, which dissolves some of the base metal content, then heated with a flux of lime or silica to slag-off most of the remaining base metals, and, finally, electrolysed in nitrate solution to give silver of better than 99.9% purity. As with copper, much of the metal used is salvage but over 10 000 tonnes of new metal were produced in 1993, mainly from Mexico (19%), the former Soviet Union, the USA and Peru (~13% each) and Australia (9%). Photography accounts for the use of about one-third of this and it is also used in silverware and jewellery, electrically, for silvering mirrors, and in the high-capacity Ag–Zn, Ag–Cd batteries. A minor though important use from 1826 until recent times was as dental amalgam (Hg/γ–Ag₃Sn).

Traditionally, gold was recovered from river sands by methods such as “panning” which depend on the high density of gold (19.3 g cm⁻³) compared with sand (~2.5 g cm⁻³)‡ but as such sources are largely worked out, modern production depends on the mining of the gold-containing rock (typically, 5–15 ppm of Au). This is crushed to a fine powder (the consistency of talcum powder) to liberate the metallic grains and these are extracted either by the cyanide process or, after gravity concentration, by amalgamation with mercury (after which the Hg is distilled off). In the former the gold and any silver present is leached from the crushed rock with an aerated, dilute solution of cyanide:

\[
4\text{Au} + 8\text{NaCN} + \text{O}_2 + 2\text{H}_2\text{O} \rightarrow 4\text{Na[Au(CN)₂]} + 4\text{NaOH}
\]

It is then precipitated by adding Zn dust. Electrolytic refining may then be used to provide gold of 99.99% purity.†

† In ancient times, gold-bearing river sands were washed over a sheep’s fleece which trapped the gold. It seems likely that this was the origin of the Golden Fleece of Greek mythology.

‡ Gold is commonly alloyed with other metals in order to make it harder and cheaper. (An appropriate mixture of Au

Total annual production of new gold is now about 2300 tonnes of which (1993) 27% comes from South Africa, 15% from the USA and 11% each from Australia and the former Soviet Union. The bulk of the gold from “Western” countries passes through the London Bullion Market which was established in 1666. Prices, which are quoted in troy oz, are affected by speculative buying and can be subject to astonishing fluctuations.

The two main uses for gold are in settling international debts and in the manufacture of jewellery, but other important uses are in dentistry, the electronics industry (corrosion-free contacts), and the aerospace industry (braiding alloys and heat reflection), while in office buildings it has been found that a mere 20 nm film on the inside face of windows cuts down heat losses in winter and reflects unwanted infrared radiation in summer.

28.2.3 Atomic and physical properties of the elements

Some important properties are listed in Table 28.1. As gold has only one naturally occurring isotope, its atomic weight is known with considerable accuracy; Cu and Ag each have 2 stable isotopes, and a slight variability of their abundance in the case of Cu prevents its atomic weight being quoted with greater precision. This is the first triad since Ti, Zr and Hf in which the ground-state electronic configuration of the free atoms is the same for the outer electrons of all three elements. Gold is the most electronegative of all metals: the value of 2.4 equals that for Se and approaches the value of 2.5 for S and I. Estimates of electron affinity vary considerably but typical values (kJ mol⁻¹) are Cu 119.2, Ag 125.6 and Au 222.8. These may be compared with values for

and Cu will maintain the golden hue.) The proportion of gold is expressed in carats, a carat being a twenty-fourth part by weight of the metal so that pure gold is 24 carats. In the case of precious stones the carat expresses mass not purity and is then defined as 200 mg. The term is derived from the name of the small and very uniform seeds of the carob tree which in antiquity were used to weigh precious metals and stones (p. 272).

† 1 troy (or fine) oz = 31.1035 g as distinct from 1 oz avoirdupois = 28.3495 g.
H 72.8, O 141.0 and I 295.2 kJ mol$^{-1}$. Consistent with this the compound CsAu has many salt-like rather than alloy-like properties and, when fused, behaves much like other molten salts. Similarly when Au is dissolved in solutions of Cs, Rb or K in liquid ammonia, the spectroscopic and other properties are best interpreted in terms of the solvated Au$^-\text{ion}$ ($d^{10}s^2$) analogous to a halide ion ($s^2p^6$).

The elements are obtainable in a state of very high purity but some of their physical properties are nonetheless variable because of their dependence on mechanical history. Their colours (Cu reddish, Ag white and Au yellow) and sheen are so characteristic that the names of the metals are used to describe them.$^\dagger$ Gold can also be obtained in red, blue and violet colloidal forms by the addition of various reducing agents to very dilute aqueous solutions of gold(III) chloride. A remarkably stable example is the “Purple of Cassius”, obtained by using SnCl$_2$ as reductant, which not only provides a sensitive test for Au$^{+1}$ but is also used to colour glass and ceramics. Colloidal silver and copper are also obtainable but are less stable.

The solid metals all have the fcc structure, like their predecessors in the periodic table, Ni, Pd and Pt, and they continue the trend of diminishing mp and bp. They are soft, and extremely malleable and ductile, gold more so than any other metal. One gram of gold can be beaten out into a sheet of $\sim 1.0 \text{m}^2$ only 230 atoms thick (i.e. 1 cm$^3$ to 18 m$^3$); likewise 1 g Au can be drawn into 165 m of wire of diameter 20 $\mu$m. The electrical and thermal conductances of the three metals are also exceptional, pre-eminence in this case belonging to silver. All these properties can be directly related to the $d^{10}s^1$ electronic configuration.

### 28.2.4 Chemical reactivity and trends

Because of the traditional designation of Cu, Ag and Au as a subdivision of the group containing the alkali metals (justified by their respective $d^{10}s^1$ and $p^6s^1$ electron configurations) some similarities in properties might be expected. Such similarities as do occur, however, are confined almost entirely to the stoichiometries (as distinct from the chemical properties) of the compounds of the $+1$ oxidation state. The reasons are not hard to find. A filled d shell is far less effective than a filled p shell in shielding an outer s electron from the attraction of the nucleus. As a result the first ionization energies of the coinage metals are much higher, and their ionic radii smaller than those of the corresponding alkali metals (Table 28.1 and p. 75). They consequently have higher mps, are harder, denser, less reactive, less soluble in liquid ammonia, and their compounds more covalent. Again, whereas the alkali metals stand at the top of the electrochemical series (with $E^o$ between $-3.045$ and $-2.714$ V), the coinage metals are near the bottom: Cu$^+$/Cu $+0.521$, Ag$^+$/Ag $+0.799$, Au$^+$/Au $+1.691$ V.

On the other hand, a filled d shell is more easily disrupted than a filled p shell. The second and third ionization energies of the coinage metals are therefore lower than those of the alkali metals so that they are able to adopt oxidation states higher than +1. They also more readily form coordination complexes. In short, Cu, Ag and Au are transition metals whereas the alkali metals are not. Indeed, the somewhat salt-like character of CsAu and the formation of the solvated Au$^-\text{ion}$ in liquid ammonia, mentioned above, can be regarded as halogen-like behaviour arising because the $d^{10}s^1$ configuration is 1 electron short of the closed configuration $d^{10}s^2$ (cf hydrogen, p. 43).

$^\dagger$ The colours arise from the presence of filled d bands near the electron energy surface of the s–p conduction band of the metals (Fermi surface). X-ray data indicate that the top of the d-band is $\sim 220$ kJ mol$^{-1}$ (2.3 eV/atom) below the Fermi surface for Cu so electrons can be excited from the d band to the s–p band by absorption of energy in the green and blue regions of the visible spectrum but not in the orange or red regions. For silver the excitation energy is rather larger ($\sim 385$ kJ mol$^{-1}$) corresponding to absorption in the ultraviolet region of the spectrum. Gold is intermediate but much closer to Cu, the absorption in the near ultraviolet and blue region of the spectrum giving rise to the characteristic golden yellow colour of the metal.
Copper, silver and gold are notable in forming an extensive series of alloys with many other metals and many of these have played an important part in the development of technology through the ages (p. 1173). In many cases the alloys can be thought of as nonstoichiometric intermetallic compounds of definite structural types and, despite the apparently bizarre formulae that emerge from the succession of phases, they can readily be classified by a set of rules first outlined by W. Hume-Rothery in 1926. The determining feature is the ratio of the number of electrons to the number of atoms ("electron concentration"), and because of this the phases are sometimes referred to as "electron compounds".

The fcc lattice of the coinage metals has 1 valency electron per atom \( (d^{10}s^1) \). Admixture with metals further to the right of the periodic table (e.g. Zn) increases the electron concentration in the primary alloy (\( \alpha \)-phase) which can be described as an fcc solid solution of M in Cu, Ag or Au. This continues until, as the electron concentration approaches 1.5 (i.e. 21/14), the fcc structure becomes less stable than a bcc arrangement which therefore crystallizes as the \( \beta \)-phase (e.g. \( \beta \)-brass, CuZn; see Fig. 28.1). Further increase in electron concentration results in formation of the more complex \( \gamma \)-brass phase of nominal formula \( \text{Cu}_5\text{Zn}_8 \) and electron concentration of \( \left\{ (5 \times 1) + (8 \times 2) \right\} / 13 = 21/13 = 1.615 \). The phase is still cubic but has 52 atoms in the unit cell (i.e. \( 4\text{Cu}_5\text{Zn}_8 \)). This \( \gamma \)-phase can itself take up more Zn until a third critical concentration is reached near 1.75 (i.e. 7/4 or 21/12) when the hcp \( \epsilon \)-phase of CuZn \(_3\) is formed. Hume-Rothery showed that this succession of phases is quite general (and also holds for Groups 8, 9 and 10 to the left of the coinage metals if they are taken to contribute no electrons to the lattice).

The reactivity of Cu, Ag and Au decreases down the group, and in its inertness gold...

Cu and Ag dissolve in hot conc H₂SO₄ and in both dil and conc HNO₃, while Au dissolves in conc HCl if a strong oxidizing agent is present. Thus *aqua regia*, a 3:1 mixture of conc HCl and conc HNO₃, was so named by alchemists because it dissolves gold, the king of metals. More recently, solutions of Cl₂ and Me₃NHCl in MeCN have been shown⁴ to be even better solvents of gold. In addition, the metals dissolve readily in aqueous cyanide solutions in the presence of air or, better still, H₂O₂.

Table 28.2 is a list of typical compounds of the elements, which reveals a further reduction in the range of oxidation states consequent on the stabilization of d orbitals at the end of the transition.

---

³ It was because of their resistance to attack by air, even when heated, that gold and silver were referred to as *noble* metals by the alchemists.

series. Apart from a single Cu$^{IV}$ fluoro-complex and possibly one or two Cu$^{IV}$ oxo-species, neither Cu nor Ag is known to exceed the oxidation state +3 and even Au does so only in a few Au$^{V}$ fluoro-compounds (see below); these may owe their existence at least in part to the stabilizing effect of the $t^6$ configuration. It is also significant that, in a number of instances, the +1 oxidation state no longer requires the presence of presumed $\pi$-acceptor ligands even though the M$^I$ metals are to be regarded mainly as class b in character. Stable, zero-valent compounds are not found, but a number of cluster compounds with the metal in a fractional (<1) oxidation state, especially of gold, are of interest. The only aquo ions of this group are those of Cu$^I$ (unstable), Cu$^{II}$, Ag$^I$ and Ag$^{II}$ (unstable). The best-known oxidation states, particularly in aqueous solution, are +2 for Cu, +1 for Ag, and +3 for Au. This accords with their ionization energies (Table 28.1) though, of course, few of the compounds are completely ionic. Silver has the lowest first ionization energy, while the sum of first and second is lowest for Cu and the sum of first, second, and third is lowest for Au. This is an erratic sequence and illustrates the most notable feature of the triad from a chemical point of view, namely that the elements are not well related either as three elements showing a monotonic gradation in properties or as a triad comprising a single lighter element together with a pair of closely similar heavier elements. “Horizontal” similarities with their neighbours in the periodic table are in fact more noticable than “vertical” ones.

The reasons are by no means certain but no doubt involve several factors, of which size is probably a major one. Thus the Cu$^{II}$ ion is smaller than Cu$^{I}$ and, having twice the charge, interacts much more strongly with solvent water (heats of hydration are $-2100$ and $-580$ kJ mol$^{-1}$ respectively). The difference is evidently sufficient to outweigh the second ionization energy of copper and to render Cu$^{II}$ more stable in aqueous solution (and in ionic solids) than Cu$^{I}$, in spite of the stable d$^{10}$ configuration of the latter. In the case of silver, however, the ionic radii are both much larger and so the difference in hydration energies will be much smaller; in addition the second ionization energy is even greater than for copper. The +1 ion with its d$^{10}$ configuration is therefore the more stable. For gold, the stability of the 6s orbital and instability of the 5d as compared to silver, and leading respectively to the possibility of Au$^-$ and enhanced stability of Au$^{III}$, have been convincingly ascribed to relativistic effects operating on s and p electrons. The high CFSE associated with square planar d$^8$ ions (see p. 1131) is a further factor favouring the +3 oxidation state.

Coordination numbers in this triad are again rarely higher than 6, but the univalent metals provide examples of the coordination number 2 which tends to be uncommon in transition metals proper (i.e. excluding Zn, Cd and Hg). Organometallic chemistry (see p. 1199) is not particularly extensive even though gold alkyls were amongst the first organo-transition metal compounds to be prepared. Those of Au$^{III}$ are the most stable in this group, while Cu$^I$ and Ag$^I$ (but not Au$^I$) form complexes, of lower stability, with unsaturated hydrocarbons.

28.3 Compounds of Copper, Silver and Gold

Binary carbides, M$_2$C$_2$ (i.e. acetylides), are obtained by passing C$_2$H$_2$ through ammoniacal solutions of Cu$^+$ and Ag$^+$. Both are explosive when dry but regenerate acetylene if treated with a dilute acid. Copper and silver also form explosive azides while the even more dangerous “fulminating” silver and gold, which probably contain M$_3$N, are produced by the action of aqueous ammonia on the metal oxides. None of the metals reacts significantly with H$_2$ but the reddish-brown precipitate, obtained when aqueous CuSO$_4$ is reduced by hypophosphorous acid (H$_3$PO$_2$), is largely CuH.

---

28.3.1 Oxides and sulfides

Two oxides of copper, Cu₂O (yellow or red) and CuO (black), are known, both with narrow ranges of homogeneity and both form when the metal is heated in air or O₂, Cu₂O being favoured by high temperatures. Cu₂O (mp 1230°C) is conveniently prepared by the reduction in alkaline solution of a Cu²⁺ salt using hydrazine or a sugar. CuO is best obtained by igniting the nitrate or basic carbonate of Cu²⁺. Addition of alkali to aqueous solutions of Cu²⁺ gives a pale-blue precipitate of Cu(OH)₂. This will redissolve in acids and also in conc alkali (amphoteric) to give deep-blue solutions probably containing species of the type [Cu(OH)₄]²⁻.

The lower affinities of silver and gold for oxygen lead to oxides of lower thermal stabilities than those of copper. Ag₂O is a dark-brown precipitate produced by adding alkali to a soluble Ag⁺ salt; AgOH is probably present in solution but not in the solid. It is readily reduced to the metal, and decomposes to the elements if heated above 160°C. The action of the vigorous oxidizing agent, S₂O₅²⁻, on Ag₂O or other Ag⁺ compounds, produces a black oxide of stoichiometry AgO. That this is not a compound of Ag²⁺ is, however, evidenced by its diamagnetism and by diffraction studies which show it to contain two types of silver ion, one with 2 colinear oxygen neighbours (Ag⁠⁺–O 218 pm) and the other with square-planar coordination (Ag⁠⁺⁺–O 205 pm). It is therefore formulated as Ag⁺Ag⁺⁺O₂⁻. Anodic oxidation of silver salts yields two further black oxides, Ag₂O₃ (Ag³⁺–O = 202 pm) and, at lower potentials, Ag₃O₄. In both of these the silver atoms are in a square planar oxygen environment. It is tempting to formulate Ag₃O₄ as Ag²⁺Ag²⁺⁺O₄ but the average Ag–O distances of 203 pm and 207 pm respectively are the wrong way round for this and instead imply non-integral oxidation states with the lower charge on the pair of silver atoms. Hydrothermal treatment of AgO in a silver tube at 80°C and 4 kbar leads to an oxide which was originally (1963) incorrectly designated as Ag₂O(II). The compound has a metallic conductivity and the stoichiometry is, in fact, Ag₃O; it can be described as an anti-BIr₃ structure (p. 559) in which oxide ions fill two-thirds of the octahedral sites in a hcp arrangement of Ag atoms (Ag–O 229 pm; Ag–Ag 276, 286, and 299 pm).

The action of alkali on aqueous Au³⁺ solutions produces a precipitate, probably of Au₂O₃.xH₂O, which on dehydration yields brown Au₂O₃. This is the only confirmed oxide of gold. It decomposes if heated above about 160°C and, when hydrous, is weakly acidic, dissolving in conc alkali and probably forming salts of the [Au(OH)₄]⁻ ion.

The sulfides are all black, or nearly so, and those with the metal in the +1 oxidation state are the more stable (p. 1174). Cu₂S (mp 1130°C) is formed when copper is heated strongly in sulfur vapour or H₂S, and CuS is formed as a colloidal precipitate when H₂S is passed through aqueous solutions of Cu²⁺. CuS, however, is not a simple copper(II) compound since it contains the S₂⁻ unit and is better formulated as Cu₃Cu⁺⁺(S₂)S. Ag₂S is very readily formed from the elements or by the action of H₂S on the metal or on aqueous Ag⁺. The action of H₂S on aqueous Au⁺ precipitates Au₂S whereas passing H₂S through cold solutions of AuCl₃ in dry ether yield Au₂S₃, which is rapidly reduced to Au⁺ or the metal on addition of water. The relationships between the crystal structures of the oxides and sulfides of Cu, Ag and Au and the binding energies of the metals’ d and p valence orbitals have been reviewed.

The selenides and tellurides of the coinage metals are all metallic and some, such as CuSe₂, CuTe₂, AgTe₃ and Au₃Te₅ are superconductors at low temperature (as also are CuS and CuS₂).
Other phases are CuSe, CuTe; Cu₃Se₂, Cu₃Te₂; AgSe, AgTe; Ag₂Se₃, Ag₂Te₃; Au₂Te₂ and AuTe₂. Most of these are nonstoichiometric.

### 28.3.2 High temperature superconductors

Without doubt the main focus of interest in the field of copper oxide chemistry has, for the past decade, been on the production of high temperature superconductors of which YBa₂Cu₃O₇ is the most familiar (see Panel). Like all "cuprate superconductors", it is an oxygen deficient perovskite (if it were an "ideal" perovskite its six metal atoms would require the composition YBa₂Cu₃O₉. This massive oxygen deficiency results in a layered structure instead of the conventional 3-dimensional array — see p. 963). As shown in Fig. 28.2, the coordination of oxygen around copper is of two types, square planar for Cu(1) and square pyramidal for Cu(2). Due to the disparate effects of the large Ba²⁺ and the smaller more highly charged Y³⁺, the Cu(2) are not situated at the centre of the square pyramid but only 30 pm above its base. They therefore lie in “puckered” or “dimpled” CuO₂ planes connected by the apical oxygens to chains of square planar Cu(1).

Esr results indicate that both Cu(1) and Cu(2) sites have a mixture of Cu²⁺ and Cu³⁺ ions. It is generally believed that superconduction occurs via positive holes in the conduction band of the CuO₂ planes and that the concentration of these holes is controlled, through the apical oxygens, by the non-conducting chains of Cu(1) which act as reservoirs of positive and negative charge. X-ray photoelectron spectroscopy shows that the conduction band has both copper (3d) and oxygen (2p) character, presumably as a result of π interactions which would be at a maximum in the linear O–Cu–O bonds of perfect CuO₂ planes. The extent of puckering of these planes, as well as the nature and composition of the charge reservoirs, are evidently crucial factors affecting the value of Tc. To obtain a proper understanding of these factors Y and Ba have been replaced by a range of other elements producing compounds with up to seven different elements as in Tl₀.₅Pb₀.₅Sr₂Ca₁₋ₓYₓCu₂O₇. La₂₋ₓMₓCuO₄ (M = Sr, Ba) and HgBa₂Ca₂Cu₃O₈+δ are other examples where the oxidation state of Cu > (II) and superconductivity occurs via positive holes, whereas in Nd₂₋ₓCeₓCuO₄, a so-called “electron superconductor”, the oxidation state of Cu < (II) and excess electrons are the charge carriers. In each case, however, the path for conduction is provided by a CuO₂ plane.

The properties of these brittle ceramics depend critically on the preparative conditions. Intimate mixtures of the oxides, carbonates or nitrates of the relevant metals in the required proportions are heated at temperatures of 900–1000°C. For YBa₂Cu₃O₇₋ₓ, all compositions in the range 0 ≤ x ≤ 0.5 superconduct and the highest Tc is found where x ~ 0. For others, the oxygen content must be stringently controlled. In all cases, the most
8.3.3 Halides

### Superconductivity

H. Kammerling Onnes (Nobel Prize for Physics, 1913) discovered superconductivity in Leiden in 1911 when he cooled mercury to the temperature of liquid helium. Many other materials, mostly metals and alloys, were subsequently found to display superconductivity at very low temperatures.

Two properties characterize a superconductor:

1. It is perfectly conducting, i.e. it has zero resistance.
2. It is perfectly diamagnetic, i.e. it completely excludes applied magnetic fields. This is the Meissner effect and is the reason why a superconductor can levitate a magnet.

Superconductivity exists within the boundaries of three limiting parameters which must not be exceeded: the critical temperature \(T_c\), the critical magnetic field \(H_c\) and the critical current density \(J_c\).

Until 1986 the highest recorded value of \(T_c\) was \(-23\,\text{K}\) for \(\text{Nb}_3\text{Ge}\) but in that year Bednorz and Müller, in pioneering work for which they received the 1987 Nobel Prize for Physics, reported \({}^{(11)}T_c = 30\,\text{K}\) in an entirely new \(\text{Ba-La-Cu-O}\) ceramic system quickly identified as \(\text{La}_{2-x}\text{Ba}_x\text{CuO}_4\). This prompted an examination of other \(\text{Cu-O}\) systems and the technologically important breakthrough in 1987 by the Houston and Alabama teams of C. W. Chu and M. K. Wu, of superconductivity at temperatures attainable in liquid nitrogen.\(^{12}\) \(T_c = 95\,\text{K}\) in a material subsequently shown to be \(\text{YBa}_2\text{Cu}_3\text{O}_7\), `"YBCO". This, and other materials in which \(Y\) is replaced by a lanthanide, are referred to as "1,2,3" materials because of their stoichiometry. This produced a quite unprecedented explosion of activity amongst chemists, physicists and material scientists around the world. Though the highest \(T_c\) has been pushed up to 135 K (or 164 K under 350 kbar pressure) in \(\text{HgBa}_2\text{Ca}_2\text{Cu}_3\text{O}_8\), YBCO is still the archetypal high temperature superconductor.

In spite of its long history, it was not until 1957 that Bardeen, Cooper and Schrieffer\(^{(13)}\) provided a satisfactory explanation of superconductivity. This "BSC theory" suggests that pairs of electrons (Cooper pairs) move together through the lattice, the first electron polarizing the lattice in such a way that the second one can more easily follow it. The stronger the interaction of the two electrons the higher \(T_c\) but it turns out as a consequence of this model that \(T_c\) should have an upper limit \(-35\,\text{K}\). The advent of high-temperature superconductors therefore necessitated a new, or at least modified, explanation for the pairing mechanism. Various suggestions have been made but none has yet gained universal acceptance.

#### 28.3.3 Halides

Table 28.3 is a list of the known halides: only gold forms a pentahalide and trihalides and, with the exception of \(\text{AgF}_2\), only copper (as yet) forms dihalides.

\(\text{AuF}_5\) is an unstable, polymeric, diamagnetic, dark-red powder, produced by heating \([\text{O}_2][\text{AuF}_6]\) under reduced pressure and condensing the product on to a "cold finger":

\[
\text{Au} + \text{O}_2 + 3\text{F}_2 \xrightarrow{370^{\circ}\text{C}/8\text{ atm}} \text{O}_2\text{AuF}_6 \xrightarrow{180^{\circ}/20^{\circ}\text{C}} \text{hot/cold} \text{AuF}_5 + \text{O}_2 + \frac{1}{2}\text{F}_2
\]

The compound tends to dissociate into \(\text{AuF}_3\) and, when treated with \(\text{XeF}_2\) in anhydrous HF solution below room temperature, yields yellow-orange crystals of the complex \([\text{Xe}_2\text{F}_3][\text{AuF}_6]\):

\[
\text{AuF}_5 + 2\text{XeF}_2 \xrightarrow{\text{HF/0}\text{O}} [\text{Xe}_2\text{F}_3][\text{AuF}_6] \xrightarrow{>60^{\circ}} \text{AuF}_3 + \text{XeF}_2 + \text{XeF}_4
\]

Again, in the +3 oxidation state, only gold is known to form binary halides, though \(\text{AuI}_3\) has not been isolated. The chloride and the

bromide are red-brown solids prepared directly from the elements and have a planar dimeric structure in both the solid and vapour phases. Dimensions for the chloride are as shown in Structure (1). On being heated, both compounds lose halogen to form first the monohalide and finally metallic gold. Au₂Cl₆ is one of the best-known compounds of gold and provides a convenient starting point for much coordination chemistry, dissolving in hydrochloric acid to give the stable [AuCl₄]⁻ ion. Treatment of Au₂Cl₆ with F₂ or BrF₃ also affords a route to AuF₃, a powerful fluorinating agent. This orange solid consists of square-planar AuF₄ units which share cis-fluorine atoms with 2 adjacent AuF₄ units so as to form a helical chain (Structure (2)).

No halides are known for gold in the +2 oxidation state and silver only forms the difluoride; this is obtained by direct heating of silver in a stream of fluorine. AgF₂ is thermally stable but is a vigorous fluorinating agent used especially to fluorinate hydrocarbons. For copper, on the other hand, 3 dihalides are stable and the anhydrous difluoride, dichloride and dibromide can all be obtained by heating the elements. The white ionic CuF₂ has a distorted rutile structure (p. 961) with four shorter equatorial distances (Cu–F 193 pm) and two longer axial distances (Cu–F 227 pm). A similar distortion is found in
§28.3.4 Photography

Photography is a good example of a technology which evolved well in advance of a proper understanding of the principles involved (see 6 sites having 2I− neighbours at 252 pm
12 sites having 3I− neighbours at 267 pm
24 sites having 4I− neighbours at 286 pm

The silver ions are almost randomly distributed on these sites, thus accounting for their high mobility. Many other fast ion conductors have subsequently been developed on this principle, e.g.

Ag2HgI, yellow hexagonal → orange-red cubic.

History of Photography

In 1727 J. H. Schulze, a German physician, found that a paste of chalk and AgNO₃ was blackened by sunlight and, using stencils, he produced black images. At the end of the eighteenth century Thomas Wedgwood (son of the potter Josiah) and Humphry Davy used a lens to form an image on paper and leather treated with AgNO₃, and produced pictures which unfortunately faded rather quickly.

The first permanent images were obtained by the French landowner J. N. Niépce using bitumen-coated pewter (bitumen hardens when exposed to light for several hours and the unexposed portions can then be dissolved away in oil of turpentine). He then helped the portrait painter, L. J. M. Daguerre, to perfect the “daguerreotype” process which utilized plates of copper coated with silver sensitized with iodine vapour. The announcement of this process in 1839 was greeted with enormous enthusiasm but it suffered from the critical drawback that each picture was unique and could not be duplicated.

Reproducibility was provided by the “calotype” process, patented in 1841 by the English landowner W. H. Fox Talbot, which used semi-transparent paper treated with AgI and a “developer”, gallic acid. This produced a “negative” from which any number of “positive” prints could subsequently be obtained. Furthermore it embodied the important discovery of the “latent image” which could be fully developed later. Even with Talbot’s very coarse papers, exposure times were reduced to a few minutes and portraits became feasible, even if uncomfortable for the subject.

Though Talbot’s pictures were undoubtedly much inferior in quality to Daguerre’s, the innovations of his process were the ones which facilitated further improvements and paved the way for photography as we now know it. Sir John Herschel, who first coined the terms “photography”, “negative” and “positive”, suggested the use of “hyposulphite” (sodium thiosulfate) for “fixing” the image, and later the use of glass instead of paper—hence, photographic “plates”. F. S. Archer’s “wet collodion” process (1851) reduced the exposure time to about 10 s and R. L. Maddox’s “dry gelatin” plates reduced it to only 0.5 s. In 1889 G. Eastman used a roll film of celluloid and founded the American Eastman Kodak Company.

Meanwhile the Scottish physicist, Clerk Maxwell (1861), recognizing that the sensitivities of the silver halides are not uniform across the spectrum, proposed a three-colour process in which separate negatives were exposed through red, green and blue filters, and thereby provided the basis for the later development of colour photography. Actually, the sensitivity is greatest at the blue end of the spectrum; a fact which seriously affected all early photographs. This problem was overcome when the German, H. W. Vogel, discovered that sensitivity could be extended by incorporating certain dyes into the photographic emulsion. “Spectral sensitization” at the present time is able to extend the sensitivity not only across the whole visible region but far into the infrared as well.

Panel). Most of the basic processes were established almost a century and a half ago, but a coherent theoretical explanation was not available until the publication in 1938 of the classic paper by R. W. Gurney and N. F. Mott. (Proc. Roy. Soc. A164, 151–67 (1938)). Since then the subject has stimulated a vast amount of fundamental research in wide areas of solid-state chemistry and physics.

A photograph is the permanent record of an image formed on a light-sensitive surface, and the essential steps in producing it are:

(a) production of light-sensitive surface;
(b) exposure to produce a “latent image”;
(c) development of the image to produce a “negative”;
(d) making the image permanent, i.e. “fixing” it;
(e) making “positive” prints from the negative.

(a) In modern processes the light-sensitive surface is an “emulsion” of silver halide in gelatine, coated on to a suitable transparent film, or support. The halide is carefully precipitated so as to produce small uniform crystals, (<1 μm diameter, containing ~10¹² Ag atoms), or “grains” as they are normally called. The particular halide used depends on the sensitivity required, but AgBr is most commonly used on films; AgI is used where especially fast film is required and AgCl and certain organic dyes are also incorporated in the emulsion.

(b) When, on exposure of the emulsion to light, a photon of energy \( hv \) impinges on a grain of AgX, a halide ion is excited and loses its electron to the conduction band, through which it passes rapidly to the surface of the grain where it is able to liberate an atom of silver:

\[ X^- + hv \rightarrow X + e^-; \quad Ag^+ + e^- \rightarrow Ag \]
These steps are, in principle, reversible but in practice are not because the Ag is evidently liberated on a crystal dislocation, or defect, or at an impurity site such as may be provided by Ag₂S, all of which allow the electron to reduce its energy and so become "trapped". The function of the dye sensitizers is to extend the sensitivity of the emulsion across the whole visible spectrum, by absorbing light of characteristic frequency and providing a mechanism for transferring the energy to X⁻ in order to excite its electron. As more photons are incident on the grain, so more electrons migrate and discharge Ag atoms at the same point. A collection of just a few silver atoms on a grain (in especially sensitive cases a mere 4–6 atoms but, more usually, perhaps 10 times that number) constitutes a "speck", too small to be visible, but the concentration of grains possessing such specks varies across the film according to the varying intensity of the incident light thereby producing an invisible "latent image". The parallel formation of X atoms leads to the formation of X₂ which is absorbed by the gelatine.

(c) The "development" or intensification of the latent image is brought about by the action of a mild reducing agent whose function is to selectively reduce those grains which possess a speck of silver, while leaving unaffected all unexposed grains. To this end, such factors as temperature and concentration must be carefully controlled and the reduction stopped before any unexposed grains are affected. Hydroquinone, 1,6-C₆H₄(OH)₂ is a common "developer" and the reduction is a good example of a catalysed solid-state reaction. Its mechanism is imperfectly understood but the complete reduction to metal of a grain (say 10¹² atoms of Ag), starting from a single speck (say 10 or 100 atoms of Ag), represents a remarkable intensification of the latent image of about 10¹⁰ times, allowing vastly reduced exposure times; this is the real reason for the superiority of silver halides over all other photosensitive materials, though an intensive search for alternative systems still continues.

(d) After development, the image on the negative is "fixed" by dissolving away all remaining silver salts to prevent their further reduction. This requires an appropriate complexing agent and sodium thiosulphate is the usual one since the reaction

$$\text{AgX(s) + 2Na}_2\text{S}_2\text{O}_3 \rightarrow \text{Na}_3[\text{Ag(S}_2\text{O}_3)_2] + \text{NaX}$$

goes essentially to completion and both products are water-soluble.

(e) A positive print is the reverse of the negative and is obtained by passing light through the negative and repeating the above steps using a printing paper instead of a transparent film.

### 28.3.5 Complexes

Oxidation states above +3 are attained only with difficulty and are confined mainly to AuF₅, mentioned above, together with salts of the octahedral anion [AuF₆]⁻, and to Cs₂[CU'VF₆], prepared by fluorinating CsCuCl₃ at high temperature and pressure.

**Oxidation state III (d⁸)**

Copper(III) is generally regarded as uncommon, being very easily reduced, but because of its possible involvement in biological electron transfer reactions (p. 1199) a number of Cu⁺⁺⁺ peptides have been prepared. The pale-green, paramagnetic (2 unpaired electrons), K₃CuF₆, is obtained by the reaction of F₂ on 3KCl + CuCl and is readily reduced. This is the only high-spin Cu⁺⁺⁺ complex, the rest being low-spin, diamagnetic, and usually square planar, as is to be expected for a cation which, like Ni⁺⁺, has a d⁸ configuration and is more highly charged. Examples are violet [CuBr₂(S₂CNBu₂)], obtained by reacting [Cu(S₂CNBu₂)] with Br₂

---

in CS$_2$, and bluish MCuO$_2$ (M = alkali metal), obtained by heating CuO and MO$_2$ in oxygen. The oxidation of Cu$^{II}$ by alkaline ClO$_-$ in the presence of periodate or tellurate ions yields salts in which chelated ligands apparently produce square-planar coordinated copper:

Silver(III) is quite similar to copper(III) and analogous, though more stable, periodate and tellurate complexes can be produced by the oxidation of Ag$I$ with alkaline S$_2$O$_8^{2-}$. The diamagnetic, red ethylenedibiguanide complex (Fig. 28.3a) is also obtained by peroxodisulfate oxidation and is again quite stable to reduction. However, yellow, diamagnetic, square-planar fluoro-complexes such as K[AgF$_4$], obtained by fluorinating AgNO$_3$ + KCl at 300°C, are much less stable; they attack glass and fume in moist air.

For gold, by contrast, +3 is the element’s best-known oxidation state and Au$^{III}$ is often compared with the isoelectronic Pt$^{II}$ (p. 1161). The usual route to gold(III) chemistry is by dissolving the metal in aqua regia, or the compound Au$_2$Cl$_6$ in conc. HCl, after which evaporation yields yellow chloroauric acid, HAuCl$_4$.4H$_2$O, from which numerous salts of the square-planar ion [AuCl$_4$]$^-$ can be obtained. Other square-planar ions of the type [AuX$_4$]$^-$ can then be derived in which X = F, Br, I, CN, SCN and NO$_3$, the last of these being of interest as one of the few authenticated examples of the unidentate nitrate ion (cf. p. 1162). [Au(SCN)$_4$]$^-$(Fig. 28.3b) is an example with the additional interest that its distorted square pyramidal structure$^{(17)}$ provides a rare example of Au$^{III}$ with a coordination number in excess of 4. Octahedral [Au$_2$(diars)$_2$]$^{1+}$ too has a “high” coordination number, though phosphine and arsine complexes are generally readily reduced to Au$I$ species. Reductions of Au$^{III}$ to Au$I$ in aqueous solution by nucleophiles such as I$^-$, SCN$^-$ and other S-donor ligands have been studied. Most take place by rapid ligand substitution followed by the rate determining electron transfer, though some reductions by I$^-$ take place without substitution. With SCN$^-$ the rates of substitution and electron transfer are finely balanced.$^{(18)}$

In forming the fluoro complex \([\text{AuF}_4]^-\) mentioned above, and indeed in forming the simple fluoride \(\text{AuF}_3\), \(\text{Au}^{\text{III}}\) differs from the isoelectronic \(\text{Pt}^{\text{II}}\) since the corresponding \([\text{PtF}_4]^2-\) and \(\text{PtF}_2\) are unknown.

**Oxidation state II (d^9)**

The importance of this oxidation state diminishes with increase in atomic number in the group, and most of the compounds ostensibly of \(\text{Au}^{\text{II}}\) are actually mixed valency \(\text{Au}^{\text{I}}/\text{Au}^{\text{III}}\) compounds. Examples include the sulfate \(\text{Au}^{\text{I}}\text{Au}^{\text{III}}(\text{SO}_4)_2\) and the chlorocomplex, \(\text{Cs}_2[\text{Au}^{\text{I}}\text{Cl}_2][\text{Au}^{\text{III}}\text{Cl}_4]\), the anions of the latter being arranged so as to give linearly coordinated \(\text{Au}^{\text{I}}\) and tetragonally distorted, octahedral \(\text{Au}^{\text{III}}\) (Fig. 28.4). The analogous mixed-metal complex, \(\text{Cs}_2\text{AgAuCl}_6\), has the same structure with \(\text{Ag}^{\text{I}}\) instead of \(\text{Au}^{\text{I}}\). One of the few authenticated examples of \(\text{Au}^{\text{II}}\) is the maleonitriledithiolato complex

\[
\begin{array}{c}
\text{NC} \quad \text{C} \quad \text{S} \quad \text{Au} \quad \text{S} \quad \text{C} \quad \text{CN} \\
\text{NC} \quad \text{C} \quad \text{S} \quad \text{C} \quad \text{CN} \\
\end{array}
\]

which has a magnetic moment at room temperature of 1.85 BM. Even here, however, esr evidence indicates appreciable delocalization of the unpaired electron on to the ligands and, in solution, the complex is readily oxidized to \(\text{Au}^{\text{III}}\).

Compounds of \(\text{Ag}^{\text{II}}\) are more familiar and are, in general, square planar and paramagnetic (\(\mu_e \sim 1.7-2.2\) BM); this is as expected for an ion which is isoelectronic with \(\text{Cu}^{\text{II}}\) (see below), particularly in view of the greater crystal field splitting associated with 4d (as opposed to 3d) electrons. The \(\text{Ag}^{\text{II}}(\text{aq})\) ion has a transitory existence when \(\text{Ag}^{\text{I}}\) salts are oxidized by ozone in a strongly acid solution, but it is an appreciably stronger oxidizing agent than \(\text{MnO}_4^-\) (\(E^\circ(\text{Ag}^{\text{II}}/\text{Ag}^+) = +1.980\) V in 4M HClO₄; \(E^\circ(\text{MnO}_4^-/\text{Mn}^{\text{II}}) = 1.507\) V) and oxidizes water even when strongly acidic,† Of the acidic solutions the most stable is that in phosphoric acid, no doubt because of complex formation, and even \(\text{NO}_3^-\) and \(\text{ClO}_4^-\) ions appear to coordinate in solution since the colours of these solutions depend on their concentrations. A variety of complexes, particularly with heterocyclic amines, has been obtained by oxidation of \(\text{Ag}^{\text{I}}\) salts with \([\text{S}_2\text{O}_8]^{2-}\) in aqueous solution in the presence of the ligand. They include \([\text{Ag(py)}_3]^{2+}\) and \([\text{Ag(bipy)}_2]^{2+}\) and are comparatively stable providing the counter-anion is a non-reducing ion such as \(\text{NO}_3^-\), \(\text{ClO}_4^-\) or \(\text{S}_2\text{O}_8^{2-}\). Other complexes include some with \(\text{N}^-\), \(\text{O}\)-donor ligands such as pyridine carboxylates, and also the violet \(\text{Ba}[\text{AgF}_4]\).

However, in this oxidation state it is copper which provides by far the most familiar and extensive chemistry. Simple salts are formed with most anions, except \(\text{CN}^-\) and \(\text{I}^-\), which instead form covalent \(\text{Cu}^{\text{I}}\) compounds which are insoluble in water. The salts are predominantly water-soluble, the blue colour of their solutions

† Solutions of this type have potential use in the destruction of a variety of waste organic materials by electrochemical oxidation — see D. F. STEELE, *Chem. in Brit.*, 27, 915–8 (1991).
arising from the \([\text{Cu(H}_2\text{O)}_6\text{]}^{2+}\) ion, and they frequently crystallize as hydrates. The aqueous solutions are prone to slight hydrolysis and, unless stabilized by a small amount of acid, are liable to deposit basic salts. Basic carbonates occur in nature (p. 1174), basic sulfates and chlorides are produced by atmospheric corrosion of copper, and basic acetates (verdigris) find use as pigments.

The best-known simple salt is the sulfate pentahydrate ("blue vitriol"), \(\text{CuSO}_4.5\text{H}_2\text{O}\), which is widely used in electroplating processes, as a fungicide (in Bordeaux mixture) to protect crops such as potatoes, and as an algicide in water purification. It is also the starting material in the production of most other copper compounds. It is significant, as will be seen presently, that in the crystalline salt 4 of the water molecules form a square plane around the \(\text{Cu}^{II}\) and 2, more remote, oxygen atoms from \(\text{SO}_4^{2-}\) ions complete an elongated octahedron. The fifth water is hydrogen-bonded between one of the coordinated waters and sulfate ions (p. 626). On being warmed, the pentahydrate loses water to give first the trihydrate, then the monohydrate; above about 200°C the virtually white anhydrous sulfate is obtained and this then forms \(\text{CuO}\) by loss of \(\text{SO}_3\) above about 700°C. Amongst the few salts of \(\text{Cu}^{II}\) which crystallize with 6 molecules of water and contain the \([\text{Cu(H}_2\text{O)}_6\text{]}^{2+}\) ion are the perchlorate, the nitrate (but the trihydrate is more easily produced) and Tutton salts.

Attempts to prepare the anhydrous nitrate by dehydration always fail because of decomposition to a basic nitrate or to the oxide, and it was previously thought that \(\text{Cu(NO}_3\text{)}_2\) could not exist. In fact it can be obtained by dissolving copper metal in a solution of \(\text{N}_2\text{O}_4\) in ethyl acetate to produce \(\text{Cu(NO}_3\text{)}_2\cdot\text{N}_2\text{O}_4\), and then driving off the \(\text{N}_2\text{O}_4\) by heating this at 85–100°C. The observation by C. C. Addison and B. J. Hathaway in 1958\(^{19}\) that the blue \(\text{Cu(NO}_3\text{)}_2\) could be sublimed (at 150–200°C under vacuum) and must therefore involve covalently bonded \(\text{NO}_3^-\), was completely counter to current views on the bonding of nitrates and initiated a spate of work on the coordination chemistry of the ion (p. 469). Solid \(\text{Cu(NO}_3\text{)}_2\) actually exists in two forms, both of which involve chains of copper atoms bridged by \(\text{NO}_3\) groups, but its vapour is monomeric (Fig. 28.5).

The most common coordination numbers of copper(II) are 4, 5 and 6, but regular geometries are rare and the distinction between square-planar and tetragonally distorted octahedral coordination is generally not easily made. The reason for this is ascribed to the Jahn–Teller effect (p. 1021) arising from the unequal occupation of the \(e_g\) pair of orbitals (\(\text{d}_{z^2}\) and \(\text{d}_{x^2-y^2}\)) when a \(\text{d}^9\) ion is subjected to an octahedral crystal field. Occasionally, as in solid \(\text{KAlCuF}_6\) for instance, this results in a compression of the octahedron, i.e. "2 + 4" coordination (2 short and 4 long bonds).\(^{20}\) The usual result, however, is an elongation of the octahedron, i.e. "4 + 2" coordination (4 short and 2 long bonds), as is expected if the metal's \(\text{d}_{z^2}\) orbital is filled and its \(\text{d}_{x^2-y^2}\) half-filled. In its most extreme form this is equivalent to the complete loss of the axial ligands leaving a square-planar complex.

\[\text{Cu(NO}_3\text{)}_2\] Figure 28.5 The \(\text{Cu(NO}_3\text{)}_2\) molecule in the vapour phase (dimensions are approximate).

---

\(^\dagger\) Tutton salts are the double sulfates \(\text{M}_2\text{Cu(SO}_4\text{)}_2.6\text{H}_2\text{O}\) which all contain \([\text{Cu(H}_2\text{O)}_6\text{]}^{2+}\) and belong to the more general class of double sulfates of \(\text{M}^I\) and \(\text{M}^{II}\) cations which are known as schöenites after the naturally occurring \(\text{K}^{II}/\text{Mg}^{II}\) compound.
The effect of configurational mixing of higher-lying s orbitals into the ligand field d-orbital basis set is also likely to favour elongation rather than contraction.\(^2\)

Elongation has the further consequence that the fifth and sixth stepwise stability constants (p. 908) are invariably much smaller than the first 4 for Cu\(^{II}\) complexes. This is clearly illustrated by the preparation of the ammines. Tetraammines are easily isolated by adding ammonia to aqueous solutions of Cu\(^{II}\) until the initial precipitate of Cu(OH)\(_2\) redissolves, and then adding ethanol to the deep blue solution,\(^+\) when Cu(NH\(_3\))\(_4\)SO\(_4\) \(\times\) H\(_2\)O slowly precipitates. Recrystallization of tetraammines from 0.880 ammonia yields violet-blue pentaammines, but the fifth NH\(_3\) is easily lost; hexaammines can only be obtained from liquid ammonia and must be stored in an atmosphere of ammonia. Pyridine and other monoamines are similar in behaviour to ammonia. Likewise, chelating N-donor ligands such as en, bipy and phen show a reluctance to form tris complexes (though these can be obtained if a high concentration of ligand is used) and a number of 5-coordinate complexes such as [Cu(bipy)\(_3\)]\(^{2+}\) with a trigonal bipyramidal structure are known. The structure of [Cu(bipy)\(_3\)]\(^{2+}\) in its perchlorate has been described\(^2\) as square pyramidal (4 short bonds, av. 202.6 pm, and 1 long, 222.3 pm) but, since the sixth N atom only 246.9 pm from the Cu, distorted octahedral is perhaps a better description. The macrocyclic N-donor, phthalocyanine, forms a square-planar complex and substituted derivatives are used to produce a range of blue to green pigments which are thermally stable to over 500°C, and are widely used in inks, paints and plastics.

In alkaline solution biuret, HN(CONH\(_2\))\(_2\) reacts with copper(II) sulfate to give a characteristic violet colour due to the formation of the complexes [Cu\(_2\)(μ-OH)\(_2\)(NHCONHCONH)\(_4\)]\(^{2-}\) (Fig. 28.6a) and [Cu(NHCONHCONH)\(_2\)]\(^{2-}\). This is the basis of the “biuret test” in which an excess of NaOH solution is added to the unknown material together with a little CuSO\(_4\) soln: a violet colour indicates the presence of a protein or other compound containing a peptide linkage.

Copper(II) also forms stable complexes with O-donor ligands. In addition to the hexaquation, the square planar β-diketonates such as [Cu(acac)\(_2\)] (which can be precipitated from aqueous solution and recrystallized from non-aqueous solvents) are well known, and tartrate complexes are used in Fehling’s test (p. 1181).

Mixed O,N-donor ligands such as Schiff bases are of interest in that they provide examples not only of square-planar coordination but also, in the solid state, examples of square-pyramidal coordination by dimerization (Fig. 28.6b)). A similar situation occurs in the bis-dimethylglyoximato complex, which dimerizes by sharing oxygen atoms, though the 4 coplanar donor atoms are all nitrogen atoms. Copper(II) carboxylates\(^1\) are easily obtained by crystallization from aqueous solution or, in the case of the higher carboxylates, by precipitation with the appropriate acid from ethanolic solutions.

\(^+\) This solution will dissolve cellulose which can be re-precipitated by acidification, a fact used in one of the processes for producing rayon.

---

**Figure 28.6** (a) Binuclear complex formed in biuret test (b) Schematic representation of square-pyramidal coordination of Cu\(^{II}\) in dimeric Schiff base complexes.
of the acetate. In the early 1950s it was found that the magnetic moment of green copper(II) acetate monohydrate is lower than the spin-only value (1.4 BM at room temperature as opposed to 1.73 BM) and that, contrary to the Curie law, its susceptibility reaches a maximum around 270 K but falls rapidly at lower temperatures. Furthermore, the compound has a dimeric structure in which 2 copper atoms are held together by 4 acetate bridges (Fig. 28.7a). Clearly the single unpaired electrons on the copper atoms interact, or "couple", antiferromagnetically to produce a low-lying singlet (diamagnetic) and an excited but thermally accessible triplet (paramagnetic) level (Fig. 28.7b). The separation is therefore only a few kJ mol\(^{-1}\) (at room temperature, \(RT\) the thermal energy available to populate the higher level \(\approx 2.5\) kJ mol\(^{-1}\)) and as the temperature is reduced the population of the ground level increases and diamagnetism is eventually approached.

Similar behaviour is found in many other carboxylates of Cu\(^{II}\) as well as their adducts in which axial water is replaced by other O- or N-donor ligands. In spite of a continuous flow of work on these compounds there is still no general agreement as to the actual mechanism of the interaction nor on possible correlations of its magnitude with relevant properties of the carboxylate and axial ligands.\(^{23}\)

The simplest interpretation is to assume that the singlet and triplet levels arise from a single interaction between the unpaired spins of the copper atoms and, with B. N. Figgis and R. L. Martin,\(^{24}\) that this takes the form of "face-to-face" or \(\delta\) overlap of the copper \(d_{z^2}\) orbitals. However, \(\sigma\) overlap of \(d_{z^2}\) orbitals, or even a "superexchange" interaction transmitted via the \(\pi\) orbitals of the bridging carboxylates, are also feasible. It seems generally true that the magnetic interaction is greater for alkylcarboxylates than arylcarboxylates and for N-donor rather than O-donor axial ligands. More extensive correlations are unfortunately difficult to deduce from published results because of the existence of polymeric or other isomeric forms beside the dinuclear, and because of the possible presence of mononuclear impurities.

Mononuclear carboxylates such as \(\text{Ca}[\text{Cu}(\text{O_2-CMe})_4]\) and \([\text{Cu} (\text{bet})_4 ](\text{NO}_3)_2\), (bet = \(N^+\text{Me}_3\text{-CH}_2\text{COO}^-\)) are also known.\(^{25}\) In these

\(^{24}\)B. N. Figgis and R. L. Martin, J. Chem. Soc. 1956, 3837–46 (cf. quadruple bond in Cr(II) acetate (pp. 1032–4)).

compounds each carboxylate ligand has one O close to the Cu (192–197 pm) and one much further away (277–307 pm) producing a distorted dodecahedral structure.

Other copper(II) complexes of stereochemical interests are the halogenocuprate(II) anions which can be crystallized from mixed solutions of the appropriate halides. The structures of the solids are markedly dependent on the counter cation. The compounds MCuCl3 (M = Li, K, NH4) contain red, planar [Cu2Cl6]2– ions, and CsCuCl3 has a polymeric structure in which chains of CuCl6 octahedra (4 + 2 coordination) share opposite faces. With larger counter cations such as [PPb]+, discrete [Cu2Cl6]2– ions are found which are distinctly non-planar, the coordination about each Cu being intermediate between square planar and tetrahedral.

The [CuCl3]– salts present an even greater variety which includes 5-coordinate trigonal bipyramidal and square-pyramidal coordination, as well as [dienH3][CuCl4]Cl which contains a square-planar anion and exhibits a curious mixture of ferro- and antiferro-magnetic properties. But it is the salts of [CuX4]2– which have received most attention: e.g. depending on the cation, [CuCl4]2– displays structures ranging from square planar to almost tetrahedral (p. 913). The former is usually green and the latter orange in colour. (NH4)2[CuCl4] is an oft-quoted example of planar geometry, but 2 long Cu–Cl distances of 279 pm (compared to 4 Cu–Cl distances of 230 pm) make 4 + 2 coordination a more reasonable description. In the [EtNH3]2+[CuCl4]– salt the longer Cu–Cl distances increase still further to 298 pm, but the clearest example of square-planar [CuCl4]2– is the methadone salt in which the fifth and sixth Cl atoms are more than 600 pm from the Cu. At the other extreme, Cs[CUX4] (X = Cl, Br) and [NMe4]2[CuCl4] approach a tetrahedral geometry and it appears that this geometry is retained in aqueous solution since the electronic spectra in the two phases are the same. For [CuCl4]2– the Cu–Cl distance is close to 223 pm and the somewhat flattened (Jahn–Teller distorted) tetrahedron has four Cl–Cu–Cl angles in the range 100–103° and the other two enlarged to 124° and 130°. The angular distortions in [CuBr4]2– are almost identical: 4 at 100–102° and the others at 126° and 130°.

Electronic spectra and magnetic properties of copper(II)

Because the d9 configuration can be thought of as an inversion of d1, relatively simple spectra might be expected, and it is indeed true that the great majority of CuII compounds are blue or green because of a single broad absorption band in the region 11 000–16 000 cm–1. However, as already noted, the d9 ion is characterized by large distortions from octahedral symmetry and the band is unsymmetrical, being the result of a number of transitions which are by no means easy to assign unambiguously. The free-ion 2D ground term is expected to split in a crystal field in the same way as the 5D term of the d4 ion (p. 1032) and a similar interpretation of the spectra is likewise expected. Unfortunately this is now more difficult because of the greater overlapping of bands which occurs in the case of CuII.

The T ground term of the tetrahedrally coordinated ion implies an orbital contribution to the magnetic moment, and therefore a value in excess of $\mu_{\text{spin-only}}$ (1.73 BM). But the E ground term of the octahedrally coordinated ion is also expected to yield a moment $[\mu_e = \mu_{\text{spin-only}} (1 - 2\lambda / 10Dq)]$ in excess of 1.73 BM, because of “mixing” of the excited T term into the ground term, and the high value of $\lambda$ (–850 cm–1) makes the effect significant. In practice, moments of magnetically dilute compounds are in the range 1.9–2.2 BM, with compounds whose geometry approaches octahedral having moments

at the lower end, and those with geometries approaching tetrahedral having moments at the higher end, but their measurements cannot be used diagnostically with safety unless supported by other evidence.

**Oxidation state I (d^{10})**

All M\(^{I}\) cations of this triad are diamagnetic and, unless coordinated to easily polarized ligands, colourless too. In aqueous solution the Cu\(^{I}\) ion is very unstable with respect to disproportionation (2Cu\(^{I}\) → Cu\(^{II}\) + Cu(s)) largely because of the high heat of hydration of the divalent ion as already mentioned. At 25°C, \(K = [\text{Cu}^{II}]/[\text{Cu}^{I}]^{-2}\) is large, \((5.38 \pm 0.37) \times 10^{5} \text{mol}^{-1}\), and standard reduction potentials have been calculated\(^{30}\) to be:

\[
E^\circ (\text{Cu}^{+}/\text{Cu}) = +0.5072 \text{ V}
\]

and

\[
E^\circ (\text{Cu}^{2+}/\text{Cu}^{+}) = +0.1682 \text{ V}
\]

Nevertheless, Cu\(^{I}\) can be stabilized either in compounds of very low solubility or by complexing with ligands having \(\pi\)-acceptor character. Its solutions in MeCN are stable and electrochemical oxidation of the metal in this solvent provides a convenient preparative route. The usual stereochemistry is tetrahedral as in complexes such as [Cu(CN)\(_4\)]\(^{3-}\), [Cu(py)\(_4\)]\(^{+}\), and [Cu(L-L)\(_2\)]\(^{+}\) (e.g. L-L = bipy, phen), but lower coordination numbers are possible such as 2, in linear [CuCl\(_2\)]\(^{-}\) formed when CuCl is dissolved in hydrochloric acid and 3, as in K[Cu(CN)\(_3\)], which in the solid contains trigonal, almost planar, Cu(CN)\(_3\) units linked in a polymeric chain (Fig. 28.8). The discrete planar anion [Cu(CN)\(_3\)]\(^{2-}\) is found in Na\(_2\)[Cu(CN)\(_3\)].3H\(_2\)O. In 2[Cu(C\(_2\)S\(_8\)N\(_3\)S\(_2\)]Cl\(^{+}\)[Cu\(_2\)Cl\(_4\)]\(^{2-}\) the bulky cation, consisting of an N\(_2\)S\(_2\) type macrocycle and a chloride ion coordinated to Cu\(^{II}\), stabilizes the Cu\(^{I}\) anion in an unusual, non-planar form\(^{31}\) (Fig. 28.9a).

Polymers and oligomers form an expanding class of Cu\(^{I}\) complexes which, Cu\(^{I}\) being a d\(^{10}\) ion, are unlikely to involve M–M bonding. A wide range of structures, which frequently give rise to characteristic charge-transfer spectra,\(^{32}\) is found. Stoichiometries of CuXL\(_n\) (\(n = 0.5, 1, 1.5\) and 2) are common and many different structures have been identified including “cubane”, open “step” (or “chair”) and “ladder” (Fig. 28.9b, c, d) depending on the nature of L and the particular halide involved as well as the stoichiometry.\(^{33}\)

---

Iodocuprates(I) provide a series of polymeric anions made up of planar \{CuL\}_3 or tetrahedral \{CuL\}_4 units, culminating in (pyH)_{24}[Cu_{36}I_{56}]L_4. The large anion in this consists of 36 \{CuL\}_4 tetrahedra joined by 2 or 3 edges, and may be visualized as a section of a c.c.p. lattice of iodides with Cu\(^{1+}\) atoms occupying some of the tetrahedral interstices.\(^{34}\)

S-donor ligands also contribute to this stereochemical diversity, Cu\(^4\) tetrahedra being found in [Cu\(_4\)(SPh)\(_6\)]\(^{2-}\) and in [Cu\(_4\)OCl\(_6\)(OPPh\(_3\))\(_4\)], while [(Bu'O)\(_3\)SiSCu\(_4\)] provided\(^{35}\) the first example of a square planar Cu\(_4\)S\(_4\) ring (Fig. 28.9e, f, g).

The +1 state is by far the best-known oxidation state of silver and salts with most anions are formed. These reveal the reluctance of Ag\(^{1+}\) to coordinate to oxygen for, with the exceptions of the nitrate, perchlorate and fluoride, most are insoluble in water. The last two of these salts are also among the very few Ag\(^{1+}\) salts which form

---

hydrates and, paradoxically, their solubilities are actually noted for their astonishingly high values (respectively 5570 and 1800 g l\(^{-1}\) at 25°C). The hydrated ion is present in aqueous solution and a coordination number of 4 has been established.\(^{36}\) Unlike Cu\(^{1+}\), however, Ag\(^{1+}\) forms 4-coordinate tetrahedral complexes less readily than 2-coordinate linear ones. A wide variety of the latter are formed with N-, P- and S-donor ligands, some of them of great practical importance. The familiar dissolution of AgCl in aqueous ammonia is due to the formation of [Ag(NH\(_3\))\(_2\)]\(^{+}\); the formation of [Ag(S\(_2\)O\(_3\))\(_2\)]\(^{3-}\) in photographic “fixing” has already been mentioned (p. 1187), and the cyanide extraction process depends upon the formation of [M(CN)\(_4\)]\(^{-}\) (M = Ag, Au) (contrast polymeric [Cu(CN)\(_2\)]\(^{-}\), Fig. 28.8). AgCN itself is a linear polymer, \{Ag–C≡N→Ag–C≡N→\} but AgSCN is non-linear mainly because the sp\(^3\) hybridization of the sulfur forces a zigzag structure; there is also slight non-linearity at the Ag\(^{1+}\) atom.

Because of their inability to form linear complexes, chelating ligands tend instead to produce polymeric species, but compounds with coordination numbers higher than 2 can be produced, e.g. the almost tetrahedral diphosphine and diarsine complexes [Ag(L-L)\(_2\)]\(^{+}\) and the almost planar 5-coordinate [Ag(quinquepyridine)][PF\(_6\)].\(^{37}\) Four-coordination is also found in tetrameric phosphine and arsine halides [AgX\(_4\)] which occur in “cubane” and “step” (or “chair”) forms like their copper analogues (Fig. 28.9). Indeed, [Ag(PPPh\(_3\))]\(_4\) exists in both forms. As with Cu\(^{1+}\), sulfur and S-donor ligands yield many complexes of high nuclearity. [Ag\(_4\)(SCH\(_2\)C\(_6\)H\(_4\)CH\(_2\)S)\(_3\)]\(^{2-}\) contains the same tetrahedral [M\(_4\)S\(_6\)] core \(^{(38)}\) found in [Cu\(_4\)(SPh)\(_6\)]\(^{2-}\) (Fig. 28.9e), while in the dark-red Na\(_2\)[Ag\(_6\)S\(_4\)] the metal atoms are disposed octahedrally.\(^{(39)}\) The cyclohexanethiolato complex [Ag(SC\(_6\)H\(_4\)S)\(_2\)]\(_2\) and (PPPh\(_3\))\(_4\)[AgSBu\(_3\)]\(_4\)\(^{(40)}\) consist respectively of 24- and 28-membered puckered rings of alternate Ag and S atoms.

Like Ag\(^{1+}\), Au\(^{1+}\) also readily forms linear 2-coordinate complexes such as [AuX\(_2\)]\(^{-}\) (X = Cl, Br, I)\(^{(41)}\) and also the technologically important [Au(CN)\(_2\)]\(^{-}\). But it is much more susceptible to oxidation and to disproportionation into Au\(^{III}\) and Au\(^{0}\) which renders all its binary compounds, except AuCN, unstable to water. It is also more clearly a class b or “soft” metal with a preference for the heavier donor atoms P, As and S. Stable, linear complexes are obtained when tertiary phosphines reduce Au\(^{III}\) in ethanol,

\[
[\text{AuCl}_4]^{-} \xrightarrow{\text{Pr}_3\text{O/EtOH}} [\text{AuCl(Pr}_3])
\]

The Cl ligand can be replaced by other halides and pseudo-halides by metathetical reactions. Trigonal planar coordination is found in phosphine complexes of the stoichiometry [Au\(_2\)X] but 4-coordination, though possible, is less prevalent. Diarsine gives the almost tetrahedral complex [Au(diars)\(_2\)]\(^{+}\) but, for reasons which are not clear, the colourless complexes [AuL\(_4\)]\(^{+}\)[BPh\(_4\)]\(^{-}\) with monodentate phosphines fail to achieve a regular tetrahedral geometry.

Complexes with dithiocarbamates involve linear S–Au–S coordination but are dimeric and the Au–Au distance of 276 pm compared with 288 pm in the metal and 250 pm in gaseous Au\(_2\) is indicative of metal–metal bonding.\(^{\dagger}\)

\(^{\dagger}\) The stability of the 6s orbital in gold already referred to (p. 1180), allows it to participate in M–M interactions. This
In the thermal production of gold coatings on ceramics and glass, paints are used which comprise Au\textsuperscript{III} chloro-complexes and sulfur-containing resins dissolved in an organic solvent. It seems likely that polymeric species are responsible for rendering the gold soluble.

**Gold cluster compounds**\(^{(42-44)}\)

Polymeric complexes of the types formed by copper and silver are not found for gold but instead a range of variously coloured cluster compounds, with gold in an average oxidation state <1 and involving M–M bonds, can be obtained by the general process of reducing a gold phosphine halide, usually with sodium borohydride. Yellow \([\text{Au}_6\{\text{P}(\text{C}_6\text{H}_4-4-\text{Me})_3\}_6]^{2+}\) consists of an octahedron of 6 gold atoms with a phosphine attached to each. Red \([\text{Au}_8\{\text{PPh}_3\}_8]^{2+}\) can be regarded as a chair-like, centred hexagon of gold atoms with an eighth gold situated above the chair, each gold atom having a phosphine attached to it (Fig. 28.10a). Clusters are known in which further gold atoms are added to the chair in a more or less spherical manner (e.g. \([\text{Au}_{11}\{\text{P}(\text{C}_6\text{H}_4-4-\text{F})_3\}_7]^{1+}\) Fig. 28.10c in which the central gold has no attached ligand) and giving ultimately a centred icosahedron as found in the dark-red \([\text{Au}_{13}\text{Cl}_2\{\text{PMe}_3\text{Ph}\}_10]^{3+}\) (Fig. 28.10d). Another series of clusters can be distinguished with flatter, ring or torus shapes as in the red-brown \([\text{Au}_8\{\text{PPh}_3\}_7]^{2+}\) and green \([\text{Au}_9\{\text{P}(\text{C}_6\text{H}_4-4-\text{Me})_3\}_8]^{3+}\) (Fig. 28.10b). This latter series is characterized by lower electron counts than the former, reflecting a lower involvement of p-orbitals in M–M bonding and therefore less tangential skeletal bonding (cf. p. 1170 for Pt). This accords with the observation that only clusters with an icosahedral structure (stabilized by both tangential and radial skeletal bonding) are stereochemically rigid on the nmr time scale at room temperature\(^{(42)}\).

Heteronuclear clusters\(^{(44)}\) incorporating a range of other transition metals can be produced by the general method of reacting \text{AuPR}_3 with a carbonyl anion of the appropriate metal. “Clusters of clusters” of \text{Au}–\text{Ag} have been synthesized with metal frameworks based on vertex sharing icosahedra, the basic unit being an Au-centred \([\text{Au}_7\text{Ag}_6]^{1+}\) icosahedron\(^{(43)}\). The largest of these is \([\text{Au}_{22}\text{Ag}_{24}\{\text{PPh}_3\}_12\text{Cl}_{10}]^{1+}\) consisting of four \([\text{Au}_7\text{Ag}_6]^{1+}\) icosahedra arranged tetrahedrally with six shared vertices. The spectacular, red-brown \([\text{Au}_{55}\{\text{PPh}_3\}_12\text{Cl}_6]^{1+}\) is prepared by reducing \text{Au(PPh}_3\text{Cl with B}_2\text{H}_6 and is probably best viewed as a cubo-octahedral fragment of close-packed Au atoms. From it, water soluble \([\text{Au}_{55}\{\text{Ph}_2\text{PC}_6\text{H}_4\text{SO}_3\text{Na. 2320}]^{1+}\) can be obtained by ligand exchange.\(^{(45)}\)

### 28.3.6 Biochemistry of copper \(^{(46,47)}\)

Metallic copper and silver both have antibacterial properties\(^\dagger\) and Au\textsuperscript{I} thiol complexes have found increasing use in the treatment of rheumatoid arthritis, but only copper of this group has a biological role in sustaining life. It is widely distributed in the plant and animal worlds, and its redox chemistry is involved in a variety of

\(^{43}\) B. K. TEO, H. ZHANG and X. SHI *ibid.*, pp. 211–34.

\(^\dagger\) This was unknowingly utilized in ancient Persia where, by law, drinking water had to be stored in bright copper vessels.
oxidation processes. A human adult contains around 100 mg of copper, mostly attached to protein, an amount exceeded only by iron and zinc amongst transition metals, and requiring a daily intake of some 3–5 mg. Copper deficiency results in anaemia, and the congenital inability to excrete Cu, resulting in its accumulation, is Wilson’s disease. The presence of copper, along with haem, in the electron transfer agent cytochrome c oxidase has already been mentioned (p. 1101).

Although complete structural details are rare, considerable progress has been made in understanding the mode of action of copper proteins, synthetic modelling being a major factor in this.\(^{48}\) Biologically active copper centres can be divided into three main types:

**Type 1:** “blue” monomeric Cu with very distorted “3 + 1” coordination of 2N- and 2S-donors. This is apparently a compromise between the square planar 4N preferred by Cu\(^{II}\) and the tetrahedral 4S preferred by Cu\(^{I}\), with a degree of flexibility facilitating a Cu\(^{II}/Cu^{I}\) couple. This type of centre is characterized by an intense blue colour because of a strong absorption at 600 nm arising from \(S \rightarrow Cu^{II}\) charge transfer.

**Type 2:** “normal” monomeric Cu\(^{II}\) in an essentially square planar environment with additional, very weak, tetragonal interactions and exhibiting normal esr.

**Type 3:** a pair of Cu\(^{I}\) atoms about 360 pm apart and attached to protein through histidine residues; these effect O\(_2\) transport by means of the reversible reaction 2Cu\(^{I}\) \(\stackrel{O_2}{\leftrightarrow}\) Cu\(^{II}\)(μ-O\(_2\))Cu\(^{II}\). Whether the O\(_2\) is bonded as a \(\eta^1:\eta^1\) linear Cu–O–O–Cu bridge or \(\eta^2:\eta^2\) (i.e. O–O

perpendicular to the Cu–Cu axis) is still uncertain. The copper are esr inactive: Cu$^+$ because of its d$^{10}$ configuration and Cu$^{2+}$ because strong antiferromagnetic interaction between the two atoms renders them diamagnetic.

A further class, Type 4, has been proposed. It is composed of three Cu$^{2+}$ atoms two of which are strongly coupled, being only $\sim$340 pm apart. The third Cu atom completes an isosceles triangle, being 390–400 pm from each of the first two, and is “normal”.

In a large number of molluscs the oxygen-carrying pigment is not haemoglobin but a haemocyanin. These proteins, with molecular weights of the order of $10^6$, are composed of differing numbers of subunits each containing a pair of type 3 copper centres. A limited cooperativity (p 1100) is displayed but its mechanism is not yet clear. The “blue proteins”$^{49}$ laccase and ascorbic oxidase are found in a variety of plants where they are involved in the oxidation of phenols, amines and ascorbate by $O_2$. They contain a type 1 copper, responsible for their colour and name, along with a type 4 trimer which together form a very distorted 4Cu tetrahedron. One-electron transfers by means of Cu$^{2+}$/Cu$^+$ couples are involved but the mechanism by which $O_2$ is reduced is far from clear. Ceruloplasmin is also a blue protein which is found in all mammals: it participates in copper transport and storage as well as in oxidation processes. It is the deficiency of this protein which is responsible for Wilson’s disease.

Another oxidase, but non-blue, is galactose oxidase found in fungi where it catalyses the oxidation of $-\text{CH}_2\text{OH}$ in galactose to $-\text{CHO}$, simultaneously reducing $O_2$ to $H_2O_2$. With a molecular weight of 68 000 and containing a single type 2 Cu, it was thought likely that a Cu$^{2+}$/Cu$^+$ couple effected the 2-electron reduction of $O_2$. However, spectroscopic evidence appears to refute this. The coordination of the Cu is square pyramidal with two histidine nitrogens, two tyrosine oxygens and an acetate oxygen. The currently favoured interpretation is that the more tightly bound of the two tyrosines undergoes a 1-electron redox change which, together with a Cu$^{2+}$/Cu$^+$ couple, affords the required 2-electron transfer.

Cytochrome c oxidase contains two, or possibly three, copper atoms referred to as Cu$_A$ and Cu$_B$ since they do not fit into the usual classification. The former (possibly a dimer) is situated outside the mitochondrial membrane, whereas the latter is associated with an iron atom within the membrane. Both have electron transfer functions but details are as yet unclear.

28.3.7 Organometallic compounds$^{50}$

Neutral binary carbonyls are not formed by these metals at normal temperatures$^\dagger$ but copper and gold each form an unstable carbonyl halide, [M(CO)Cl]. These colourless compounds can be obtained by passing CO over MCl or, in the case of copper only (since the gold compound is very sensitive to moisture), by bubbling CO through a solution of CuCl in conc HCl or in aqueous NH$_3$. The latter reactions can in fact be used for the quantitative estimation of the CO content of gases. A silver carbonyl [Ag(CO)]([B(OTeF$_5$)$_4$] has also been prepared by mixing AgOTeF$_5$ and B(OTeF$_5$)$_3$ under CO$^{51}$ but the weakness of the Ag–C bond is indicated by the fact that the CO stretching frequency (2204 cm$^{-1}$) is the highest of any metal carbonyl. Complexes of the type [MLX], which are often polymeric, can be obtained for Cu$^+$ and Ag$^+$ with many olefins (alkenes) and acetylenes (alkynes) either by anhydrous methods or in solution. They are generally rather labile, often decomposing when

---

isolated. The silver complexes have received most attention and the silver–olefin bonds are found to be thermodynamically weaker than, for instance, corresponding platinum–olefin bonds. Since the former bonds are also found to be somewhat unsymmetrical it seems likely that \( \pi \) bonding is weaker for the group 11 metals. Gold also forms olefin complexes, but not nearly so readily as silver and then only with high molecular weight olefins.

\( \text{M} - \text{C} \sigma \) bonds can be formed by each of the \( \text{M}^1 \) metals. The simple alkyls and aryls of \( \text{Ag}^1 \) are less stable than those of \( \text{Cu}^1 \), while those of \( \text{Au}^1 \) have not been isolated. Copper alkyls and aryls\(^{(52)} \) are prepared by the action of \( \text{LiR} \) or a Grignard reagent on a \( \text{Cu}^1 \) halide:

\[
\text{CuX} + \text{LiR} \rightarrow \text{CuR} + \text{LiX}
\]

\[
\text{CuX} + \text{RMgX} \rightarrow \text{CuR} + \text{MgX}_2
\]

\( \text{CuMe} \) is a yellow polymeric solid which explodes if allowed to dry in air, and \( \text{CuPh} \), which is white and also polymeric, though more stable, is still sensitive to both air and water. Much greater stability is achieved by the \( \sigma \)-cyclopentadienyl complex \([\text{Cu}(\eta^1-\text{C}_5\text{H}_5)(\text{PEt}_3)]\) prepared by the reaction of \( \text{C}_5\text{H}_6, \text{CuO} \) and \( \text{PEt}_3 \) in petroleum ether; a similar \( \text{Au}^1 \) compound, \([\text{Au}(\eta^1-\text{C}_5\text{H}_4\text{Me})(\text{PPh}_3)]\), is also known. \( \text{Au}^1 \) alkyls can be obtained like those of copper but only with an appropriate ligand present, e.g.:

\[
[\text{Au(PEt}_3)]X \rightarrow [\text{Au}(\text{PEt}_3)\text{R}] + \text{LiX}
\]

The colourless solids are composed of linear monomers. A few anionic \( \text{Au}^1 \) alkyls are known of which \([\text{N(PPh}_3)_2]^+\text{[Au(acac}_2]^-\) might be mentioned.\(^{(53)} \) In this it is the central \( \text{C} \) of the ligand, \( \text{HC(COMe}_2) \), which is attached to the metal.

The alkyl derivatives of \( \text{Au}^{\text{III}} \) were discovered by W. J. Pope and C. S. Gibson in 1907; they include some of the most familiar and stable organo compounds of the group, and are notable for not requiring the stabilizing presence of \( \pi \)-bonding ligands. They are of three types:

\[\text{AuR}_3 \text{ (stable, when they occur at all, only in ether below \(-35^\circ\text{C}\);)}\]

\[\text{AuR}_2X \text{ (much the most stable); } X = \text{anionic ligand especially Br;)}\]

\[\text{AuRX}_2 \text{ (unstable, only dibromides characterized).}\]

Corresponding aryl derivatives are rare and unstable. Thus, while \( \text{AuMe}_3 \) decomposes above \(-35^\circ\text{C} \) but is stabilized in \([\text{AuMe}_3(\text{PPh}_3)]\), \( \text{AuPh}_3 \) is unknown.

The dialkylgold(III) halides are generally prepared from the tribromide and a Grignard reagent:

\[
\text{AuBr}_3 + 2\text{RMgBr} \rightarrow \text{AuR}_2\text{Br} + 2\text{MgBr}_2
\]

Many other anions can then be introduced by metathetical reactions with the appropriate silver salt:

\[
\text{AuR}_2\text{Br} + \text{AgX} \rightarrow \text{AuR}_2\text{X} + \text{AgBr}
\]

In all cases where the structure has been determined, the \( \text{Au}^{\text{III}} \) attains planar four-fold coordination and polymerizes as appropriate to achieve this. The halides for instance are dimeric but with the cyanide, which forms linear rather than bent bridges, tetramers are produced:

\[\text{Au}(\text{PEt}_3)\text{X} + \text{LiR} \rightarrow [\text{Au}(\text{PEt}_3)\text{R}] + \text{LiX}\]

---

29

Zinc, Cadmium and Mercury

29.1 Introduction

The reduction of ZnO by charcoal requires a temperature of 1000°C or more and, because the metal is a vapour at that temperature and is liable to reoxidation, its collection requires some form of condenser and the exclusion of air. This was apparently first achieved in India in the thirteenth century. The art then passed to China where zinc coins were used in the Ming Dynasty (1368–1644). The preparation of alloyed zinc by smelting mixed ores does not require the isolation of zinc itself and is much more easily achieved. The small amounts of zinc present in samples of early Egyptian copper no doubt simply reflect the composition of local ores, but Palestinian brass dated 1400–1000 BC and containing about 23% Zn must have been produced by the deliberate mixing of copper and zinc ores. Brass was similarly produced by the Romans in Cyprus and later in the Cologne region of Germany.

Zinc was not intentionally made in medieval Europe, though small amounts were obtained by accidental condensation in the production of lead, silver and brass; it was imported from China by the East India Company after about 1605. The English zinc industry started in the Bristol area in the early eighteenth century and production quickly followed in Silesia and Belgium. The origin of the name is obscure but may plausibly be thought to be derived from Zinke (German for spike, or tooth) because of the appearance of the metal.

Mercury is more easily isolated from its ore, cinnabar, and was used in the Mediterranean world for extracting metals by amalgamation as early as 500 BC, possibly even earlier. Cinnabar, HgS, was widely used in the ancient world as a pigment (vermilion). For over a thousand years, up to AD 1500, alchemists regarded the metal as a key to the transmutation of base metals to gold and employed amalgams both for gilding and for producing imitation gold and silver. Because of its mobility, mercury is named after the messenger of the gods in Roman mythology, and the symbol, Hg, is derived from hydrargyrum (Latin, liquid silver).

Cadmium made its appearance much later. In 1817 F. Stromeyer of Göttingen noticed that a sample of “cadmia” (now known as “calamine”), used in a nearby smelting works, was yellow
instead of white. The colour was not due to iron, which was shown to be absent, but arose instead from a new element which was named after the (zinc) ore in which it had been found (Greek κάδμιος, cadmean earth, the ancient name of calamine).

29.2 The Elements

29.2.1 Terrestrial abundance and distribution

Zinc (76 ppm of the earth’s crust) is about as abundant as rubidium (78 ppm) and slightly more abundant than copper (68 ppm). Cadmium (0.16 ppm) is similar to antimony (0.2 ppm); it is twice as abundant as mercury (0.08 ppm), which is itself as abundant as silver (0.08 ppm) and close to selenium (0.05 ppm). These elements are “chalcophiles” (p. 648) and so, in the reducing atmosphere prevailing when the earth’s crust solidified, they separated out in the sulfide phase, and their most important ores are therefore sulfides. Subsequently, as rocks were weathered, zinc was leached out to be precipitated as carbonate, silicate or phosphate.

The major ores of zinc are ZnS (which is known as zinc blende in Europe and as sphalerite in the USA) and ZnCO₃ (calamine in Europe, smithsonite in the USA†). Large deposits are situated in Canada, the USA and Australia. Less important ores are hemimorphite, Zn₄Si₂O₇(OH)₂·H₂O and franklinite, (Zn,Fe)O·Fe₂O₃. Cadmium is found as greenockite, CdS, but its only commercially important source is the 0.2-0.4% found in most zinc ores. Cinnabar, HgS, is the only important ore and source of mercury and is found along lines of previous volcanic activity. The most famous and extensive deposits are at Almaden in Spain; these contain up to 6–7% Hg and have been worked since Roman times. Other deposits, usually containing <1% Hg, are situated in the former Soviet Union, Algeria, Mexico, Yugoslavia and Italy.

29.2.2 Preparation and uses of the elements

The isolation of zinc, over 90% of which is from sulfide ores, depends on conventional physical concentration of the ore by sedimentation or flotation techniques. This is followed by roasting to produce the oxides; the SO₂ which is generated is used to produce sulfuric acid. The ZnO is then either treated electrolytically or smelted with coke. In the former case the zinc is leached from the crude ZnO with dil H₂SO₄, at which point cadmium is precipitated by the addition of zinc dust. The ZnSO₄ solution is then electrolysed and the metal deposited — in a state of 99.95% purity — on to aluminium cathodes.

A variety of smelting processes have been employed to effect the reduction of ZnO by coke:

\[ \text{ZnO + C} \longrightarrow \text{Zn + CO} \]

These formerly involved the use of banks of externally heated, horizontal retorts, operated on a batch basis. They were replaced by continuously operated vertical retorts, in some cases electrically heated. Unfortunately none of these processes has the thermal efficiency of a blast furnace process (p. 1072) in which the combustion of the fuel for heating takes place in the same chamber as the reduction of the oxide. The inescapable problem posed by zinc is that the reduction of ZnO by carbon is not spontaneous below the boiling point of Zn (a problem not encountered in the smelting of Fe, Cu or Pb, for instance), and the subsequent cooling to condense the vapour is liable, in the presence of the combustion products, to result in the reoxidation of the metal:

\[ \text{Zn + CO}_2 \longrightarrow \text{ZnO + CO} \]

The problem can be overcome by spraying the zinc vapour with lead as it leaves the top of the furnace. This chills and dissolves the zinc

† After James Smithson, founder of the Smithsonian Institution, Washington. The name calamine is applied in the USA to a basic carbonate.

so rapidly that reoxidation is minimal. The zinc then separates as a liquid of nearly 99% purity and is further refined by vacuum distillation to give a purity of 99.99%. Any cadmium present is recovered in the course of this distillation. The use of a blast furnace has the further advantage that the composition of the charge is not critical, and mixed Zn/Pb ores can be used (ZnS and PbS are commonly found together) to achieve the simultaneous production of both metals, the lead being tapped from the bottom of the furnace.

World production of zinc (1995) is about 7 million tonnes pa: of this, about 1 million tonnes pa is produced by each of Canada and Australia and 800 000 tonnes pa by China. Cadmium is produced in much smaller quantities (~20 000 tonnes pa) and these are dependent on the supply of zinc.

Zinc finds a wide range of uses. The most important, accounting for 40% of output, is as an anti-corrosion coating. The application of the coating takes various forms: immersion in molten zinc (hot-dip galvanizing), electrolytic deposition, spraying with liquid metal, heating with powdered zinc (“Sherardizing”), and applying paint containing zinc powder. In addition to brasses (Cu plus 20–50% Zn), a rapidly increasing number of special alloys, predominantly of zinc, are used for diecasting and, indeed, the vast majority of pressure diecastings are now made in these alloys. Zinc sheeting is used in roof cladding and the manufacture of dry batteries (see Panel, p. 1204) is a further use, though this has declined considerably in recent years.

The major uses of cadmium are in batteries (67%) and coatings (7%). In the form of its compounds it is used in pigments (CdS –15%) and stabilizers, in PVC for instance, to prevent degradation by heat or ultraviolet radiation (10%).

The isolation of mercury is comparatively straightforward. The most primitive method consisted simply of heating cinnabar in a fire of brushwood. The latter acted as fuel and condenser, and metallic mercury collected in the ashes. Modern techniques are of course less crude than this but the basic principle is much the same. After being crushed and concentrated by flotation, the ore is roasted in a current of air and the vapour condensed:

$$\text{HgS} + \text{O}_2 \rightarrow 600^\circ \text{C} \rightarrow \text{Hg} + \text{SO}_2$$

Alternatively, in the case of especially rich ores, roasting with scrap iron or quicklime is used:

$$\text{HgS} + \text{Fe} \rightarrow \text{Hg} + \text{FeS}$$

$$4\text{HgS} + \text{CaO} \rightarrow 4\text{Hg} + 3\text{CaS} + \text{CaSO}_4$$

Blowing air through the hot, crude, liquid metal oxidizes traces of metals such as Fe, Cu, Zn and Pb which form an easily removable scum. Further purification is by distillation under reduced pressure. About 4000 tonnes of mercury are used annually but only half is from primary, mine production. About half being secondary production and sales from stockpiles. The main primary producer is now Spain, but several other countries, including the former Soviet Union, China and Algeria, have capacity for production.

The use of mercury for extracting precious metals by amalgamation has a long history and was extensively used by Spain in the sixteenth century when her fleet carried mercury from Almaden to Mexico and returned with silver. However, environmental concerns have resulted in falling demand and excess production capacity. It is still used in the extraction of gold and in the Castner-Kellner process for manufacturing chlorine and NaOH (p. 72), and a further major use is in the manufacture of batteries. It is also used in street lamps and AC rectifiers, while its small-scale use in thermometers, barometers and gauges of different kinds, are familiar in many laboratories.

29.2.3 Properties of the elements

A selection of some important properties of the elements is given in Table 29.1. Because the elements each have several naturally occurring isotopes their atomic weights cannot be quoted with great precision.

$\dagger$ Mercury is sold in iron flasks holding 76 lb of mercury and this is the unit in which output is normally measured.
Dry Batteries

A portable source of electricity, if not a necessity, is certainly a great convenience in modern life and is dependent on compact, sealed, dry batteries. The main types are listed below and they incorporate the metals Zn, Ni, Hg and Cd as well as MnO₂.

(a) Carbon–zinc cell

The first dry battery was that patented in 1866 by the young French engineer, G. Leclanché. The positive pole consisted of carbon surrounded by MnO₂ (p. 1048) contained in a porous pot, and the negative pole was simply a rod of zinc. These were situated inside a glass jar containing the electrolyte, ammonium chloride solution thickened with sand or sawdust. This is still the basis of the most common type of modern dry cell in which a carbon rod is the positive pole, surrounded by a paste of MnO₂, carbon black, and NH₄Cl, inside a zinc can which is both container and negative pole. The reactions are:

\[
\text{negative pole: } \text{Zn} \rightarrow \text{Zn}^{2+} + 2e^- \\
\text{electrolyte: } \text{Zn}^{2+} + 2\text{NH}_4\text{Cl} + 2\text{OH}^- \rightarrow \text{[ZnCl}_2\text{(NH}_3\text{)}_2\text{]} + 2\text{H}_2\text{O} \\
\text{positive pole: } 2\text{MnO}_2 + 2\text{H}_2\text{O} + 2e^- \rightarrow 2\text{MnO(OH)} + 2\text{OH}^- \\
\text{net reaction: } \text{Zn} + 2\text{NH}_4\text{Cl} + 2\text{MnO}_2 \rightarrow \text{[ZnCl}_2\text{(NH}_3\text{)}_2\text{]} + 2\text{MnO(OH)}
\]

(b) Mercury cell

The negative pole of pressed amalgamated zinc powder and the positive pole of mercury(II) oxide and graphite are separated by an absorbent impregnated with the electrolyte, conc KOH:

\[
\text{negative pole: } \text{Zn} + 2\text{OH}^- \rightarrow \text{ZnO} + \text{H}_2\text{O} + 2e^- \\
\text{positive pole: } \text{HgO} + \text{H}_2\text{O} + 2e^- \rightarrow \text{Hg} + 2\text{OH}^- \\
\text{net reaction: } \text{Zn} + \text{HgO} \rightarrow \text{Hg} + \text{ZnO}
\]

(c) Alkaline manganese cell

This is similar in principle to (a) but is constructed in a manner akin to (b). The negative pole of powdered zinc, formed into a paste with the electrolyte KOH, and the positive pole of compressed graphite and MnO₂ are separated by an absorbent impregnated with the electrolyte:

\[
\text{negative pole: } \text{Zn} + 2\text{OH}^- \rightarrow \text{ZnO} + \text{H}_2\text{O} + 2e^- \\
\text{positive pole: } 2\text{MnO}_2 + \text{H}_2\text{O} + 2e^- \rightarrow 2\text{MnO}_3 + 2\text{OH}^- \\
\text{net reaction: } \text{Zn} + 2\text{MnO}_2 \rightarrow \text{ZnO} + 2\text{MnO}_3
\]

(d) Nickel–cadmium cell

Unlike the cells above, which are all primary cells, this is a secondary (i.e. rechargeable) cell, and the two poles are composed in the uncharged condition of nickel and cadmium hydroxides respectively. These are each supported on microporous nickel, made by a sintering process, and separated by an absorbent impregnated with electrolyte. The charging reactions are:

\[
\text{negative pole: } \text{Cd(OH)}_2 + 2e^- \rightarrow \text{Cd} + 2\text{OH}^- \\
\text{positive pole: } \text{Ni(OH)}_2 + 2\text{OH}^- \rightarrow \text{NiO(OH)} + 2\text{H}_2\text{O} + 2e^- \\
\text{net reaction: } \text{Ni(OH)}_2 + \text{Cd(OH)}_2 \rightarrow \text{NiO(OH)} + \text{Cd} + 2\text{H}_2\text{O}
\]

During discharge these reactions are reversed. A crucial feature of the construction of this cell is that oxygen produced at the positive pole during charging by the side-reaction:

\[
4\text{OH}^- \rightarrow 2\text{H}_2\text{O} + \text{O}_2 + 4e^-
\]

can migrate readily to the negative pole to be recombined in the reaction:

\[
\text{O}_2 + 2\text{H}_2\text{O} + 2\text{Cd} \rightarrow 2\text{Cd(OH)}_2
\]

But for this rapid migration and recombination, the cell could not be sealed.

\(^{(a)}\)The half-life of 9.3 ± 1.9 × 10\(^{15}\) y for \(^{113}\)Cd is the longest known for any β-emitter; note that this is 2 million times the age of the earth (4.6 × 10\(^{9}\) y).

Their most noticeable features compared with other metals are their low melting and boiling points, mercury being unique as a metal which is a liquid at room temperature. Zinc and cadmium are silvery solids with a bluish lustre when freshly formed. Mercury is also unusual in being the only element, apart from the noble gases, whose vapour is almost entirely monatomic, while its appreciable vapour pressure (1.9 × 10\(^{-3}\) mmHg, i.e. 0.25 Pa, at 25°C), coupled with its toxicity, makes it necessary to handle it with care. The electrical resistivity of liquid mercury is exceptionally high for a metal, and this facilitates its use as an electrical standard (the international ohm is defined as the resistance of 14.4521 g of Hg in a column 106.300 cm long and 1 mm\(^2\) cross-sectional area at 0°C and a pressure of 760 mmHg.

The structures of the solids, although based on the typically metallic hexagonal close-packing, are significantly distorted. In the case of Zn and Cd the distortion is such that, instead of having 12 equidistant neighbours, each atom has 6 nearest neighbours in the close-packed plane with the 3 neighbours in each of the adjacent planes being about 10% more distant. In the case of (rhombohedral) Hg the distortion, again uniquely, is the reverse, with the coplanar atoms being the more widely separated (by some 16%). The consequence is that these elements are much less dense and have a lower tensile strength than their predecessors in Group 11. These facts have been ascribed to the stability of the d electrons which are now tightly bound to the nucleus: the metallic bonding therefore involves only the outer s electrons, and is correspondingly weakened.

### 29.2.4 Chemical reactivity and trends

Zinc and cadmium tarnish quickly in moist air and combine with oxygen, sulfur, phosphorus and the halogens on being heated. Mercury also reacts with these elements, except phosphorus and its reaction with oxygen was of considerable practical importance in the early work of J. Priestley and A. L. Lavoisier on oxygen (p. 601). The reaction only becomes appreciable at temperatures of about 350°C, but above about 400°C HgO decomposes back into the elements.
None of the three metals reacts with hydrogen, carbon or nitrogen.

Non-oxidizing acids dissolve both Zn and Cd with the evolution of hydrogen. With oxidizing acids the reactions are more complicated, nitric acid for instance producing a variety of oxides of nitrogen dependent on the concentration and temperature. Mercury is unreactive to non-oxidizing acids but dissolves in conc HNO₃ and in hot conc H₂SO₄ forming the Hg²⁺ salts along with oxides of nitrogen and sulfur. Dilute HNO₃ slowly produces Hg₂(NO₃)₂. Zinc is the only element in the group which dissolves in aqueous alkali to form ions such as aquated [Zn(OH)₄]₂⁻ (zincates).

All three elements form alloys with a variety of other metals. Those of zinc include the brasses (p. 1178) and, as mentioned above, are of considerable commercial importance. Those of mercury are known as amalgams and some, such as sodium and zinc amalgams, are valuable reducing agents: in a number of cases, high heats of formation and stoichiometric compositions suggest chemical combination. Na₅Hg₈ and Na₃Hg for instance have been isolated and structurally characterized. They consist of “widespread” close-packed mercury (Hg–Hg > 500 pm) with respectively, all vacancies filled and all octahedral vacancies plus 5/6 tetrahedral vacancies filled with sodium atoms.² From caesium amalgams CsHg has been obtained and shown³ to contain isolated square planar Hg₄ clusters (Hg–Hg ~ 300 pm whereas intercluster separation = 419 pm). Amalgams are most readily formed by heavy metals, whereas the lighter metals of the first transition series (with the exception of manganese and copper) are insoluble in mercury. Hence iron flasks can be used for its storage.

Chemically, it is clear that Zn and Cd are rather similar and that Hg is somewhat distinct. The lighter pair are more electropositive, as indicated both by their electronegativity coefficients and electrode potentials (Table 29.1), while Hg has a positive electrode potential and is comparatively inert. With the exception of the metallic radii, all the evidence indicates that the effects of the lanthanide contraction have died out by the time this group is reached. Compounds are characterized by the d¹⁰ configuration and, with the exception of derivatives of the Hg₂²⁺ ion, which formally involve Hg⁺, they almost exclusively involve M⁺ (but see page 1213). The ease with which the s² electrons are removed compared with the more firmly held d electrons is shown by the ionization energies. The sum of the first and second is in each case smaller than for the preceding element in Group 11, whereas the third is appreciably higher. Even so the first two ionization energies are high for mercury (as they are for gold) — perhaps reflecting the poor nuclear shielding afforded by the filled 4f shell — and this, coupled with the small hydration energy associated with the large Hg⁺⁺ cation, accounts for the positive value of its electrode potential.

In view of the stability of the filled d shell, these elements show few of the characteristic properties of transition metals (p. 905) despite their position in the d block of the periodic table. Thus zinc shows similarities with the main-group metal magnesium, many of their compounds being isomorphous, and it displays the class-a characteristic of complexing readily with O-donor ligands. On the other hand, zinc has a much greater tendency than magnesium to form covalent compounds, and it resembles the transition elements in forming stable complexes not only with O-donor ligands but with N-, P- and S-donor ligands, with which Hg⁺⁺ forms complexes whose stability is rarely exceeded by those of any other divalent cation. Compounds of the M⁺⁺ ions of this group are characteristically diamagnetic and those of Zn⁺⁺, like those of Mg⁺⁺, are colourless. By contrast, many compounds of

The range of stereochemistries found in compounds of the $\text{M}^\text{II}$ ions is illustrated in Table 29.2. Since the $d^{10}$ configuration affords no crystal field stabilization, the stereochemistry of a particular compound depends on the size and polarizing power of the $\text{M}^\text{II}$ cation and the steric requirements of the ligands. Thus both Zn$^\text{II}$ and Cd$^\text{II}$ favour 4-coordinate tetrahedral complexes though Cd$^\text{II}$, being the larger, forms 6-coordinate octahedral complexes more readily than does Zn$^\text{II}$. However, the still larger Hg$^\text{II}$ also commonly adopts a tetrahedral stereochemistry, and octahedral 6-coordination is less prevalent than for either of its congeners.\(^\dagger\) When it does occur it is usually highly distorted with 2 short and 4 long bonds, a distortion which in its extreme form produces the 2-coordinate, linear stereochemistry which is characteristic of

\(^{(a)}\text{H}_2\text{dapp} = 2,6\text{-diacetylpyridinebis(2'-pyridylhydrazone).}\)

\(^{(b)}\text{The 2 nitrate ions are not equivalent (both are bidentate but one is coordinated symmetrically, the other asymmetrically) and the structure of the complex is by no means regular (p. 1217).}\)

\(^{(c)}\text{The distortion arises because the bidentate nitrate ions are coordinated asymmetrically to such an extent that the stereochemistry may alternatively be regarded as approaching tetrahedral (p. 1217).}\)
Hg\textsuperscript{II}. This is also found in organozinc and organocadmium compounds but only with Hg\textsuperscript{II} is it one of the predominant stereochemistries. Explanations of this fact have been given in terms of the promotional energies involved in various hybridization schemes, but it may be regarded pictorially as a consequence of the greater deformability of the d\textsuperscript{10} configuration of the large Hg\textsuperscript{II} ion. Thus, if 2 ligands are considered to approach the cation from opposite ends of the z-axis, the resulting deformation increases the electron density in the xy-plane and so discourages the close approach of other ligands. Coordination numbers greater than 6 are rare and generally involve bidentate, O-donor ligands with a small “bite”, such as NO\textsubscript{3}\textsuperscript{−} and NO\textsubscript{2}\textsuperscript{−}.

### 29.3 Compounds of Zinc, Cadmium and Mercury\textsuperscript{(4–6)}

Zinc hydride can be isolated from the reaction of LiH with ZnBr\textsubscript{2} or NaH with ZnI\textsubscript{2}:

\[
2\text{MH} + \text{ZnX}_2 \xrightarrow{\text{thf}} \text{ZnH}_2 + 2\text{MX}
\]

The alkali metal halide remains in solution and ZnH\textsubscript{2} is precipitated as a white solid of moderate stability at or below room temperature.\textsuperscript{(7)} CdH\textsubscript{2} and HgH\textsubscript{2} are much less stable and decompose rapidly even below 0\textdegree C. The complex metal hydrides LiZnH\textsubscript{3}, Li\textsubscript{2}ZnH\textsubscript{4} and Li\textsubscript{2}ZnH\textsubscript{5} have each been prepared as off-white powders by the reaction of LiAlH\textsubscript{4} with the appropriate organometallic complex Li\textsubscript{2}ZnR\textsubscript{n+2}.

The carbides of these metals (which are actually acetylides, MC\textsubscript{2}, p. 297) and also the nitrides are unstable materials, those of mercury explosively so.

### 29.3.1 Oxides and chalcogenides

The principal compounds in this category are the monochalcogenides, which are formed by all three metals. It is a notable indication of the stability of tetrahedral coordination for the elements of Group 12 that, of the 12 compounds of this type, only CdO, HgO and HgS adopt a structure other than wurtzite or zinc blende (both of which involve tetrahedral coordination of the cation — see below). CdO adopts the 6-coordinate rock-salt structure; HgO features zigzag chains of almost linear O–Hg–O units; and HgS exists in both a zinc-blende form and in a rock-salt form.

The normal oxide, formed by each of the elements of this group, is MO, and peroxides MO\textsubscript{2} are known for Zn and Cd. Reported lower oxides, M\textsubscript{2}O, are apparently mixtures of the metal and MO.

ZnO is by far the most important manufactured compound of zinc\textsuperscript{(8)} and, being an inevitable byproduct of primitive production of brass, has been known longer than the metal itself. It is manufactured by burning in air the zinc vapour obtained on smelting the ore or, for a purer and whiter product, the vapour obtained from previously refined zinc. It is normally a white, finely divided material with the wurtzite structure. On heating, the colour changes to yellow due to the evaporation of oxygen from the lattice to give a nonstoichiometric phase Zn\textsubscript{1+x}O (x \leq 70 ppm); the supernumerary Zn atoms produce lattice defects which trap electrons which can subsequently be excited by absorption of visible light.\textsuperscript{(9)} Indeed, by “doping” ZnO with an excess of 0.02–0.03% Zn metal, a whole range of colours — yellow, green, brown, red — can be obtained. The reddish hues of the naturally

The major industrial use of ZnO is in the production of rubber where it shortens the time of vulcanization. As a pigment in the production of paints it has the advantage over the traditional “white lead” (basic lead carbonate) that it is nontoxic and is not discoloured by sulfur compounds, but it has the disadvantage compared to TiO₂ of a lower refractive index and so a reduced “hiding power” (p. 959). It improves the chemical durability of glass and so is used in the production of special glasses, enamels and glazes. Another important use is in antacid cosmetic pastes and pharmaceuticals. In the chemical industry it is the usual starting material for other zinc chemicals of which the soaps (i.e. salts of fatty acids, such as Zn stearate, palmitate, etc.) are the most important, being used as paint driers, stabilizers in plastics, and as fungicides. An important small scale use is in the production of “zinc ferrites”. These are spinels of the type Zn$^{II}$M$^{II}$–Fe$^{III}$O$_4$ involving a second divalent cation (usually Mn$^{II}$ or Ni$^{III}$). When $x = 0$ the structure is that of an inverse spinel (i.e. half the Fe$^{III}$ ions occupy octahedral sites — see p. 1081). Where $x = 1$, the structure is that of a normal spinel (i.e. all the Fe$^{III}$ ions occupy octahedral sites), since Zn$^{II}$ displaces Fe$^{III}$ from the tetrahedral sites. Reducing the proportion of Fe$^{III}$ ions in tetrahedral sites lowers the Curie temperature. The magnetic properties of the ferrite can therefore be controlled by adjustment of the zinc content.

ZnO is amphoteric (p. 640), dissolving in acids to form salts and in alkalis to form zincates, such as [Zn(OH)₂]$^-$ and [Zn(OH)₄]$^{2-}$. The gelatinous, white precipitate obtained by adding alkali to aqueous solutions of Zn$^{II}$ salts is Zn(OH)$_₂$ which, like ZnO, is amphoteric.

CdO is produced from the elements and, depending on its thermal history, may be greenish-yellow, brown, red or nearly black. This is partly due to particle size but more importantly, as with ZnO, is a result of lattice defects — this time in an NaCl lattice. It is more basic than ZnO, dissolving readily in acids but hardly at all in alkalis. White Cd(OH)$_₂$ is precipitated from aqueous solutions of Cd$^{II}$ salts by the addition of alkali and treatment with very concentrated alkali yields hydroxocadmiate such as Na₂(Cd(OH)$_₂$). Cadmium oxide and hydroxide find important applications in decorative glasses and enamels and in Ni–Cd storage cells. CdO also catalyses a number of hydrogenation and dehydrogenation reactions.

Treatment of the hydroxides of Zn and Cd with aqueous H₂O₂ produces hydrated peroxides of rather variable composition. That of Zn has antiseptic properties and is widely used in cosmetics. HgO exists in a red and a yellow variety. The former is obtained by pyrolysis of Hg(NO₃)$_₂$ or by heating the metal in O₂ at about 350°C; the latter by cold methods such as precipitation from aqueous solutions of Hg$^{II}$ by addition of alkali (Hg(OH)$_₂$ is not known). The difference in colour is entirely due to particle size, both forms having the same structure which consists of zigzag chains of virtually linear O–Hg–O units with Hg–O 205 pm and angle Hg–O–Hg 107°. The shortest Hg···O distance between chains is 282 pm.

Zinc blende, ZnS, is the most widespread ore of zinc and the main source of the metal, but ZnS is also known in a second naturally occurring though much rarer form, wurtzite, which is the more stable at high temperatures. The names of these minerals are now also used as the names of their crystal structures which are important structure types found in many other AB compounds. In both structures each Zn is tetrahedrally coordinated by 4 S and each S is tetrahedrally coordinated by 4 Zn; the structures differ significantly only in the type of close-packing involved, being cubic in zinc-blende and hexagonal in wurtzite (Fig. 29.1). Pure ZnS is white and, like ZnO, finds use as a pigment for which purpose it is often obtained (as “lithopone”) along with BaSO₄ from aqueous solution of ZnSO₄ and Ba₂:

$$\text{ZnSO}_4 + \text{BaS} \rightarrow \text{ZnS} \downarrow + \text{BaSO}_4 \downarrow$$

Freshly precipitated ZnS dissolves readily in mineral acids with evolution of H₂S, but roasting renders it far less reactive and it is then an acceptable pigment in paints for children’s toys since it is harmless if ingested. ZnS also has
Figure 29.1 Crystal structures of ZnS. (a) Zinc blende, consisting of two, interpenetrating, ccp lattices of Zn and S atoms displaced with respect to each other so that the atoms of each achieve 4-coordination (Zn–S = 235 pm) by occupying tetrahedral sites of the other lattice. The face-centred cube, characteristic of the ccp lattice, can be seen—in this case composed of S atoms, but an extended diagram would reveal the same arrangement of Zn atoms. Note that if all the atoms of this structure were C, the structure would be that of diamond (p. 275). (b) Wurtzite. As with zinc blende, tetrahedral coordination of both Zn and S is achieved (Zn–S = 236 pm) but this time the interpenetrating lattices are hexagonal, rather than cubic, close-packed.

interesting optical properties. It turns grey on exposure to ultraviolet light, probably due to dissociation to the elements, but the process can be inhibited by trace additives such as cobalt salts. Cathode rays, X-rays and radioactivity also produce fluorescence or luminescence in a variety of colours which can be extended by the addition of traces of various metals or the replacement of Zn by Cd and S by Se. It is widely used in the manufacture of cathode-ray tubes and radar screens.

Yellow ZnSe and brown ZnTe are structurally akin to the sulfide and the former especially is used mainly in conjunction with ZnS as a phosphor.

Chalcogenides of Cd are similar to those of Zn and display the same duality in their structures. The sulfide and selenide are more stable in the hexagonal form whereas the telluride is more stable in the cubic form. CdS is the most important compound of cadmium and, by addition of CdSe, ZnS, HgS, etc., it yields thermally stable pigments of brilliant colours from pale yellow to deep red, while colloidal dispersions are used to colour transparent glasses.

CdS and CdSe are also useful phosphors. CdTe is a semiconductor used as a detector for X-rays and γ-rays, and mercury cadmium telluride has found widespread (particularly military) use as an ir detector for thermal imaging.

HgS is polymorphic. The red α-form is the mineral cinnabar, or vermilion, which has a distorted rock-salt structure and can be prepared from the elements. β-HgS is the rare, black, mineral metacinnabar which has the zinc-blende structure and is converted by heat to the stable α-form. In the laboratory the most familiar form is the highly insoluble† black precipitate obtained by the action of H₂S on aqueous solutions of Hg²⁺. HgS is an unreactive substance, being attacked only by conc HBr, HI or aqua regia. HgSe and

---

† The solubility product, [Hg²⁺][S²⁻] = 10⁻⁵² mol² dm⁻⁶ but the actual solubility is greater than that calculated from this extremely low figure, since the mercury in solution is present not only as Hg²⁺ but also as complex species. In acid solution [Hg(SH)₂] is probably formed and in alkaline
### 29.3.2 Halides

The known halides are listed in Table 29.3. All 12 dihalides are known and in addition there are 4 halides of Hg$_{2}^{2+}$ which are conveniently considered separately. It is immediately obvious that the difluorides are distinct from the other dihalides, their mps and bps being much higher, suggesting a predominantly ionic character, as also indicated by their typically ionic three-dimensional structures (ZnF$_2$, 6:3 rutile; CdF$_2$ and HgF$_2$, 8:4 fluorite). ZnF$_2$ and CdF$_2$, like the alkaline earth fluorides, have high lattice energies and are only sparingly soluble in water, while HgF$_2$ is hydrolysed to HgO and HF. The anhydrous difluorides can be prepared by the action of HF (in the case of Zn) or F$_2$ (Cd and Hg) on the metal.

The other halides of Zn$^{2+}$ and Cd$^{2+}$ are in general hygroscopic and very soluble in water (~400 g per 100 cm$^3$ for ZnX$_2$ and ~100 g per 100 cm$^3$ for CdX$_2$). This is at least partly because of the formation of complex ions in solution, and the anhydrous forms are best prepared by the dry methods of treating the heated metals with HCl, Br$_2$ or I$_2$ as appropriate. Aqueous preparative methods yield hydrates of which several are known. Significant covalent character is revealed by their comparatively low mps, their solubilities in ethanol, acetone and other organic solvents, and by their layer-lattice (2D) crystal structures. In all cases these may be regarded as close-packed lattices of halides ions in which the Zn$^{2+}$ ions occupy tetrahedral, and the Cd$^{2+}$ ions octahedral, sites. The structures of CdCl$_2$ (CdBr$_2$ is similar) and CdI$_2$ are of importance (Fig. 29.2) since they are typical of MX$_2$ compounds in which marked polarization effects are expected (see chap. 3, pp. 37–61 of ref. 9). Electron diffraction studies show that ZnX$_2$ (X = Cl, Br, I) have linear X–Zn–X structures in the gas phase.\(^{12}\)

Concentrated, aqueous solutions of ZnCl$_2$ dissolve starch, cellulose (and therefore cannot be filtered through paper!), and silk. Commercially ZnCl$_2$ is one of the important compounds of zinc. It has applications in textile processing and, because when fused it readily dissolves other oxides, it is used in a number of metallurgical fluxes as well as in the manufacture of magnesia cements in dental fillings. Cadmium halides are used in the preparation of electroplating baths and in the production of pigments.

HgTe are easily obtained from the elements and have the zinc-blende structure.

---

halides of Zn and Cd. These compounds are readily prepared from the elements and are low-melting volatile solids, soluble in many organic solvents. Their solubilities in water, where they exist almost entirely as HgX2 molecules, decrease with increasing molecular weight, HgI2 being only slightly soluble, and they may be precipitated anhydrous from aqueous solutions by metathetical reactions. Their crystalline structures reveal an interesting gradation. HgCl2 is composed of linear Cl–Hg–Cl molecules (Hg–Cl = 225 pm and the next shortest Hg⋯Cl distance is 334 pm); HgBr2 and HgI2 have layer structures. However, in the bromide although the HgII may be regarded as 6-coordinated, two Hg–Br distances are much shorter than the other four (248 pm compared to 323 pm). In the red variety of the iodide the HgII is unambiguously tetrahedrally 4-coordinated (Hg–I = 278 pm). At temperatures above 126°C HgI2 exists as a less-dense, yellow form similar to HgBr2. In the gaseous phase all 3 of these HgII halides exist as discrete linear HgX2 molecules. Comparison of the Hg–X distances in these molecules (Hg–Cl = 228 pm, Hg–Br = 240 pm; Hg–I = 257 pm) with those given above, indicate an increasing departure from molecularity in passing from the solid chloride to the solid iodide.

HgCl2 is the “corrosive sublimate” of antiquity, formerly obtained by sublimation from HgSO4 and NaCl and used as an antiseptic. It is, however, a violent poison and was widely used as such in the Middle Ages. (5)

The halides are the most familiar compounds of mercury(I) and all contain the Hg22+ ion (see below). Hg2F2 is obtained by treating Hg2CO3 (itself precipitated by NaHCO3 from aqueous Hg(NO3)2 which in turn is obtained by the action of dil HNO3 on an excess of metallic mercury) with aqueous HF. It dissolves in water

Figure 29.2 The layer structure of crystalline CdI2: (a) Shows the hexagonal close-packing of I atoms with Cd atoms in alternate layers of octahedral sites sandwiched between layers of I atoms. In CdCl2 the individual composite layers are identical with those in CdI2, but they are arranged so that the Cl atoms are ccp. (b) Shows a portion of an individual composite layer of CdI6 (or CdCl6) octahedra. (c) Shows the same portion of a composite layer as in (b) and viewed from the same angle, but with CdI2 (or CdCl2) units represented by solid, edge-sharing octahedra.
but is at once hydrolysed to the “black oxide” which is actually a mixture of Hg and HgO. On heating, it disproportionates to the metal and HgF₂. The other halides are virtually insoluble in water and so, being free from the possibility of hydrolysis, may be precipitated from aqueous solutions of Hg₂(NO₃)₂ by addition of X⁻. Alternatively, they may be prepared by treatment of HgX₂ with the metal. Hg₂Cl₂ and Hg₂Br₂ are easily volatilized and their vapour densities correspond to “monomeric HgX”. However, the diamagnetism of the vapour (Hg¹ in HgX would be paramagnetic) and the ultraviolet absorption at the wavelength (253.7 nm) characteristic of Hg vapour, make it clear that decomposition to Hg + HgX₂ is the real reason for the halved vapour density. Hg₂I₂ decomposes similarly but even more readily, and the presence of finely divided metal is thought to be the cause of the greenish tints commonly found in samples of this otherwise yellow solid.

Calomel,† Hg₂Cl₂, has been widely used medicinally but possibly contamination by the more soluble and poisonous HgCl₂ renders this a hazardous nostrum.

29.3.3 Mercury(I)

Raman spectra, indicative of [M−M]²⁺ ions, are produced by the yellow glass obtained from the melt of Zn in ZnCl₂ and also by the colourless, very moisture sensitive crystals of Cd₂Al₂Cl₈ obtained from melts of Cd in CdCl₂ and AlCl₃. X-ray studies show that the latter contains “ethane-like” [Cd₂Cl₆]⁴⁻ groups with Cd–Cd reported as 257.6 pm(13) and 256.1 pm(14) (cf 302 pm in the metal itself). The ¹¹³Cd nmr spectrum(15) of [Cd(HB(3,5-Me₂Pz)₃)]₂ (pz = polycyclic pyrazolyl ligand) yields a ¹¹¹Cd−¹¹³Cd coupling constant of 20646 Hz, indicating a Cd–Cd bond; the first to be observed in a molecular complex of Cd. However, only for mercury is the formal oxidation state I of importance.

Mercury(I) compounds in general may be prepared, like the halides just discussed, by the reduction of the corresponding Hg¹¹ salt, often by the metal itself, or by precipitation from aqueous solutions of the nitrate. The nitrate is known as the dihydrate, Hg₂(NO₃)₂·2H₂O, and is stable in water if this is acidified, otherwise basic salts such as Hg(OH)(NO₃) and Hg₂(OH)(NO₃) are precipitated. The perchlorate is the only other appreciably soluble salt, the rest being either insoluble or, like the sulfate, chlorate and salts of organic acids, only sparingly soluble. In all cases the dinuclear Hg₂²⁺ ion is present rather than mononuclear Hg⁺. The evidence for this is overwhelming and includes the following:

1. In crystalline mercury(I) compounds, instead of the sequence of alternate M⁺ and X⁻ expected for MX compounds, Hg–Hg pairs are found in which the separation, though not constant, lies in the range 250–270 pm(5) which is shorter than the Hg–Hg separation of 300 pm found in the metal itself.

2. The Raman spectrum of aqueous mercury(I) nitrate has, in addition to lines characteristic of the NO₃⁻ ion, a strong absorption at 171.7 cm⁻¹ which is not found in the spectra of other metal nitrates and is not active in the infrared; it is therefore diagnostic of the Hg–Hg stretching vibration since homonuclear diatomic vibrations are Raman active not infrared active.† Similar data have subsequently been produced for a number of other compounds in the solid state and in solution.

† Calomel, derived from the Greek words kalos (beautiful) and pēira (black), seems an odd name for a white solid. It might arise from the colour of the material obtained when Hg₂Cl₂ is treated with ammonia; this is a product of variable composition (see below) which owes its colour to the presence of metallic mercury. Other more fanciful derivations are listed in the Oxford English Dictionary. 2, 41 (1970).

(3) Mercury(1) compounds are diamagnetic, whereas the monatomic \( \text{Hg}^+ \) ion would have a \( \text{d}^{10}\text{s}^{1} \) configuration and so be paramagnetic.

(4) The measured emfs of concentration cells of mercury(1) salts are only explicable on the assumption that a 2-electron transfer is involved. This would not be the case if \( \text{Hg}^+ \) were involved: 
\[
E = (2.303RT/nF) \log a_1/a_2 \text{ where } n = 2 \text{ for } \text{Hg}^{2+} \text{ and } n = 1 \text{ for } \text{Hg}^{+}.
\]

(5) It is found that “equilibrium constants” are in fact only constant if the concentration \( [\text{Hg}^{2+}] \) is employed rather than \( [\text{Hg}^+] \), i.e. the equilibria must be of the type:
\[
2\text{Hg} + 2\text{Ag}^+ \rightleftharpoons \text{Hg}^{2+} + 2\text{Ag}  
\]
(rather than
\[
\text{Hg} + \text{Ag}^+ \rightleftharpoons \text{Hg}^+ + \text{Ag})
\]
or
\[
\text{Hg} + \text{Hg}^{2+} \rightleftharpoons \text{Hg}^{2+}  
\]
(rather than
\[
\text{Hg} + \text{Hg}^{2+} \rightleftharpoons 2\text{Hg}^+  
\]

In order to understand the formation and stability of mercury(1) compounds it is helpful to consider the relevant reduction potentials:
\[
\text{Hg}^{2+} + 2e^- \rightleftharpoons 2\text{Hg}(1); \quad E^o = 0.7889 \text{ V}
\]
and
\[
2\text{Hg}^{2+} + 2e^- \rightleftharpoons 2\text{Hg}^{2+}; \quad E^o = 0.920 \text{ V}
\]

From this it follows that
\[
\text{Hg}^{2+} + 2e^- \rightleftharpoons \text{Hg}(1); \quad E^o = 0.8545 \text{ V}
\]
and
\[
\text{Hg}_2^{2+} \rightleftharpoons \text{Hg}(l) + \text{Hg}^{2+}; \quad E^o = -0.131 \text{ V}
\]

Now, 
\[
E^0 = (RT/nF) \ln K, 
\]
i.e. 
\[
E^0 = (0.0591/n) \log_{10} K 
\]

Hence, 
\[
\log_{10} K = -(0.131/0.0591) = -2.217, 
\]
i.e. 
\[
K = [\text{Hg}^{2+}]/[\text{Hg}_2^{2+}] = 0.0061
\]

Thus, at equilibrium, aqueous solutions of mercury(I) salts will contain around 0.6% of mercury(II) and the rather finely balanced equilibrium is easily displaced. The presence of any reagent which reduces the activity (in effect the concentration) of \( \text{Hg}^{2+} \) more than that of \( \text{Hg}_2^{2+} \), either by forming a less-soluble salt or a more-stable complex of \( \text{Hg}^{2+} \) will displace the equilibrium to the right and cause the disproportionation of the \( \text{Hg}_2^{2+} \). There are many such reagents, including \( \text{S}^{2-} \), \( \text{OH}^- \), \( \text{CN}^- \), \( \text{NH}_3 \) and acetylacetone. This is why the most stable \( \text{Hg}_2^{2+} \) salts are the insoluble ones and why there are few stable complexes. Those which are known all involve either \( \text{O}^- \) or \( \text{N}^- \)-donor ligands, the linear \( \text{O}_{-}\text{Hg}_{-}\text{Hg}_{-}\text{O} \) group being a common feature of the former.

**Polycations of mercury**

The \( \text{Hg}^-\text{Hg} \) bond in \( \text{Hg}_2^{2+} \) may be ascribed to overlap of the 6s orbitals with little involvement of 6p orbitals or of the filled d\(^{10}\) shell of each atom. If this is regarded as the coordination of \( \text{Hg} \) to an \( \text{Hg}^{2+} \) cation, the coordination of a second \( \text{Hg} \) ligand is also feasible. Accordingly, \( \text{Hg}_3(\text{AlCl}_4)_2 \) can be obtained from a molten mixture of \( \text{HgCl}_2 \), \( \text{Hg} \) and \( \text{AlCl}_3 \) and contains the discrete, virtually linear cation
\[
[\text{Hg} \overset{255\text{pm}}{\rightleftharpoons} \text{Hg} \rightleftharpoons \text{Hg}^{2+}
\]
in which the formal oxidation state of \( \text{Hg} \) is \( +2\frac{2}{3} \).

Still more interesting is the oxidation of \( \text{Hg} \) by \( \text{AsF}_5 \) in liquid \( \text{SO}_2 \):\(^{16,17}\) in this process the \( \text{AsF}_5 \) serves both as an oxidant (being reduced to \( \text{AsF}_3 \)) and also as a fluoride-ion acceptor to give \( \text{AsF}_6^- \). In a matter of minutes the colour of the solution becomes bright yellow then deepens to red as the \( \text{Hg} \) simultaneously turns to a shiny golden-yellow solid; the solid then begins to dissolve to give an orange and, finally, a colourless solution. By controlling the quantity of oxidant, \( \text{AsF}_5 \), and removing the solution at the appropriate stages, it is possible to crystallize a series of extremely moisture-sensitive materials:

\[\text{For this reason, although } \text{Hg}_2^{2+} \text{ must be regarded as a class-b cation (e.g. the aqueous solubilities of its halides decrease in the order } \text{F}^- \text{ to } \text{I}^- \text{), it is evidently less so than } \text{Hg}^{2+} \text{ which has a notable preference for } \text{S} \text{ donors.} \]

29.3.4 Zinc(II) and cadmium(II)

The almost invariable oxidation state of these elements is +2 and, in addition to the oxides, chalcogenides and halides already discussed, salts of most anions are known. Oxo-salts are often isomorphous with those of MgII but with lower thermal stabilities. The carbonates, nitrates, and sulfates all decompose to the oxides on heating. Several, such as the nitrates, perchlorates and sulfates, are very soluble in water and form more than one hydrate. $[\text{Zn(H}_2\text{O)}_6]^{2+}$ is probably the predominant aquo species in solutions of ZnII salts. Aqueous solutions are appreciably hydrolysed to species such as $[\text{M(OH)}(\text{H}_2\text{O})_2]^{3+}$ and $[\text{M}_2(\text{OH})(\text{H}_2\text{O})_2]^{3+}$ and a number of basic (i.e. hydroxo) salts such as $\text{ZnCO}_3.2\text{Zn(OH)}_2.\text{H}_2\text{O}$ and $\text{CdCl}_2.4\text{Cd(OH)}_2$ can be precipitated. Distillation of zinc acetate under reduced pressure yields a crystalline basic acetate, $[\text{Zn}_4\text{O(OCOMe)}_6]$. The molecular structure of this consists of an oxygen atom surrounded by a tetrahedron of Zn atoms bridged across each edge by acetates. It is isomorphous with the basic acetate of beryllium (p. 122) but, in contrast, the ZnII compound hydrolys rapidly in water, no doubt because of the ability of ZnII to increase its coordination number above 4.

The coordination chemistry of ZnII and CdII, although much less extensive than for preceding transition metals, is still appreciable. Neither element forms stable fluoro complexes but, with the other halides, they form the complex anions $[\text{MX}_3]^{-}$ and $[\text{MX}_4]^{2-}$, those of CdII being moderately stable in aqueous solution. By using the large cation $[\text{Co(NH}_3)_6]^{3+}$ it is also possible to isolate the trigonal bipyramidal $[\text{CdCl}_3]^{2-}$.

---

[MX$_3$]$^{-}$ and [MX$_4$]$^{2-}$ are formed in CH$_3$CN solutions also.\(^{20}\) Tetrahedral complexes are the most common type and are formed with a variety of O-donor ligands (more readily with Zn$^{II}$ than Cd$^{II}$), more stable ones with N-donor ligands such as NH$_3$ and amines. Some of the apparently 3-coordinate complexes have a higher coordination number because of aquation or association but, no doubt because the ligand is bulky, 2-coordinated Zn occurs in [Zn(N(CMe$_3$)(SiMe$_3$))]$_2$, the first homoleptic zinc amide to be structurally characterized.\(^{21}\)

The ability of CN$^-$ to co-ordinate through either C or N has interesting stereochemical consequences. Crystalline M(CN)$_2$ consist of linear M–C–N–M “rods” and tetrahedrally co-ordinated M$^{II}$, arranged so as to form interpenetrating “adamantine” frameworks (Fig. 29.3a). Each “rod” projects through a cyclohexane-like “window” of the other framework.\(^{22}\) When aqueous solutions of CdCl$_2$ + K[Cd(CN)$_4$] are left in contact with liquids such as CCl$_4$, CMeCl$_3$ . . . . CMe$_4$, crystals of the clathrates Cd(CN)$_2$.G form at the interface.

---

of the immiscible liquids.\( {\text{23}} \) In these, the guest molecules \( G \), occupy the cavities of a single adamantane framework. \((\text{NMe}_4)_2[\text{Cu}^2\text{Zn(CN)}_4]\) consists of a similar framework but this time half the cavities are occupied by \( \text{NMe}_4^+ \) cations. Another type of framework is found in \( \text{Cd(CN)}_2\cdot\text{H}_2\text{O}\cdot\text{Bu}^+\text{OH} \) which crystallizes from 50% aqueous \( \text{Bu}^+\text{OH} \) solutions of \( \text{Cd(CN)}_2 \). It contains \( \text{CdCNCd} \) “rods” but this time they are bent, \( \frac{1}{3} \) of the \( \text{Cd} \) atoms are tetrahedrally co-ordinated by 4CN-, the other \( \frac{2}{3} \) being octahedrally co-ordinated by 4CN- and 2H\(_2\)O. The result is a honeycomb framework with linear channels of hexagonal cross-section containing disordered \( \text{Bu}^+\text{OH} \) molecules.\( {\text{24}} \) Linear channels are also found in \( \text{Cd(CN)}_2\cdot\text{G} \) \((\text{G} = \text{dmf}, \text{dmso})\)\( {\text{25}} \) but the large cation in \( (\text{PPh}_4)_3 [(\text{CN})_3\text{CdCNCd(CN)}_3] \) apparently prevents the formation of a 3D framework and instead stabilizes the discrete anion.\( {\text{26}} \)

Complexes of higher coordination number are often in equilibrium with the tetrahedral form and may be isolated by increasing the ligand concentration or by adding large counter ions, e.g. \([\text{M(NH}_3)_6\text{I}_2^+\), \([\text{M(en)}_3\text{I}_2^+\) or \([\text{M(bipy)}_3\text{I}_2^+\). With acetylacetone, zinc achieves both 5- and 6-coordination by trimerizing to \([\text{Zn(acac)}_2]_3\) (Fig. 29.3b). Five-coordination is also found in adducts such as the distorted trigonal bipyramidal \([\text{Zn(acac)}_2(\text{H}_2\text{O})]\) and \([\text{Zn(glcyinate)}_2(\text{H}_2\text{O})]\) while the hydrazinium sulfate \((\text{N}_2\text{H}_5\text{H}_2\text{SO}_4)\) contains 6-coordinated zinc. This is isomorphous with the \( \text{Cr}^{II} \) compound (p. 1031) and in the crystalline form consists of chains of \( \text{Zn}^{II} \) bridged by \( \text{SO}_4^{2-} \) ions, with each \( \text{Zn}^{II} \) additionally coordinated to two \( \text{trans-N}_2\text{H}_5^+ \) ions. The zinc porphyrin complex, \([\text{Zn(porph)(thf)}]_2\) \((\text{porph} = \text{meso-tetraphenyltetrabenzoporphyrin})\) is approximately square pyramidal with thf at its apex. Being somewhat flexible the porphyrin is distorted into a saddle shape, 2 \( \text{N} \) being displaced above its mean plane and 2 \( \text{N} \) below it.\( {\text{27}} \)

Complexes with \( \text{SCN}^- \) throw light on the relative affinities of the two metals for \( \text{N}^- \) and \( \text{S}^- \)-donors. In \([\text{Zn(NCS)}_4]^{2-}\) the ligand is \( \text{N}^- \)-bonded whereas in \([\text{Cd(SCN)}_4]^{2-}\) it is \( \text{S}^- \)-bonded. \( \text{SCN}^- \) can also act as a bridging group, as in \([\text{Cd}[\text{S}=(\text{NHCH}_2)_2]_2(\text{SCN})_2] \) when linear chains of octahedrally coordinated \( \text{Cd}^{II} \) are formed (Fig. 29.3c). A number of zinc–sulfur compounds are used as accelerators in the vulcanization of rubber. Among these are the dithiocarbamates, of which \([\text{Zn(S_2\text{CNEt}_2)}_2]\) apparently prevents the formation of a 3D framework and instead stabilizes the discrete anion.\( {\text{26}} \)

Coordination numbers higher than 6 are rare and in some cases are known to involve chelating \( \text{NO}_3^- \) ions which not only have a small “bite” but, may also be coordinated asymmetrically so that the coordination number is not well defined.

### 29.3.5 Mercury(II)\( ^{28} \)

The oxide (p. 1209), chalcogenides (p. 1210) and halides (p. 1211) have already been described. Of them, the only ionic compound is \( \text{HgF}_2 \) but other compounds in which there is appreciable charge separation are the hydrated salts of strong oxoacids, e.g. the nitrate, perchlorate, and sulfate. In aqueous solution such salts are extensively hydrolysed (\( \text{HgO} \) is only very weakly basic) and they require acidification to prevent the formation of polynuclear hydroxo-bridged species or the precipitation of basic salts such as \( \text{Hg(OH)(NO}_3) \) which contains infinite zigzag chains:

\[ \text{Hg}^2+ \text{O} \sim \text{Hg} \sim \text{O} \sim \text{Hg} \sim \text{O} \sim \text{Hg} \sim \text{O} \sim \text{Hg}^2+ \]

---

Their ionic character is symptomatic of the marked reluctance of Hg$^{II}$ to form covalent bonds to oxygen. In the presence of excess NO$_3^-$ ions the aqueous nitrate forms the complex anion [Hg(NO$_3$)$_4$]$^{2-}$ in which 8 oxygen atoms from the bidentate nitrate groups are equidistant from the mercury at 240 pm, which is almost precisely the sum of the ionic radii (140 + 102 pm). Also, the unusual regular octahedral coordination is found in complexes with O-donor ligands: [Hg(C$_5$H$_5$NO)$_6$]$^{2+}$ (Hg–O = 235 pm), [Hg(H$_2$O)$_6$]$^{2+}$ (Hg–O = 234 pm), and [Hg(Me$_2$SO)$_6$]$^{2+}$ (Hg–O = 234 pm). In contrast, the more covalently bonding B-diketonates do not form complexes.

The most usual type of coordination in compounds of Hg$^{II}$ with other donor atoms is a distorted octahedron with 2 bonds much shorter than the other 4. In the extreme, this results in linear 2-coordination in which case the bonds are largely covalent. Hg(CN)$_2$ is actually composed of discrete linear molecules (C-bonded CN$^-$), whereas crystalline† Hg(SCN)$_2$ is built up of distorted octahedral units, all SCN groups being bridging:

With both these pseudo halides, an excess produces complex anions [HgX$_3$]$^-$ and the tetrahedral [HgX$_4$]$^{2-}$.

Similar halogeno complexes are produced in solution, and several salts of [HgX$_3$]$^-$ have been isolated and characterized; they display a variety of stereochemistries. In [HgCl$_3$]$^-$ the environment of the Hg$^{II}$ is either distorted octahedral (with small cations such as NH$_4^+$ or Na$^+$) or distorted trigonal bipyramidal (with larger cations such as [NEH$_4$]$^+$, [SMe$_3$]$^+$ or [NH$_2$((CH)$_2$)$_2$NH$_3$]$_2$$^{3+}$), whereas in salts of [HgBr$_3$]$^-$ and [HgI$_3$]$^-$ the coordination is more commonly distorted tetrahedral. In [NBu$_4$][HgI$_3$] the anion is planar but, with one I–Hg–I angle 115°, its symmetry is $C_2v$, rather than $D_{3h}$. In aqueous solution spectroscopic evidence suggests that [HgCl$_3$]$^-$ is planar with 2H$_2$O completing a trigonal bipyramidal coordination sphere; [HgI$_3$]$^-$ is pyramidal with H$_2$O completing a tetrahedral coordination sphere, while [HgBr$_3$]$^-$ shows features of both structures.†‡

In the presence of excess halide, [HgX$_4$]$^{2-}$ complex ions are produced and in comparison with those of Zn$^{II}$ and Cd$^{II}$ it can be seen that their stabilities increase with the sizes of the anion and the cation so that [HgI$_3$]$^{2-}$ is the most stable of all. Thus, the normally very insoluble HgI$_2$ will dissolve in aqueous solutions of I$^-$ which can then be made strongly alkaline without precipitation occurring. Such solutions are known as Nessler’s reagent, which is used as a sensitive test for ammonia since this produces a yellow or brown coloration due to the formation of Hg$_2$NIL$_2$O, the iodo salt of Millon’s base (see p. 1220). Adducts of the halides HgX$_2$, with N-, S-, and P-donor ligands are known, those with N-donors being especially numerous. Their stereochemistries are largely of the expected tetrahedral, or grossly distorted octahedral, types.

Hg$^{II}$–N compounds

Mercury has a characteristic ability to form not only conventional ammine and amine complexes but also, by the displacement of hydrogen, direct covalent bonds to nitrogen, e.g.:

\[
\text{Hg}^{2+} + 2\text{NH}_3 \rightleftharpoons [\text{Hg} - \text{NH}_2]^+ + \text{NH}_4^+
\]

† Pellets of the dry powder, when ignited in air, form snake-like tubes of spongy ash of unknown composition — the so-called “Pharaoh’s serpents”.

Thus in the presence of an excess of NH$_4^+$, which suppresses this forward reaction, and counteranions such as NO$_3^-$ and ClO$_4^-$, which have little tendency to coordinate, complexes such as [Hg(NH$_3$)$_4$]$^{2+}$, [Hg(L-L)$_2$]$^{2+}$ and even [Hg(L-L)$_3$]$^{*+}$ (L-L = en, bipy, phen) can be prepared. But, in the absence of such precautions, amino, or imino-compounds are likely to be formed, often together. Because of this variety of simultaneous reactions and their dependence on the precise conditions, many reactions between Hg$^{ll}$ and amines, although first performed by alchemists in the Middle Ages, remained obscure until the application of X-ray crystallography and, still more recently, spectroscopic techniques such as nmr, infrared and Raman.

The action of aqueous ammonia on HgCl$_2$, for instance, may be described by the three reactions:

\[
\text{HgCl}_2 + 2\text{NH}_3 \rightleftharpoons \text{[Hg(NH}_3)_2\text{Cl}_2] } \quad (1)
\]

\[
\text{[Hg(NH}_3)_2\text{Cl}_2] \rightleftharpoons \text{[Hg(NH}_2\text{)Cl]} + \text{NH}_4\text{Cl } \quad (2)
\]

\[
2\text{[Hg(NH}_2\text{)Cl]} + \text{H}_2\text{O} \rightleftharpoons \text{[Hg}_2\text{NCl(H}_2\text{O)] } + \text{NH}_4\text{Cl } \quad (3)
\]

In general, all these products are obtained in proportions which depend on the concentrations of NH$_3$ and NH$_4^+$ and on the temperature, but more or less pure products can be prepared by suitably adjusting the conditions.

The diammine [Hg(NH$_3$)$_2$Cl$_2$], descriptively known as "fusible white precipitate", can be isolated by maintaining a high concentration of NH$_4^+$, since reactions (2) and (3) are thereby inhibited, or better still by using non-polar solvents. It is made up of a cubic lattice of Cl$^-$ ions with linear H$_3$N–Hg–NH$_3$ groups inserted so as to give the common, distorted octahedral coordination about Hg$^{ll}$ (Hg–N = 203 pm, Hg–Cl = 287 pm) (Fig. 29.4a).

By using a low concentration of NH$_3$ and with no NH$_4^+$ initially present, the amide [Hg(NH$_2$)Cl], “infusible white precipitate” is
obtained. This consists of parallel chains of \([\text{Hg}(\text{NH}_2)_2]\) as above, separated by Cl\(^-\) ions.

\([\text{Hg}_2\text{NCI}(\text{H}_2\text{O})]\) is the chloride of Millon’s base, \([\text{Hg}_2\text{N} (\text{OH})_2(\text{H}_2\text{O})_2]\), and can be obtained either by heating the diammine, or amide with water or, better still, by the action of hydrochloric acid on Millon’s base which is best prepared by the method, used in 1845 by its discoverer, of warming yellow HgO with aqueous NH\(_3\). Replacement of the OH\(^-\) yields a series of salts, \([\text{Hg}_2\text{NX}(\text{H}_2\text{O})]\), the structures of which (and that of the base itself) consist, with only minor variations, of a network of \([\text{Hg}_2\text{N}]^+\) units linked so that each N is tetrahedrally linked to 4 Hg and each Hg is linearly linked to 2 N (Hg–N = 204–209 pm depending on X).\(^{31}\) The X\(^-\) ions and water molecules are accommodated interstitially and these materials behave as anion exchangers.

When Hg\(_2\)Cl\(_2\) is treated with aqueous NH\(_3\) disproportionation occurs (Hg\(_2\)Cl\(_2\) → HgCl\(_2\) + Hg); the HgCl\(_2\) then reacts as outlined above to give a precipitate of variable composition. The liberated mercury, however, renders the precipitate black, as previously mentioned, and so forms the basis of a distinctive qualitative test for Hg\(_2\)\(^{2+}\).

**Hg\(^{II}\) – S compounds\(^{32}\)**

As indicated by the insolubility and inertness of HgS, Hg\(^{II}\) has a great affinity for sulfur. HgO reacts vigorously with mercaptans (which is why RSH were given the name mercaptans\(^\dagger\)), displacing the H as with amines:

\[
\text{HgO} + 2\text{RSH} \longrightarrow \text{Hg(SR)}_2 + \text{H}_2\text{O}
\]

These mercaptides are low-melting solids, soluble in CHCl\(_3\) and C\(_6\)H\(_6\). Though their structures depend on R and some, such as Hg(SR)\(_2\), (R = Bu\(^I\), Ph) are polymers containing tetrahedral HgS\(_4\) units, most contain linear (or nearly linear) S–Hg–S. Even in [Hg(SC\(_6\)H\(_5\)Bu\(^3\))\(_2\)(py)] where the Hg is 3-coordinate and T-shaped the S–Hg–S is still nearly linear (172°).\(^{33}\) Most of the thioether (SR\(_2\)) complexes which have been prepared are adducts of the Hg\(^{II}\) halides and include both monomeric and polymeric (i.e. X-bridged) species as is the case with mixed thiolate–halide complexes. In [Hg\(_7\)(SC\(_6\)H\(_{11}\))\(_{12}\)Br\(_6\)], which is obtained as colourless crystals when methanolic solutions of HgBr\(_2\) and sodium cyclohexanethiolate are mixed, six Hg atoms are 4-coordinate but contain almost linear S–Hg–S (av. angle = 159.3°) and the seventh Hg is tetrahedrally coordinated. The six Hg atoms form a distorted octahedron around a central Br (Fig. 29.4b).\(^{34}\) The dithiocarbamate [Hg(S\(_2\)CNEt\(_2\))\(_2\)] exists in two forms, one of which has the same structure as the corresponding Zn\(^{II}\) and Cd\(^{II}\) compounds (Fig. 29.3d), while the other is polymeric.

**Cluster compounds involving mercury\(^{35,36}\)**

Mercury has a marked ability to bond to other metals. In addition to the amalgams already mentioned (p. 1206) it acts as a versatile structural building block by forming Hg–M bonds with cluster fragments of various types: e.g. reduction

\(^\dagger\) Mercaptans were discovered in 1834 by W. C. Zeise (pp. 930, 1167) who named them from the Latin *mercurium captans*, catching mercury.

29.3.6 Organometallic compounds

Although they were not the first organometallic compounds to be prepared (Zeise’s salt was discovered in 1827) the discovery of zinc alkyls in 1849 by Sir Edward Frankland may be taken as the beginning of organometallic chemistry. Frankland’s studies led to their employment as intermediates in organic synthesis, while the measurements of vapour densities led to his suggestion, crucial to the development of valency theory, that each element has a limited but definite combining capacity. After their discovery in 1900 Grignard reagents largely superseded the zinc alkyls in organic synthesis, but by then many of the reactions for which they are now used had already been worked out on the zinc compounds.

Alkyls of the types RZnX and ZnR₂ are both known and may be prepared by essentially the original method of heating Zn with boiling RX in an inert atmosphere (CO₂ or N₂):

\[ \text{Zn} + \text{RX} \rightarrow \text{RZnX} \]

and then raising the temperature to distil the dialkyl:

\[ 2\text{RZnX} \rightarrow \text{ZnR}_2 + \text{ZnX}_2 \]

These reactions work best with X = I but the less-expensive RBr can be used in conjunction with a Zn–Cu alloy instead of pure Zn. Diaryls are best obtained from appropriate organoboranes or organomercury compounds:

\[ 3\text{ZnMe}_2 + 2\text{BR}_3 \rightarrow 3\text{ZnR}_2 + 2\text{BMe}_3 \]

or

\[ \text{Zn} + \text{HgR}_2 \rightarrow \text{ZnR}_2 + \text{Hg} \]

ZnR₂ are covalent, non-polar liquids or low-boiling solids (Table 29.4). They are invariably monomeric in solution with linear C–Zn–C coordination at the Zn atom. They are very susceptible to attack by air and those of low molecular weight are spontaneously flammable, producing a smoke of ZnO. Their reactions with water, alcohols and ammonia, etc., are generally similar to, but less vigorous than, those of Grignard reagents (p. 132) with the important difference that they are unaffected by CO₂; indeed, they are often prepared under an atmosphere of this gas.

Organocadmium compounds are normally prepared from the appropriate Grignard reagents:

\[ \text{CdX}_2 + 2\text{RMgX} \rightarrow \text{CdR}_2 + 2\text{MgX}_2 \]

and then if desired:

\[ \text{CdR}_2 + \text{CdX}_2 \rightarrow 2\text{RCdX} \]

They are thermally less stable than their Zn counterparts but generally less reactive (not normally

catching fire in air), and so their most important use (but see also ref. 38) is to prepare ketones from acid chlorides:

\[ 2R'\text{COCl} + \text{CdR}_2 \rightarrow 2R'\text{COR} + \text{CdCl}_2 \]

The use of Grignard reagents is impracticable here since they react further with the ketone.

An enormous number of organomercury compounds are known. They are predominantly of the same stoichiometries as those of Zn and Cd, viz. RHgX and HgR₂, and may be prepared by the action of sodium amalgam on RX:

\[ 2\text{Hg} + 2RX \rightarrow \text{HgR}_2 + \text{HgX}_2 \]

\[ \text{HgCl}_2 + 2\text{Na} \rightarrow \text{Hg} + 2\text{NaCl} \]

More usually they are made by the reaction of Grignard reagents on HgCl₂ in thf:

\[ \text{RMgX} + \text{HgCl}_2 \rightarrow \text{RHgCl} + \text{MgXCl} \]

\[ \text{RMgX} + \text{RHgCl} \rightarrow \text{HgR}_2 + \text{MgXCl} \]

or simply by the action of HgX₂ on a hydrocarbon:

\[ \text{HgX}_2 + \text{RH} \rightarrow \text{RHgX} + \text{HX} \] (mercuration).

RHgX are crystalline solids, and HgR₂ are extremely toxic liquids or low-melting solids (Table 29.4). They are essentially covalent materials except when \( X^- = \text{F}^-, \text{NO}_3^- \) or \( \text{SO}_4^{2-} \), in which cases the former are water-soluble and apparently ionic, \([\text{RHg}]^+X^-\). There are several reasons for the attention which these compounds have received. The search for pharmacologically valuable drugs has provided a continuing stimulus, and the existence of convenient preparative methods, coupled with their remarkable stability to air and water, has led to their extensive use in mechanistic studies. This stability sets them apart from the organic derivatives of Zn, Cd and Group 2 metals but arises from the extreme weakness of the Hg–O bond rather than an inherently strong Hg–C bond. In fact the latter is weak, being commonly only \(~60 \text{kJ mol}^{-1}\) and organomercury compounds are thermally and photochemically unstable, in some cases requiring to be stored at low temperatures in the dark. Indeed, because of the weakness of the bond, Hg can be replaced by many metals which give stronger M–C bonds and the preparation of organo derivatives of other metals (e.g. of Zn and Cd as referred to above) is the most important application of these compounds.

It appears that all RHgX and HgR₂ compounds are made up of linear R–Hg–X or R–Hg–R units, which could arise from sp hybridization of the metal. In some cases polymerization is necessary to achieve this linearity. Thus, for instance, \( \sigma \)-phenylene-mercury, which could conceivably be formulated as

![Diagram](image)

is in fact a cyclic trimer (Fig. 29.5a). Organomercury compounds generally have little tendency to coordinate to further ligands. Exceptions include irregularly 3-coordinated [HgMe(bipy)]NO₃ [40] and [HgR(Hdz)], [41] T-shaped [Hg(2-pyridylphenyl)Cl] [42] (Fig. 29.5b, c, d) and the tetrahedral [HgMe(np₃)]⁺ (np₃ is the “tripod” phosphine N{CH₂CH₂PPh₂}) [43].

Among the versatile and synthetically useful reactions are those typified by the absorption of alkenes (olefins) by methanolic solutions of salts, particularly, the acetate of Hg⁺. The products are not \( \pi \) complexes, but \( \sigma \)-bonded addition.

---

Methanolic solutions of Hg\textsuperscript{II} also absorb CO and the products, of the type XHgC(=O)OMe are again \(\sigma\)-bonded.

A similar reluctance to form \(\pi\) bonds is seen in the cyclopentadienyls of mercury such as \([\text{Hg}(\eta^1\text{-C}_5\text{H}_5)_2]\) and \([\text{Hg}(\eta^1\text{-C}_5\text{H}_5)\text{X}]\). As they are photosensitive and single crystals are very difficult to obtain, structural information has been derived mainly from infrared and nmr data. These show that the rings are monohapto and the compounds fluxional, i.e. the point of attachment of the Hg to the ring changes rapidly on the nmr time scale so that the 5 carbons are indistinguishable — the phenomenon of “ring whizzing”. In the case of \([\text{Hg}(\eta^1\text{-C}_5\text{H}_4\text{PPh}_3)_2]\) it has been possible to determine the structure by
X-ray diffraction\(^{44}\) which confirms the presence of an Hg–C \(\sigma\) bond (Fig. 29.6).

### 29.3.7 Biological and environmental importance\(^{45,46,46a}\)

It is a remarkable contrast that, whereas Zn is biologically one of the most important metals and is apparently necessary to all forms of life,\(^{47}\) Cd and Hg have no known beneficial biological role and are amongst the most toxic of elements.

The body of an adult human contains about 2 g of Zn but, as Zn enzymes are present in most body cells, its concentration is very low and realization of its importance was therefore delayed. The two Zn enzymes which have received most attention are carboxypeptidase A and carbonic anhydrase.

**Carboxypeptidase A** catalyses the hydrolysis of the terminal peptide bond in proteins during the process of digestion:

\[
\begin{align*}
\text{NH} & \quad \text{C} & \quad \text{C} & \quad \text{NH} & \quad \text{C} & \quad \text{O} \\
\text{R} & \quad & & & & \\
\text{H} & \quad & \text{O} & & & \\
\text{PhCH}_2 & \quad & & & & 
\end{align*}
\]

\[+ \text{H}_2\text{O} \xrightarrow{\text{enzyme}}\]

\[
\begin{align*}
\text{NH} & \quad \text{C} & \quad \text{C} & \quad \text{OH} & \quad \text{N} & \quad \text{C} & \quad \text{O} \\
\text{R} & \quad & & & & & \\
\text{H} & \quad & \text{O} & & & & \\
\text{PhCH}_2 & \quad & & & & &
\end{align*}
\]

It has a molecular weight of about 34,000 and contains one Zn tetrahedrally coordinated to two histidine N atoms, a carboxyl O of a glutamate residue, and a water molecule. The precise mechanism of its action is not finally settled in spite of the intensive study of model systems,\(^{48}\) but it is agreed that the first step is coordination of the terminal peptide to the Zn by its \(\text{C}=\text{O}\) group. This is thereby polarized, giving the C a positive charge and making it susceptible to nucleophilic attack. This attack is probably by the \(\text{–OH}\) of the attached water molecule, followed by proton-rearrangement and breaking of the C–N peptide bond,\(^{49}\) though alternative possibilities.

such as attack by the carboxyl group of a second glutamate residue in the enzyme have also been considered. In any event it is evident that the conformation of the enzyme provides a hydrophobic pocket, close to the Zn, which accommodates the non-polar side-chain of the protein being hydrolysed, and that this protein is, throughout, held in the correct position by H bonding to appropriate groups in the enzyme.

Carbonic anhydrase was the first Zn metallo-enzyme to be discovered (1940) and in its several forms is widely distributed in plants and animals. It catalyses the equilibrium reaction:

$$\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{HCO}_3^- + \text{H}^+$$

In mammalian erythrocytes (red blood-cells) the forward (hydration) reaction occurs during the uptake of CO$_2$ by blood in tissue, while the backward (dehydration) reaction takes place when the CO$_2$ is subsequently released in the lungs. The enzyme increases the rates of these reactions by a factor of about one million.

The molecular weight of the enzyme is about 30000 and the roughly spherical molecule contains just one zinc atom situated in a deep protein pocket, which also contains a number of water molecules arranged in an ice-like order. This Zn is coordinated tetrahedrally to 3 imidazole nitrogen atoms of histidine residues and to a water molecule. Once again the precise details of the enzyme’s action are not settled, but it seems probable that the coordinated H$_2$O ionizes to give Zn-OH$^-$ and the nucleophilic OH$^-$ then interacts with the C of CO$_2$ (which may be held in the correct position by H bonds to its two oxygen atoms) to yield HCO$_3^-$. This is equivalent to replacing the slow hydration of CO$_2$ with H$_2$O, by the fast reaction:

$$\text{CO}_2 + \text{OH}^- \rightarrow \text{HCO}_3^-$$

The latter would normally require a high pH and the contribution of the enzyme is therefore presumed to be the provision of a suitable environment, within the protein pocket, which allows the dissociation of the coordinated H$_2$O to occur in a medium of pH 7 which would otherwise be much too low.

A more recently established function of zinc is in proteins responsible for recognizing base-sequences in DNA and so regulating the transfer of genetic information during the replication of DNA. These so-called “zinc-finger” proteins contain 9 or 10 Zn$^{2+}$ ions each of which, by coordinating to 4 amino acids, stabilizes a protruding fold (finger) in the protein. The protein wraps around the double strand of DNA, each of the fingers binding to the DNA, their spacing matching the base sequence in the DNA and thus ensuring accurate recognition. ($^5$)

Cadmium is extremely toxic and accumulates in humans mainly in the kidneys and liver; prolonged intake, even of very small amounts, leads to dysfunction of the kidneys. It acts by binding to the —SH group of cysteine residues in proteins and so inhibits SH enzymes. It can also inhibit the action of zinc enzymes by displacing the zinc.

The toxic effects of mercury have long been known, ($^5$) and the use of HgCl$_2$ as a poison has already been mentioned. The use of mercury salts in the production of felt† for hats and the dust generated in ill-ventilated workshops by the subsequent drying process, led to the nervous disorder known as “hatter’s shakes” and possibly also to the expression “mad as a hatter”.

The metal itself, having an appreciable vapour pressure, is also toxic, and produces headaches, tremors, inflammation of the bladder and loss of memory. The best documented case is that of Alfred Stock (p. 151) whose constant use of mercury in the vacuum lines employed in his studies of boron and silicon hydrides, caused him to suffer for many years. The cause was eventually recognized and it is largely due to Stock’s publication in 1926 of details of his experiences that the need for care and adequate ventilation is now fully appreciated.

---

† It was apparently helpful to add Hg$^{II}$ to the dil HNO$_3$ used to roughen the surface of the animal hair employed in the making of felt which is a non-woven fabric of randomly oriented hairs.
Still more dangerous than metallic mercury or inorganic mercury compounds are organomercury compounds of which the methyl mercury ion HgMe$^+$ is probably the most ubiquitous.\(^{51}\) This and other organomercurials are more readily absorbed in the gastrointestinal tract than Hg$^{II}$ salts because of their greater ability to permeate biomembranes. They concentrate in the blood and have a more immediate and permanent effect on the brain and central nervous system, no doubt acting by binding to the –SH groups in proteins. Naturally occurring anaerobic bacteria in the sediments of sea or lake floors are able to methylate inorganic mercury (Co–Me groups in vitamin B$_{12}$ are able to transfer the Me to Hg$^{II}$) which is then concentrated in plankton and so enters the fish food chain.

The Minamata disaster in Japan, when 52 people died in 1952, occurred because fish, which formed the staple diet of the small fishing community, contained abnormally high concentrations of mercury in the form of MeHgSMe. This was found to originate from a local chemical works where Hg$^{II}$ salts were used (inefficiently) to catalyse the production of acetylene from acetaldehyde, and the effluent then discharged into the shallow sea. Evidence of a similar bacterial production of organomercury is available from Sweden where methylation of Hg$^{II}$ in the effluent from paper mills has been shown to occur. The use of organomercurials as fungicidal seed dressings has also resulted in fatalities in many parts of the world when the seed was subsequently eaten.

It is now apparent that bacteria have developed resistance to heavy metals and the detoxifying process is initiated and controlled by metalloregulatory proteins which are able selectively to recognize metal ions. MerR is a small DNA-binding protein which displays a remarkable sensitivity to Hg$^{2+}$. The metal apparently binds to S atoms of cysteine and this has been a major incentive to recent work on Hg–S chemistry.\(^{32}\)

Public concern about mercury poisoning has led to more stringent regulations for the use of mercury cells in the chlor-alkali industry (pp. 71–3, 798). The health record of this industry has, in fact, been excellent, but the added costs of conforming to still higher standards have led manufacturers to move from mercury cells to diaphragm cells, and this change has been made a legal requirement in Japan.

30

The Lanthanide Elements

\((Z = 58 - 71)\)

30.1 Introduction

Not least of the confusions associated with this group of elements is that of terminology. The name “rare earth” was originally used to describe almost any naturally occurring but unfamiliar oxide and even until about 1920 generally included both \(\text{ThO}_2\) and \(\text{ZrO}_2\). About that time the name began to be applied to the elements themselves rather than their oxides, and also to be restricted to that group of elements which could only be separated from each other with great difficulty. On the basis of their separability it was convenient to divide these elements into the “cerium group” or “light earths” (La to about Eu) and the “yttrium group” or “heavy earths” (Gd to Lu plus Y which, though much lighter than the others, has a comparable ionic radius and is consequently found in the same ores, usually as the major component). It is now accepted that the “rare-earth elements” comprise the fourteen elements from \(^{58}\text{Ce}\) to \(^{71}\text{Lu}\), but are commonly taken to include \(^{57}\text{La}\) and sometimes Sc and Y as well.

To avoid this confusion, and because many of the elements are actually far from rare, the terms “lanthanide”, “lanthanon” and “lanthanoid” have been introduced. Even now, however, there is no general agreement about the position of La, i.e. whether the group is made up of the elements La to Lu or Ce to Lu. Throughout this chapter the term “lanthanide” and the general symbol, Ln, will be used to refer to the fourteen elements cerium to lutetium inclusive, the Group 3 elements, scandium, yttrium and lanthanum having already been dealt with in Chapter 20.

The lanthanides comprise the largest naturally-occurring group in the periodic table. Their properties are so similar that from 1794, when J. Gadolin isolated “yttria” which he thought was the oxide of a single new element, until 1907, when lutetium was discovered, nearly a hundred claims were made for the discovery of elements.
History of the Lanthanides (2-4)

In 1751 the Swedish mineralogist, A. F. Cronstedt, discovered a heavy mineral from which in 1803 M. H. Klaproth in Germany and, independently, J. J. Berzelius and W. Hisinger in Sweden, isolated what was thought to be a new oxide (or "earth") which was named ceria after the recently discovered asteroid, Ceres. Between 1839 and 1843 this earth, and the previously isolated yttria (p. 944), were shown by the Swedish surgeon C. G. Mosander to be mixtures from which, by 1907, the oxides of Sc, Y, La and the thirteen lanthanides other than Pm were to be isolated. The small village of Ytterby near Stockholm is celebrated in the names of no less than four of these elements (Table 30.1).

The classical methods used to separate the lanthanides from aqueous solutions depended on: (i) differences in basicity, the less-basic hydroxides of the heavy lanthanides precipitating before those of the lighter ones on gradual addition of alkali; (ii) differences in solubility of salts such as oxalates, double sulfates, and double nitrates; and (iii) conversion, if possible, to an oxidation state other than +3, e.g. Ce(IV), Eu(II). This latter process provided the cleanest method but was only occasionally applicable. Methods (i) and (ii) required much repetition to be effective, and fractional recrystallizations were sometimes repeated thousands of times. (In 1911 the American C. James performed 15,000 recrystallizations in order to obtain pure thulium bromate).

The minerals on which the work was performed during the nineteenth century were indeed rare, and the materials isolated were of no interest outside the laboratory. By 1891, however, the Austrian chemist C. A. von Welsbach had perfected the thoria gas "mantle" to improve the low luminosity of the coal-gas flames then used for lighting. Woven cotton or artificial silk of the required shape was soaked in an aqueous solution of the nitrates of appropriate metals and the fibre then burned off and the nitrates converted to oxides. A mixture of 99% ThO₂ and 1% CeO₂ was used and has not since been betted. CeO₂ catalyses the combustion of the gas and apparently, because of the poor thermal conductivity of the ThO₂, particles of CeO₂ become hotter and so brighter than would otherwise be possible. The commercial success of the gas mantle was immense and produced a worldwide search for thorium. Its major ore is monazite, which rarely contains more than 12% ThO₂ but about 45% Ln₂O₃. Not only did the search reveal that thorium, and hence the lanthanides, are more plentiful than had previously been thought, but the extraction of the thorium produced large amounts of lanthanides for which there was at first little use.

Applications were immediately sought and it was found that electrolysis of the fused chloride of the residue left after the removal of Th yielded the pyrophoric "mischmetall" (approximately 50% Ce, 25% La, 25% other light lanthanides) which, when alloyed with 30% Fe, is ideal as a lighter flint. Besides small amounts of lanthanides used in special glasses to control absorption at particular wavelengths, this was the pattern of usage until the 1940s. Before then there was little need for the pure metals and, because of the difficulty in obtaining them (high mps and very easily oxidized), such samples as were produced were usually impure. Attempts were also made to find element 61, which had not been found in the early studies, and in 1926 unconfirmed reports of its discovery from Illinois and Florence produced the temporary names illinium and florentium.

During the 1939-45 war, Mg-based alloys incorporating lanthanides were developed for aeronautical components and the addition of small amounts of mischmetall to cast-iron, by causing the separation of carbon in nodular rather than flake form, was found to improve the mechanical properties. But, more significantly from the chemical point of view, electrolysis of the fused chloride of the residue left after the removal of Th by C. J. Marinsky, L. E. Glendenin and C. D. Coryell at Oak Ridge, Tennessee, finally established the existence of element 61 in the fission products of 235U and at the suggestion of Coryell's wife it was named promethium (later promethium) after Prometheus who, according to Greek mythology, stole fire from heaven for the use of mankind. Since about 1955, individual lanthanides have been obtainable in increasing amounts in elemental as well as combined forms.

\(^{(a)}\) Terbiurn and erbium were originally named in the reverse order.

\(^{(b)}\) Originally spelled lutegium, but changed to lutetium in 1949.

### 30.2 The Elements

#### 30.2.1 Terrestrial abundance and distribution

Apart from the unstable \(^{147}\)Pm (half-life 2.623 y) of which traces occur in uranium ores, the lanthanides are actually not rare. Cerium (66 ppm in the earth’s crust) is the twenty-sixth most abundant of all elements, being half as abundant as Cl and 5 times as abundant as Pb. Even Tm (0.5 ppm), the rarest after Pm, is rather more abundant in the earth’s crust than is iodine.

There are over 100 minerals known to contain lanthanides but the only two of commercial importance are monazite, a mixed La, Th, Ln phosphate, and bastnaesite, an La, Ln fluorocarbonate (\(M^{III}CO_3F\)). Monazite is widely but sparsely distributed in many rocks but, because of its high density and inertness, it is concentrated by weathering into sands on beaches and river beds, often in the presence of other similarly concentrated minerals such as ilmenite (\(FeTiO_3\)) and cassiterite (\(SnO_2\)). Deposits occur in southern India, South Africa, Brazil, Australia and Malaysia and, until the 1960s, these provided the bulk of the world’s La, Ln and Th. Then, however, a vast deposit of bastnaesite, which had been discovered in 1949 in the Sierra Nevada Mountains in the USA, came into production. Bastnaesite is also now extracted in China in large quantities, and has become the most important single source of La and Ln.

The bulk of both monazite and bastnaesite is made up of Ce, La, Nd and Pr (in that order) but, whereas monazite typically contains around 5–10% ThO\(_2\) and 3% yttrium earths, these and the heavy lanthanides are virtually absent in bastnaesite. Although thorium is only weakly radioactive it is contaminated with daughter elements such as \(^{228}\)Ra which are more active and therefore require careful handling during the processing of monazite. This is a complication not encountered in the processing of bastnaesite.
30.2.2 Preparation and uses of the elements⁵⁻⁸

Conventional mineral dressing yields concentrates of the minerals of better than 90% purity. These can then be broken down ("opened") by either acidic or alkaline attack, the latter being more usual nowadays. Details vary considerably since they depend on the ore being used and on the extent to which the metals are to be separated from each other, but the schemes outlined in Fig. 30.1 are typical of those used for monazite and bastnaesite to obtain solutions of the mixed chlorides. At this point the classical methods (see Panel, p. 1228) were formerly employed to separate the individual elements where this was required and, indeed the separation of lanthanum by the fractional crystallization of La(NO₃)₃·2NH₄NO₃·4H₂O is still used. However the separations can now be effected on a large scale by solvent extraction(⁷,⁹) using aqueous solutions of the nitrates and a solvent such as tri-n-butylphosphate, (Bu₃O)₃PO (often with kerosene as an inert diluent), in which the solubility of Ln³⁺ increases with its atomic weight. This type of process has the advantage of being continuous and is ideal where the product and feed are not to be changed.

Alternatively, for high-purity or smaller-scale production the more easily adapted ion-exchange

---

techniques are ideal, the best of these being "displacement chromatography". Two separate columns of cation exchange resin are generally employed for this purpose. The first column is loaded with the Ln$^{III}$ mixture and the second, or development, column is loaded with a so-called "retaining ion" such as Cu$^{II}$ (Zn$^{II}$ and Fe$^{III}$ have also been used), and the two columns are coupled together. An aqueous solution (the "eluant") of a complexing agent, of which the triammonium salt of edta$^{4-}$ is typical, is then passed through the columns, and Ln$^{II}$ is displaced from the first column (barred species are bound to the resin):

\[
\text{Ln}^{3+} + (\text{NH}_4)_3(\text{edta-H}) \rightleftharpoons 3(\text{NH}_4^+) + \text{Ln}(	ext{edta-H})
\]

The reaction at any point in the column becomes progressively displaced to the right as fresh complexing agent arrives and the reaction products are removed. The solution of Ln(edta-H) and (NH$_4$)$_3$(edta-H) then reaches the development column where Cu$^{II}$ is displaced and Ln$^{III}$ redeposited in a compact band at the top of the column:

\[
3\text{Cu}^{2+} + 2\text{Ln}(\text{edta-H}) \rightarrow 2\text{Ln}^{3+} + \text{Cu}_3(\text{edta-H})_2
\]

This occurs because Cu$^{II}$, being smaller than Ln$^{III}$, is able to form in the solution phase, a complex with (edta-H)$^{3-}$ of comparable stability, in spite of its lower charge. The Cu$^{II}$ serves the additional purpose of keeping the complexing agent in a soluble form. If the resin were loaded instead with H$^+$, edta-H$_4$ would be precipitated and would clog the resin. Even using Cu$^{II}$ the composition of the eluant must be carefully controlled. The concentration of edta must not exceed 0.015 M, otherwise Cu$_2$(edta).5H$_2$O precipitates, and it is to encourage the formation of the more soluble salt of (edta-H)$^{3-}$ that an acidic rather than neutral ammonium salt of edta$^{4-}$ is used.

Once the Ln$^{III}$ ions have been deposited on to the resin they are displaced yet again by the NH$_4^+$ in the eluant. Now, the affinity of Ln$^{III}$ ions for the resin decreases with increasing atomic weight, but so slightly that elution of the development column with NH$_4^+$ ions alone would not discriminate to an effective extent between the different lanthanides. However, the values of $\Delta G^\circ$ (and therefore of log $K$) for the formation of Ln(edta-H) complexes, increase steadily along the series by a total of ca. 25% from Ce$^{III}$ to Lu$^{III}$. Thus in the presence of the complexing agent, the tendency to leave the resin and go into solution is significantly greater for the heavy than for the light lanthanides. As a result, displacement of the Ln$^{III}$ ions from the resin concentrates the heavier cations in the solution. The Ln$^{III}$ ions therefore pass down the development column in a band, being repeatedly deposited and redissolved in what is effectively an automatic fractionation process, concentrating the heavier members in the solution phase. The result is that when all the copper has come off the column the lanthanides emerge in succession, heaviest first. They may then be precipitated from the eluant as insoluble oxalates and ignited to the oxides.

The production of mischmetall by the electrolysis of fused (Ln,La)Cl$_3$, and the difficulties in obtaining pure metals because of their high mps and ease of oxidation, have already been mentioned (Panel, p. 1228). Two methods are in fact available for producing the metals.

(i) Electrolysis of fused salts. A mixture of LnCl$_3$ with either NaCl or CaCl$_2$ is fused and electrolysed in a graphite or refractory-lined steel cell, which serves as the cathode, with a graphite rod as anode. This is used primarily for mischmetall, the lighter, lower-melting Ce, and for Sm, Eu and Yb for which method (ii) yields Ln$^{II}$ ions.

(ii) Metallothermic reduction. This consists of the reduction of the anhydrous halides with calcium metal. Fluorides are preferred, since they are non-hygroscopic and the CaF$_2$ produced is stable, unlike the other Ca halides which are liable to boil at the temperatures reached in the process. LnF$_3$ + Ca are heated in a tantalum crucible to a temperature 50° above the mp of Ln under an atmosphere of argon. After completion of the reaction, the charge is cooled and the slag and metal (of 97–99% purity) broken apart. The main impurity is Ca which is removed by melting
The Lanthanide Elements (Z = 58 – 71) Ch. 30

under vacuum. With the exceptions of Sm, Eu and Yb this method has general applicability.

In 1995 total world production of “rare earth oxides” was 68 000 tonnes of which China and the USA produced 30 000 and 29 000 tonnes of bastnaesite respectively with smaller quantities of monazite from Australia (as a by-product of TiO₂ production) and India. The bulk of output is used without separation of individual lanthanides. Major uses are in the production of low alloy steels for plate and pipe where < 1% Ln/La added in the form of mischmetall or silicides greatly improves strength and workability, and in petroleum “cracking” catalysis where various mixed metal oxides are employed. The walls of domestic “self-cleaning” ovens are treated with CeO₂ which prevents the formation of tarry deposits, and CeO₂ of varying purity is used to polish glass. Other small-scale uses include that of mischmetall in Mg-based alloys to produce lighter flints, while Ln/Co alloys are used for the construction of permanent magnets, and individual Ln oxides are used as phosphors in television screens and similar fluorescent surfaces.

Current availability of individual lanthanides (plus Y and La) in a state of high purity and relatively low cost has stimulated research into potential new applications. These are mainly in the field of solid state chemistry and include solid oxide fuel cells, new phosphors and perhaps most significantly high temperature superconductors (p. 1182.)

30.2.3 Properties of the elements

The metals are silvery in appearance (except for Eu and Yb which are pale yellow, see p. 112 and below) and are rather soft, but become harder across the series. Most of them exist in more than one crystallographic form, of which hcp is the most common; all are based on typically metallic close-packed arrangements, but their conductivities are appreciably lower than those of other close-packed metals.

The more important physical properties of the elements are summarized in Table 30.2. The alternation between several and few stable isotopes for even and odd atomic number respectively, is mirrored by an even–odd variation in the natural abundances of the elements (see p. 4) and in the uncertainty of their atomic weights (see p. 17).

The electronic configurations of the free atoms are determined only with difficulty because of the complexity of their atomic spectra, but it is generally agreed that they are nearly all [Xe]4fⁿ5d⁰6s². The exceptions are:

1. Cerium, for which the sudden contraction and reduction in energy of the 4f orbitals immediately after La is not yet sufficient to avoid occupancy of the 5d orbital.
2. Gd, which reflects the stability of the half-filled 4f shell;
3. Lu, at which point the shell has been filled.

However, only in the case of cerium (see below) does this have any marked effect on the aqueous solution chemistry, which is otherwise dominated by the +3 oxidation state, for which the configuration varies regularly from 4f¹ (Ce³⁺) to 4f¹⁴ (Lu³⁺). It is notable that a regular variation is found for any property for which this 4fⁿ configuration is maintained across the series, whereas the variation in those properties for which this configuration is not maintained can be highly irregular. This is illustrated dramatically in size variations (Fig. 30.2). On the one hand, the radii of Ln³⁺ ions decrease regularly from La³⁺ (included for completeness) to Lu³⁺. This “lanthanide contraction” occurs because, although each increase in nuclear charge is exactly balanced by a simultaneous increase in electronic charge, the directional characteristics of the 4f orbitals cause the 4fⁿ electrons to shield themselves and other electrons from the nuclear charge only imperfectly. Thus, each unit increase in nuclear charge produces a net increase in attraction for the whole extranuclear electron charge cloud and each ion shrinks slightly in comparison with its predecessor. On the other hand, although a similar overall reduction is seen in the metal radii, Eu and Yb are spectacularly irregular. The reason is that most of the metals are composed of a lattice of Ln³⁺ ions with a 4fⁿ configuration and 3 electrons in the

(a)CN = 8.
(b)CN = 7.
(c)Estimated values since these M$^{IV}$ are not stable in aqueous solution.
5d/6s conduction band. Metallic Eu and Yb, however, are composed predominantly of the larger Ln$^{ll}$ ions with 4f$^{n+1}$ configurations and only 2 electrons in the conduction band. The smaller and opposite irregularity for metallic Ce is due to the presence of ions in an oxidation state somewhat above +3. Similar discontinuities are found in other properties of the metals, particularly at Eu and Yb.

A contraction resulting from the filling of the 4f electron shell is of course not exceptional. Similar contractions occur in each row of the periodic table and, in the d block for instance, the ionic radii decrease by 20.5 pm from Sc$^{ll}$ to Cu$^{lll}$, and by 15 pm from Y$^{ll}$ to Ag$^{lll}$. The importance of the lanthanide contraction arises from its consequences:

1. The reduction in size from one Ln$^{lll}$ to the next makes their separation possible, but the smallness and regularity of the reduction makes the separation difficult.

2. By the time Ho is reached the Ln$^{lll}$ radius has been sufficiently reduced to be almost identical with that of Y$^{lll}$ which is why this much lighter element is invariably associated with the heavier lanthanides.

3. The total lanthanide contraction is of a similar magnitude to the expansion found in passing from the first to the second transition series, and which might therefore have been expected to occur also in passing from second to third. The interpolation of the lanthanides in fact almost exactly cancels this anticipated increase with the result, noted in preceding chapters, that in each group of transition elements the second and third members have very similar sizes and properties.

Redox processes, which of necessity entail a change in the occupancy of the 4f shell, vary in a very irregular manner across the series. Quantitative data from direct measurements are
 Chemical reactivity and trends

Figure 30.3  Variation with atomic number of some properties of La and the lanthanides: A, the third ionization energy \(I_3\); B, the sum of the first three ionization energies \(\Sigma I\); C, the enthalpy of hydration of the gaseous trivalent ions \(-\Delta H_{\text{hyd}}\). The irregular variations in \(I_3\) and \(\Sigma I\), which refer to redox processes, should be contrasted with the smooth variation in \(\Delta H_{\text{hyd}}\), for which the 4f\(^n\) configuration of Ln\(^{3+}\) is unaltered.

far from complete for such processes, but the use of thermodynamic (Born–Haber) cycles\(^{(10)}\) greatly improves the situation. Enthalpies of atomization \(\Delta H_f\) and ionization energies are given in Table 30.2 and the variations of \(I_3\) and \(\Sigma I\) are shown in Fig. 30.3. \(I_3\) refers to the 1-electron change, \(4f^{n+1}(\text{Ln}^{2+}) \rightarrow 4f^{n}(\text{Ln}^{3+})\) and the close similarity of the two curves indicates that this change is the dominant factor in determining the shape of the \(\Sigma I\) curve. The variation of \(I_3\) across the series is in fact typical of the variation in energy of any process (e.g. \(-\Delta H_f\) which refers essentially to \(4f^{n+1}6s^2 \rightarrow 4f^n5d^16s^2\)) which involves the reduction of Ln\(^{3+}\) to Ln\(^{2+}\). It is characterized by an increase in energy, first as each of the 4f orbitals of the Ln\(^{II}\) ions are singly occupied and the stability of the 4f shell steadily increases due to the corresponding increase in nuclear charge (La → Eu); then again as each 4f orbital is doubly occupied (Gd → Lu). The sudden falls at Gd and Lu reflect the ease with which it is possible to remove the single electrons in excess of the stable 4f\(^7\) and 4f\(^{14}\) configurations. Explanations have been given for the smaller irregularities at the quarter- and three-quarter-shell stages, but require a careful consideration of interelectronic repulsion, as well as exchange energy, terms.\(^{(11)}\)

30.2.4 Chemical reactivity and trends

The lanthanides are very electropositive and reactive metals. With the exception of Yb

---

their reactivity apparently depends on size so that Eu which has the largest metal radius is much the most reactive. They tarnish in air and, if ignited in air or O₂, burn readily to give Ln₂O₃ or, in the case of cerium, CeO₂ (praseodymium and terbium yield nonstoichiometric products approximating to Pr₆O₁₁ and Tb₄O₇ respectively). When heated, they also burn in halogens producing LnX₃, and in hydrogen producing LnH₂ and LnH₃ (see below). They will, indeed, react, though usually less vigorously, with most non-metals if heated. Treatment with water yields hydrous oxides, and the metals dissolve rapidly in dilute acids, even in the cold, to give aqueous solutions of Ln³⁺ salts.

The great bulk of lanthanide chemistry is of the +3 oxidation state where, because of the large sizes of the Ln³⁺ ions, the bonding is predominantly ionic in character, and the cations display the typical class-a preference of O-donor ligands (p. 909). Three-dimensional lattices, characteristic of ionic character, are common and the coordination chemistry is quite different from, and less extensive than, that of the d-transition metals. Coordination numbers are generally high and stereochemistries, being determined largely by the requirements of the ligands and lacking the directional constraints of covalency, are frequently ill-defined, and the complexes distinctly labile. Thus, in spite of widespread opportunities for isomerism, there appears to be no confirmed example of a lanthanide complex existing in more than one molecular arrangement. Furthermore, only strongly complexing (i.e. usually chelating) ligands yield products which can be isolated from aqueous solution, and the comparative tenacity of the small H₂O molecule commonly leads to its inclusion, often with consequent uncertainty as to the coordination number involved. This is not to say that other types of complex cannot be obtained, but complexes with uncharged monodentate ligands, or ligands with donor atoms other than O, must usually be prepared in the absence of water.

Some typical compounds are listed in Table 30.3. Coordination numbers below 6 are found only with very bulky ligands and even the coordination number of 6 itself is unusual, 7, 8 and 9 being more characteristic. Coordination numbers of 10 and over require chelating ligands with small “bites” (p. 917), such as NO₃⁻ or SO₄²⁻, and are confined to compounds of the larger, lighter lanthanides. The stereochemistries quoted, especially for the high coordination numbers, are idealized and in most cases appreciable distortions are in fact found.

A number of trends connected with ionic radii are noticeable across the series. In keeping with Fajans’ rules, salts become somewhat less ionic as the Ln³⁺ radius decreases; reduced ionic character in the hydroxide implies a reduction in basic properties and, at the end of the series, Yb(OH)₃ and Lu(OH)₃, though undoubtedly mainly basic, can with difficulty be made to dissolve in hot conc NaOH. Paralleling this change, the [Ln(H₂O)₆]³⁺ ions are subject to an increasing tendency to hydrolyse, and hydrolysis can only be prevented by use of increasingly acidic solutions.

However, solubility, depending as it does on the rather small difference between solvation energy and lattice energy (both large quantities which themselves increase as cation size decreases) and on entropy effects, cannot be simply related to cation radius. No consistent trends are apparent in aqueous, or for that matter nonaqueous, solutions but an empirical distinction can often be made between the lighter “cerium” lanthanides and the heavier “yttrium” lanthanides. Thus oxalates, double sulfates and double nitrates of the former are rather less soluble and basic nitrates more soluble than those of the latter. The differences are by no means sharp, but classical separation procedures depended on them.

Although lanthanide chemistry is dominated by the +3 oxidation state, and a number of binary compounds which ostensibly involve Ln²⁺ are actually better formulated as involving Ln³⁺ with an electron in a delocalized conduction band, genuine oxidation states of +2 and +4 can be obtained. Ce⁴⁺ and Eu²⁺ are stable in water and, though they are respectively strongly oxidizing and strongly reducing, they have well-established

</table>

\(^{(a)}\)Except where otherwise stated, Ln is used rather loosely to mean most of the lanthanides; the Pm compound, for instance, is usually missing simply because of the scarcity and consequent expense of Pm.

\(^{(b)}\)dpdm = dipivaloylmethane, Me\(_3\)CC(O)CH==C(O)==CMe\(_3\).

\(^{(c)}\)The structure can be visualized as octahedral if each NO\(_3\)\(^-\) is considered to occupy a single coordination site (p. 1245).

aqueous chemistries. Ln\(^{IV}\) (Ln = Pr, Nd, Tb, Dy) and Ln\(^{III}\) (Ln = Nd, Sm, Eu, Dy, Tm, Yb) also are known in the solid state but are unstable in water. The rather restricted aqueous redox chemistry which this implies is summarized in the oxidation state diagram (Fig. 30.4).

The prevalence of the +3 oxidation state is a result of the stabilizing effects exerted on different orbitals by increasing ionic charge. As successive electrons are removed from a neutral lanthanide atom, the stabilizing effect on the orbitals is in the order 4f > 5d > 6s, this being the order in which the orbitals penetrate through the inert core of electrons towards the nucleus. By the time an ionic charge of +3 has been reached, the preferential stabilization of the 4f orbitals is such that in all cases the 6s and 5d orbitals have been emptied. Also, in most cases, the electrons remaining in the 4f orbitals are themselves so far embedded in the inert core as to be immovable by chemical means. Exceptions are Ce and, to
a lesser extent, Pr which are at the beginning of the series where, as already noted, the 4f orbitals are still at a comparatively high energy and can therefore lose a further electron. Tb\(^{IV}\) presumably owes its existence to the stability of the 4f\(^7\) configuration. The stabilizing effects of half, and completely, filled shells can be similarly invoked to explain the occurrence of the divalent state in Eu\(^{III}(4f^7)\) and Yb\(^{III}(4f^{14})\) while these, and the other known divalent ions are of just those elements which occupy elevated positions on the I\(_3\) plot (Fig. 30.3). The absence of 5d electrons and the inertness of the lanthanides' 4f shell makes backbonding energetically unfavourable and simple carbonyls, for instance, have only been obtained in argon matrices at 8–12 K. On the other hand, essentially ionic cyclopentadienides are well known and an increasing number of \(\sigma\)-bonded Ln–C compounds have been produced (see section 30.3.5).

### 30.3 Compounds of the Lanthanides\(^{12-15}\)

The reaction between H\(_2\) and the gently heated (300–350°C) metals produces black, reactive and highly conducting solids, LnH\(_2\). These hydrides have the fcc fluorite structure (p. 118) and are evidently composed of Ln\(^{III}\), 2H\(^{-}\), e\(^-\), the electron being delocalized in a metallic conduction band. Further hydrogen can be accommodated in the interstices of the lattice and, with the exceptions of Eu and Yb, which are the two lanthanides most favourably disposed to divalency, a limiting stoichiometry of LnH\(_3\) can be achieved if high pressures are employed (p. 66). The composition of LnH\(_3\) is Ln\(^{III}\), 3H\(^{-}\) with conductivity correspondingly reduced as the additional H atom traps the previously delocalized electron (to form H\(^-\)). Metallic conductivity, arising from the presence of Ln\(^{III}\) ions with the balance of electrons situated in a conduction band, is also found in some of the borides (p. 145) and carbides (p. 297).

### 30.3.1 Oxides and chalcogenides\(^{16,17}\)

Ln\(_2\)O\(_3\) are all well characterized. With three exceptions they are the final products of combustion of the metals or ignition of the hydroxides, carbonate, nitrate, etc. The exceptions are Ce, Pr and Tb, the most oxidized products of which are the dioxides, from which the sesquioxides can be obtained by controlled reduction with H\(_2\). Ln\(_2\)O\(_3\) adopt three structure types conventionally classified as:\(^{18}\)

- **A-type**, consisting of \(\{\text{LnO}_2\}\) units which approximate to capped octahedral geometry, and favoured by the lightest lanthanides.
- **B-type**, also consisting of \(\{\text{LnO}_2\}\) units but now of three types, two are capped trigonal prisms and one is a capped octahedron; favoured by the middle lanthanides.
- **C-type**, related to the fluorite structure but with one-quarter of the anions removed in such a way as to reduce the metal coordination number from 8 to 6 (but not octahedral); favoured by the middle and heavy lanthanides.

Ln\(_2\)O\(_3\) are strongly basic and the lighter, more basic, ones resemble the oxides of Group 2

---

in this respect. All are insoluble in water but absorb it to form hydroxides. They dissolve readily in aqueous acids to yield solutions which, providing they are kept on the acid side of pH 5 to avoid hydrolysis, contain the \([\text{Ln}(\text{H}_2\text{O})_3]^{3+}\) ions. Hydrous hydroxides can be precipitated from these solutions by addition of ammonia or aqueous alkali. Crystalline \(\text{Ln(OH)}_3\) have a 9-coordinate, tricapped, trigonal prismatic structure, and may be obtained by prolonged treatment of \(\text{Ln}_2\text{O}_3\) with conc NaOH at high temperature and pressure (hydrothermal ageing).

The pale-yellow \(\text{CeO}_2\) is a rather inert material when prepared by ignition, but in the hydrous, freshly precipitated form it redissolves quite easily in acids. The analogous dark-coloured \(\text{PrO}_2\) and \(\text{TbO}_2\) can be obtained by ignition but require more extreme conditions (\(\text{O}_2\) at 282 bar and 400°C for \(\text{PrO}_2\), and atomic oxygen at 450°C for \(\text{TbO}_2\)). All three dioxides have the fluorite structure. Since this is the structure on which \(\text{C-type Ln}_2\text{O}_3\) is based (by removing a quarter of the anions) it is not surprising that these three oxide systems involve a whole series of nonstoichiometric phases between the extremes represented by \(\text{Ln}_2\text{O}_3\) and \(\text{LnO}_2\) (p. 643). The compositions and structures of these phases arise because the basic unit from which they are built is a so-called “coordination defect”, \([\text{M}^{\text{III}}\text{M}^{\text{IV}}_1\text{O}_3]^{-}\).

Claims for the existence of several lower oxides, \(\text{LnO}\), have been made but most have been rejected, and it seems that only \(\text{NdO}, \text{SmO}\) (both lustrous golden yellow), \(\text{EuO}\) (dark red) and \(\text{YbO}\) (greyish-white) are genuine. They are obtained by reducing \(\text{Ln}_2\text{O}_3\) with the metal at high temperatures and, except for \(\text{EuO}\), at high pressures. They have the NaCl structure but whereas \(\text{EuO}\) and \(\text{YbO}\) are composed of \(\text{Ln}^{\text{II}}\) and are insulators or semiconductors, \(\text{NdO}\) and \(\text{SmO}\) like the dihydrides consist essentially of \(\text{Ln}^{\text{III}}\) ions with the extra electrons forming a conduction band. \(\text{EuO}\) was unexpectedly found to be ferromagnetic at low temperatures. The absence of conduction electrons, and the presence of 4f orbitals which are probably too contracted to allow overlap between adjacent cations, makes it difficult to explain the mechanism of the ferromagnetic interaction. \(\text{EuO}\) and the monochalcogenides have potential applications in memory devices.

Chalcogenides of similar stoichiometry to the oxides, but for a wider range of metals, are known, though their characterization is made more difficult by the prevalence of nonstoichiometry and the occurrence of phase changes in several instances. In general the chalcogenides are stable in dry air but are hydrolysed if moisture is present. If heated in air they oxidize (sulfides especially) to basic salts of the corresponding oxo-anion and they show varying susceptibility to attack by acids with evolution of \(\text{H}_2\text{Z}\).

Monochalcogenides, \(\text{LnZ}\) (\(Z = \text{S}, \text{Se}, \text{Te}\)), have been prepared for all the lanthanides except \(\text{Pm}\), mostly by direct combination. \(\text{SmZ}, \text{EuZ}, \text{YbZ}, \text{TmSe}\) and \(\text{TmTe}\) have metallic conductivity and evidently consist of \(\text{Ln}^{\text{II}}+\text{Z}^{2-}\) ions with 1 electron from each cation delocalized in a conduction band. \(\text{EuZ}\) and \(\text{YbZ}\), by contrast, are semiconductors or insulators with genuinely divalent cations, but \(\text{SmZ}\) seem to be intermediate and may involve the equilibrium:

\[
\text{Sm}^{\text{II}} + \text{Z}^{2-} \rightleftharpoons \text{Sm}^{\text{III}} + \text{Z}^{2-} + \text{e}^{-}
\]

Trivalent chalcogenides, \(\text{Ln}_2\text{Z}_3\), can be obtained by a variety of methods which include direct combination and, in the case of the sulfides, the action of \(\text{H}_2\text{S}\) on the chloride or oxide. As with \(\text{Ln}_2\text{O}_3\), various crystalline modifications occur. When \(\text{Ln}_2\text{Z}_3\) are heated with an excess of chalcogen in a sealed tube at 600°C, products with compositions up to or nearing \(\text{LnZ}_3\) are obtained. They seem to be polychalcogenides, however, with the metal uniformly in the +3 state; \(\text{Ln}^{\text{IV}}\) chalcogenides are not known.

---

20 Pages 23–41 of ref. 11.
30.3.2 Halides^{(12,13,21)}

Halides of the lanthanides are listed in Table 30.4 and are of the types LnX₄, LnX₃, and LnX₂. Not surprisingly, LnX₄ occur only as the fluorides of Ce⁺⁺, Pr⁺⁺ and Tb⁺⁺. CeF₄ is comparatively stable and can be prepared either directly from the elements or by the action of F⁻ on aqueous solutions of Ce⁺⁺ when it crystallizes as the monohydrate. The other tetrafluorides are thermally unstable and, as they oxidize water, can only be prepared dry; TbF₄ from TbF₃ + F₂ at 320°C, and PrF₄ by the rather complex procedure of fluorinating a mixture of NaF and PrF₃ with F₂ (→ Na₂PrF₆) and then extracting NaF from the reaction mixture with liquid HF.

Promethium apart, all possible trihalides (52) are known. The trifluorides, being very insoluble, can be precipitated as LnF₃·½H₂O by the action of HF on aqueous Ln(NO₃)₃. Aqueous solutions of the other trihalides are obtained by simply dissolving the oxides or carbonates in aqueous HX. Hydrated (6–8H₂O) salts can be crystallized, though with difficulty because of their high solubilities. Preparation of the anhydrous trihalides by thermal dehydration of these hydrates is possible for fluorides and chlorides of the lighter lanthanides, and an atmosphere of HX extends the applicability of the method to heavier lanthanides. Because of the possible formation of oxohalides in preparations involving halides and oxygen-containing materials, direct combination, which is a completely general method, is often preferred for the anhydrous halides.

The anhydrous trihalides are ionic, high melting, crystalline substances which, apart from the trifluorides are extremely deliquescent. As can be seen from Table 30.4, the coordination number of the Ln⁺⁺ changes with the radii of the ions, from 9 for the trifluorides of the large lanthanides to 6 for the triiodides of the smaller lanthanides. Their chief importance has been as materials from which the pure metals can be prepared.

The dihalides are obtained from the corresponding trihalides, most generally by reduction with the lanthanide metal itself^{(22)} or with an alkali metal^{(23,24)} and also, in the case of the more stable of the diiodides (SmI₂, EuI₂, YbI₂), by thermal decomposition.† SmI₂ and YbI₂ can also be conveniently prepared in quantitative yield by reacting the metal with 1,2-diiodoethane in anhydrous tetrahydrofuran at room temperature;^{(25)} Ln + ICH₂CH₂I → LnI₂ + CH₂=CH₂. With the exception of EuX₂, all the dihalides are very easily oxidized and will liberate hydrogen from water. The occurrence of these dihalides parallels the occurrence of high values of the third ionization energy amongst the metals^{(10,11)} (Fig. 30.3), with the reasonable qualification that, in this low oxidation state, iodides are more numerous than fluorides. The same types of structures are found as for the alkaline earth dihalides with the coordination number of the cation ranging from 9 to 6 and, like CaI₂, the diiodides of Dy, Tm and Yb form layer structures (CdCl₂, CdI₂; see Fig. 29.2) typical of compounds with large anions where marked polarization effects are expected.

The isomorphous diiodides of Ce, Pr and Gd stand apart from all the other, salt-like, dihalides. These three, like LaI₂, are notable for their metallic lustre and very high conductivities and are best formulated as [Lnᵢı⁺⁺,2I⁻,e⁻], the electron being in a delocalized conduction band. Besides the dihalides, other reduced species have been obtained such as Ln₅Cl₁₁ (Ln = Sm, Gd, Ho). They have fluorite-related structures (p. 118) in which the anionic sublattice is partially rearranged to accommodate additional anions.

---

22 J. D. Corbett, pp. 159-73 of ref. 13.
† Dilute solid solutions of Lnᵢı⁺⁺ ions in CaF₂ may be reduced by Ca vapour to produce Lnᵢı⁺⁺ ions trapped in the crystal lattice. By their use it has been possible to obtain the electronic spectra of Lnᵢı⁺⁺ ions.

leading to irregular 7-and 8-coordination of the cations. In the case of Gd and Tb, further reduction gives rise to Ln\(_7\)Cl\(_3\) phases which are constructed from Ln\(_6\) octahedra sharing trans-edges and sheathed with chlorine atoms which bridge adjacent chains. Gd\(_2\)Cl\(_3\) is a semiconductor and provided the first example of a lanthanide in an oxidation state \(< +2\). Continued reduction finally produces “graphite-like” LnCl phases originally thought to be binary halides like ZrX (p. 966) but in fact, like ScCl (p. 950), requiring the presence of interstitial H atoms to stabilize the structure. They are therefore formulated as LnXH\(_8\). Structural characteristics are summarised in Table 30.5.\(^{22,26–28}\)

Other interstitial atoms stabilizing such clusters are B, C, N and O.\(^{22}\) Examples of carbon stabilized clusters include: isolated metal octahedra in Cs[Ln\(_6\)I\(_{12}\)C] (Ln = Er, Lu)\(^{29}\) and Gd[Gd\(_6\)Cl\(_{12}\)C]; pairs of edge-sharing metal octahedra in Gd\(_{10}\)Cl\(_{18}\)(C\(_2\))\(_2\); and chains of edge-sharing metal octahedra in Gd\(_4\)I\(_5\)C.

### 30.3.3 Magnetic and spectroscopic properties\(^{12}\)

The electronic configurations of the lanthanides are described by using the Russell–Saunders coupling scheme. Values of the quantum numbers \(S\) and \(L\) corresponding to the lowest energy are derived in the conventional manner.\(^{12}\) These are then expressed for each ion in the form of a ground term with the symbol that \(S, P, D, F, G, H, I, \ldots\) correspond to \(L = 0, 1, 2, 3, 4, 5, 6, \ldots\) in that order. The angular momentum vectors associated with \(S\) and \(L\) couple together (spin–orbit coupling) to produce a resultant angular momentum associated with an overall quantum number \(J\). Because the 4f electrons of lanthanide ions are largely buried in the inner core, they are effectively shielded from their chemical environments. As a result, spin–orbit coupling is much larger than the crystal field (of the order of 2000 cm\(^{-1}\) compared to 100 cm\(^{-1}\)) and must be considered first. Note that this is precisely the reverse of the situation in the d-block elements where the d electrons are exposed directly to the influence of neighbouring groups and the crystal field is therefore much greater than the spin–orbit coupling.

\(J\) can take the values \(J = L + S, L + S - 1, \ldots, L - S\) (or \(S = L\) if \(S > L\)), each corresponding to a different energy, so that a “term” (defined

(a) These are the values of \( \mu_e \) at room temperature. The values fall as the temperature is reduced (see text).

by a pair of \( S \) and \( L \) values) is said to split into a number of component "states" (each defined by the same \( S \) and \( L \) values plus a value of \( J \)). The "ground state" of the ion is that with \( J = L - S \) (or \( S - L \)) if the \( f \) shell is less than half-full, and that with \( J = L + S \) if the \( f \) shell is more than half-full. It is indicated simply by adding this value of \( J \) as a subscript to the symbol for the "ground term".

The magnitude of the separation between the adjacent states of a term indicates the strength of the spin–orbit coupling, and in all but two cases (Sm\textsuperscript{III} and Eu\textsuperscript{III}) it is sufficient to render the first excited state of the Ln\textsuperscript{III} ions thermally inaccessible, and so the magnetic properties are determined solely by the ground state. It can be shown that the magnetic moment expected for such a situation is given by:

\[
\mu_e = g \sqrt{J(J+1)} \text{ BM},
\]

where \( g = \frac{3}{2J(J+1)} + \frac{S(S+1) - L(L+1)}{2J(J+1)} \)

As can be seen in Table 30.6, this agrees very well with experimental values except for Sm\textsuperscript{III} and Eu\textsuperscript{III} and agreement is reasonable for these also if allowance is made for the temperature-dependent population of excited states.

Electronic absorption spectra are produced when electromagnetic radiation promotes the ions from their ground state to excited states. For the lanthanides the most common of such transitions involve excited states which are either components of the ground term\(^ \dagger \) or else belong to excited terms which arise from the same 4f\textsuperscript{n} configuration as the ground term. In either case the transitions therefore involve only a redistribution of electrons within the 4f orbitals (i.e. \( f \rightarrow f \) transitions) and so are orbitally forbidden just like \( d \rightarrow d \) transitions. In the case of the latter the rule is partially relaxed by a mechanism which depends on the effect of the crystal field in distorting the symmetry of the metal ion. However, it has already been pointed out that crystal field effects are very much smaller in the case of Ln\textsuperscript{III} ions and they

\(^ \dagger \)The separation of these component states being, as pointed out above, of the order of a few thousand wavenumbers, such transitions produce absorptions in the infrared region of the spectrum. Ions which have no terms other than the ground term will therefore be colourless, having no transitions of sufficiently high energy to absorb in the visible region. This accounts for the colourless ions listed in Table 30.6.
cannot therefore produce the same relaxation of the selection rule. Consequently, the colours of Ln\textsuperscript{III} compounds are usually less intense. A further consequence of the relatively small effect of the crystal field is that the energies of the electronic states are only slightly affected by the nature of the ligands or by thermal vibrations, and so the absorption bands are very much sharper than those for d→d transitions. Because of this they provide a useful means of characterizing, and quantitatively estimating, Ln\textsuperscript{III} ions.

Nevertheless, crystal fields cannot be completely ignored. The intensities of a number of bands ("hypersensitive" bands) show a distinct dependence on the actual ligands which are coordinated. Also, in the same way that crystal fields lift some of the orbital degeneracy \((2L+1)\) of the terms of \(d^\text{r}\) ions, so they lift some of the \(2J+1\) degeneracy of the sates of \(f^\text{m}\) ions, though in this case only by the order of \(100\text{cm}^{-1}\). This produces fine structure in some bands of Ln\textsuperscript{III} spectra.

Ce\textsuperscript{III} and Tb\textsuperscript{III} are exceptional in providing (in the ultraviolet) bands of appreciably higher intensity than usual. The reason is that the particular transitions involved are of the type \(4f^\text{m}\rightarrow4f^{m-1}5d^1\), and so are not orbitally forbidden. These 2 ions have 1 electron more than an empty f shell and 1 electron more than a half-full f shell, respectively, and the promotion of this extra electron is thereby easier than for other ions.

Sm, Dy but more especially Eu and Tb have excited states which are only slightly lower in energy than excited states of typical ligands. If electrons on the ligand are excited, the possibility therefore exists that, instead of falling back to the ground state of the ligand, they may pass first to the excited state of the Ln\textsuperscript{III} and then fall to the metal ground state, emitting radiation of characteristic frequency in doing so (fluorescence or, more generally, luminescence). This is the basis of the commercial use of oxide phosphors of these elements on TV screens where the excitation is provided by electrical discharge. Excitation by uv light produces luminescence spectra which yield information about the donor atoms and co-ordination symmetry.\(^{(30,31)}\)

It has been possible, as already noted (footnote, p. 1240) to study the spectra of Ln\textsuperscript{II} ions stabilized in CaF\textsubscript{2} crystals. It might be expected that these spectra would resemble those of the +3 ions of the next element in the series. However, because of the lower ionic charge of the Ln\textsuperscript{II} ions their 4f orbitals have not been stabilized relative to the 5d to the same extent as those of the Ln\textsuperscript{III} ions. Ln\textsuperscript{II} spectra therefore consist of rather broad, orbitally allowed, 4f→5d bands overlaid with weaker and much sharper f→f bands.

### 30.3.4 Complexes\(^{(12,14,32)}\)

#### Oxidation state IV

The +4 oxidation state is found in LnO\textsubscript{2}, LnF\textsubscript{4}, the ternary oxides M\textsubscript{2} LnO\textsubscript{3} and Li\textsubscript{3} LnO\textsubscript{6} (Ln = Ce, Pr, Tb), and in the ternary fluorides M\textsubscript{2} LnF\textsubscript{7} (Ln = Ce, Pr, Tb, Nd, Dy). M\textsuperscript{III} TbO\textsubscript{6}.\textsubscript{xH\textsubscript{2}O} has been obtained from aqueous alkaline solution\(^{(33)}\) but Ce is the only lanthanide with a significant aqueous or co-ordination chemistry in this oxidation state. Fig. 30.4 shows that this situation is in no way surprising.

Aqueous "ceric" solutions are widely used as oxidants in quantitative analysis; they can be prepared by the oxidation of Ce\textsuperscript{III} ("cerous") solutions with strong oxidizing agents such as peroxodisulfate, S\textsubscript{2}O\textsubscript{8}\textsuperscript{2-}, or bismuthate, BiO\textsubscript{3}-. Complexation and hydrolysis combine to render \(E(\text{Ce}^{4+}/\text{Ce}^{3+})\) markedly dependent on anion and acid concentration. In relatively strong perchloric acid the aquo ion is present but in other acids coordination of the anion is likely. Also, if the pH is increased, hydrolysis to

---

Ce(OH)$_3^+$ occurs followed by polymerization and finally, as the solution becomes alkaline, by precipitation of the yellow, gelatinous CeO$_2$$_x$$\cdot$$H$_2$O.

Of the various salts which can be isolated from aqueous solution, probably the most important is the water-soluble double nitrate, (NH$_4$)$_2$[Ce(NO$_3$)$_6$], which is the compound generally used in Ce$^{IV}$ oxidations. The anion involves 12-coordinated Ce (Fig. 30.5a). Two trans-nitrates of this complex can be replaced by Ph$_3$PO to give the orange 10-coordinate neutral complex [Ce(NO$_3$)$_4$(OPPh$_3$)$_2$] (Fig. 30.5b). The sulfates Ce(SO$_4$)$_2$$\cdot$$n$H$_2$O ($n = 0, 4, 8, 12$) and (NH$_4$)$_2$Ce(SO$_4$)$_3$, and the iodate are also known. Also obtainable from aqueous solutions are complexes with other O-donor ligands such as β-diketonates, and fluoro complexes such as [CeF$_8$]$^{4-}$ and [CeF$_6$]$^{2-}$. This last ion is not in fact 6-coordinated but achieves an 8-coordinate, square-antiprismatic geometry with the aid of fluoride bridges. In the orange [CeCl$_6$]$^{2-}$ by contrast, the larger halide is able to stabilize a 6-coordinate, octahedral geometry. It is prepared by treatment of CeO$_2$ with HCl but, because Ce$^{IV}$ in aqueous solution oxidizes HCl to Cl$_2$, the reaction must be performed in a nonaqueous solvent such as pyridine or dioxan.

### Oxidation state III

The coordination chemistry of the large, electropositive Ln$^{III}$ ions is complicated, especially in solution, by ill-defined stereochemistries and uncertain coordination numbers. This is well illustrated by the aquo ions themselves.$^{(34)}$ These are known for all the lanthanides, providing the solutions are moderately acidic to prevent hydrolysis, with hydration numbers probably about 8 or 9 but with reported values depending on the methods used to measure them. It is likely that the primary hydration number decreases as the cationic radius falls across the series. However, confusion arises because the polarization of the H$_2$O molecules attached directly to the cation facilitates hydrogen bonding to other H$_2$O molecules. As this tendency will be the greater, the smaller the cation, it is quite reasonable that the secondary hydration number increases across the series.

Hydrated salts with all the common anions can be crystallized from aqueous solutions and frequently, but by no means invariably, they contain the [Ln(H$_2$O)$_9$]$^{3+}$ ion. An enormous number of salts of organic acids such as oxalic, citric and

---

tartaric have been studied, often for use in separation methods. These anions are, in fact, chelating O ligands which as a class provide the most extensive series of LnIII complexes. NO^3− is an inorganic counterpart and is notable for the high coordination numbers it yields, as in the 10-coordinate bicapped dodecahedral [Ce(NO3)3]2−, and in [Ce(NO3)6]3− which like its CeIV analogue, has the 12-coordinate icosahedral geometry (Fig. 30.5a) (see also p. 469).

β-diketonates (L-L) provide further important examples of this class of ligand, and yield complexes of the type [Ln(L-L)3L'] (L' = H2O, py, etc.) and [Ln(L-L)4]−, which are respectively 7- and 8-coordinate. Dehydration, under vacuum, of the hydrated tris-diketonates produces [Ln(L-L)3] complexes which probably increase their coordination by dimerizing or polymerizing. They may be sublimed, the most volatile and thermally stable being those with bulky alkyl groups R in [RC(O)CHC(O)R]−; they are soluble in non-polar solvents, and have received much attention as “nmr shift” reagents. Thus, in the case of organic molecules which are able to coordinate to LnIII (i.e. if they contain groups such as −OH or −COO−), the addition of one of these coordinatively unsaturated reagents produces a labile adduct; because this adduct is anisotropic the paramagnetic LnIII ion shifts the resonance line of each proton by an amount which is critically dependent on the spatial relationship of the LnIII and the proton. Greatly improved resolution is thereby obtained along with the possibility of distinguishing between alternative structures of the organic molecule.

Various crown ethers (p. 96) with differing cavity diameters provide a range of coordination numbers and stoichiometries, although crystallographic data are sparse. An interesting series, illustrating the dependence of coordination number on cationic radius and ligand cavity diameter, is provided by the complexes formed by the lanthanide nitrates and the 18-crown-6 ether (i.e. 1,4,7,10,13,16-hexaoxacyclo-octadecane). For Ln = La–Gd the most thermally-stable product is that with a ratio of Ln:crown ether = 4:3, but the larger of these lanthanides (i.e. La, Ce, Pr and Nd) also form a 1:1 complex. This is [Ln(NO3)2L] in which the LnIII is 12-coordinate (Fig. 30.6a). The 4:3 complex, on the other hand, is probably [Ln(NO3)2L]3[Ln(NO3)6] in which, compared to the 1:1 complex, the LnIII in the complex cation has lost one NO3−, so reducing its coordination number to 10. The remaining, still smaller lanthanides (Tb–Lu) find the cavity of this ligand too large and form [Ln(NO3)3(H2O)3]L, in which the ligand is uncoordinated.

Unidentate O donors such as pyridine-N-oxide and triphenylphosphine oxide also form many complexes, as do alkoxides. This last group, like the alkoxides of Sc and Y (p. 951) is of special interest because of possible applications in the deposition of pure metal oxides by MOCVD techniques. Attempts to prepare Ln(OR)3 usually produce polynuclear clusters. Two examples will suffice: [Nd6(OPr')7Cl], made up of 6 Nd atoms held together around a central Cl atom by means of bridging OCHMe2 groups (Fig. 30.6b). [Yb5O(OPr')13] which consists of a square pyramid of Yb atoms containing a μ₃-O. Four μ₂-OPr groups cap the faces of the square pyramid. A single terminal alkoxide completes a distorted octahedral coordination sphere for each metal atom.

Complexes with O-donor ligands are more numerous than those with N donors, probably because the former ligands are more often negatively charged — a clear advantage when forming essentially ionic bonds. However, by using polar organic solvents such as ethanol, acetone or acetonitrile in order to avoid competitive coordination by water, complexes with

830.3.4 Complexes

Figure 30.6 (a) Ln(NO₃)₃ (18-crown-6). For clarity only 2 of the oxygen atoms of each nitrate ion are shown, and only the 6 oxygen atoms of the crown ether. (Note the boat conformation of the crown ether which allows access to two NO₃⁻ on the open side and only one on the hindered side.) (b) [Nd₄(OPr')₄Cl]. Only the oxygens of the OPr' groups are shown. Note that the 6 Nd atoms surrounding the Cl atom are situated at the corners of a trigonal prism, held together by 2 face-bridging and 9 edge-briding alkoxides.

...chelating ligands such as en, dien, bipy,(39a) and terpy can be prepared. Coordination numbers of 8, 9 and 10 as in [Ln(en)₄]³⁺, [Ln(terpy)₃]³⁺ and [Ln(dien)₄(NO₃)]²⁺ are typical. Nor do complexes such as the well-known [Ln(edta)(H₂O)₃]⁻ show any destabilization because of the N donor atoms (edta has 4 oxygen and 2 nitrogen donor atoms). More pertinent, whereas the complexes of 18-crown-6-ethers mentioned above dissociate instantly in water, complexes of the N-donor analogues are sufficiently stable to remain unchanged.

As with other transition elements, the lanthanides can be induced to form complexes with exceptionally low coordination numbers by use of the very bulky ligand, N(SiMe₃)₂⁻:

\[ 3\text{LiN(SiMe}_3\text{)}_2 + \text{LnCl}_3 \rightarrow \text{[Ln[N(SiMe}_3\text{)}_2\text{]}_3} + 3\text{LiCl} \]

The volatile, but air-sensitive, and very easily hydrolysed products have a coordination number of 3, the lowest found for the lanthanides; they are apparently planar in solution (zero dipole moment) but pyramidal in the solid state. With Ph₃PO the 4-coordinate distorted tetrahedral adducts [Ln[N(SiMe₃)₂]₃(OPPh₃)] are obtained. So difficult is it to expand the coordination sphere that attempts to prepare bis-(Ph₃PO) adducts produce instead the dimeric peroxo bridged complex, [(Ph₃PO){(Me₃Si)₂N}₂LnO₂⁻Ln[N(SiMe₃)₂]₂(OPPh₃)] (see p. 619).

Coordination by halide ions is rather weak, that of I⁻ especially so, but from nonaqueous solutions it is possible to isolate anionic complexes of the type [LnX₆]³⁻. These are apparently, and unusually for Ln³⁺, 6-coordinate and octahedral. The heavier donor atoms S, Se, P(40) and As form only a few

---

compounds. Chelating dithiocarbamate ligands provide the best known examples such as [Ln(S₂CNMe₂)₃] and [Ln(S₂CNMe₂)₄]⁻. Trigonal planar [Sm(SAr)₃], (Ar = C₆H₄Bu₂'-2,4,6) is a rare example of an Ln complex with a unidentate S-donor ligand and also an unusually low coordination number.⁴⁰

**Oxidation state II**⁴¹

The coordination chemistry in this oxidation state is essentially confined to the ions Sm²⁺, Eu²⁺ and Yb²⁺. These are the only ones with an aqueous chemistry and their solutions may be prepared by electrolytic reduction of the Ln³⁺ solutions or, in the case of Eu³⁺, by reduction with amalgamated Zn. These solutions are blood-red for Sm²⁺, colourless or pale greenish-yellow for Eu²⁺ and yellow for Yb²⁺, and presumably contain the aquo ions. All are rapidly oxidized by air, and Sm²⁺ and Yb²⁺ are also oxidized by water itself although aqueous Eu²⁺ is relatively stable, especially in the dark.

A number of salts have been isolated but, especially those of Sm²⁺ and Yb²⁺, are susceptible to oxidation even by their own water of crystallization. Carbonates and sulfates, however, have been characterized and shown to be isomorphous with those of Sr²⁺ and Ba²⁺.

Europium and Yb display further similarity with the alkaline earth metals in dissolving in liquid ammonia to give intense blue solutions, characteristic of solvated electrons and presumably also containing [Ln(NH₃)₂]²⁺. The solutions are strongly reducing and decompose on standing with the precipitation of orange Eu(NH₂)₂ and brown Yb(NH₂)₂ (always contaminated with Yb(NH₂)₃) which are isostructural with the Ca and Sr amides.

**30.3.5 Organometallic compounds**⁴¹

The organometallic chemistry of lanthanides is far less extensive than that of transition elements but, in spite of the lanthanides' inability to engage in π backbonding, it is one which has shown appreciable growth in the last quarter of a century. The compounds are of two main types: the predominantly ionic cyclopentadienides, and the σ-bonded alkyls and aryls. Organolanthanides of any type are usually thermally stable, but unstable with respect to water and air.

**Cyclopentadienides and related compounds**

The series [Ln(C₅H₅)₃], [Ln(C₅H₅)₂Cl] and the less numerous [Ln(C₅H₅)Cl₂] are salts of the C₅H₅⁻ anion and their most general preparation is by the reaction of anhydrous LnCl₃ and NaC₅H₅ in appropriate molar ratios in thf. The metal atoms in these compounds display an apparent tendency to increase their coordination numbers: solvates and other adducts are readily formed. In polar solvents, where they are no doubt solvated, they are monomeric but, in non-polar solvents the tris(C₅H₅) compounds are insoluble, while the bis(C₅H₅) compounds dimerize. In the solid state the tris(C₅H₅) compounds show considerable structural diversity. Those of Er and Tm have η⁵ rings arranged in a trigonal plane around the metal and those of Lu and Pr are isostructural with the Sc and La analogues respectively (p. 953). In the Sm compound each C₅H₅⁻ ion is pentahapto towards 1 metal atom but some also act as bridges by presenting a ring vertex (η¹) or edge (η²) towards an adjacent metal atom, so producing a chain structure.⁴² In a less complicated way the blue [Nd(C₅H₅Me)₃] is actually tetrameric, each Nd being attached to three rings in a pentahapto mode with one ring being further attached in a monohapto manner to an adjacent Nd. In spite of the steric bulk of the ligand, [Sm(η⁵-C₅Me₅)₃] has been obtained.⁴²

---

are actually dimers \([(\eta^5\text{-}C_5\text{H}_5)_2\text{Ln}(\mu\text{-Cl})_2\text{Ln}(\eta^5\text{-}C_5\text{H}_5)_2]\). The Cl bridges can be replaced by, for instance, H, CN and OR and donor solvents will cleave the bridges. Most mono \((C_5\text{H}_5)\) and \((C_5\text{Me}_5)\) compounds are tris solvates such as \([\text{Ln}(\eta^5\text{-}C_5\text{H}_5)_2(\text{thf})_3]\).

Complexes with the two analogous ligands, indenide, \(C_9\text{H}_7^-\),

and cyclooctatetraenide, cot, \(C_8\text{H}_8^{2-}\), ions can be prepared by similar means. In solid \([\text{Sm}(C_9\text{H}_7)_3]\) the 5-membered rings of the 3 ligands are bonded in a pentahapto manner and the compound shows little tendency to solvate, presumably because of the bulky nature of the \(C_9\text{H}_7^-\) ions. The lighter (and therefore larger) \(\text{Ln}^{\text{III}}\) ions form \(\text{K}[\text{Ln}(\eta^8\text{-}C_8\text{H}_8)_2]\). The \(\text{Ce}^{\text{III}}\) member of the series has a similar “sandwich” structure to the so-called “uranocene” (p. 1279). The other members of the series have the same infrared spectrum and so also are presumed to have this structure.

Cyclopentadienyl derivatives of divalent lanthanides are also known \((\text{LnII}(\eta^5\text{-}C_5\text{H}_5)_2)\) (\(\text{Ln} = \text{Sm}, \text{Eu}, \text{Yb}\)) might be expected to be isostructural with ferrocene but are “bent” ie rather than the two rings being parallel they are tilted relative to each other.

**Alkyls and aryls**

These are prepared by metathesis in thf or ether solutions:

\[
\text{LnCl}_3 + 3\text{LiR} \rightarrow \text{LnR}_3 + 3\text{LiCl}
\]

\[
\text{LnCl}_3 + 4\text{LiR} \rightarrow \text{Li}[\text{LnR}_4] + 3\text{LiCl}
\]

The triphenyls are probably polymeric and the first fully-characterized compound was \([\text{Li}(\text{thf})_4][\text{Lu}(C_6\text{H}_3\text{Me}_2)_4]\) in which the Lu is tetrahedrally coordinated to four \(\sigma\)-aryl groups. More stable products, of the form \([\text{LnR}_3(\text{thf})_2]\), are obtained by the use of bulky alkyl groups such as \(-\text{CH}_2\text{CMe}_3\) and \(-\text{CH}_2\text{SiMe}_3\).

Methyl derivatives, octahedral \([\text{LnMe}_6]^{3-}\) species, are known for most of the lanthanides. The first homoleptic, neutral lanthanide alkyl \((\text{Sm})\) was obtained using the bulky alkyl \(\text{CH(SiMe}_3)_2\):

\[
\text{Sm(OR)}_3 + 3\text{LiCH(SiMe}_3)_2 \rightarrow [\text{Sm(CH(SiMe}_3)_2]_3 + 3\text{LiOR}
\]

Compounds containing lanthanide–carbon \(\sigma\)-bonds have recently been reviewed.\(^{45}\)

Novel, mixed alkyl cyclopentadienides have also been prepared for the heavy lanthanides.\(^{46}\)

---

---

31

The Actinide and Transactinide Elements
\((Z = 90 - 103 \text{ and } 104 - 112)\)

31.1 Introduction

The “actinides” (“actinons” or “actinoids”) are the fourteen elements from thorium to lawrencium inclusive, which follow actinium in the periodic table. They are analogous to the lanthanides and result from the filling of the 5f orbitals, as the lanthanides result from the filling of the 4f. The position of actinium, like that of lanthanum, is somewhat equivocal and, although not itself an actinide, it is often included with them for comparative purposes.

Prior to 1940 only the naturally occurring actinides (thorium, protactinium and uranium) were known; the remainder have been produced artificially since then. The “transactinides” are still being synthesized and so far the nine elements with atomic numbers 104–112 have been reliably established. Indeed, the 20 manmade transuranium elements together with technetium and promethium now constitute one-fifth of all the known chemical elements.

In 1789 M. H. Klaproth examined pitchblende, thought at the time to be a mixed oxide ore of zinc, iron and tungsten, and showed that it contained a new element which he named uranium after the recently discovered planet, Uranus. Then in 1828 J. J. Berzelius obtained an oxide, from a Norwegian ore now known as “thorite”; he named this thoria after the Scandinavian god of war and, by reduction of its tetrachloride with potassium, isolated the metal thorium. The same method was subsequently used in 1841 by B. Peligot to effect the first preparation of metallic uranium.

The much rarer element, protactinium, was not found until 1913 when K. Fajans and O. Göhring identified \(^{234}\text{Pa}\) as an unstable member of the \(^{238}\text{U}\) decay series:

\[
^{238}\text{U} \rightarrow^{\alpha} \rightarrow^{234}\text{Th} \rightarrow^{\beta^-} \rightarrow^{234}\text{Pa} \rightarrow^{\beta^-} \rightarrow^{234}\text{U}
\]

They named it brevium because of its short half-life (6.70 h). The more stable isotope \(^{231}\text{Pa}\)
(\frac{1}{2} \tau 32,760 \text{ y}) was identified 3 years later by O. Hahn and L. Meitner and independently by F. Soddy and J. A. Cranston as a product of $^{235}\text{U}$ decay:

$$^{235}\text{U} \rightarrow ^{231}\text{Th} \rightarrow ^{231}\text{Pa} \rightarrow ^{227}\text{Ac}$$

As the parent of actinium in this series it was named protoactinium, shortened in 1949 to protactinium. Because of its low natural abundance its chemistry was obscure until 1960 when A. G. Maddock and co-workers at the UK Atomic Energy Authority worked up about 130 g from 60 tons of sludge which had accumulated during the extraction of uranium from UO$_2$ ores. It is from this sample, distributed to numerous laboratories throughout the world, that the bulk of our knowledge of the element's chemistry was gleaned.

In the early years of this century the periodic table ended with element 92 but, with J. Chadwick's discovery of the neutron in 1932 and the realization that neutron-capture by a heavy atom is frequently followed by $\beta^{-}$ emission yielding the next higher element, the synthesis of new elements became an exciting possibility. E. Fermi and others were quick to attempt the synthesis of element 93 by neutron bombardment of $^{238}\text{U}$, but it gradually became evident that the main result of the process was not the production of element 93 but nuclear fission, which produces lighter elements. However, in 1940, E. M. McMillan and P. H. Abelson in Berkeley, California, were able to identify, along with the fission products, a short-lived isotope of element 93 ($\frac{1}{2} \tau 2.355$ days): \footnote{239Np itself also decays by $\beta^{-}$ emission to produce element 94 but this was not appreciated until after that element (plutonium) had been prepared from $^{238}\text{U}$.}

$$^{238}\text{U} + ^{1}\text{n} \rightarrow ^{239}\text{U} \rightarrow ^{239}\text{Np}$$

As it was the next element after uranium in the now extended periodic table it was named neptunium after Neptune, which is the next planet beyond Uranus.

The remaining actinide elements were prepared\footnote{1 G. T. Seaborg (ed.), Transuranium Elements: Products of Modern Alchemy, Dowden, Hutchinson & Ross, Stroudsburg, 1978. This reproduces, in their original form, 122 key papers in the story of man-made elements. \footnote{2 G. T. Seaborg and W. D. Loveland, The Elements Beyond Uranium, Wiley, New York, 1990, 359 pp. \footnote{3 J. J. Katz, L. R. Morss and G. T. Seaborg (eds.) The Chemistry of the Actinide Elements, Chapman and Hall, London, 1986; Vol. 1, 1004 pp.; Vol 2, 912 pp. \footnote{4 L. R. Morss and J. Fuger (eds.), Transuranium Elements: A Half Century, Am. Chem. Soc., Washington, 1992, 700 pp.}} by various "bombardment" techniques fairly regularly over the next 25 years (Table 31.1) though, for reasons of national security, publication of the results was sometimes delayed. The dominant figure in this field has been G. T. Seaborg, of the University of California, Berkeley, in early recognition of which, he and E. M. McMillan were awarded the 1951 Nobel Prize for Chemistry.

The isolation and characterization of these elements, particularly the heavier ones, has posed enormous problems. Individual elements are not produced cleanly in isolation, but must be separated from other actinides as well as from lanthanides produced simultaneously by fission. In addition, all the actinides are radioactive, their stability decreasing with increasing atomic number, and this has two serious consequences. Firstly, it is necessary to employ elaborate radiation shielding and so, in many cases, operations must be carried out by remote control. Secondly, the heavier elements are produced only in the minutest amounts. Thus mendelevium was first prepared in almost unbelievably small yields of the order of 1 to 3 atoms per experiment! Paradoxically, however, the intense radioactivity also facilitated the detection of these minute amounts: first by the development and utilization of radioactive decay systematics, which enabled the detailed properties of the expected radiation to be predicted, and secondly, by using the radioactive decay itself to detect and count the individual atoms synthesized. Accordingly, the separations were effected by ion-exchange techniques, and the elements

(a) The first claim for element 102 was in 1957 by an international team working at the Nobel Institute for Physics in Stockholm. Their results could not be confirmed but their suggested name for the element was accepted.
(b) A full assessment of this work and that done at Berkeley and elsewhere has been carried out by the Transfermium Working Group, a neutral international group appointed jointly by IUPAC and IUPAP in 1987.(5).
(c) Formerly Lw; the present symbol was recommended by IUPAC in 1965.
(d) The Transfermium Working Group concluded that “In the complicated situation presented by element 103, with several papers of varying degrees of completeness and conviction, none conclusive, and referring to several isotopes, it is impossible to say other than that full confidence was built up over a decade with credit attaching to work in both Berkeley and Dubna”. The detailed analysis of the many relevant publications is given in ref. 5.

§37.2. Terrestrial abundance and distribution of the actinide elements

identified by chemical tracer methods and by their characteristic nuclear decay properties. In view of the quantities involved, especially of californium and later elements, it is clear that this would not have been feasible without accurate predictions of the chemical properties also. It was Seaborg's realization in 1944 that these elements should be regarded as a second f series akin to the lanthanides that made this possible. (Thorium, protactinium and uranium had previously been regarded as transition elements belonging to groups 4, 5 and 6, respectively.)

Elements beyond 103 are expected to be 6d elements forming a fourth transition series, and attempts to synthesize them have continued during the past thirty years. All 10 (including, of course, actinium) are now known and are discussed in the section on transactinide elements on p. 1280. The work has required the dedicated commitment of extensive national facilities and has been carried out at the Lawrence-Berkeley Laboratories, the Joint Institute for Nuclear Research at Dubna, and the Heavy-Ion Research Centre (GSI) at Darmstadt, Germany.

**Superheavy elements**

Since the radioactive half-lives of the known transuranium elements and their resistance to spontaneous fission decrease with increase in atomic number, the outlook for the synthesis of further elements might appear increasingly bleak. However, theoretical calculations of nuclear stabilities, based on the concept of closed nucleon shells (p. 13) suggest the existence of an "island of stability" around $Z = 114$ and $N = 184$.(6) Attention has therefore been directed towards the synthesis of element 114 (a congenor of Pb in Group 14 and adjacent "superheavy" elements, by bombardment of heavy nuclides with a wide range of heavy ions, but so far without success.

Searches have been made for naturally occurring superheavies ($Z = 112-15$) in ores of Hg, Tl, Pb and Bi, on the assumption that they would follow their homologues in their geochemical evolution and could be recognized by the radiation damage caused over geological time by their very energetic decay. Early claims to have detected such superheavies in natural ores have been convincingly discounted.(7) More recent uncorroborated claims to success have been made but, even if confirmed, the concentrations found in the samples examined, are exceedingly small(8) (less than 1 in $10^{13}$).

31.2 The Actinide Elements(2,3,9–12)

31.2.1 Terrestrial abundance and distribution

Every known isotope of the actinide elements is radioactive and the half-lives are such that only $^{232}$Th, $^{235}$U, $^{238}$U and possibly $^{244}$Pu could have survived since the formation of the solar system. In addition, continuing processes produce equilibrium traces of some isotopes of which the most prominent is $^{234}$U ($t_{1/2} = 2.45 \times 10^5$ y,

---

comprising 0.0054% of naturally occurring U isotopes). $^{231}$Pa (and therefore $^{227}$Ac) is formed as a product of the decay of $^{235}$U, while $^{237}$Np and $^{239}$Pu are produced by the reactions of neutrons with, respectively, $^{235}$U and $^{238}$U. Traces of Pa, Np and Pu are consequently found, but only Th and U occur naturally to any useful extent. Indeed, these two elements are far from rare: thorium comprises 8.1 ppm of the earth’s crust, and is almost as abundant as boron, whilst uranium at 2.3 ppm is rather more abundant than tin. The radioactive decay schemes of the naturally occurring long-lived isotopes of $^{232}$Th, $^{235}$U and $^{238}$U, together with the artificially generated series based on $^{241}$Pu, are summarized in Fig 31.1.

Figure 31.1 The radioactive decay series.
Thorium is widely but rather sparsely distributed and its only commercial sources are monazite sands (see p. 1229) and the mineral conglomerates of Ontario. The former are found in India, South Africa, Brazil, Australia and Malaysia, and in exceptional cases may contain up to 20% ThO₂ but more usually contain less than 10%. In the Canadian ores the thorium is present as uranothorite, a mixed Th,U silicate, which is accompanied by pitchblende. Even though present as only 0.4% ThO₂, the recovery of Th, as a co-product of the recovery of uranium, is viable.

Uranium, too, is widely distributed and, since it probably crystallized late in the formation of igneous rocks, tends to be scattered in the faults of older rocks. Some concentration by leaching and subsequent re-precipitation has produced a large number of oxide minerals of which the most important are pitchblende or uraninite, U₃O₈, and carnotite, K₂(UO₂)₂(VO₄)₂.₃H₂O. However, even these are usually dispersed so that typical ores contain only about 0.1% U, and many of the more readily exploited deposits are nearing exhaustion. The principal sources are Canada, Africa and countries of the former USSR.

The transuranium elements must all be prepared artificially. In the case of plutonium about 1200 tonnes have so far been produced worldwide, about three-quarters of it still being devoted to the production of gas mantles (p. 1228). In view of its availability as a by-product of lanthanide and uranium production, output could be increased easily if it were to be used on a large scale as a nuclear fuel (see below).

Uranium production depends in detail on the nature of the ore involved but, after crushing and concentrating by conventional physical means, the ore is usually roasted and leached with sulfuric acid in the presence of an oxidizing agent such as MnO₂ or NaClO₃ to ensure conversion of all uranium to UO₂²⁺. In a typical process the uranium is concentrated as a sulfato complex on an anion exchange resin from which it is eluted with strong HNO₃ and further purified by solvent extraction into tributyl phosphate (TBP) in either kerosene or hexane. The uranium is then stripped from the organic phase to give an aqueous sulfate solution from which so-called “yellow cake” is precipitated* by addition of ammonia. This is converted to UO₃ by heating at 300°C, and then to UO₂ by reducing in H₂ at 700°C. Conversion to the metal is generally effected by reduction of UF₄ with Mg at 700°C.

Apart from its long-standing though small-scale use for colouring glass and ceramics, uranium’s only significant use is as a nuclear fuel. The extent of this use depends on environmental and political considerations. In 1994 world production after nearly a decade of decline was 31 000 tonnes, 30% of which came from Canada and 23% each from the former Soviet Union and African countries (Niger, Namibia, the Republic of South Africa and Gabon). This, however, represented only half the reactor requirements. The rest came from recycling and stockpiles

---

Metallic thorium can be obtained by reduction of ThO₂ with Ca or by reduction of ThCl₄ with Ca or Mg under an atmosphere of Ar (like Ti, finely divided Th is extremely reactive when hot).

The uses of Th are at present limited and only a few hundred tonnes are produced annually, about half of this still being devoted to the production of gas mantles (p. 1228). In view of its availability as a by-product of lanthanide and uranium production, output could be increased easily if it were to be used on a large scale as a nuclear fuel (see below).

* Yellow cake is a complicated mixture of salts and oxides, the composition of which approximates to (NH₄)₂U₂O₇ but is dependent on the method by which it is produced (see p. 276 of ref. 2).
of production of neutrons is balanced by the rate of their absorption.

The first manmade self-sustaining nuclear fission chain reaction was achieved on 2 December 1942 in a disused squash court at the University of Chicago by a team which included E. Fermi. This was before nuclear-fuel enrichment had been developed: alternate sections of natural-abundance UO₂ and graphite moderator were piled on top of each other (hence, nuclear reactors were originally known as “atomic piles”) and the reaction was controlled by strips of cadmium which could be inserted or withdrawn as necessary. In this crude structure, 6 tonnes of uranium metal, 50 tonnes of uranium oxide and nearly 400 tonnes of graphite were required to achieve criticality. The dramatic success of Fermi’s team in achieving a self-sustaining nuclear reaction invited the speculation as to whether such a phenomenon could occur naturally. In one of the most spectacular pieces of scientific detection work ever conducted, it has now unambiguously been established that such natural chain reactions have indeed occurred in the geological past when conditions were far more favourable than at present (see Panel).

If a chain reaction is to provide useful energy, the heat it generates must be extracted by means of a suitable coolant and converted, usually by steam turbines, into electrical energy. The high temperatures and the intense radioactivity generated within a reactor pose severe, and initially totally new, constraints on the design. The choices of fuel and its immediate container (cladding), of the moderator, coolant and controller involve problems in nuclear physics, chemistry, metallurgy and engineering. Nevertheless, the first commercial power station (as opposed to experimental reactors or those whose function was to produce plutonium for bomb manufacture) was commissioned in 1956 at Calder Hall in Cumberland, UK. Since then a variety of different types has been developed in several countries, as summarized in Fig. 31.2. At

\[ ^{235}_{92}\text{U} + ^{1}_{0}\text{n} \rightarrow 2\text{fragments} + ^{x}_{0}\text{n} \quad (x = 2 - 3) \]

...
§31.2.2 Preparation and uses of the actinide elements

Natural Nuclear Reactors — The Oklo Phenomenon\(^1\)

Natural uranium consists almost entirely of the \(\alpha\) emitters \(^{235}\text{U}\) and \(^{238}\text{U}\). As \(^{235}\text{U}\) decays more than six times faster than \(^{238}\text{U}\) (Fig. 31.1) the proportion of \(^{235}\text{U}\) is very slowly but inexorably decreasing with time. Prior to 1972, all analyses of naturally occurring uranium had shown this proportion to be notably constant at 0.7202 ± 0.0006%. \(^2\) In that year, however, workers at the French Atomic Energy laboratories in Pierrelatte performing routine mass spectrometric analyses recorded a value of 0.7171%. The difference was small but significant.

Contamination with commercially depleted \(\text{U}\) was immediately assumed, but it was gradually realized that the depletion was characteristic of the ore, which came from a mine at Oklo in Gabon, near the west coast (\(1^\circ\) 25' S, \(13^\circ\) 10' W). An intensive examination of the mine was quickly mounted and it was found that the depletion was not uniform but was greatest near those areas where the total \(\text{U}\) content was highest. The record depletion was an astonishingly low 0.296% \(^{235}\text{U}\) from an area where the total \(\text{U}\) content of the ore rose to around 60%. Incredible as it may appear in view of the diverse and exacting requirements for the construction of a manmade nuclear reactor, the only satisfactory explanation is that the Oklo mine is the site of a spent, prehistoric, natural nuclear reactor. There are now known to have been 14 such reactors in the Franceville basin at Oklo, all of which have been mined, plus a further one some 30 km to the southeast at Bangombe, which it is hoped to preserve essentially undisturbed.

The Oklo ore bed consists of sedimentary rocks believed to have been laid down about \(1.8 \times 10^9\) y ago. \(\text{U}^{IV}\) minerals in the igneous rocks, formed in the early history of the earth when the atmosphere was a reducing one, were converted to soluble \(\text{U}^{IV}\) salts by the atmosphere which had since become oxidizing. These were then re-precipitated as \(\text{U}^{IV}\) by bacterial reduction in the silt of a river delta and gradually buried under other sedimentary deposits. During this process the underlying granite rocks were tilted, the ores which contained about 0.5% \(\text{U}\) were fractured, and water percolating through the fissures created rich pockets of ore which in places consisted of almost pure \(\text{UO}_2\). At that time the \(^{235}\text{U}\) content of the uranium was about 3%, which is the value to which the fuel used in most modern water-moderated reactors is now artificially enriched.

Under these circumstances the critical mass could be attained and a nuclear chain reaction initiated, with water as the necessary moderator. The 15% \(\text{H}_2\text{O}\) of water in the clays associated with the ore would be ideal for this purpose. As the reaction proceeded, the consequent rise in temperature would have driven off water, so producing "undermoderation" and slowing the reaction, thereby avoiding a "run away" reaction. As a result, a particular reactor may have operated in a steady manner or perhaps in a slowly pulsating manner, as water was alternately driven off (causing loss of criticality and cooling) and re-absorbed (recovering criticality and again heating).

Further control of the reactions must have been effected by neutron-absorbing "poisons", such as lithium and boron, which are nearly always present in clays. That these are present in the Oklo clays in comparatively low concentrations is one of the factors which allowed the reactions to take place. As the nuclear fuel in the original, rich pockets was being used up, the poisons in the surrounding ore would be simultaneously "burned out" by escaping neutrons. Thus ore of only slightly poorer quality, which was initially prevented only by the poisons from being critical, would gradually become so and the chain reaction would be propagated further through the ore bed. It is thought that these reactors operated for about \((0.2 - 1) \times 10^9\) y with output in the region of 10–100 kW, consuming altogether 4–6 tonnes of \(^{235}\text{U}\) from a total deposit of the order of 400,000 tonnes of uranium. Subsequent preservation of the fossil reactors is a result of continued burial which protected the uranium from redissolution.

Confirmation of this explanation is unequivocally provided by the presence in the reactor zones of at least half of the more than 30 fission products of uranium. Although soluble salts, such as those of the alkali and alkaline earth metals, have been leached out, lanthanide and platinum metals remain along with traces of trapped krypton and xenon. Most decisively, the observed distribution of the various isotopes of these elements is that of fission products as opposed to the distribution normally found terrestrial. The reasons for the retention of these elements on this particular site is clearly germane to the problem of the long-term storage of nuclear wastes, and is therefore the subject of continuing study.

The circumstances which led to the Oklo phenomenon may well have occurred in other, yet unidentified, places, but in view of the intervening natural depletion of \(^{235}\text{U}\), the possibility of a natural chain reaction being initiated at the present time or in the future may be discounted.

\(^{3}\) If, as is believed (p. 13), the earth was formed about \(4.6 \times 10^9\) y ago it follows that the proportion of \(^{235}\text{U}\) at that time must have been about 25%.
**Figure 31.2** Various types of nuclear reactor currently in use or being developed (F fuel; E enrichment, expressed as $\%^{235}\text{U}$ present; M moderator; C coolant).

The present time (1996) some 30 countries are operating nuclear power stations to supply energy.

**Fuels.** Although the concentration of $^{235}\text{U}$ in natural uranium is sufficient to sustain a chain reaction, its effective dilution by the fuel cladding and other materials used to construct the reactor make fuel enrichment advantageous. Indeed, if ordinary (light) water is used as moderator or coolant, a concentration of 2–3% $^{235}\text{U}$ is necessary to compensate for the inevitable
absorption of neutrons by the protons of the water. Enrichment also has the advantage of reducing the critical size of the reactor but this must be balanced against its enormous cost.

Early reactors used uranium in metallic form but this has been superseded by UO₂ which is chemically less reactive and has a higher melting point. UC₂ is also sometimes used but is reactive towards O₂.

In addition to ²³⁵U, which occurs naturally, two other fissile nuclei are available artificially. These are ²³⁹Pu and ²³³U which are obtained from ²³⁸U and ²³²Th respectively:

\[
\begin{align*}
^{238}\text{U} + \beta^- &\rightarrow ^{239}\text{Pu} \\
^{235}\text{U} + \beta^- &\rightarrow ^{236}\text{Np} \\
^{239}\text{Pu} &\rightarrow ^{239}\text{Np} \\
^{232}\text{Th} + \beta^- &\rightarrow ^{233}\text{Pa} \\
^{233}\text{Pa} &\rightarrow ^{233}\text{U} \\
^{235}\text{U} &\rightarrow ^{233}\text{Pa}
\end{align*}
\]

²³⁹Pu is therefore produced to some extent in all currently operating reactors because they contain ²³⁸U, and this contributes to the reactor efficiency. More significantly, it offers the possibility of generating more fissile material than is consumed in producing it. Such “breeding” of ²³⁹Pu is not possible in thermal reactors because the net yield of neutrons from the fission of ²³⁵U is inadequate. But, if the moderator is dispensed with and the chain reaction sustained by using enriched fuel, then there are sufficient fast neutrons to “breed” new fissile material. Fast-breeder reactors are not yet in commercial use but prototypes are operating in France, the UK and Japan and use a core of PuO₂ in “depleted” UO₂ (i.e. ²³⁸UO₂) surrounded by a blanket of more depleted UO₂ in which the ²³⁹Pu is generated. By making use of the ²³⁸U as well as the ²³⁵U, such reactors can extract 50–60 times more energy from natural uranium, so using more efficiently the reserves of easily accessible ores. Sadly there are possible dangers associated with a “plutonium economy” which have led to well-publicized objections, and future developments will be determined by social and political as well as by economic considerations.

The net yield of thermal neutrons from the fission of ²³³U is higher than from that of ²³⁵U and, furthermore, ²³²Th is a more effective neutron absorber than ²³⁸U. As a result, the breeding of ²³³U is feasible even in thermal reactors. Unfortunately the use of the ²³²Th/²³³U cycle has been inhibited by reprocessing problems caused by the very high energy γ-radiation of some of the daughter products.

**Fuel enrichment.** All practicable enrichment processes require the uranium to be in the form of a gas. UF₆, which readily sublimes (p. 1269), is universally used and, because fluorine occurs in nature only as a single isotope, the compound has the advantage that separation depends solely on the isotopes of uranium. The first, and until recently the only, large-scale enrichment process was by gaseous diffusion which was originally developed in the “Manhattan Project” to produce nearly pure ²³⁵U for the first atomic bomb (exploded at Alamogordo, New Mexico, 5.30 a.m., 16 July 1945). UF₆ is forced to diffuse through a porous membrane and becomes very slightly enriched in the lighter isotope. This operation is repeated thousands of times by pumping, in a kind of cascade process in which at each stage the lighter fraction is passed forward and the heavier fraction backwards. Unfortunately gaseous diffusion plants are large, very demanding in terms of membrane technology, and extremely expensive in energy: alternatives have therefore actively been sought.¹⁸ So far the only viable alternative is the gas centrifuge process currently operating in the UK, The Netherlands, Germany, Japan and Russia. In a cylindrical centrifuge ²³⁸UF₆ concentrates towards the walls and ²³⁵UF₆ towards the centre. In practice the radial concentration gradient is transformed into an axial gradient by injecting the UF₆ so as to set up an axial counter current so that both the enriched and depleted materials can be drawn off from

---

The centrifuges rotate at about 1000 revolutions per second and are arranged in a cascade system.

A promising alternative is provided by “Laser isotope separation”. Because the ionization energies of $^{235}$U and $^{238}$U differ slightly, it is possible to ionize the former selectively by irradiating U vapour with laser beams precisely tuned to the appropriate wavelength. The ions can then be collected at a negative electrode.

**Cladding.** The Magnox reactors get their name from the magnesium-aluminium alloy used to clad the fuel elements, and stainless steels are used in other gas-cooled reactors. In water reactors zirconium alloys are the favoured cladding materials.

**Moderators.** Neutrons are most effectively slowed by collisions with nuclei of about the same mass. Thus the best moderators are those light atoms which do not capture neutrons. These are $^2$H, $^4$He, $^9$Be and $^{12}$C. Of these, He, being a gas, is insufficiently dense and Be is expensive and toxic, so the common moderators are highly purified graphite or the more expensive heavy water. In spite of its neutron-absorbing properties, which as mentioned above must be offset by using enriched fuel, ordinary water is also used because of its cheapness and excellent neutron-moderating ability.

**Coolants.** Because they must be mobile, coolants are either gases or liquids. $^4$CO$_2$ and He are appropriate gases and are used in conjunction with graphite moderators. The usual liquids are heavy and light water, with water also as moderator. In order to keep the water in the liquid phase it must be pressurized (PWR), otherwise it boils in the reactor core (BWR, etc.) in which case the coolant is actually steam. In the case of breeder reactors the higher temperatures of their more compact cores pose severe cooling problems and liquid Na (or Na/K alloy) is favoured, although highly compressed He is another possibility.

**Control rods.** These are usually made of boron steel or boron carbide (p. 149), but other good neutron absorbers which can be used are Cd and Hf.

**Nuclear fuel reprocessing**$^{3,10}$

Many of the fission products formed in a nuclear reactor are themselves strong neutron absorbers (i.e. “poisons”) and so will stop the chain reaction before all the $^{235}$U (and $^{239}$Pu which has also been formed) has been consumed. If this wastage is to be avoided the irradiated fuel elements must be removed periodically and the fission products separated from the remaining uranium and the plutonium. Such reprocessing is of course inherent in the operation of fast-breeder reactors, but whether or not it is used for thermal reactors depends on economic and political factors. Reprocessing is currently undertaken in the UK, France and Russia but is not considered to be economic in the USA.

Irradiated nuclear fuel is one of the most complicated high-temperature systems found in modern industry, and it has the further disadvantage of being intensely radioactive so that it must be handled exclusively by remote control. The composition of the irradiated nuclear fuel depends on the particular reactor in question, but in general it consists of uranium, plutonium, neptunium, americium and various isotopes of over 30 fission-product elements. The distribution of fission products is such as to produce high concentrations of elements with mass numbers in the regions 90–100 (second transition series) and 130–145 ($^{44}$Xe, $^{55}$Cs, $^{56}$Ba and lanthanides). The more noble metals, such as $^{44}$Ru, $^{45}$Rh and $^{46}$Pd, tend to form alloy pellets while class-a metals such as $^{38}$Sr, $^{56}$Ba, $^{46}$Zr, $^{41}$Nb and the lanthanides are present in complex oxide phases.

The first step is to immerse the fuel elements in large “cooling ponds” of water for a hundred days or so, during which time the short-lived, intensely radioactive species such as $^{131}$I ($t_\frac{1}{2} = 8.04$ days) lose most of their activity and the generation of heat subsides.

Then the fuel elements are dissolved in 7M HNO$_3$ to give a solution containing U$^{VI}$ and Pu$^{IV}$ which, in the widely used plutonium–uranium-reduction, or Purex process, are extracted into 20% tributyl phosphate (TBP) in kerosene leaving most of the fission products
(FP) in the aqueous phase. Subsequent separation of U and Pu depends on their differing redox properties (Fig. 31.3). The separations are far from perfect (see p. 1097), and recycling or secondary purification by ion-exchange techniques is required to achieve the necessary overall separations.

This reprocessing requires the handling of kilogram quantities of Pu and must be adapted to avoid a chain reaction (i.e. a criticality accident). The critical mass for an isolated sphere of Pu is about 10 kg, but in saturated aqueous solutions may be little more than 500 g. (Because of the large amounts of “inert” $^{238}$U present, U does not pose this problem.)

The solution of waste products is concentrated and stored in double-walled, stainless steel tanks shielded by a metre or more of concrete.

Figure 31.3 Flow diagram for the reprocessing of nuclear fuel [FP = fission products; TBP = (Bu°O)$_3$PO].
Vitrification processes are being developed in several countries in which the dried waste is calcined and heated with ground glass “frit” to produce a borosilicate glass which can be stored or disposed of more permanently if there is agreement on suitable sites. 237\textsuperscript{m}Np, 241\textsuperscript{m}Am and 243\textsuperscript{m}Am can be extracted from reactor wastes and are available in kg quantities. Prolonged neutron irradiation of 239\textsuperscript{m}Pu is used at the Oak Ridge laboratories in Tennessee to produce 244\textsuperscript{m}Cm on a 100-g scale, 242\textsuperscript{m}Cm, 249\textsuperscript{m}Bk, 252\textsuperscript{m}Cf and 253\textsuperscript{m}Es all on a mg scale; and 257\textsuperscript{m}Fm on a μg scale. For trace amounts of these mixtures, dissolution in nitric acid, absorption of the +3 ions on to a cation exchange resin and elution with ammonium α-hydroxyisobutyrate provides an efficient separation of the elements from each other and from accompanying lanthanides, etc. The separation of macro amounts of these elements, however, is not feasible by this method because of radiolytic damage to the resin caused by their intense radioactivity. Much quicker solvent extraction processes similar to those used for reprocessing nuclear fuels are therefore used.

Because the sequence of neutron captures inevitably leads to 258\textsuperscript{m}Fm which has a fission half-life of only a few seconds, the remaining three actinides, 10\textsuperscript{m}Md, 10\textsuperscript{m}No and 10\textsuperscript{m}Lr, can only be prepared by bombardment of heavy nuclei with the light atoms 2\textsuperscript{m}He to 20\textsuperscript{m}Ne. This raises the mass number in multiple units and allows the 258\textsuperscript{m}Fm barrier to be avoided; even so, yields are minute and are measured in terms of the number of individual atoms produced.

Apart from 239\textsuperscript{m}Pu, which is a nuclear fuel and explosive, the transuranium elements have in the past been produced mainly for research purposes. A number of specialized applications, however, have led to more widespread uses. 238\textsuperscript{m}Pu (produced by neutron bombardment of 237\textsuperscript{m}Np to form 238\textsuperscript{m}Np which decays by β-emission to 238\textsuperscript{m}Pu) is a compact heat source (0.56 W g\textsuperscript{-1} as it decays by α-emission) which, in conjunction with PbTe thermoelectric elements, for instance, provides a stable and totally reliable source of electricity with no moving parts. It has been used in the form of PuO\textsubscript{2} in kg quantities in the American Apollo and Galileo spacecraft. Since its α-emission is harmless and is not accompanied by γ-radiation it is also used in heart pacemakers (~160 mg 238\textsuperscript{m}Pu) where it lasts about 5 times longer than conventional batteries before requiring replacements. 241\textsuperscript{m}Am is also widely used as an ionization source in smoke detectors and thickness gauges.

### 31.2.3 Properties of the actinide elements

The dominant feature of the actinides is their nuclear instability, as manifest in their radioactivity (mostly α-decay) and tendency to spontaneous fission; both of these modes of decay become more pronounced (shorter half-lives) with the heavier elements. The radioactivity of Th and U is probably responsible for much of the earth’s internal heat, but is of a sufficiently low level to allow their compounds to be handled and transported without major problems. By contrast, the instability of the heavier elements not only imposes most severe handling problems\textsuperscript{(19)} but drastically limits their availability. Thus, for instance, the crystal structures of Cf and Es were determined on only microgram quantities\textsuperscript{(1)} while the concept of “bulk” properties is not applicable at all to elements such as Md, No and Lr which have never been seen and have only been produced in unweighably small amounts. Even where adequate amounts are available, the constant build-up of decay products and the associated generation of heat may seriously affect the measured properties (see also p. 753). An indication of the difficulties of working with these elements can be gained from the fact that two phases described in 1974 as two forms of Cf metal were subsequently shown, in fact, to be hexagonal Cf\textsubscript{2}O\textsubscript{2}S and fcc CfS.\textsuperscript{(20)}

Some of the more important known properties of the actinides are summarized in Table 31.2.

</table>

1^{(a)} The rate of decay by spontaneous fission increases with atomic number and is an important additional cause of instability in the later actinides (trans-Np).

2^{(a)} This value refers to the natural mixture of uranium isotopes, i.e. it is the atomic weight. Variations are possible because (i) some geological samples have anomalous isotopic compositions, and (ii) commercially available samples may have been depleted in $^{235}$U. The value for $^{238}$U itself is 238.0058.

3^{(a)} For Pa, CN = 10 and for U, Np and Pu the structures are rather irregular so that the coordination number is not a precise concept.

4^{(a)} For Am, radius refers to CN = 8.

5^{(a)} Polymorphism is common amongst the actinides and these data refer to the form most stable at room temperature.
The metals are silvery in appearance but display a variety of structures. All except Cf have more than one crystalline form (Pu has six) but most of these are based on typically metallic close-packed arrangements. Structural variability is mirrored by irregularities in metal radii (Fig. 31.4) which are far greater than are found in lanthanides and probably arise from a variability in the number of electrons in the metallic bands of the actinide elements. From Ac to U, since the most stable oxidation state increases from +3 to +6, it seems likely that the sharp fall in metal radius is due to an increasing number of electrons being involved in metallic bonding. Neptunium and Pu are much the same as U but thereafter increasing metal radius is presumably a result of fewer electrons being involved in metallic bonding since it roughly parallels the reversion to a lanthanide-like preference for tervalency in the heavier actinides.

By contrast, the ionic radius in a given oxidation state falls steadily and, though the available data are less extensive, it is clear that an "actinide contraction" exists, especially for the +3 state, which is closely similar to the "lanthanide contraction" (see p. 1232).

### 31.2.4 Chemical reactivity and trends

The actinide metals are electropositive and reactive, apparently becoming increasingly so with atomic number. They tarnish rapidly in air, forming an oxide coating which is protective in the case of Th but less so for the other elements. Because of the self-heating associated with its radioactivity (100 g $^{239}$Pu generates ~0.2 watts of heat) Pu is best stored in circulating dried air. All are pyrophoric when finely divided.

The metals react with most non-metals especially if heated, but resist alkali attack and are less reactive towards acids than might be expected. Concentrated HCl probably reacts most rapidly, but even here insoluble residues remain in the cases of Th (black), Pa (white) and U (black). Those of Th and U have the approximate compositions $\text{HThO(OH)}$ and $\text{UH(OH)}_2$. Concentrated HNO$_3$ passivates Th, U and Pu, but the addition of F$^-$ ions avoids this and provides the best general method for dissolving these metals.

Reactions with water are complicated and are affected by the presence of oxygen. With boiling water or steam, oxide is formed on the surface of the metal and $\text{H}_2$ is liberated. Since the metals react readily with the latter, hydrides are produced which themselves react rapidly with

</table>

(a) bl = blue; br = brown; c-less = colourless; gr = green; o = orange; r = red; v = violet; y = yellow.
(b) Because of disproportionation, PuO₂⁺ is never observed on its own and its colour must therefore be deduced from the spectrum of a mixture involving Pu in several oxidation states.
(c) This is probably too simple, hydroxo species such as [MO₄(OH)₂]³⁻ being more likely.

Knowledge of the detailed chemistry of the actinides is concentrated mainly on U and, to a lesser extent, Th and Pu. Availability and safety are, of course, major problems for the remaining elements, but self-heating and radiolytic damage can be troublesome, the energy evolved in radioactive decay being far greater than that of chemical bonds. Thus in aqueous solutions of concentrations greater than 1 mg cm⁻³ (i.e., 1 g l⁻¹), isotopes with half-lives less than, say, 20 years, will produce sufficient H₂O₂ to produce appreciable oxidation or reduction where the redox behaviour of the element allows this. Fortunately, the nuclear instability which produces these problems also assists in overcoming them: by performing chemical reactions with appropriate, non-radioactive, carrier elements containing only trace amounts of the actinide in question, it is possible to detect the presence of the latter, and hence explore its chemistry because of the extreme sensitivity of radiation detectors. Such “tracer” techniques have provided remarkably extensive information particularly about the aqueous solution chemistry of the actinides.

Table 31.3 lists the known oxidation states. For the first three elements (Th, Pa, and U) the most stable oxidation state is that involving all the valence electrons, but after this the most stable becomes progressively lower until, in the second half of the series, the +3 state becomes dominant. Appropriate quantitative data for elements up to Am are summarized in Fig. 31.5. The highest oxidation state attainable by Th, and the only one occurring in solution, is +4. Data for Pa are difficult to obtain because of its propensity for hydrolysis which results in the formation of colloidal precipitates, except in concentrated acids or in the presence of complexing anions such as F⁻ or C₂O₄²⁻. However, it is clear that +5 is its most stable oxidation state since its reduction to +4 requires rather strong reducing agents such as Zn/H⁺, Cr³⁺ or Ti³⁺ and the +4 state in solution is rapidly reoxidized to +5 by air. In the case of uranium the shape of the volt-equivalent versus oxidation state curve (pp. 435–8) reflects the ready disproportionation of UO₂⁺ into the more stable U⁴⁺ and UO₂²⁺; it should also be possible for atmospheric oxygen (1/2O₂ + 2H⁺ +
A given actinide ion is only about 4 pm larger than the corresponding Ln$^{3+}$.

It is evident from the above behaviour that the ionization energies of the early actinides, though not accurately known, must be lower than for the early lanthanides. This is quite reasonable since it is to be expected that, when the 5f orbitals of the actinides are beginning to be occupied, they will penetrate less into the inner core of electrons, and the 5f electrons will therefore be more effectively shielded from the nuclear charge than are the 4f electrons of the corresponding lanthanide series (i.e. the relationship between 4f and 5f series may be compared to that between 3d and 4d). Because the outer electrons are less firmly held, they are all available for bonding in the actinide series as far as Np (4th member), but only for Ce (1st member) in the lanthanides, and the onset of the dominance of the +3 state is accordingly delayed in the actinides. That the 5f and 6d orbitals of the early actinides are energetically closer than the 4f and 5d orbitals of the early lanthanides is evidenced by the more extensive occupation of the 6d orbitals in the neutral atoms of the former (compare the outer electron configuration in Tables 31.2 and 30.2). These 5f orbitals also extend spatially further than the 4f and are able to make a covalent contribution to the bonding which is much greater than that in lanthanide compounds. This leads to a more extensive actinide coordination chemistry and to crystal-field effects, especially with ions in oxidation states above +3, much larger than those found for lanthanide complexes. It is also important to remember that relativistic effects on the atomic properties and chemistry of these heavy elements cannot be safely ignored in attempts to explain or predict their behaviour.

Table 31.4 is a list of typical compounds of the actinides and demonstrates the wider range of oxidation states compared to lanthanide compounds. High coordination numbers are still evident, and distortions from the idealized stereochemistries which are quoted are again general. However, no doubt at least partly because the early actinides have received most attention, the widest range of stereochemistries is

(a) These compounds are isostuctural with the corresponding compounds of Ce (see Fig. 30.5, p. 1245) and can be visualized as octahedral if each \(\text{NO}_3^-\) is considered to occupy a single coordination site.

(b) The polyhedra of these complexes are actually flattened because the two trans \(\text{U}^{-}\text{O}\) bonds of the \(\text{UO}_2^{2+}\) group are shorter than the bonds to the remaining groups which form an equatorial plane.

Now to be found in the +4 oxidation state rather than +3 as in the lanthanides.

### 31.3 Compounds of the Actinides

Compounds with many non-metals are prepared, in principle simply, by heating the elements.

(a) br = brown; g = green; o = orange; r = red; y = yellow.
(b) This is the only known oxide of Es. It is expected to be the most stable for this actinide but investigation of the Eu/O system is hampered not only by low availability but also by the high $\alpha$-activity ($t_1 = 20.5$ days) which causes crystals to disintegrate. Es$_2$O$_3$ was characterized by electron diffractometry using microgram samples measuring only about 0.03 μm on edge.

but with supernumerary electrons in a delocalized conduction band.

### 31.3.1 Oxides and chalcogenides of the actinides

Oxides of the actinides are refractory materials and, in fact, ThO$_2$ has the highest mp (3390°C) of any oxide. They have been extensively studied because of their importance as nuclear fuels. However, they are exceedingly complicated because of the prevalence of polymorphism, nonstoichiometry and intermediate phases. The simple stoichiometries quoted in Table 3.15 should therefore be regarded as idealized compositions.

The only anhydrous trioxide is UO$_3$, a common form of which (γ-UO$_3$) is obtained by heating UO$_2$(NO$_3$)$_3$·6H$_2$O in air at 400°C; six other forms are also known. Heating any of these, or indeed any other oxide of uranium, in air at 800–900°C yields U$_3$O$_8$ which contains pentagonal bipyramidal UO$_7$ units and can be used in gravimetric determinations of uranium. Reduction with H$_2$ or H$_2$S leads to a series of intermediate nonstoichiometric phases (of which U$_2$O$_5$ may be mentioned) and ending with UO$_2$. Pentoxides are known also for Pa and Np. Pa$_2$O$_5$ is prepared by igniting Pa$^{4+}$ hydroxide in air, and the nonstoichiometric Np$_2$O$_5$ by treating Np$^{4+}$ hydroxide with ozone and heating the resulting NpO$_3$·H$_2$O at 300°C under vacuum.

Dioxides are known for all the actinides as far as Cf. They have the fcc fluorite structure (p. 118) in which each metal atom has CN = 8; the most common preparative method is ignition of the appropriate oxalate or hydroxide in air. Exceptions are CmO$_2$ and CfO$_2$, which require O$_2$ rather than air, and PaO$_2$ and UO$_2$, which are obtained by reduction of higher oxides.

From Pu onwards, sesquioxides become increasingly stable with structures analogous to those of Ln$_2$O$_3$ (p. 1238); BkO$_2$ is out-of-sequence but this is presumably due to the stability of the f$^7$ configuration in Bk$^{IV}$. For each actinide the C-type M$_2$O$_3$ structure (metal CN = 6) is the most common but A and B types (metal CN = 7) are often also obtainable.

Reports of monoxides formed as surface layers on the metals have not been substantiated although their existence in the vapour phase is not disputed (see pp. 237–8 of ref. 22).

The oxides are basic in character but their reactivity is usually strongly influenced by their thermal history, being much more inert if they have
been ignited. Dioxides of Th, Np and Pu are best dissolved in conc HNO₃ with added F⁻, but all oxides of U dissolve readily in conc HNO₃ or conc HClO₄ to yield salts of UO₂²⁺.

Hydroxides are not well-characterized but gelatinous precipitates, which redissolve in acid, are produced by the addition of alkali to aqueous solutions of the actinides. Those of Th⁴⁺, Pa⁵⁺, Np⁵⁺, Pu⁴⁺, Am³⁺ and Cm³⁺ are stable to oxidation but lower oxidation states of these metals are rapidly oxidized. Aqueous solutions of hexavalent U, Np and Pu yield hydrous precipitates of AnO₂(OH)₂, which contain AnO₂²⁺ units linked by OH bridges, but they are often formulated as hydrated trioxides AnO₃.xH₂O.

Actinide chalcogenides can be obtained for instance by reaction of the elements, and thermal stability decreases S > Se > Te. Those of a given actinide differ from those of another in much the same way as do the oxides. Nonstoichiometry is again prevalent and, where the actinide appears to have an uncharacteristically low oxidation state, semimetallic behaviour is usually observed.

### 31.3.2 Mixed metal oxides

Alkali and alkaline earth metallates are obtained by heating the appropriate oxides, in the presence of oxygen where necessary. For instance, the reaction

\[
\frac{5}{2} \text{Li}_2\text{O} + \text{AnO}_2 \xrightarrow{400-420°C} \text{Li}_5\text{AnO}_6 \quad \text{[An = Np, Pu]}
\]

provides a means of stabilizing Np⁷⁺ and Pu⁷⁺ in the form of isolated [AnO₆]³⁻ octahedra.

By suitable adjustment of the proportions of the reactants, An⁶⁺ species (An = U → Am) are obtained of which the “uranates” are the best known. These are of the types M₄U₂O₇, M₃UO₄, M₅UO₅ and M₅UO₆ in each of which the U atoms are coordinated by 6 O atoms disposed octahedrally but distorted by the presence of 2 short trans U–O bonds, characteristic of the uranyl UO₂²⁺ group. In view of the earlier inclusion of U in Group 6 it is interesting to note that, unlike Mo⁶⁺ and W⁶⁺, U⁶⁺ apparently does not show any tendency to form iso- or hetero-poly anions in aqueous solution.

\[
\text{M}_2\text{AnV}_2\text{O}_5, \text{M}_3\text{AnV}_4\text{O}_4 \quad \text{and} \quad \text{M}_2\text{AnV}_6\text{O}_6 \quad \text{have been characterized for An = Pa → Am. Compounds of the first of these types have the perovskite structure (p. 963), those of the second a defect-rock-salt structure (p. 242), and those of the third have structures based on hexagonally close-packed O atoms. In all cases, therefore, the actinide atom is octahedrally coordinated. It is also notable that magnetic and spectroscopic evidence shows that, for uranium, these compounds contain the usually unstable U⁵⁺ and not, as might have been supposed, a mixture of U⁴⁺ and U⁶⁺.
\]

\[
\text{BaAnIV}_2\text{O}_3, \quad \text{[An = Th → Am] all have the perovskite structure and are obtained from the actinide dioxide. In accord with normal redox behaviour, the Pa and U compounds are only obtainable if O₂ is rigorously excluded, and the Am compound if O₂ is present. Actinide dioxides also yield an extensive series of nonstoichiometric, mixed oxide phases in which a second oxide is incorporated into the fluorite lattice of the AnO₂. The UO₂/PuO₂ system, for example, is of great importance in the fuel of fast-breeder reactors.}
\]

### 31.3.3 Halides of the actinide elements

The known actinide halides are listed in Table 31.6. They range from AnX₆ to AnX₂ and their distribution follows much the same trends as have been seen already in Tables 31.3 and 31.5. Thus the hexahalides are confined to the hexafluorides of U, Np and Pu (which are volatile solids obtained by fluorinating AnF₄) and the hexachloride of U, which is obtained by the reaction of AlCl₃ and UF₆. All are powerful oxidizing agents and are extremely sensitive to moisture:

\[
\text{AnX}_6 + 2\text{H}_2\text{O} \rightarrow \text{AnO}_2\text{X}_2 + 4\text{HX}
\]

---

\(^{(a)}\)Key: Colour († indicates preparation but no report of colour); mp/°C (na indicates value not reported); coordination 9 tp = tricapped trigonal prismatic; 8 d = dodecahedral; 8 sa = square antiprismatic; 8 btp = bicapped trigonal prismatic; 8,7 = mixed 8- and 7-coordination (SrBr\(_2\) structure); 7 cc = capped octahedral; 7 pbp = pentagonal bipyramidal; 6 o = octahedral; 6 och = octahedral chain; 6 ol = octahedral layered.
UF₆ is important in the separation of uranium isotopes by gaseous diffusion (p. 1259).

Pentahalides are, perhaps surprisingly, not found beyond Np (for which the pentafluoride alone is known) but all four are known for Pa. All the pentahalides as well as PaCl₅ are polymeric and attain 7-coordination by means of double X-bridges between adjacent metal atoms (Fig. 31.6); by contrast UCl₅ and PaBr₅ consist of halogen-bridged dimeric An₂X₁₀ units, e.g. Cl₄U(μ-Cl)₂UCl₄. All are very sensitive to water, the hydrolysis of the U⁷⁺ halides being complicated by simultaneous disproportionation. Fluorides of intermediate compositions An₂F₉ (An = Pa, U) and AmF₁₇ (An = U, Pu) have also been reported. U₂F₉ is the best known; its black colour probably results from charge transfer between U⁴⁺ and U⁷⁺.

Figure 31.6 The polymeric structure of AnF₅ (An = Pa, U, Np) and PaCl₅, showing the distorted pentagonal bipyramidal coordination of the metal.

A much more extensive series is formed by the tetrahalides of which the tetrafluorides are known as far as Cf. The early tetrafluorides ThF₄ → PuF₄ are produced by heating the dioxides in HF in the presence of H₂ for PaF₄ (in order to prevent oxidation) and in the presence of O₂ for NpF₄ and PuF₄ (in order to prevent reduction). The later tetrafluorides AmF₄ → CfF₄ are obtained by heating the corresponding trifluoride with F₂. In all cases the metal is 8-coordinated, being surrounded by a slightly distorted square-antiprismatic array of F⁻ ions. The tetrachlorides (Th → Np) are prepared by heating the dioxides in CC₁₄ or a similar chlorinated hydrocarbon, whereas the tetrabromides (Th → Np) and tetraiodides (Th → U) are obtained from the elements. Eight-coordination is again common (this time dodecahedral) but a reduction to 7-coordination occurs with UBr₄ and NpBr₄, and to octahedral coordination for UI₄. AnF₄ are insoluble in water and, for Th, U and Pu at least, are precipitated as the hydrate AnF₄.₂½H₂O when F⁻ is added to any aqueous solution of AnIV⁺. AnCl₄, AnBr₄ and AnI₄ are rather hygroscopic, and dissolve readily in water and other polar solvents. An extensive coordination chemistry is based on the actinide tetrahalides, and UCl₄ is one of the best-known compounds of uranium, providing the usual starting point for most studies of U⁴⁺ chemistry.

The trihalides are the most nearly complete series, all members having been obtained for the elements U → Es and the series could no doubt be extended. Preparative methods are varied and depend in particular on the actinide involved. For the heavier actinides (Am → Cf) heating the sesquioxide or dioxide in HX is generally applicable, but the lighter actinides require reducing conditions. For NpF₃ and PuF₃ the addition of H₂ to the reaction suffices, but UF₃ is best obtained by the reduction of UF₄ with metallic U or Al. Trichlorides and tribromides of these lighter actinides can be obtained by heating the actinide hydride with HX, and the triiodides by heating the metal with I₂ (U, Np) or HI (Pu). PaI₃ is said to be obtained by heating PaI₅ in a vacuum.

With the exception of their redox properties, the actinide trihalides form a homogeneous group showing strong similarities with the lanthanide trihalides. The ionic, high-melting trifluorides are insoluble in water, from which they can be precipitated as monohydrates; at CfIII⁺ (ionic radius = 95 pm) they show the same structural change from CN 9 to CN 8 as the lanthanides do at GdIII⁺ (ionic radius = 93.8 pm). The other trihalides are all hygroscopic, water-soluble solids, many of which crystallize as hexahydrates featuring 8-coordinate cations [AnX₂(H₂O)₆]⁺. Reduction in coordination number as the cations get smaller, again parallels behaviour observed in the lanthanide trihalides but of course it occurs further along the series because of the larger size of the actinides.

Not surprisingly, in view of the stability of ThIV⁺, ThI₃ is quite different from the above
trihalides. It is rapidly oxidized by air, reduces water with vigorous evolution of $H_2$, and is probably best regarded as $[\text{Th}^{IV}, 3I^-, e^-]$. The air-sensitive $\text{ThI}_2$, which is obtained by heating $\text{ThI}_4$ with stoichiometric amounts of the metal, is similarly best formulated as $[\text{Th}^{IV}, 2I^-, 2e^-]$. It has a complicated layer structure and its lustre and high electrical conductivity indicate a close similarity with the diiodides of Ce, Pr and Gd.

Halides of truly divalent americium, however, can be prepared:

$$\text{Am} + \text{HgX}_2 \xrightarrow{400-500^\circ C} \text{AmX}_2 + \text{Hg} \ (X = \text{Cl, Br, I})$$

Like those of Eu with which they are structurally similar, these dihalides presumably owe their existence to their $f^7$ configuration. $\text{CfBr}_2$ and $\text{CfI}_2$ are also known and it seems probable that actinide dihalides would be increasingly stable as far as No if the problems of availability, etc., were overcome.

Several oxohalides$^{22}$ are also known, mostly of the types $\text{An}^{V} \text{O}_2 \text{X}_2$, $\text{An}^{V} \text{O}_2 \text{X}$, $\text{An}^{IV} \text{O}_2 \text{X}_2$ and $\text{An}^{III} \text{O}_2 \text{X}$, but they have been less thoroughly studied than the halides. They are commonly prepared by oxygenation of the halide with $\text{O}_2$ or $\text{Sb}_2\text{O}_3$, or in case of $\text{AnOX}$ by hydrolysis (sometimes accidental) of $\text{AnX}_3$. As is to be expected, the higher oxidation states are formed more readily by the lighter actinides; thus $\text{AnO}_2 \text{X}_2$, apart from the fluoro compounds, are confined to $\text{An} = \text{U}$. Conversely the lower oxidation states are favoured by the heavier actinides (from Am onwards).

### 31.3.4 Magnetic and spectroscopic properties$^{3,11}$

As the actinides are a second $f$ series it is natural to expect similarities with the lanthanides in their magnetic and spectroscopic properties. However, while previous treatments of the lanthanides (p. 1242) provide a useful starting point in discussing the actinides, important differences are to be noted. Spin–orbit coupling is again strong ($2000-4000 \text{ cm}^{-1}$) but, because of the greater exposure of the $5f$ electrons, crystal-field splittings are now of comparable magnitude and $J$ is no longer such a good quantum number. Furthermore, as already mentioned (p. 1266), the energy levels of the $5f$ and $6d$ orbitals are sufficiently close for the lighter actinides at least, to render the $6d$ orbitals accessible. As a result, rigorous treatments of electronic properties must consider each actinide compound individually. They must allow for the mixing of "$J$ levels" obtained from Russell–Saunders coupling and for the population of thermally accessible excited levels. Accordingly, the expression $\mu_e = g\sqrt{J(J+1)}$ is less applicable than for the lanthanides: the values of magnetic moment obtained at room temperature roughly parallel those obtained for compounds of corresponding lanthanides (see Table 30.6), but they are usually appreciably lower and are much more temperature-dependent.

The electronic spectra of actinide compounds arise from three types of electronic transition:

(i) $f \rightarrow f$ transitions (see p. 1243). These are orbitally forbidden, but the selection rule is partially relaxed by the action of the crystal field in distorting the symmetry of the metal ion. Because the field is stronger than for the lanthanides, the bands are more intense by about a factor of 10 and, though still narrow, are about twice as broad and are more complex than those of the lanthanides. They are observed in the visible and ultraviolet regions and produce the colours of aqueous solutions of simple actinide salts as given in Table 31.3.

(ii) $5f \rightarrow 6d$ transitions. These are orbitally allowed and give rise to bands which are therefore much more intense than those of type (i) and are usually rather broader. They occur at lower energies than do the $4f \rightarrow 5d$ transitions of the lanthanides but are still normally confined to the ultraviolet region and do not affect the colour of the ion.

(iii) Metal→ligand charge transfer. These again are fully allowed transitions and
produce broad, intense absorptions usually found in the ultraviolet but sometimes trailing into the visible region. They produce the intense colours which characterize many actinide complexes, especially those involving the actinide in a high oxidation state with readily oxidizable ligands.

In view of the magnitude of crystal-field effects it is not surprising that the spectra of actinide ions are sensitive to the latter’s environment and, in contrast to the lanthanides, may change drastically from one compound to another. Unfortunately, because of the complexity of the spectra and the low symmetry of many of the complexes, spectra are not easily used as a means of deducing stereochemistry except when used as “fingerprints” for comparison with spectra of previously characterized compounds. However, the dependence on ligand concentration of the positions and intensities, especially of the charge-transfer bands, can profitably be used to estimate stability constants.

### 31.3.5 Complexes of the actinide elements

Because of the technical importance of solvent extraction, ion-exchange and precipitation processes for the actinides, a major part of their coordination chemistry has been concerned with aqueous solutions, particularly that involving uranium. It is, however, evident that the actinides as a whole have a much stronger tendency to form complexes than the lanthanides and, as a result of the wider range of available oxidation states, their coordination chemistry is more varied.

#### Oxidation state VI

Fluorocomplexes of $\text{U}^{VI}$ are known of which $(\text{NH}_4)_4\text{UF}_{10}$ with a probable coordination number of ten is notable. Otherwise, apart from $\text{UO}_3$ and the $\text{An}^{VI}$ halides already discussed, this oxidation state is dominated by the dioxo, or “actinyl” $\text{AnO}_2^{2+}$ ions which are found both in aqueous solutions and in solid compounds of $\text{U}$, $\text{Np}$, $\text{Pu}$ and $\text{Am}$. These dioxo ions retain their identity throughout a wide variety of reactions and are present, for instance, in the oxohalides $\text{AnO}_2\text{X}_2$. The $\text{An}–\text{O}$ bond strength and the resistance of the group to reduction decreases in the order $\text{U} > \text{Np} > \text{Pu} > \text{Am}$. Thus yellow uranyl salts are the most common salts of uranium and are the final products when other compounds of the element are exposed to air and moisture. The nitrate is the most familiar and has the remarkable property, utilized in the extraction of $\text{U}$, of being soluble in nonaqueous solvents such as tributyl phosphate. On the other hand, the formation of $\text{AmO}_2^{2+}$ requires the use of such strong oxidizing agents as peroxodisulfate, $\text{S}_2\text{O}_8^{2–}$. Similarly, whereas the oxofluorides $\text{AnO}_2\text{F}_2$ are known for $\text{U}$, $\text{Np}$, $\text{Pu}$ and $\text{Am}$, only $\text{U}$ forms the corresponding oxochloride and oxobromide, $\text{Cl}^–$ and $\text{Br}^–$ reducing $\text{AmO}_2^{2+}$ to $\text{Am}^{V}$ species.

In aqueous solutions hydrolysis of the actinyl ions is important and such solutions are distinctly acidic. The reactions are complicated but, at least in the case of $\text{UO}_2^{2+}$, it appears that loss of $\text{H}^+$ from coordinated $\text{H}_2\text{O}$ is followed by polymerization involving $–\text{OH}–$ bridges and yielding species such as $[\text{(UO}_2\text{(OH)}])^+$, $[\text{(UO}_2\text{)}_2\text{(OH)}_2]^{2+}$ and $[\text{(UO}_2\text{)}_3\text{(OH)}_3]^{3+}$.

---

Actinyl ions seem to behave rather like divalent, class-a, metal ions of smaller size (or metal ions of the same size but higher charge) and, accordingly, they readily form complexes with $F^-$ and $O$-donor ligands such as $\text{OH}^-$, $\text{SO}_4^{2-}$, $\text{NO}_3^-$ and carboxylates.\(^{31}\) The $\text{O}--\text{An}--\text{O}$ groups are in all cases linear, and coordination of a further 4, 5 or 6 ligands is possible in the equatorial plane. Octahedral, pentagonal bipyramidal, and hexagonal bipyramidal geometries result;\(^{32}\) some examples are shown in Fig. 31.7. These ligands lying in the plane may be neutral molecules such as $\text{H}_2\text{O}$, $\text{OPR}_3$, $\text{OAsR}_3$, py or the anions mentioned above, many of which are bidentate.

The axial $\text{O}--\text{An}$ bonds are clearly very strong. They cannot be protonated and are nearly always shorter than the equatorial bonds. In the case of $\text{UO}_2^{2+}$, for instance, it is likely that the $\text{U}--\text{O}$ bond order is even greater than 2, since the $\text{U}--\text{O}$ distance is only about 180 pm; in spite of the difference in the ionic radii of the metal ions ($\text{U}^{VI} = 73$ pm, $\text{Os}^{VI} = 54.5$ pm), this is close to that of the $\text{Os}--\text{O}$ double bond found in the isostructural, osmyl group (175 pm, see p. 1085). It is usually assumed that combinations of appropriate metal 6$\text{d}$ and 5$\text{f}$ orbitals overlap with the three $\text{p}$ orbitals (or two $\text{p}$ and one $\text{sp}$ hybrid) of each oxygen to produce one $\sigma$ and two $\pi$ bonds, i.e. $\text{O} \equiv \text{U} \equiv \text{O}$. This interpretation implies that the change from bent to linear geometries in comparing $\text{MoO}_2^{2+}$ (p. 1024) and $\text{UO}_2^{2+}$ is due to the involvement of empty $\text{f}$ orbitals in the latter case. More pertinently, the unstable Th$\text{O}_2$ which is isoelectronic with $\text{UO}_2^{2+}$, is bent (angle $\text{O}--\text{Th}--\text{O} 122^\circ$) and the difference has been convincingly explained in a relativistic extended Hückel treatment, on the basis that $\text{d}$-orbitals favour bent and $\text{f}$-orbitals linear geometries; in $\text{UO}_2^{2+}$ the 6$\text{d}$ orbitals are lower in energy than the 5$\text{f}$ whereas in Th$\text{O}_2$ the order is reversed.\(^{33}\)

**Oxidation state V**

In aqueous solution the $\text{AnO}_2^+$ ions ($\text{An} = \text{Pa} \rightarrow \text{Am}$) may be formed, at least in the absence of strongly coordinating ligands. They are linear cations like $\text{AnO}_2^{2+}$ but are less persistent and, indeed, it is probable that $\text{PaO}_2^+$ should be formulated as $[\text{PaO(OH)}_2]^+$ and $[\text{PaO(OH)}]^2+$. Hydolysis is extensive in aqueous solutions of $\text{Pa}^\text{V}$ and colloidal hydroxo species are formed which readily lead to precipitation of

---

32 See pp. 1424–31 of ref. 3.
§31.3.5

Complexes of the actinide elements

$\text{Pa}_2\text{O}_5\cdot n\text{H}_2\text{O}$. $\text{NpO}_2^+$ in aqueous $\text{HClO}_4$ is stable but $\text{UO}_2^{2+}$, $\text{PuO}_2^+$ and $\text{AmO}_2^+$ are unstable to disproportionation:

$$2\text{UO}_2^{2+} \leftrightarrow \text{U}^{IV} + \text{UO}_2^{2+}$$

(very rapid except in the range $\text{pH} 2-4$)

$$2\text{PuO}_2^{2+} \leftrightarrow \text{Pu}^{IV} + \text{PuO}_2^{2+}$$

and then $\text{PuO}_2^{2+} + \text{Pu}^{IV} \leftrightarrow \text{Pu}^{III} + \text{PuO}_2^{2+}$.†

Likewise:

$$3\text{AmO}_2^{2+} \leftrightarrow \text{Am}^{III} + 2\text{AmO}_2^{2+}$$

Though the low charge on $\text{AnO}_2^+$ ions precludes the formation of very stable complexes, and disproportionation into $\text{An}^{IV}$ and $\text{An}^{VI}$ species is common, a number of complexes of $\text{NpO}_2^+$ have been prepared, several containing the pentagonal bipyramidal $\{\text{NpO}_2(\text{SO}_4)_2\text{L}\}$ unit. In other cases, strongly coordinating ligands are able to replace the oxygen atoms of the $\text{AnO}_2^+$ ions and so inhibit disproportionation where this might otherwise occur. $\text{F}^-$ is notable in this respect and complex ions, $\text{AnF}_6^-$ ($\text{An} = \text{Pa}, \text{U}, \text{Np}, \text{Pu}$), $\text{PaF}_7^{2-}$ and $\text{PaF}_8^{3-}$ can be precipitated from aqueous HF solutions. However, in nonaqueous solvents, preparations such as the oxidation of $\text{M}^{IV}$ and $\text{AnF}_2$ by $\text{F}_2$ are more common for $\text{U}$, $\text{Np}$ and $\text{Pu}$ and extend the range of complex ions to include $\text{AnF}_7^{2-}$ ($\text{An} = \text{U}, \text{Np}, \text{Pu}$) and $\text{AnF}_8^{3-}$ ($\text{An} = \text{U}, \text{Np}$). The stereochemistries of these anions are dependent on the particular counter cation as well as on $\text{An}$, and involve 6-, 7-, 8- and 9-coordination. The most remarkable of these complexes are the compounds $\text{Na}_3\text{AnF}_8$ ($\text{An} = \text{Pa}, \text{U}, \text{Np}$) in which the actinide ion is surrounded by 8 $\text{F}^-$ at the corners of a nearly perfect cube in spite of the large inter-ligand repulsions which this entails.

† In the diagram of volt-equivalent versus oxidation state of $\text{Pu}$ (Fig. 31.5) the oxidation states $\text{III}$ to $\text{VI}$ inclusive lie virtually on a straight line. It follows that if either $\text{Pu}^{IV}$ or $\text{Pu}^{V}$ is dissolved in water, disproportionations are thermodynamically feasible, and within a matter of hours mixtures of $\text{Pu}$ in all four oxidation states are obtained.

Finally, the alkoxides $\text{U(OR)}_5$ must be mentioned. Although easily hydrolysed, they are thermally stable and unusually resistant to disproportionation. They are usually dimeric, $[\text{RO}_3\text{U}(\mu-\text{OR})_2\text{U(OH)}_4]$, and are best obtained by the reactions:

$$2[\text{U(OEt)}_4] \xrightarrow{\text{Br}_2 + 2\text{NaOEt}} \xrightarrow{(-2\text{NaBr})} [\text{U(OEt)}_3\text{L}] \xrightarrow{10\text{ROH}} [\text{U(OR)}_3\text{L}]$$

Oxidation state $\text{IV}$

This is the only important oxidation state for $\text{Th}$, and is one of the two for which $\text{U}$ is stable in aqueous solution; it is moderately stable for $\text{Pa}$ and $\text{Np}$ also. In water $\text{Pu}^{IV}$, like $\text{Pu}^{V}$, disproportionate into a mixture of oxidation states $\text{III}$, $\text{IV}$, $\text{V}$ and $\text{VI}$, while $\text{Am}^{IV}$ not only disproportionate into $\text{Am}^{III} + \text{Am}^{V}$ but also (like the strongly oxidizing $\text{Cm}^{IV}$) undergoes rapid self-reduction due to its $\alpha$-radioactivity. As a result, aqueous $\text{Am}^{IV}$ and $\text{Cm}^{IV}$ require stabilization with high concentrations of $\text{F}^-$ ion. Berkelium($\text{IV}$), though easily reduced, clearly has an enhanced stability, presumably due to its $f^7$ configuration, and the only other $+4$ ion is $\text{Cf}^{IV}$, found in the solids $\text{CfF}_4$ and $\text{CfO}_2$.

In aqueous solutions the hydrated cations are probably 8- or even 9-coordinated and, because they are the most highly charged ions in the actinide series, they have the greatest tendency to split-off protons and so function as quite strong acids (slightly stronger in most cases than $\text{H}_2\text{SO}_3$). This hydrolysis is followed by polymerization which has been most extensively studied in the case of $\text{Th}$. The aquated, dimeric ion, $[\text{Th}_2(\text{OH})_2]^{6+}$, which probably involves two $\text{OH}$ bridges, seems to predominate even in quite acidic solutions, but in solutions more alkaline than pH 3 polymerization increases considerably and eventually yields an amorphous precipitate of the hydroxide. Just before precipitation it is noticeable that the polymerization process slows down and equilibrium may take weeks to attain.

The Actinide and Transactinide Elements (Z = 90 – 112)  Ch. 31

The same effect is found also with Pu IV where the persistence of polymers, even at acidities which would prevent their formation, can cause serious problems in the reprocessing of nuclear fuels.

The isolation of An IV salts with o xoanions is limited by hydrolysis and redox compatibility. Thus, with the possible exception of Pu(CO3)2, carbonate ions furnish only basic carbonates or carbonato complexes such as [An(CO3)5]2– (An = Th, U, Pu). Stable tetramnitrates are isolable only for Th and Pu, but Th(NO3)4.5H2O is the most common salt of Th and is notable as the first confirmed example of 11-coordination (Fig. 31.8(a)). Pu(NO3)4.5H2O is isomorphous, and stabilization of Pu IV by strong nitric acid solutions is crucial in the recovery of Pu by solvent extraction. O-donor ligands such as dmso, Ph3PO and C5H5NO form adducts, of which [Th(NO3)4(OPPh3)2] is known to have a 10-coordinate structure like its Ce IV analogue (Fig. 30.5b, p. 1245) and [Th(C5H5NO)6(NO3)2]2+ has a 10-coordinate distorted bicapped antiprismatic structure.36

Anionic complexes [An(NO3)6]2– (An = Th, U, Np, Pu) are also obtained, that of Th, and probably the others, having bidentate NO3– ions forming a slightly distorted icosahedron similar to that of the Ce IV analogue (see Fig. 30.5a). Th(ClO4)4.4H2O is readily obtained from aqueous solutions but attempts to prepare the U IV salt have produced a green explosive solid of uncertain composition. Hydrated sulfates are known for Th, U, Np and Pu. That of Np is of uncertain hydration but the others can be prepared with both 4H2O and 8H2O, PuSO4.4H2O having possible use as an analytical standard.

The actinides provide a wider range of complexes in their +4 oxidation state than in any other, and these display the usual characteristics of actinide complexes, namely high coordination numbers and varied geometry. Complexes with halides and with O-donor chelating ligands are particularly numerous. The main fluoro-complexes are of the types [AnF5]–, [AnF6]2–, [AnF7]3–, [AnF8]4– and [An6F31]7– which are nearly all known for An = Th → Bk. Their stoichiometries have not all been determined but, in some cases at least, are known

Figure 31.8  (a) Eleven-coordinate Th in Th(NO3)4.5H2O: av. Th–O (of NO3) = 257 pm; av. Th–O (of H2O) = 246 pm. (b) The 10-coord. bicapped square antiprismatic anion in K4[Th(C2O4)4].4H2O. Note that two pyramidal (267 pm) and three equatorial edges (276 pm) are spanned by oxalate groups, but none of the longer edges of the squares (311 pm). The oxalate groups on the pyramidal edges are actually quadridentate, being coordinated also to adjacent Th atoms.

to depend on the counter cation. For instance, $\text{UF}_6^{2-}$ has a distorted cubic structure in its $\text{K}^+$ salt and a distorted dodecahedral structure in its $\text{Rb}^+$ salt.

Several carboxylates, both simple salts and complex anions, have been prepared often as a means of precipitating the $\text{An}^{IV}$ ion from solution or, as in the case of simple oxalates, in order to prepare the dioxides by thermal decomposition. In $\text{K}_4[\text{Th}(\text{C}_2\text{O}_4)_4].4\text{H}_2\text{O}$ the anion is known to have a 10-coordinate, bicapped square antiprismatic structure (Fig. 31.8b). $\beta$-diketonates are precipitated from aqueous solutions of $\text{An}^{IV}$ and the ligand by addition of alkali, and nearly all are sublimable under vacuum. $[\text{An}(\text{acac})_4]$, ($\text{An} = \text{Th, U, Np, Pu}$) are apparently dimorphic but both structures are based on an 8-coordinate, distorted square antiprism.

Complexes with $\text{S}$-donor ligands are generally less stable and more liable to hydrolysis than those with $\text{O}$-donors but can be obtained if the ligand is anionic and chelating. Diethyldithiocarbamates $[\text{An}(\text{S}_2\text{CNEt}_2)_4]$ ($\text{An} = \text{Th, U, Np, Pu}$) are the best known and possess an almost ideal dodecahedral structure.

Finally, the borohydrides $\text{An}($B$\text{H}_4)_4$ must be mentioned. Those of $\text{Th}$ and $\text{U}$ were originally prepared as part of the Manhattan Project and those of $\text{Pa}$, $\text{Np}$ and $\text{Pu}$ have been prepared more recently, all by the general reaction

$$\text{AnF}_4 + 2\text{Al}(\text{B}$H$_4)_3 \rightarrow \text{An}($B$\text{H}_4)_4 + 2\text{AlF}_2\text{BH}_4$$

The compounds are isolated by sublimation from the reaction mixture. Perhaps surprisingly the compounds fall into two quite distinct classes. Those of $\text{Np}$ and $\text{Pu}$ are unstable, volatile, monomeric liquids which at low temperatures crystallize with the 12-coordinate structure of $\text{Zr}($B$\text{H}_4)_4$ (Fig. 21.7, p. 969). The borohydrides of $\text{Th}$, $\text{Pa}$ and $\text{U}$, on the other hand, are thermally more stable and less reactive solids. They possess a curious helical polymeric structure in which each $\text{An}$ is surrounded by 6 $\text{BH}_4^-$ ions, 4 being bridging groups attached by 2 $\text{H}$ atoms and 2 being $\text{cis}$ terminal groups attached by 3 $\text{H}$ atoms. The coordination number of the actinide is therefore 14 and the stereochemistry may be described as bicapped hexagonal antiprismatic.

**Oxidation state III**

This is the only oxidation state which, with the possible exception of $\text{Pa}$, is displayed by all actinides. From $\text{U}$ onwards, its resistance to oxidation in aqueous solution increases progressively with increase in atomic number and it becomes the most stable oxidation state for $\text{Am}$ and subsequent actinides (except $\text{No}$ for which the $\text{f}^{14}$ configuration confers greater stability on the $+2$ state).

Amber $\text{Th}^{3+}(\text{aq})$ has recently been prepared from aqueous solutions of $\text{ThCl}_4$ and $\text{HN}_3$, and is stable for over 1 h before being oxidized by water. $\text{U}^{III}$ can be obtained by reduction of $\text{UO}_2^{2+}$ or $\text{U}^{IV}$, either electrolytically or with Zn amalgam, but is thermodynamically unstable to oxidation not only by $\text{O}_2$ and aqueous acids but by pure water also. It is nevertheless possible to crystallize double sulfates or double chlorides from aqueous solution and these can then be used to prepare other $\text{U}^{III}$ complexes in nonaqueous solvents. Crystallographic data are not plentiful but it has been shown that in $(\text{NH}_4)_2\text{U}^{III}($$\text{SO}_4)_2(\text{H}_2\text{O})_4$ each $\text{SO}_4^{2-}$ is bidentate to one $\text{U}$ and monodentate to a second. Three $\text{H}_2\text{O}$ complete a coordination sphere of 9 oxygens for each uranium with a geometry intermediate between tricapped trigonal prismatic and monocapped square antiprismatic. A number of cationic amide complexes are also known for which infrared evidence suggests

---

the low symmetry coordination of 8 oxygen atoms to each uranium atom.

Instability also limits the number of complexes of NpIII and PuIII but for AmIII the number so far prepared is apparently limited mainly by unavailability of the element. As has already been pointed out, the problem becomes still more acute as the series is traversed. While it is clear that lanthanide-like dominance by the tervalent state occurs with the actinides after Pu, the experimental evidence though compelling, is understandably sparse, being largely restricted to solvent extraction and ion-exchange behaviour.\(^{[40]}\)

**Oxidation state II**

This state is found for the six elements Am and Cf → No, though in aqueous solution only for Fm, Md and No. However, for No, alone amongst all the f-series elements, it is the normal oxidation state in aqueous solution. The greater stabilization of the +2 state at the end of the actinides as compared to that at the end of the lanthanides which this implies, has been taken\(^{[40]}\) to indicate a greater separation between the 5f and 6d than between the 4f and 5d orbitals at the ends of the two series. This is the reverse of the situation found at the beginnings of the series (p. 1266).

Reports of the observation of the +1 oxidation state in aqueous solutions of Md have not been substantiated despite attempts in several major laboratories, and it has been concluded that MdI does not exist in either aqueous or ethanolic solutions.\(^{[41]}\)

### 31.3.6 Organometallic compounds of the actinides\(^{[42]}\)

The growth of organoactinide chemistry, like that of organolanthanide chemistry, is comparatively recent. Attempts in the 1940s to prepare volatile carboxyls and alkyls of uranium for isotopic separations were unsuccessful though, as with the lanthanides, simple carboxyls of uranium have since been obtained in argon matrices quenched to 4 K. Subsequent work has mainly centred on cyclopentadienyls and, to a lesser extent, cyclooctatetraenyls; \(\sigma\)-bonded alkyl and aryl derivatives of the cyclopentadienyls have also been obtained. In general, these compounds are thermally stable, sublimable, but extremely air-sensitive solids which are sometimes watersensitive also. Their bonding is evidently more covalent than that in organolanthanides, presumably because of the involvement of 5f orbitals, and relativistic effects.

The cyclopentadienyls are of the three main types: (a) \([\text{An}^{III}(\text{C}_5\text{H}_5)_3]\), (b) \([\text{An}^{IV}(\eta^5\cdot\text{C}_5\text{H}_5)_2]\) and (c) derivatives of the type \([\text{An}^{IV}(\eta^5\cdot\text{C}_5\text{H}_5)_2\text{X}]\) where X is a halogen atom, an alkyl or alkoxy group, or BH4.

(a) \([\text{An}^{III}(\text{C}_5\text{H}_5)_3]\) (An = Th → Cf): the uranium compound is prepared directly from UCl3 and K(C5H5) but those of the heavier actinides are best made by the reaction:

\[
2\text{AnCl}_3 + 3\text{Be(C}_5\text{H}_5)_2 \xrightarrow{65^\circ C} 2\text{An(C}_5\text{H}_5)_3 + 3\text{BeCl}_2
\]

Complete structural data are sparse but X-ray diffraction patterns suggest that both \(\eta^5\) and \(\eta^1\) bonding modes are involved (cf. Sm(C5H5)3 p. 1248). In \([\text{Th}^{III}(\eta^5\cdot\text{C}_5\text{H}_5(\text{SiMe}_3)_2)_3]\) the centres of three rings form a trigonal plane around the Th atom.\(^{[43]}\) The spectroscopic properties of this blue paramagnetic compound imply a 6d\(^1\) rather than 5f\(^1\) configuration.\(^{[44]}\)

(b) \([\text{An}^{IV}(\text{C}_5\text{H}_5)_4]\) (An = Th → Np): the Pa compound is prepared by treating PaCl4 with Be(C5H5)2 but the general method of preparation is:

\[
\text{AnCl}_4 + 4\text{K(C}_5\text{H}_5) \xrightarrow{\text{reflux in C}_6\text{H}_6} [\text{An(C}_5\text{H}_5)_4] + 4\text{KCl}
\]

---

\(^{[40]}\) See, for instance, E. K. Hulet, ref. 37, pp. 239–63.

[M(C₅H₅)₄] (M = Th, U) contain four identical $n^5$ rings arranged tetrahedrally around the metal atom (Fig. 31.9). The corresponding compounds of Pa and Np are probably the same since all four compounds have very similar nmr and ir spectra.

![Structure of [An($n^5$-C₅H₅)₄]](image)

**Figure 31.9** Structure of [An($n^5$-C₅H₅)₄] showing the tetrahedral arrangement of the four rings around the metal atom.

(c) Halide derivatives: the most plentiful are of the type [AnIV(C₅H₅)₃X] (An = Th, Pa, U, Np); they can be prepared by the general reaction:

$$\text{An}^4 + 3\text{M}^1(C₅H₅) \rightarrow [\text{An}(C₅H₅)₃X] + 3\text{M}^1X$$

Indeed, the first report of an organoactinide was that of the pale brown [U(C₅H₅)₂Cl] by L. T. Reynolds and G. Wilkinson in 1956. They showed that, unlike Ln(C₅H₅)₃, this compound does not yield ferrocene on reaction with FeCl₂, suggesting greater covalency in the bonding of C₅H₅⁻ to UIV than to LnIII.

Replacement of Cl in [U(C₅H₅)₂Cl] and [Th(C₅H₅)₂Cl], by other halogens or by alkoxy, alkyl, ary1 or BH₄ groups, provides the most extensive synthetic route in this field. An essentially tetrahedral disposition of three ($n^5$-C₅H₅) rings and the fourth group around the metal appears to be general. The alkyl and aryl derivatives [An($n^5$-C₅H₅)₃R] (An = Th, U), are of interest as they provide a means of investigating the An–C σ bond, and mechanistic studies of their thermal decomposition (thermolysis) have been prominent. The precise mechanism is not yet certain but it is clearly not β-elimination (of an olefin, see p. 926) since the eliminated molecule is RH, the H of which originates from a cyclopentadienyl ring. The decomposition of the Th compounds are cleaner than those of U and a crystalline product can be isolated from the thermolysis at 170°C of a solution of [Th($n^5$-C₅H₅)₃Bu"]. This product is a dimer with the 2 Th atoms bridged by a pair of ($n^5$, $η^1$-C₅H₅) rings, i.e. [Th($n^5$-C₅H₅)$_2$-µ-($n^5$, $η^1$-C₅H₅)]₂. This remarkable bridge system is like that in niobocene (Fig. 22.12a, p. 1001) but each Th has two additional ($n^5$-C₅H₅) rings instead of one ($n^5$-C₅H₅) and an H atom.

It has not so far been possible to obtain either AnIII or AnIV compounds with three C₅Me₅ rings around a single metal atom. However, [M($n^5$-C₅Me₅H)₃Cl] (M = Th, U) and [U($n^5$-C₅Me₅P)₃Cl] have been prepared.

The complexes [An($n^5$-C₅H₅)₂] of cyclooctatetraene (cot) have been prepared for An = Th → Pu by the reactions:

$$\text{AnCl}_4 + 2\text{K}_2\text{C}_8\text{H}_8 \xrightarrow{\text{thf}} [\text{An}(\text{C}_8\text{H}_8)₂] + 4\text{KCl}$$

(An = Th → Np)

and

$$[\text{NEt}_4][\text{PuCl}_6] + 2\text{K}_2\text{C}_8\text{H}_8 \xrightarrow{\text{thf}} [\text{Pu}(\text{C}_8\text{H}_8)₂] + 4\text{KCl} + 2[\text{NEt}_4]\text{Cl}$$

followed by sublimation under vacuum. They are “sandwich” molecules with parallel and eclipsed rings (see Fig. 19.31, p. 942). This structure is strikingly similar to that of ferrocene (Fig. 19.27, p. 937), and extensive discussions on the nature of the metal-ring bonding suggests that this too is very similar. In order to emphasise these resemblances with the d-series cyclopentadienyls, the names “uranocene”, etc., have been coined. Although thermally stable, these compounds are extremely sensitive to air and, except for uranocene, are also decomposed by water.

---

However, uranocene can be made more air-stable by use of sufficiently bulky substituents, and 1,3,5,7-tetraphenylcyclo-octatetraene yields the completely air-stable \([U(\eta^8-C_8H_8Ph_4)_2]\), in which the parallel ligands are virtually eclipsed but the phenyl substituents staggered and rotated on average 42° out of the C_8 ring plane (Fig. 31.10).

Figure 31.10 The structure of \([U(\eta^8-C_8H_8Ph_4)_2]\).

### 31.4 The Transactinide Elements \((Z = 104–112)\)

#### 31.4.1 Introduction

The addition of nine further elements \((Z = 104–112)\) to the Periodic Table during the past three decades has involved outstanding feats of intellectual and experimental virtuosity. Some of the discoveries have been widely accepted but others have been hotly contested and this has led to distressingly persistent disagreements concerning priority. For this reason IUPAC and IUPAP set up a neutral international group in 1987 to establish “the criteria that must be satisfied for the discovery of a new element to be recognised” and to apply these criteria to questions of priority in the discovery of the transfermium elements. Some of the conclusions of this group have already been briefly mentioned (see Table 31.1). Their detailed Reports were accepted by both IUPAC and IUPAP and the group’s final recommendations, which form the basis of this Section, have been very widely though not universally accepted by the scientific community. Many subtle and difficult points are involved and the full reports repay careful reading. It is also worth noting that the word discovery is something of a misnomer in this context; synthesis and characterization of new elements would perhaps be a better description.

The separate question of names and symbols for the new elements has, unfortunately, taken even longer to resolve, but definitive recommendations were ratified by IUPAC in August 1997 and have been generally accepted. It is clearly both unsatisfactory and confusing to have more than one name in current use for a given element and to have the same name being applied to two different elements. For this reason the present treatment refers to the individual elements by means of their atomic numbers. However, to help readers with the nomenclature used in the references cited, a list of the various names that are in use or that have been suggested from time to time is summarised in Table 31.7.

Two general types of nuclear reaction have been used to produce transfermium elements. The first type, hot fusion reactions, uses accelerated light particles with \(Z\) in the range 5–10 (typically 5B, 6C, 7N, 8O or 10Ne) to bombard targets with \(Z = 92–98\) (typically 92U, 94Pu, 95Am, 96Cm or 98Cf). This method can be used effectively up to about element 106 but, increasingly, the compound nucleus is formed with such high excitation energy that many particles, including charged ones, evaporate off before the desired product nucleus is reached. To solve this problem the group at Dubna suggested an ingenious alternative route, cold fusion, which exploits the fact that nuclei such as 82Pb or 83Bi have high binding energies due to closed nuclear shells. If these nuclei are bombarded with moderately heavy ions which are preferably also near closed nuclear shells (e.g. 24Cr, 26Fe or 28Ni) at energies just above the Coulomb

(a) The hyphens in the systematic names have been inserted here to assist comprehension and pronunciation; they are not part of the names. The roots nil, un, bi, etc. were chosen to allow a unique set of three-letter symbols to be generated for any (atomic) number.

---

31.4.2 Element 104

The first (inconclusive) work bearing on the synthesis of element 104 was published by the Dubna group in 1964. However, the crucial Dubna evidence (1969–70) for the production of element 104 by bombardment of $^{94}$Pu with $^{10}$Ne came after the development of a sophisticated method for rapid in situ chlorination of the product atoms followed by their gas-chromatographic separation on an atom-by-atom basis. This was a heroic enterprise which combined cyclotron nuclear physics and chemical separations. As we have seen, the actinide series of elements ends with $^{103}$Lr. The next element should be in Group 4 of the transition elements, i.e. a heavier congenor of Ti, Zr and Hf.* As such it would be expected to have a chloride which is significantly more volatile than those of the actinide elements. After extensive preliminary work to develop and prove the method, the recoil products emitted from the target were chlorinated with a stream of gaseous NbCl$_5$ or ZrCl$_4$ within a fraction of a second from the instant of formation of the new atom, and then separated gas-chromatographically in a 4-metre-long quartz tube at either 250°C or 300°C before being detected by spontaneous fission. When part of the tube was replaced by a KCl capillary the activity in the detection zone ceased, because of the formation of an involatile complex, presumably K$_2$[104]Cl$_6$. As no nucleus with $Z > 104$ can be formed by bombarding $^{94}$Pu with $^{10}$Ne, and no spontaneously fissioning atom with $Z < 104$ forms a volatile chloride, the new activity must be due to element 104. During the later stages of this work, and essentially contemporaneously with it, the Berkeley group established the reactions $^{249}$Cf($^{12}$C,4$n$)$^{257}$104, $^{249}$Cf($^{13}$C,3$n$)$^{259}$104 and $^{248}$Cm($^{16}$O,6$n$)$^{258}$104 by elegant work which included the observation of generic parent–daughter $\alpha$-decays to the known isotopes $^{253}$102 and $^{255}$102. It was concluded that credit for the discovery of element 104 should be shared between the groups at Dubna and Berkeley. Detailed references to the original papers, and an assessment of the many scientific points involved are in ref. 5. The name rutherfordium now recommended and adopted by IUPAC for element 104 was first suggested by the Berkeley group in 1969.

---

* A happy consequence of nuclear systematics is that element 104 is in Group 4, element 105 is in Group 5, etc. This mnemonic holds to the end of the transition series at element 112 and presumably beyond; it can be compared with the similar relation between the group numbers of the post-transition main-group elements (13–18) and the group numbers of the preceding transition elements (3–8).
Nine isotopes of element 104 are now known with certainty in the mass range 255–264 and a tenth, 254Rf, is possible. They have half-lives in the range 7 ms–65 s and can only be produced slowly one atom at a time. This clearly restricts chemical studies, though ingenious techniques have been developed to overcome some of the problems.\(^{(47)}\) It has been found that element 104 is indeed a Group 4 homologue and tends to resemble Zr and Hf rather than Th in its aqueous solution chemistry and extractability. The predominant oxidation state is +4 and complexes such as RfCl\(_6\)^{2−} have been confirmed. Distribution coefficients obtained for its extraction into thenoyltrifluoroacetone (TTA) lead to an ionic radius of 102 pm for 8-coordinated Rf, between those of Th and Pu. Gas-phase studies of element 104 by isothermal chromatography indicate that its bromides are more volatile than those of Hf, and that the chlorides of both Hf and Rf are more volatile than the bromides.\(^{(48,49)}\)

### 31.4.3 Element 105

Attempts at the synthesis of element 105 were first reported from Dubna in 1968 but it was a further two years before cyclotron physics, combined with a thermal-gradient variant of gas-phase chromatography, plus parent–daughter α-particle generic relations finally succeeded in convincingly establishing its formation. The main reactions studied were \(^{243}\text{Am}(^{22}\text{Ne},4\text{n})^{261}105\) and \(^{243}\text{Am}(^{22}\text{Ne},5\text{n})^{260}105\). During the later stages of this work the Berkeley group published a convincing synthesis via \(^{249}\text{Cf}(^{15}\text{N},4\text{n})^{260}105\) which was also secured, amongst much other evidence, by an α-particle generic relation with \(^{256}103\). The independent work from the two laboratories was essentially contemporaneous and credit for the discovery of element 105 was shared.\(^{(5)}\) The name now internationally accepted for element 105 is dubnium.

The pioneering gas thermochromatographic studies of I. Zvara and his group in the mid-1970s suggested that element 105 was a homologue of Nb and Ta. No further work on its chemistry was reported until 1988 when the first studies of aqueous solutions of element 105 were published.\(^{(50)}\) Using the 35 s isotope formed by the reaction \(^{249}\text{Bk}(^{18}\text{O},5\text{n})^{267}105\), some 800 manual experiments (taking about 50 s each) were performed. It was found that, after fuming with concentrated nitric acid, atoms of element 105, dubnium, sorbed on glass surfaces just like the Group 5 elements Nb and Ta but unlike Zr and Hf in the preceding Group. Extraction studies also confirmed the affinity to Group 5, though dubnium appeared closer to Nb than to Ta, perhaps due to the influence of relativistic effects. Later work using computer-controlled procedures reduced the timescale to less than 40 s per experiment;\(^{(49)}\) halide complexation and extraction behaviour showed element 105 to be most like Pa, a pseudo Group 5 element.

### 31.4.4 Element 106

Work at Berkeley-Livermore in 1974 first convincingly demonstrated the synthesis of this element via the reaction \(^{249}\text{Cf}(^{18}\text{O},4\text{n})^{263}106\). Contemporaneous work at Dubna applied their novel cold fusion method (p. 1280) to reactions such as \(^{82}\text{Pb} + ^{24}\text{Cr}\) although this methodology was crucial to the synthesis of all later elements (107–112) it did not at that time demonstrate the formation of element 106 with adequate conviction. Very recently, element 106 was resynthesized by a new group at Berkeley using exactly the same reaction as employed in 1974.\(^{(51)}\) The isotope \(^{263}106\) decays with a half-life of 0.8 ± 0.2 s to \(^{259}104\) and then by a second
α-particle emission to $^{255}$No, both of which were positively identified. The recommended name for element 106 is seaborgium, Sg.

Six isotopes of element 106 are now known (see Table 31.8) of which the most recent has a half-life in the range 10–30 s, encouraging the hope that some chemistry of this fugitive species might someday be revealed.\(^\dagger\) This heaviest isotope was synthesized by the reaction $^{248}$Cm($^{22}$Ne,4n)$^{266}$106 and the present uncertainty in the half-life is due to the very few atoms which have so far been observed. Indeed, one of the fascinating aspects of work in this area is the development of philosophical and mathematical techniques to define and deal with the statistics of a small number of random events or even of a single event.\(^{52}\)

### 31.4.5 Elements 107, 108 and 109

These three elements were all first synthesized by the cold fusion method at GSI, Darmstadt,\(^{5}\) using a very sophisticated set of techniques. For element 107 (1981) an accelerated beam of ionized $^{54}$Cr atoms was made to impinge on a thin $^{209}$Bi foil; the reaction recoils were separated in flight from the incoming beam and from the unwanted products of transfer reactions by a velocity filter consisting of a combination of magnetic and electric fields. This facility is known by the acronym SHIP, i.e. separated heavy-ion reaction products. The product atoms were then implanted in position-sensitive solid-state detectors which recorded α-particle decay energies or spontaneous fission events in position- and time-correlation with each other and with the time of implantation. Time-of-flight was also used to estimate the masses of these particles. Five atoms of $^{262}$107 were detected and characterized in this way in the discovery experiments. Later work showed that the half-life was $102 \pm 26$ ms and also established a second isotope, $^{261}$107, with $t_{1/2} = 11.8$ ms having an (unsymmetrical) uncertainty at the 68% level of $(+5.3, -2.8)$. The recommended name for element 107 is bohrium, Bh.

Element 108 was unequivocally established in 1984 using the SHIP facilities in Darmstadt to detect three atoms formed by the reaction $^{208}$Pb($^{58}$Fe,n)$^{265}$108. The half-life for α-decay was 1.8 ms with an uncertainty of $(+2.2, -0.7)$ ms, and both the daughter and grand-daughter nuclides $^{261}$106 and $^{257}$104 were detected and characterized. Other isotopes of element 108 were in all probability obtained in Dubna at about the same time using reactions such as $^{209}$Bi($^{55}$Mn,n)$^{263}$108, $^{207}$Pb($^{58}$Fe,n)$^{264}$108 and $^{208}$Pb($^{58}$Fe,2n)$^{264}$108.\(^{5}\) The recommended name for element 108 is hassium, Hs, after the Latin name for Hesse, the region of Germany in which the GSI Laboratories are located.

Element 109 was also discovered by the Darmstadt GSI group in 1982 in an astonishingly virtuoso experiment which convincingly detected and unambiguously identified just one atom of $^{266}$109 from the reaction $^{209}$Bi($^{58}$Fe,n). A further two atoms were synthesized at GSI six years later in 1988. The isotope is an α-emitter with a “half-life” of 3.4 ms $(+1.6, -1.3)$ ms.\(^{5}\) The recommended name for element 109 is meitnerium, Mt. It is salutary to contemplate the towering intellectual insights and prodigious technical achievements required to accomplish such experiments which can precisely identify a single atom amongst some $10^{18}$ accompanying events.

### 31.4.6 Elements 110, 111 and 112

These three elements were first made during a 15-month period of intense activity from late 1994 to early 1996 at GSI, Darmstadt. They therefore post-date the deliberations of the IUPAC/IUPAP international working group,\(^{5}\) but the publications convincingly meet the stringent criteria for discovery elaborated by that group and have been widely accepted by the scientific community. So far, no names have been officially proposed or recommended for elements 110–112.

---

\(^\dagger\) The chemistry of 4 atoms of Sg in solution and of 3 atoms in the gas phase indicate that the element resembles its lighter homologues in Group 6, Mo and W; see M. SCHADEL and 17 others, *Nature* **388**, 55–7 (1997).

Initially, one atom of $^{269}110$ was detected on 9 November 1994 by the SHIP facilities at Darmstadt following the reaction $^{208}\text{Pb}(^{62}\text{Ni},n)^{269}110$ and observation of the subsequent chain of four $\alpha$-decays:\(^{53,54}\)

\[
^{269}110 \rightarrow 265\text{108} \rightarrow 261\text{106} \rightarrow 257\text{104} \rightarrow 253\text{No}
\]

A further three atoms of $^{269}110$ were observed during the next eight days leading to an average “half-life” of 170 $\mu$s ($\pm 160, -60\, \mu$s). [Note that the decay times listed for the above single-atom observations are not identical with the best values of the statistical half-lives for the species mentioned.] Subsequent work also identified a second isotope $^{271}110$ with $t_{1/2}$ 623 $\mu$s.

Element 111 was synthesized and characterized by the same group during the period 8–17 December 1994 using the analogous cold-fusion reaction, $^{209}\text{Bi}(^{64}\text{Ni},n)^{272}111$, followed by observation of up to five successive $\alpha$-emissions which could be assigned to the chain: \(^{54,55}\)

\[
^{272}111 \rightarrow 268\text{109} \rightarrow 264\text{107} \rightarrow 260\text{105} \rightarrow 256\text{Lr} \rightarrow 252\text{Md}
\]

Note also the production of new isotopes of elements 107 and 109 in this chain.

Element 112 emerged close to midnight on 9 February 1996 when the team at GSI unambiguously detected one atom of the new element after two weeks of bombarding a lead target with high-energy ionized atoms of zinc $^{208}\text{Pb}(^{70}\text{Zn},n)^{277}112$. \(^{56}\) The new element emitted an $\alpha$-particle after 280 $\mu$s, followed by several others which formed a coherent decay scheme down to Fm:

\[
^{277}112 \rightarrow 273\text{110} \rightarrow 269\text{108} \rightarrow 265\text{106} \rightarrow 263\text{104} \rightarrow 259\text{No} \rightarrow 255\text{Fm}
\]

This work is particularly significant for a number of reasons. Not only does $^{277}112$ have the highest atomic number and the highest mass of any nuclide so far, but it is also expected to complete the 6d transition series of elements. Will the next elements 113, 114, etc. prove to be members of the boron and carbon groups or will relativistic effects supervene to stabilize other electronic configurations? Perhaps even more significantly, the new atomic species is approaching the “island of stability” which has been predicted on the basis of the expected nuclear closed shells of 114 protons and 184 or 178 neutrons, and it does indeed show clear signs of this increasing stability (decreasing instability). Moreover, the decay chain generates two new isotopes of elements 110 and 108 which themselves are the heaviest (and most stable) isotopes of these elements so far. Further increases in stability might well make chemical experimentation feasible. Clearly, exciting prospects lie ahead.

At present, some 36 isotopes of the transactinide elements have been characterized and these are summarized in Table 31.8.

Appendix 1
Atomic Orbitals

The spacial distribution of electron density in an atom is described by means of atomic orbitals \( \psi(r, \theta, \phi) \) such that for a given orbital \( \psi \) the function \( \psi^2 dV \) gives the probability of finding the electron in an element of volume \( dV \) at a point having the polar coordinates \( r, \theta, \phi \). Each orbital can be expressed as a product of two functions, i.e. \( \psi_{n,l,m}(r, \theta, \phi) = R_{n,l}(r)A_{l,m}(\theta, \phi) \), where

(a) \( R_{n,l}(r) \) is a radial function which depends only on the distance \( r \) from the nucleus (independent of direction) and is defined by the two quantum numbers \( n, l \);

(b) \( A_{l,m}(\theta, \phi) \) is an angular function which is independent of distance but depends on the direction as given by the angles \( \theta, \phi \); it is defined by the two quantum numbers \( l, m \).

Normalized radial functions for a hydrogen-like atom are given in Table A1.1 and plotted graphically in Fig. A1.1 for the first ten combinations of \( n \) and \( l \). It will be seen that the radial functions for 1s, 2p, 3d, and 4f orbitals have no nodes and are everywhere of the same sign (e.g. positive). In general \( R_{n,l}(r) \) becomes zero \( (n-l-1) \) times between \( r \) equals 0 and \( \infty \). The probability of finding an electron at a distance \( r \) from the nucleus is given by \( 4\pi R_{n,l}^2(r)r^2 dr \), and this is also plotted in Fig. A1.1. However, the probability of finding an electron frequently depends also on the direction chosen. The probability of finding an electron in a given direction, independently of distance from the nucleus, is given by the square of the angular dependence function \( A_{l,m}^2(\theta, \phi) \). The normalized functions \( A_{l,m}(\theta, \phi) \) are listed in Table A1.2 and illustrated schematically by the models in Fig. A1.2. It will be seen that for s orbitals \( (l = 0) \) the angular dependence function \( A \) is constant, independent of \( \theta \), and \( \phi \), i.e. the function is spherically symmetrical. For p orbitals \( (l = 1) \) \( A \) comprises two spheres in contact, one being positive and one negative, i.e. there is one planar node. The d and f functions \( (l = 2, 3) \) have more complex angular dependence with 2 and 3 nodes respectively.
### Table A1.1  Normalized radial functions $R_{n,l}(r)$ for hydrogen-like atoms

$$R_{n,l}(r) = -\sqrt{\frac{4(n-l-1)!Z^l}{n![(n+l)!!]^2}} \cdot \frac{Z^l r^l}{a_0 n} \cdot \frac{L_{n+l}^{2l+1}}{a_0 n} \times e^{-Zr/a_0 n}$$

Table A1.2 Normalized angular dependence functions, $A_{l,m}(\theta, \phi) = \Theta_{l,m}(\theta)\Phi_{m}(\phi)$. 

- $f_x^3$ $\frac{\sqrt{70}}{8\sqrt{\pi}} \sin^3 \theta(3 \sin \phi - 4 \sin^3 \phi)$
- $f_y^3$ $\frac{\sqrt{70}}{8\sqrt{\pi}} \sin^3 \theta(3 \sin \phi - 4 \sin^3 \phi)$
Appendix 2
Symmetry Elements, Symmetry Operations and Point Groups

An object has symmetry when certain parts of it can be interchanged with others without altering either the identity or the apparent orientation of the object. For a discrete object such as a molecule 5 elements of symmetry can be envisaged:

- axis of symmetry, $C$;
- plane of symmetry, $\sigma$;
- centre of inversion, $i$;
- improper axis of symmetry, $S$; and
- identity, $E$.

These elements of symmetry are best recognized by performing various symmetry operations, which are geometrically defined ways of exchanging equivalent parts of a molecule. The 5 symmetry operations are:

- $C_n$, rotation of the molecule about a symmetry axis through an angle of $360^\circ/n$; $n$ is called the order of the rotation (twofold, threefold, etc.);
- $\sigma$ reflection of all atoms through a plane of the molecule;
- $i$, inversion of all atoms through a point of the molecule;
- $S_n$, Rotation of the molecule through an angle $360^\circ/n$ followed by reflection of all atoms through a plane perpendicular to the axis of rotation; the combined operation (which may equally follow the sequence reflection then rotation) is called improper rotation;
- $E$, the identity operation which leaves the molecule unchanged.

The rotation axis of highest order is called the principal axis of rotation; it is usually placed in the vertical direction and designated the $z$-axis of the molecule. Planes of reflection which are perpendicular to the principal axis are called horizontal planes ($h$). Planes of reflection which contain the principal axis are called vertical planes ($v$), or dihedral planes ($d$) if they bisect 2 twofold axes.

The complete set of symmetry operations that can be performed on a molecule is called the symmetry group or point group of the molecule and the order of the point group is the number of symmetry operations it contains. Table A2.1 lists the various point groups, together with their elements of symmetry and with examples of each.

</tbody>
</table>

It is instructive to add to these examples from the numerous instances of point group symmetry mentioned throughout the text. In this way a facility will gradually be acquired in discerning the various elements of symmetry present in a molecule.

A convenient scheme for identifying the point group symmetry of any given species is set out in the flow chart. Starting at the top of the chart, each vertical line asks a question: if the answer is "yes" then move to the right, if "no" then move to the left until the correct point group is arrived at. Other similar schemes have been devised.²⁻⁵

†Taken from W. S. Fyfe, Geochemistry, Oxford University Press, 1974, with some modifications and additions to incorporate later data. The detailed numbers are subject to various assumptions in the models of the global distribution of the various rock types within the crust, but they are broadly acceptable as an indication of elemental abundances. See also Table 1 in C. K. Jørgensen, Comments Astrophys. 17, 49–101 (1993).

### Notes
- For coord. no. 6 unless indicated by superscript numerals III, IV, etc. (All data taken from R. D. Shannon, Acta Cryst. A32, 751–67 (1976).)
- Coordinates are given in parentheses unless indicated by superscript numerals or other symbols.
1901  **J. H. van’t Hoff** (Berlin): discovery of the laws of chemical dynamics and osmotic pressure in solutions.
1902  **E. Fischer** (Berlin): sugar and purine syntheses.
1903  **S. Arrhenius** (Stockholm): electrolytic theory of dissociation.
1904  **W. Ramsay** (University College, London): discovery of the inert gaseous elements in air and their place in the periodic system.
1905  **A. von Baeyer** (Munich): advancement of organic chemistry and the chemical industry through work on organic dyes and hydroaromatic compounds.
1906  **H. Moissan** (Paris): isolation of the element fluorine and development of the electric furnace.
1907  **E. Buchner** (Berlin): biochemical researches and the discovery of cell-free fermentation.
1908  **E. Rutherford** (Manchester): investigations into the disintegration of the elements and the chemistry of radioactive substances.
1909  **W. Ostwald** (Gross-Bothen): work on catalysis and investigations into the fundamental principles governing chemical equilibria and rates of reaction.
1910  **O. Wallach** (Göttingen): pioneer work in the field of alicyclic compounds.
1911  **Marie Curie** (Paris): discovery of the elements radium and polonium, the isolation of radium, and the study of the nature and compounds of this remarkable element.
1912  **V. Grignard** (Nancy): discovery of the Grignard reagent.
   **P. Sabatier** (Toulouse): method of hydrogenating organic compounds in the presence of finely disintegrated metals.
1913  **A. Werner** (Zürich): work on the linkage of atoms in molecules which has thrown new light on earlier investigations and opened up new fields of research especially in inorganic chemistry.
1914  **T. W. Richards** (Harvard): accurate determination of the atomic weight of a large number of chemical elements.
1915  **R. Willstätter** (Munich): plant pigments, especially chlorophyll.
1916  Not awarded
1917  Not awarded
1918  **F. Haber** (Berlin–Dahlem): the synthesis of ammonia from its elements.
1919 Not awarded
1920 **W. Nernst** (Berlin): work in thermochemistry.
1921 **F. Soddy** (Oxford): contributions to knowledge of the chemistry of radioactive substances and investigations into the origin and nature of isotopes.
1922 **F. W. Aston** (Cambridge): discovery, by means of the mass spectrograph, of isotopes in a large number of non-radioactive elements and for enunciation of the whole-number rule.
1923 **F. Pregl** (Graz): invention of the method of microanalysis of organic substances.
1924 Not awarded
1925 **R. Zsigmondy** (Göttingen): demonstration of the heterogeneous nature of colloid solutions by methods which have since become fundamental in modern colloid chemistry.
1926 **T. Svedberg** (Uppsala): work on disperse systems.
1927 **H. Wieland** (Munich): constitution of the bile acids and related substances.
1928 **A. Windaus** (Göttingen): constitution of the sterols and their connection with the vitamins.
1929 **A. Harden** (London) and **H. von Euler-Chelpin** (Stockholm): investigations on the fermentation of sugars and fermentative enzymes.
1930 **H. Fischer** (Munich): the constitution of haemin and chlorophyll and especially for the synthesis of haemin.
1931 **C. Bosch** and **F. Bergius** (Heidelberg): the invention and development of chemical high pressure methods.
1932 **I. Langmuir** (Schenectady, New York): discoveries and investigations in surface chemistry.
1933 Not awarded
1936 **P. Debye** (Berlin–Dahlem): contributions to knowledge of molecular structure through investigations on dipole moments and on the diffraction of X-rays and electrons in gases.
1937 **W. N. Haworth** (Birmingham): investigations on carbohydrates and vitamin C.
**P. Karrer** (Zürich): investigations of carotenoids, flavins, and vitamins A and B_2_.
1938 **R. Kuhn** (Heidelberg): work on carotenoids and vitamins.
1939 **A. F. J. Butenandt** (Berlin): work on sex hormones.
**L. Ruzicka** (Zürich): work on polymethylenes and higher terpenes.
1940 Not awarded.
1941 Not awarded.
1942 Not awarded.
1943 **G. Hevesy** (Stockholm): use of isotopes as tracers in the study of chemical processes.
1944 **O. Hahn** (Berlin–Dahlem): discovery of the fission of heavy nuclei.
1945 **A. J. Virtanen** (Helsingfors): research and inventions in agricultural and nutrition chemistry, especially fodder preservation.
1946 **J. B. Sumner** (Cornell): discovery that enzymes can be crystallized.
1947 **R. Robinson** (Oxford): investigations on plant products of biological importance, especially the alkaloids.
1948 **A. W. K. Tiselius** (Uppsala): electrophoresis and adsorption analysis, especially for discoveries concerning the complex nature of the serum proteins.
1949 **W. F. Giauque** (Berkeley): contributions in the field of chemical thermodynamics, particularly concerning the behaviour of substances at extremely low temperatures.
1950 **O. Diels** (Kiel) and **K. Alder** (Cologne): discovery and development of the diene synthesis.
1951 **E. M. McMillan** and **G. T. Seaborg** (Berkeley): discoveries in the chemistry of the transuranium elements.
1953 H. Staudinger (Freiburg): discoveries in the field of macromolecular chemistry.
1954 L. Pauling (California Institute of Technology, Pasadena): research into the nature of the chemical bond and its application to the elucidation of the structure of complex substances.
1955 V. du Vigneaud (New York): biochemically important sulfur compounds, especially the first synthesis of a polypeptide hormone.
1956 C. N. Hinshelwood (Oxford) and N. N. Semenov (Moscow): the mechanism of chemical reactions.
1957 A. Todd (Cambridge): nucleotides and nucleotide co-enzymes.
1958 F. Sanger (Cambridge): the structure of proteins, especially that of insulin.
1959 J. Heyrovský (Prague): discovery and development of the polarographic method of analysis.
1961 M. Calvin (Berkeley): research on the carbon dioxide assimilation in plants.
1963 K. Ziegler (Mülheim/Ruhr) and G. Natta (Milan): the chemistry and technology of high polymers.
1964 Dorothy Crowfoot Hodgkin (Oxford): determinations by X-ray techniques of the structures of important biochemical substances.
1966 R. S. Mulliken (Chicago): fundamental work concerning chemical bonds and the electronic structure of molecules by the molecular orbital method.
1967 M. Eigen (Göttingen), R. G. W. Norrish (Cambridge) and G. Porter (London): studies of extremely fast chemical reactions, effected by disturbing the equilibrium by means of very short pulses of energy.
1968 L. Onsager (Yale): discovery of the reciprocity relations bearing his name, which are fundamental for the thermodynamics of irreversible processes.
1969 D. H. R. Barton (Imperial College, London) and O. Hassel (Oslo): development of the concept of conformation and its application in chemistry.
1971 G. Herzberg (Ottawa): contributions to the knowledge of electronic structure and geometry of molecules, particularly free radicals.
1972 C. B. Anfinsen (Bethesda): work on ribonuclease, especially concerning the connection between the amino-acid sequence and the biologically active conformation.
1973 E. O. Fischer (Munich) and G. Wilkinson (Imperial College, London): pioneering work, performed independently, on the chemistry of the organometallic so-called sandwich compounds.
1974 P. J. Flory (Stanford): fundamental achievements both theoretical and experimental in the physical chemistry of macromolecules.
Nobel prize for chemistry

1977 **I. Prigogine** (Brussels): non-equilibrium thermodynamics, particularly the theory of dissipative structures.

1978 **P. Mitchell** (Bodmin, Cornwall): contributions to the understanding of biological energy transfer through the formulation of the chemiosmotic theory.

1979 **H. C. Brown** (Purdue) and **G. Wittig** (Heidelberg): for their development of boron and phosphorus compounds, respectively, into important reagents in organic synthesis.

1980 **P. Berg** (Stanford): the biochemistry of nucleic acids, with particular regard to recombinant-DNA.

**W. Gilbert** (Harvard) and **F. Sanger** (Cambridge): the determination of base sequences in nucleic acids.

1981 **K. Fukui** (Kyoto) and **R. Hoffmann** (Cornell): quantum mechanical studies of chemical reactivity.

1985 **H. A. Hauptman** (Buffalo, NY) and **J. Karle** (Washington, DC): outstanding achievements in the development of direct methods for the determination of crystal structures.

1986 **D. R. Herschbach** (Harvard), **Y. T. Lee** (Berkeley) and **J. C. Polanyi** (Toronto): contributions concerning the dynamics of chemical elementary processes.

1987 **D. J. Cram** (Los Angeles), **J.-M. Lehn** (Strasbourg) and **C. J. Pedersen** (Wilmington, Delaware): development and use of molecules with structure specific interactions of high selectivity.

1988 **J. Deisenhofer** (Dallas, Texas), **R. Huber** (Martinsried) and **H. Michel** (Frankfurt am Main): determination of the three-dimensional structure of a photosynthetic reaction centre.

1989 **S. Altman** (Yale) and **T. Cech** (Boulder, Colorado): discovery of the catalytic properties of RNA.

1991 **R. R. Ernst** (Eidgenössische Technische Hochschule, Zürich): contributions to the development of the methodology of high resolution nmr spectroscopy.

1992 **R. A. Marcus** (California Institute of Technology): contributions to the theory of electron transfer reactions in chemical systems.

1993 **K. B. Mullis** (La Jolla, California): invention of the polymerase chain reaction.

**M. Smith** (University of British Columbia): fundamental contributions to the establishment of oligonucleotide-based, site-directed mutagenesis and its development for protein studies.

1994 **G. A. Olah** (University of Southern California): contributions to carbocation chemistry.

1995 **P. Crutzen** (Max Planck Institute for Chemistry, Mainz), **M. Molina** (Massachusetts Institute of Technology) and **F. S. Rowland** (Irvine, California): work in atmospheric chemistry, particularly concerning the formation and decomposition of ozone.

1996 **R. F. Curl** (Rice University, Texas), **H. Kroto** (Sussex University) and **R. E. Smalley** (Rice University, Texas): discovery of a new form of carbon, the fullerenes.

1997 **P. D. Boyer** (Los Angeles) and **J. E. Walker** (Cambridge): pioneering work on enzymes that participate in the conversion of ATP.

**J. C. Scou** (Aarhus): discovery of the first molecular pump, an ion-transporting enzyme Na+-K+ ATPase.
Appendix 7
Nobel Prize for Physics

1901 W. C. Röntgen (Munich): discovery of the remarkable rays subsequently named after him.
1902 H. A. Lorentz (Leiden) and P. Zeeman (Amsterdam): influence of magnetism upon radiation phenomena.
   P. Curie and Marie Curie (Paris): researches on the radiation phenomena discovered by H. Becquerel.
1904 Lord Rayleigh (Royal Institution, London): investigations of the densities of the most important gases and for the discovery of argon in connection with these studies.
1905 P. Lenard (Kiel): work on cathode rays.
1907 A. A. Michelson (Chicago): optical precision instruments and the spectroscopic and metrological investigations carried out with their aid.
1909 G. Marconi (London) and F. Braun (Strasbourg): the development of wireless telegraphy.
1910 J. D. van der Waals (Amsterdam): the equation of state for gases and liquids.
1911 W. Wien (Würzburg): the laws governing the radiation of heat.
1912 G. Dalén (Stockholm): invention of automatic regulators for use in conjunction with gas accumulators for illuminating lighthouses and buoys.
1913 H. Kamerlingh Onnes (Leiden): properties of matter at low temperatures and production of liquid helium.
1914 M. von Laue (Frankfurt): discovery of the diffraction of X-rays by crystals.
1915 W. H. Bragg (University College, London) and W. L. Bragg (Manchester): analysis of crystal structure by means of X-rays.
1916 Not awarded.
1917 C. G. Barkla (Edinburgh): discovery of the characteristic Röntgen radiation of the elements.
1918 M. Planck (Berlin): services rendered to the advancement of physics by discovery of energy quanta.
1919 **J. Stark** (Greifswald): discovery of the Doppler effect on canal rays and of the splitting of spectral lines in electric fields.

1920 **C. E. Guillaume** (Sévres): service rendered to precise measurements in physics by discovery of anomalies in nickel steel alloys.

1921 **A. Einstein** (Berlin): services to theoretical physics, especially discovery of the law of the photoelectric effect.

1922 **N. Bohr** (Copenhagen): investigations of the structure of atoms, and of the radiation emanating from them.

1923 **R. A. Millikan** (California Institute of Technology, Pasadena): work on the elementary charge of electricity and on the photo-electric effect.

1924 **M. Siegbahn** (Uppsala): discoveries and researches in the field of X-ray spectroscopy.

1925 **J. Franck** (Göttingen) and **G. Hertz** (Halle): discovery of the laws governing the impact of an electron upon an atom.

1926 **J. Perrin** (Paris): the discontinuous structure of matter, and especially for the discovery of sedimentation equilibrium.

1928 **O. W. Richardson** (King’s College, London): thermonal phenomenon and especially discovery of the law named after him.

1929 **L. V. de Broglie** (Paris): discovery of the wave nature of electrons.

1930 **V. Raman** (Calcutta): work on the scattering of light and discovery of the effect named after him.

1931 Not awarded.

1932 **W. Heisenberg** (Leipzig): the creation of quantum mechanics, the application of which has, inter alia, led to the discovery of the allotropic forms of hydrogen.

1933 **E. Schrödinger** (Berlin) and **P. A. M. Dirac** (Cambridge): discovery of new productive forms of atomic theory.

1934 Not awarded.

1936 **V. F. Hess** (Innsbruck): discovery of cosmic radiation.

1938 **E. Fermi** (Rome): demonstration of the existence of new radioactive elements produced by neutron irradiation and for the related discovery of nuclear reactions brought about by slow neutrons.

1939 **E. O. Lawrence** (Berkeley): invention and development of the cyclotron and for results obtained with it, especially with regard to artificial radioactive elements.

1940 Not awarded.

1941 Not awarded.

1942 Not awarded.

1943 **O. Stern** (Pittsburgh): development of the molecular ray method and discovery of the magnetic moment of the proton.

1944 **I. I. Rabi** (Columbia, New York): resonance method for recording the magnetic properties of atomic nuclei.

1945 **W. Pauli** (Zürich): discovery of the Exclusion Principle, also called the Pauli Principle.

1946 **P. W. Bridgman** (Harvard): invention of an apparatus to produce extremely high pressures and discoveries in the field of high-pressure physics.

1947 **E. V. Appleton** (London): physics of the upper atmosphere, especially the discovery of the so-called Appleton layer.

1948 **P. M. S. Blackett** (Manchester): development of the Wilson cloud chamber method and discoveries therewith in the field of nuclear physics and cosmic radiation.

1949 **H. Yukawa** (Kyoto): prediction of the existence of mesons on the basis of theoretical work on nuclear forces.
1950 C. F. Powell (Bristol): development of the photographic method of studying nuclear processes and discoveries regarding mesons made with this method.
1951 J. D. Cockcroft (Harwell) and E. T. S. Walton (Dublin): pioneer work on the transmutation of atomic nuclei by artificially accelerated atomic particles.
1952 F. Bloch (Stanford) and E. M. Purcell (Harvard): development of new methods for nuclear magnetic precision measurements and discoveries in connection therewith.
1953 F. Zernike (Groningen): demonstration of the phase contrast method and invention of the phase contrast microscope.
1954 M. Born (Edinburgh): fundamental research in quantum mechanics, especially for the statistical interpretation of the wave function.
W. Bothe (Heidelberg): the coincidence method and discoveries made therewith.
1955 W. E. Lamb (Stanford): the fine structure of the hydrogen spectrum.
P. Kusch (Columbia, New York): precision determination of the magnetic moment of the electron.
1956 W. Shockley (Pasadena), J. Bardeen (Urbana) and W. H. Brattain (Murray Hill): investigations on semiconductors and discovery of the transistor effect.
1957 T. Lee (Columbia) and C. Yang (Princeton): penetrating investigation of the so-called parity laws, which has led to important discoveries regarding the elementary particles.
1960 D. A. Glaser (Berkeley): invention of the bubble chamber.
1961 R. Hofstadter (Stanford): pioneering studies of electron scattering in atomic nuclei and discoveries concerning the structure of the nucleons.
R. L. Mössbauer (Munich): resonance absorption of gamma radiation and discovery of the effect which bears his name.
1962 L. D. Landau (Moscow): pioneering theories for condensed matter, especially liquid helium.
1963 E. P. Wigner (Princeton): the theory of the atomic nucleus and elementary particles, particularly through the discovery and application of fundamental symmetry principles.
Maria Goeppert-Mayer (La Jolla) and J. H. D. Jensen (Heidelberg): discoveries concerning nuclear shell structure.
1964 C. H. Townes (Massachusetts Institute of Technology), and N. G. Basov and A. M. Prokhorov (Moscow): fundamental work in the field of quantum electronics, which led to the construction of oscillators and amplifiers based on the maser-laser-principle.
1967 H. A. Bethe (Cornell): contributions to the theory of nuclear reactions, especially discoveries concerning the energy production in stars.
1968 L. W. Alvarez (Berkeley): decisive contributions to elementary particle physics, in particular the discovery of a large number of resonance states, made possible by the hydrogen bubble chamber technique and data analysis.
1969 M. Gell-Mann (California Institute of Technology, Pasadena): contributions and discoveries concerning the classification of elementary particles and their interactions.
1970 H. Alfvén (Stockholm): discoveries in magneto-hydrodynamics with fruitful applications in different parts of plasma physics.
L. Néel (Grenoble): discoveries concerning antiferromagnetism and ferrimagnetism which have led to important applications in solid state physics.

1971 D. Gabor (Imperial College, London): invention and development of the holographic method.

1972 J. Bardeen (Urbana), L. N. Cooper (Providence) and J. R. Schrieffer (Philadelphia): theory of superconductivity, usually called the BCS theory.

1973 L. Esaki (Yorktown Heights) and I. Giaever (Schenectady): experimental discoveries regarding tunnelling phenomena in semiconductors and superconductors respectively.

B. D. Josephson (Cambridge): theoretical predictions of the properties of a supercurrent through a tunnel barrier, in particular those phenomena which are generally known as the Josephson effects.

1974 M. Ryle and A. Hewish (Cambridge): pioneering research in radioastrophysics: Ryle for his observations and inventions, in particular of the aperture-synthesis technique, and Hewish for his decisive role in the discovery of pulsars.

1975 A. Bohr (Copenhagen), B. Mottelson (Copenhagen) and J. Rainwater (New York): discovery of the connection between collective motion and particle motion in atomic nuclei and the development of the theory of the structure of the atomic nucleus based on this connection.

1976 B. Richter (Stanford) and S. C. C. Ting (Massachusetts Institute of Technology): discovery of a heavy elementary particle of a new kind.

1978 P. L. Kapitsa (Moscow): basic inventions and discoveries in the area of low-temperature physics.

1979 S. L. Glashow (Harvard), A. Salam (Imperial College, London) and S. Weinberg (Harvard): contributions to the theory of the unified weak and electromagnetic interaction between elementary particles, including, inter alia, the prediction of the weak neutral current.

1983 S. Chandrasekar (Chicago): theoretical studies of the physical processes of importance to the structure and evolution of the stars.
W. A. Fowler (California Institute of Technology, Pasadena): theoretical and experimental studies of the nuclear reactions of importance in the formation of the chemical elements in the universe.

1984 C. Rubbia and S. Van der Meer (CERN, Geneva): decisive contributions to the discovery of the field particles W and Z, communicators of weak interaction.

1986 E. Ruska (Berlin): fundamental work in electron optics and the design of the first electron microscope.

G. Binning and H. Rohrer (Zurich): design of the scanning tunneling microscope.
1987 G. Bednorz and K. A. Müller (Zürich): for their important breakthrough in the discovery of superconductivity in ceramic materials.

1988 L. Lederman (Batavia, Illinois), M. Schwartz (Mountain View, California) and J. Steinberger (Geneva): for the neutrino beam method and the demonstration of the doublet structure of the leptons through the discovery of the muon neutrino.

H. G. Dehmelt (University of Washington, Seattle) and W. Paul (Bonn): development of the ion trap technique.

1990 J. I. Friedman and H. W. Kendall (Massachusetts Institute of Technology) and R. E. Taylor (Stanford): pioneering investigations concerning deep elastic scattering of electrons on protons and bound neutrons, of essential importance for the development of the quark model in particle physics.

1991 P.-G. de Gennes (Collège de France, Paris): discovery that methods developed for studying order phenomena in simple systems can be generalized to more complex forms of matter, in particular to liquid crystals and polymers.

1992 G. Charpak (École Supérieure de Physique et Chimie, Paris, and CERN Geneva): invention and development of particle detectors, in particular the multiwire proportional chamber.

1994 B. N. Brockhouse (McMaster University) and C. G. Schull (Massachusetts Institute of Technology): pioneering contributions to neutron scattering techniques for studies of condensed matter (namely neutron spectroscopy and neutron diffraction techniques, respectively).

1995 M. L. Perl (Stanford) and F. Reines (Irvine, California): pioneering experimental contributions to lepton physics (discovery of the tau particle and detection of the neutrino, respectively).

1996 D. M. Lee (Cornell), D. D. Osheroff (Stanford) and R. C. Richardson (Cornell): discovery of the superfluid phase of helium-3.

Standard Atomic Weights of the Elements 1995

[Scaled to $A_1(^{12}{C}) = 12$, where $^{12}{C}$ is a neutral atom in its nuclear and electronic ground state]

The atomic weights of many elements are not invariant but depend on the origin and treatment of the material. The standard values of $A(E)$ and the uncertainties (in parentheses, following the last significant figure to which they are attributed) apply to elements of natural terrestrial origin. The footnotes to this Table elaborate the types of variation which may occur for individual elements and which may be larger than the listed uncertainties of values of $A(E)$. Names have not yet been assigned to elements with atomic numbers 110, 111 and 112 (see p. 1280).

</table>

*Element has no stable nuclides; the value given in parentheses is the atomic mass number of the isotope of longest known half-life. However, three such elements (Th, Pa and U) do have a characteristic terrestrial isotopic composition, and for these an atomic weight is tabulated.

†Commercially available Li materials have atomic weights that range between 6.939 and 6.996; if a more accurate value is required, it must be determined for the specific material.

g Geological specimens are known in which the element has an isotopic composition outside the limits for normal material. The difference between the atomic weight of the element in such specimens and that given in the Table may exceed the stated uncertainty.

m Modified isotopic compositions may be found in commercially available material because it has been subjected to an undisclosed or inadvertent isotopic fractionation. Substantial deviations in atomic weight of the element from that given in the Table can occur.

r Range in isotopic composition of normal terrestrial material prevents a more precise $A(E)$ being given; the tabulated $A(E)$ value should be applicable to any normal material.
### Recommended Consistent Values of Some Fundamental Physical Constants (1986)

(The numbers in parentheses are the standard deviation in the last digits of the quoted value.)

**Notes:**
- The Greek alphabet is used to denote various physical quantities and constants.
- The table lists recommended values for fundamental physical constants along with their uncertainties in parts per million (ppm).
- Units and symbols are provided for each quantity.
- The numbers in parentheses indicate the standard deviation in the last digits of the quoted value.

Perbromyl fluoride, FBrO3 881

Perchlorates, ClO4– 865–871
bridging ligand 791, 868–871
celating ligand 868–871
coordinating ability 791, 868–871, 1020
monodentate ligand 791, 868–871
production and uses 865, 867
redox systems 854, 855
structure 868

Perchloric acid, HClO4 865–868
chemical reactions 867, 868
hydrates 867
physical properties 865, 866
preparation 865, 866
structure 868

Perchloeryl fluoride, FClO3 881

Perhalates, xo4– 854, 855, 865–875

Perhalic acids, HOX03 872–875

Periodate 872–875
acid-base systems 874
nomenclature 872
preparation 873
redox systems 854, 855
structural relations 873

Periodic reactions
Belousov-Zhabotinskii reactions 865, 865
Bray’s reaction 865

Periodic table see inside front cover
and atomic structure 20–23
history of 20, 21
and predictions of new elements 29–31

Permanganates 1050, 1051
Perorosmate 1082, 1085
Perovskite structure 963
in ternary sulfides 681
Peroxo anions 638
Peroxodisulfates, S2O82– 713
Peroxodisulfuric acid, H2S2O8 713
Peroxo complexes of O2 616
Peroxo compounds, fluorinated 639, 640
Peroxochromium complexes 637, 1024
Peroxodiposphoric acid, H2P2O8 512
Peroxomonophosphoric acid, H3PO3 512
Peroxomonosulfuric acid, H2SO3 705, 712
Peroxonitric acid, HOONO2 458
Peroxonitrous acid, HOONO 459
Peroxoselenous acid 783
Peroxostellurates 783
atomic properties 482–483  
black allotropes 481–483, 551  
bond energies 483

Technetates  1050
Technetium
abundance  1041
carbonyls  928, 1062–1063
chalcogenides  1049
complexes
+7 oxidation state  1054
+6 oxidation state  1055
+5 oxidation state  1055
+4 oxidation state  1056
+3 oxidation state  1057–1058
+2 oxidation state  1058
lower oxidation states  1061
cyclopentadienyls  1067–1068
discovery  1040
halides and oxoalides  1051–1054
nuclear medicine, role in  1042
organometallic compounds  1062–1067
oxides  1045
production and uses  1041
see also Group 7 elements
Tectites  394
Tecto-silicates  414–416, 347
Teflon (PTFE)  304, 791
Tellurates  782
Telluric acid, Te(OH)6  782
Tellurides  765, 766
Tellurites  781
Tellurium
abundance  748
allotropy  751
atomic and physical properties  753, 754
chemical reactivity  754–759
coordination geometries  756–757
dioxide  779, 780
discovery  747
halide complexes  776
halides  767–776
hydride, H2Te  759, 766
nitrate  786
nitride, Te3N4  783
organocompounds  786–788
oxides  779–780
oxoacids  781–783
oxoalides  777
polyatomic anions  762–5
polyatomic cations
Te3+n−  759, 761
[Te3Se4−]2+  761
production and uses  748, 749
redox properties  755–756
sulfide, TeS7  783
toxicity  759
trioxide  780
Tellurocyanate ion, TeCN−  779
Telluropolythionates  783
Tellurous acid  781
Terbium  1229
+4 oxidation state  1237, 1239

Tetracyanoethylene complexes, bonding in  931
Tetrafluoroethylene complexes, bonding in  932
Tetrafluoronitronium cation NF4+  439
Tetrahalogenophosphonium cations PX4+  499–500
Tetrahedral complexes  914
Tetrahydroaluminate ion, as ligand  231
Tetrahydroborates
  of Al 260, 228, 229
  of Ga 231
  of Zr and Hf 969
  use in synthesis 166–168
Tetrametaphosphinate conformers 542
Tetrahionates, $\text{S}_4\text{O}_6^{2-}$, preparation and structure 717, 718
Thallium
  abundance 217
  chalcogenides 252–254
  III–V compounds 255–258
  discovery 217
  halide complexes 240
  lower halides 241
  monohalides 241, 242
  organometallic compounds 261, 265
  oxides 246
  production 221
  similarity of $\text{Tl}^+$ to alkali metals 226
  trihalides 239
  triiodide $\text{TlI}_3^-$ 239, 240
  see also Group 13 elements
Thiaryl halides NSX 736–738
Thioarsenites 580
Thiocarbonyl (CS) complexes 319
Thiocyanates 320, 324
  as ambidentate ligands
  Thioethers as ligands 673
Thionitrosyl (NS) complexes 453, 454
Thionyl bromide 694
  relation to $\text{SO}_2$ and $\text{Me}_2\text{SO}$ as ionizing solvent 694
Thionyl chloride 693, 694
Thiophosphoryl halides, $\text{PSX}_3$ 500, 502
  pseudohalides 501
Thioselenates 783
Thiosulfates, $\text{S}_2\text{O}_3^{2-}$ 705, 714, 715
  as ligands 714, 715
  redox reactions in analysis 714, 715
  structure 714, 715
  use in photography 714, 1186, 1187
Thiosulfuric acid, $\text{H}_2\text{S}_2\text{O}_3$ 705, 714
  isomeric $\text{H}_2\text{S}_2\text{SO}_3$ 714
  redox interconversions in water 714
Thio-urea 317
Thiovanadyl ion
Thioxotropy 356, 968
Thorium
  abundance 1253
  bis(cyclooctatetraene) 942
  production and uses 1255
  radioactive decay series 1254
  redox behaviour 1265–1267
  use as a nuclear fuel 1258, 1259
