PREFACE TO THE 46th EDITION

This is the Golden Jubilee Year of the publication of *the Principles of Physical Chemistry* and the occasion calls for some kind of celebration. It is a matter of immense pleasure and satisfaction that this text has successfully retained its prestigious position for five decades (the first edition of the book appeared in 1962). This has been due to the fact that we have been revising the book almost every year to highlight modern topics. At several places the text has been thoroughly revised.

Physical chemistry is traditionally divided into three parts—structure, equilibrium, change—and usually taught in that sequence though certain topics cannot be neatly accommodated in this scheme. The syllabus suggested by the UGC broadly conforms to this pattern and we have produced a text which deals with the subject in a rigorous and comprehensive way to cater to the needs of the graduate and post-graduate students of physical chemistry in the Indian universities and colleges.

The significant feature of this edition is that two new chapters have been added : Quantum mechanics is dealt with in three chapters, instead of the earlier two, and statistical thermodynamics is spread over two chapters. Some material has been shifted at several places within the chapters to maintain continuity and impart lucidity and simplicity to the treatment. Structure dominates science and chemistry is no exception. And quantum mechanics and spectroscopy are the chemist's tools to deal adequately with structure. Complete quantum mechanical treatment of the hydrogen atom, with special emphasis on the detailed solution of the Schrödinger equation, has been given. The radial equation and the spherical harmonics have at last received the emphasis they really deserved. Also, the approximate methods for the wave mechanical treatment of many-electron atoms have been updated. The perturbation theory—both non-degenerate and degenerate—has been adequately dealt with and applied to the first excited state of hydrogen atom. Several other modern topics which were earlier written as Appendices or *Further information* have been shifted to where they properly belong in the text. The treatment of angular momentum and atomic spectra is fairly comprehensive; the inessential details have been avoided. Several solved examples have been added.

The partition function dominates statistical thermodynamics even as the wavefunction is of paramount importance in quantum mechanics. The chapter on statistical thermodynamics centres around the partition function derived from quantum mechanics. The new chapter on classical statistical mechanics builds on the concepts of phase space and Gibbsian ensembles and rederives results already known from conventional thermodynamics.

We have deliberately highlighted the new material to show where physical chemistry is going. It has benefited from developments in physics and mathematics.

Physical chemistry has, in fact, become chemical physics. The quantum revolution of the 1920s has drastically changed the face of all science from physics, chemistry and the life sciences to pharmaceutical sciences. The impact of physical chemistry is felt on biology, engineering, materials science, nanoscience, astronomy and technology. There is no denying the fact that physical chemistry is a magnificent edifice whose range is truly interdisciplinary.

We make no claim for originality of treatment. Original books are written by excellent teachers and eminent researchers; we have all the regard for their excellence and eminence. (These qualities are unfortunately conspicuous in us by their absence. However, we are very enthusiastic about chemistry). We have attempted to build on their legacy by incorporating about nine hundred solved examples in all the chapters. These examples illustrate and illuminate theoretical concepts and are, indeed, the distinguishing feature of this book. The reader is urged to master them to have an adequate understanding of the subject. It goes without saying that without the available goldmine of definitive information listed in the bibliography it would not have been possible to write this book. The bibliography is fairly representative and lists some of the best and modern books for further reading. Great books fascinate us for they are a perennial source of entertainment, instruction and edification. The chapter-end material is limited to review questions and simple problems.

Several teachers and students have over the years been sending their valuable suggestions for the improvement of the text to keep it upto date. Their feedback has tremendously helped us in introducing novel innovations in the book. We take this opportunity to thank them and hope that they would judge our efforts indulgently and continue obliging us with their constructive criticism in future also. We take pleasure in recording our sincerest thanks to M/s Vishal Publishing Co., our efficient publishers, for their courtesy, full cooperation and determination to go with us to any length in publishing the book to our entire satisfaction.

CONTENTS

CHAPTER 0

MATHEMATICAL CONCEPTS

We summarize here key concepts of mathematics often encountered in physical chemistry. It is mathematics which makes science a fascinating, frustrating and magnificent edifice.

CURVE SKETCHING, LINEAR GRAPHS AND SLOPES

Inclination of a Line and the Slope of a Line

The angle which a line makes with the positive direction of x-axis, measured in the anti-clockwise direction, is called its **inclination** (or angle of inclination), usually denoted by θ (Fig. 1). It may be mentioned that *(a)* the inclination of a line parallel to x-axis or the x-axis itself is $0°$ and *(b)* the inclination of a line parallel to the y-axis or the y-axis itself is $90°$.

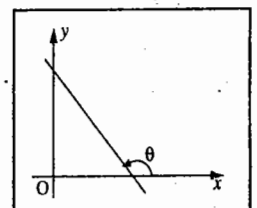

Fig. 1. Inclination of a straight line.

If $\theta (\neq 90°)$ is the inclination of a line, then $\tan\theta$ is called its **slope** (or gradient), usually denoted by m : $m = \tan\theta$.

Scientific data, obtained through painstaking research, can be best appreciated and understood by plotting graphs. Linear graphs are described by the appropriate equation of a straight line. There are several equations of a straight line, all of them first degree in x and y.

Equtions of a Straight Line

1. ***General equation of a straight line*** **is**

$$ax + by + c = 0 \qquad ...(i)$$

where both a and b are not equal to 0 and a, b, c are real numbers.

2. ***Slope–Intercept form*** **:** $y = mx + b$ ...(2)

where m is the slope of the line and b is the intercept on the y-axis.

3. ***Slope–Point form*** **:** The equation of a line with slope m and passing through a point (x_1, y_1) is

$$y - y_1 = m(x - x_1) \qquad ...(3)$$

4. ***Two–Point form*** **:** The equation of a line passing through two points (x_1, y_1) and (x_2, y_2) is

$$y - y_1 = \frac{y_2 - y_1}{x_2 - x_1}(x - x_1) \; ; \quad x_2 \neq x_1 \qquad ...(4)$$

5. ***Intercept form*** **:** $\dfrac{x}{a} + \dfrac{y}{b} = 1$ ...(5)

where x-intercept of the line is a and y-intercept is b.

The slope, m, of a line is the ratio of the change in y compared with the change in x. Thus,

$$m = \frac{\text{Change in } y}{\text{Change in } x} = \frac{dy}{dx} \qquad ...(6)$$

where dy is the infinitesimal change in y corresponding to infinitesimal change in x, dx. If (x_1, y_1) and (x_2, y_2) are two points on a line and m is the slope of the line, then

$$m = \frac{y_2 - y_1}{x_2 - x_1}; \; x_1 \neq x_2 \qquad ...(7)$$

Parallel and Perpendicular Lines : Two **non-vertical** lines are parallel if and only if the slopes of the two lines are equal, *i.e.*,

$$m_1 = m_2 \qquad ...(8)$$

Two non-vertical lines are perpendicular if and only if the product of their slopes is -1, *i.e.*,

$$m_1 m_2 = -1 \qquad ...(9)$$

Curve Sketching. In the study of motion of a particle, the displacement–time graphs and the velocity—time graphs are among the simplest graphs. The shortest distance between the initial and the final positions of an object (or a particle) is called its *displacement*, $\vec{S}$. Velocity is the rate of change of displacement : $\vec{v} = d\vec{S}/dt$. Acceleration is the rate of change of velocity : $\vec{a} = d\vec{v}/dt$.

Fig. 2 shows the commonly encountered displacement *versus* time graphs.

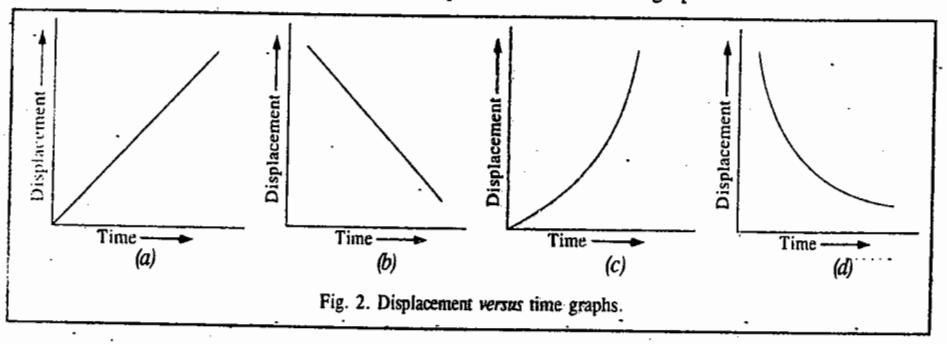

Fig. 2. Displacement *versus* time graphs.

Fig. 2*(a)* shows uniform positive velocity. Fig. 2*(b)* shows uniform negative velocity. Fig. 2*(c)* shows variable positive velocity whereas Fig. 2*(d)* shows negative variable velocity.

Functions of a Real Variable. A variable y is said to be a function of another variable x, written as $y = f(x)$, if there is a rule which relates one value of y with value of x in its range of values. For instance, if $f(x) = x^2 + 5x$, then $f(1) = 6$. That is, there is only one value of y corresponding to a single value of x. Such a function $f(x)$ is called a *single-valued function*. The variable y whose value depends on the chosen value of x is called the *dependent variable* while x is called the *independent variable*. A function $f(x)$ may have more than one value associated with it corresponding to a single value of x. Such a function is called a *multivalued function*, *e.g.*, if $y^2 = x - 5$ then $y = \pm(x-5)^{1/2}$ which indicates that corresponding to a single value of x, the function $y = f(x)$ is a double-valued function. The range (interval) of the independent variable is called the *domain* of the function. Some frequently encountered elementary functions are :

1. ***Polynomial.*** A polynomial is a function

$$f(x) = a_0 + a_1 x + a_2 x^2 + \ldots\ldots + a_n x^n \qquad ...(10)$$

where a_i are *constants* and the exponent n, which is a positive integer, is called the *degree* of the polynomial. If $f(x) = 0$, then the equation has exactly n equal roots. Thus, $x^3 - 6x^2 + 12x - 8 = 0$, *i.e.*, $(x-2)^3 = 0$ has three equal roots.

2. ***Exponential functions,*** $f(x) = e^x$ where $e = 2{\cdot}7182818\ldots\ldots$ The algebraic operations with respect to exponential functions are

$$e^x \times e^y = e^{x+y}; \quad e^x/e^y = e^{x-y}; \quad \frac{1}{e^x} = \ln x \qquad ...(11)$$

The inverse of e^x is called the **natural logarithm** of x, $\ln x$ and e is called the *base* of the logarithm. When e is replaced by 10, then $1/10^x = \log x$. This is called the **common logarithm** of x. The $\ln x$ and $\log x$ are related by $\ln x = 2{\cdot}303 \log x$. The fundamental relations satisfied by the natural (and also by the common) logarithm are

$$\ln(xy) = \ln x + \ln y \qquad \text{(Product formula)} \; ...(12)$$

$$\ln(x/y) = \ln x - \ln y \qquad \text{(Quotient formula)} \; ...(13)$$

$$\ln x^n = n \ln x \qquad \text{(Power formula)} \; ...(14)$$

3. ***Trigonometric functions*** such as $f(x) = \sin x$, $\cos x$, $\tan x$, $\cot x$, $\sec x$ and $\operatorname{cosec} x$ are *periodic*, *i.e.*, they satisfy the relation

$$f(x + k) = f(x) \qquad ...(15)$$

where k in radians is the *period* for all the periodic functions. For example, $\sin x$ and $\cos x$ have the period 2π. Note that $\sin(-x) = -\sin x$ and $\cos(-x) = \cos x$. Hence, $\sin x$ is called an *odd function* and $\cos x$ is an *even function*. Some fundamental relations among trigonometric functions are mentioned below :

(a) $\sin^2 x + \cos^2 x = 1$; $\sec^2 x = 1 + \tan^2 x$; $\operatorname{cosec}^2 x = 1 + \cot^2 x$

(b) $\sin(x \pm y) = \sin x \cos y \pm \cos x \sin y$

(c) $\cos(x \pm y) = \cos x \cos y \pm \sin x \sin y$

(d) $\tan(x \pm y) = (\tan x \pm \tan y) / (1 \pm \tan x \tan y)$

(e) $\cos 2x = \cos^2 x - \sin^2 x$; $\sin 2x = 2 \sin x \cos x = \dfrac{2 \tan x}{1 + \tan^2 x}$

(f) $\sin^2 x = \frac{1}{2}(1 - \cos 2x)$; $\cos^2 x = \frac{1}{2}(1 + \cos 2x)$

(g) $\sin 3x = 3 \sin x - 4 \sin^3 x$; $\cos 3x = 4 \cos^3 x - 3 \cos x$

(h) $\sin x + \sin y = 2 \sin \dfrac{x+y}{2} \cos \dfrac{x-y}{2}$; $\sin x - \sin y = 2 \cos \dfrac{x+y}{2} \sin \dfrac{x-y}{2}$

(i) $\cos x + \cos y = 2 \cos \dfrac{x+y}{2} \cos \dfrac{x-y}{2}$

(j) $\cos x - \cos y = 2 \sin \dfrac{x+y}{2} \sin \dfrac{y-x}{2} = -2 \sin\left(\dfrac{x+y}{2}\right) \sin\left(\dfrac{x-y}{2}\right)$

4. ***Inverse trigonometric functions*** such as $f(x) = \sin^{-1} x$, $\cos^{-1} x$, $\tan^{-1} x$, etc., are the inverse of the corresponding trigonometric functions. For example, if $x = \sin y$, then

$$y = (-1)^n \sin^{-1}(x + n\pi), \; n = 0, 1, 2, \ldots\ldots \text{ and } -\pi/2 \leq \sin^{-1} x \leq \pi/2 \qquad ...(16)$$

When $n = 0$, $y = \sin^{-1} x$ is the *principal value* of the angle y.

5. ***Hyperbolic functions*** are defined in terms of the exponential functions as

$$\sinh x = \tfrac{1}{2}(e^x - e^{-x}); \qquad \cosh x = \tfrac{1}{2}(e^x + e^{-x}) \qquad ...(17)$$

$$\tanh x = \frac{e^x - e^{-x}}{e^x + e^{-x}}; \qquad \coth x = \frac{e^x + e^{-x}}{e^x - e^{-x}} \qquad ...(18)$$

DIFFERENTIATION

Derivative of a Function. The derivative of a function $y = f(x)$ at a point x is defined as

$$f'(x) = \lim_{h\to 0} \frac{f(x+h)-f(x)}{h} = \lim_{\Delta x\to 0} \frac{\Delta y}{\Delta x} = \frac{dy}{dx} \quad \ldots(19)$$

where $\Delta x = h$ and $\Delta y = f(x + h) - f(x)$ are the increments in the variables x and y, respectively. The derivative of $f(x)$ is denoted by dy/dx provided the limit exists, *i.e.*,

$$\frac{dy}{dx} = \lim_{h\to 0} \frac{f(x+h)-f(x)}{h} \quad \ldots(20)$$

and may be interpreted as the rate of change of y w.r.t. x. The process of finding the derivative is called *differentiation*. The derivative of the function $f(x)$ at a given point represents a slope of the tangent drawn to the curve of $y = f(x)$ at the point where the function is defined. The derivative is also called *differential coefficient (d.c.)*.

Differentiation Formulas. We give below a few differentiation formulas which the reader should memorize. In these formulas it is assumed that u and v are differentiable functions of x and c, n are arbitrary constants :

1. $\frac{d}{dx}(c) = 0$

2. $\frac{d}{dx}(u+v) = \frac{du}{dx} + \frac{dv}{dx}$

3. $\frac{d}{dx}(cx) = c\frac{du}{dx}$ [The constant multiple rule]

4. $\frac{d(uv)}{dx} = u\frac{dv}{dx} + v\frac{du}{dx}$ [The product rule]

5. $\frac{d}{dx}(u/v) = \frac{v\frac{du}{dx} - u\frac{dv}{dx}}{v^2}, \; v \neq 0$ [The quotient rule]

6. $\frac{dx^n}{dx} = nx^{n-1}$ [The power rule for positive and negative integers]

7. $\frac{de^x}{dx} = e^x$

8. $\frac{da^x}{dx} = a^x \log a$

9. $\frac{d}{dx}(\log x) = \frac{1}{x}$

10. $\frac{d}{dx}(\sin x) = \cos x$

11. $\frac{d}{dx}(\cos x) = -\sin x$

12. $\frac{d}{dx}(\tan x) = \sec^2 x$

13. $\frac{d}{dx}(\cot x) = -\operatorname{cosec}^2 x$

14. $\frac{d}{dx}(\sec x) = \sec x \times \tan x$

15. $\frac{d}{dx}(\operatorname{cosec} x) = -\operatorname{cosec} x \times \cot x$

16. $\frac{d}{dx}(\sin^{-1} x) = \frac{1}{\sqrt{1-x^2}}$

17. $\frac{d}{dx}(\cos^{-1} x) = -\frac{1}{\sqrt{1-x^2}}$

18. $\frac{d}{dx}(\tan^{-1} x) = \frac{1}{1+x^2}$

19. $\frac{d}{dx}(\cot^{-1} x) = -\frac{1}{1+x^2}$

20. $\frac{d}{dx}(\sec^{-1} x) = \frac{1}{x\sqrt{x^2-1}}$

21. $\frac{d}{dx}(\operatorname{cosec}^{-1} x) = -\frac{1}{x\sqrt{x^2-1}}$

The Chain Rule. It states that the derivative of the composite of two differentiable functions is the product of their derivatives evaluated at appropriate points. Thus,

$$\frac{dy}{dx} = \frac{dy}{du} \times \frac{du}{dx} \quad \ldots(21)$$

Example 1. Differentiate x^x w.r.t. x

Solution : Let $y = x^x$

Taking logs, $\log y = x \log x$ [Note this step]

Differentiating w.r.t. x, $\frac{1}{y}\frac{dy}{dx} = x\left(\frac{1}{x}\right) + \log x(1) = 1 + \log x$

$\therefore$ $dy/dx = y(1 + \log x) = x^x(1 + \log x)$

Maxima and Minima. Graphs of functions show maxima and/or minima and in some cases the functions are merely increasing or decreasing. The first derivative $f'(x)$ and the second derivative $f''(x)$ of a function $f(x)$ play a key role here.

A function $f(x)$ is said to have a *maximum* for $x = a$ if $f(x) - f(a)$ is negative for all x when $|x-a| < \varepsilon$, where ε is a small positive number. A function $f(x)$ is said to have a *minimum* for $x = a$ if $f(x) - f(a)$ is positive for all x when $|x - a| < \varepsilon$, where ε is a small positive number.

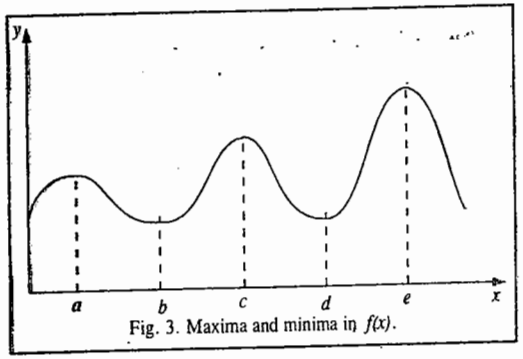

Fig. 3. Maxima and minima in $f(x)$.

Fig. 3 shows a plot of $f(x)$ versus x showing several maxima and minima. We see from the figure that a, c and e are the maxima and b and d are the minima. It should be pointed out that the maximum value of $f(x)$ at a point is not necessarily its greatest value and similarly, the minimum value of the function at a point is not necessarily its smallest value. The following points should be noted :

(*i*) At least one maximum or one minimum lies between two equal values of a function.

(*ii*) Maxima and minima must occur alternately.

(*iii*) A function may have several maxima and minima.

(*iv*) A function $y = f(x)$ is maximum at $x = a$ if dy/dx changes its sign from +ve to -ve as x passes through a.

(*v*) A function $y = f(x)$ is minimum at $x = a$ if dy/dx changes its sign from -ve to +ve as x passes through a.

(*vi*) If the sign of dy/dx does not change while x passes through a, then the function $y=f(x)$ is neither maximum nor minimum at $x = a$.

(*vii*) A function $f(x)$ is said to be *monotonically increasing* if $f'(x) > 0$.

(*viii*) A function $f(x)$ is said to be *monotonically decreasing* if $f'(x) < 0$.

Rules for finding Maxima-Minima

(*i*) Find $f'(x)$.

(*ii*) Solve $f'(x) = 0$. Each value of x so obtained is a candidate for a maximum or a minimum. Let $x = c$ be one of its points.

(*iii*) Find $f''(x)$. (*a*) If $f''(c) > 0$, then $x = c$ is a point of minima. (*b*) If $f''(c) < 0$, then $x = c$ is a point of maxima.

Maxima or Minima in an Interval :

Let $f(x)$ be a function defined in an interval $[a, b]$. Let $x = c$ be a candidate for a maximum. Then, max. $\{f(a), f(b), f(c)\}$ is the maximum value of the function. Similarly, let $x = d$ be a point of a minimum. Then, min. $\{f(a), f(b), f(d)\}$ is the minimum value of the function.

Example 2. Determine the interval in which

(i) $f(x) = x^3 + 3x^2 - 105x + 5$ is decreasing.

(ii) $f(x) = 2x^3 - 15x^2 + 36x + 7$ is increasing.

Solution : *(i)* $f'(x) = 3x^2 + 6x - 105 = 3(x - 5)(x + 7)$. Clearly, $f'(x) < 0$ when $-7 < x < 5$. Hence, $f(x)$ is decreasing in the interval $]-7, 5[$

(ii) $$f'(x) = 6x^2 - 30x + 36 = 6(x - 3)(x - 2)$$

Clearly, $f'(x) > 0$ when $x < 2$ and also when $x > 3$. Hence $f(x)$ is increasing in the interval $]-\infty, 2[\cup]3, \infty[$.

Example 3. Determine the interval in which

(i) $f(x) = x^4 - 2x^2$ is decreasing

(ii) $f(x) = x^3 + 2x^2 - 3$ is increasing.

Solution : *(i)* $f'(x) = 4x^3 - 4x = 4x(x - 1)(x + 1)$

Clearly, $f'(x) < 0$ when $x < -1$ and also when $x > 1$. Hence, $f(x)$ is decreasing in the interval $]-\infty, -1[\cup]1, \infty[$

(ii) $$f'(x) = 3x^2 + 4x = 3x\left(x + \frac{4}{3}\right)$$

Clearly, $f'(x) > 0$ when $x < -\frac{4}{3}$ and also when $x > 0$. Hence, $f(x)$ is increasing in the interval $]-\infty, -\frac{4}{3}[\cup]0, \infty[$

Example 4. When x is positive, what is the maximum value of $(1/x)^x$?

Solution : Let $$y = (1/x)^x = x^{-x}$$

Taking logs, $$\log y = -x \log x$$

Differentiating, $$\frac{1}{y}\frac{dy}{dx} = -x \times \frac{1}{x} - \log x \times 1 = -(1 + \log x)$$

$$\therefore \quad \frac{dy}{dx} = -x^{-x}(1 + \log x)$$

$$\frac{d^2y}{dx^2} = x^{-x}(1 + \log x)^2 - x^{-x} \times \frac{1}{x}$$

$$= x^{-x}(1 + \log x)^2 - x^{-x-1}$$

Now, $dy/dx = 0$ implies that $(1 + \log x) = 0$

or $$\log x = -1 = \log (1/e) \text{ so that } x = 1/e.$$

$$\therefore \quad \left[\frac{d^2y}{dx^2}\right]_{x=1/e} = -\left(\frac{1}{e}\right)^{-\frac{1}{e}-1} < 0$$

Hence, $x = 1/e$ is a point of maxima.

$$\therefore \quad \text{Maximum value} = e^{1/e}$$

Example 5. Show that the function $y = x^5 - 5x^4 + 5x^3 - 10$ has a maximum for $x = 1$, a minimum for $x = 3$ and neither a maximum nor a minimum for $x = 0$. (The point $x = 0$ is called an inflection point).

Solution. $$y = x^5 - 5x^4 + 5x^3 - 10$$

$$dy/dx = 5x^4 - 20x^3 + 15x^2 = 5x^2(x^2 - 4x + 3)$$

For the given function to have a maximum or a minimum, $dy/dx = 0$ so that

$$5x^2(x^2 - 4x + 3) = 0 \text{ ; whence } x = 0, 1, 3$$

Now, $$d^2y/dx^2 = 20x^3 - 60x^2 + 30x$$

$$\left[\frac{d^2y}{dx^2}\right]_{x=1} = 20(1)^3 - 60(1)^2 + 30(1) = -10 < 0.$$

Hence, $x = 1$ is a point of maximum.

Again, $$\left[\frac{d^2y}{dx^2}\right]_{x=3} = 20(3)^3 - 60(3)^2 + 30(3) = 90 > 0.$$

Hence, $x = 3$ is a point of minimum.

Now, $$\left[\frac{d^2y}{dx^2}\right]_{x=0} = 0 \text{ and } d^3y/dx^3 = 60x^2 - 120x + 30$$

$$\left[\frac{d^3y}{dx^3}\right]_{x=0} = 30 \neq 0$$

Hence, there is neither a maximum nor a minimum at $x = 0$. This is called a ***point of inflection.***

Partial Differentiation

We can extend the concept of differentiation of a function of one variable to that of a function of two or more variables. Let $z = f(x, y)$ be a function of two independent variables (x, y). The *partial derivatives* of $f(x, y)$ with respect to x and y are defined by

$$\frac{\partial z}{\partial x} = \frac{\partial f}{\partial x} = \lim_{\Delta x \to 0} \frac{f(x + \Delta x, y) - f(x, y)}{\Delta x} \qquad \ldots(22)$$

$$\frac{\partial z}{\partial y} = \frac{\partial f}{\partial y} = \lim_{\Delta y \to 0} \frac{f(x, y + \Delta y) - f(x, y)}{\Delta y} \qquad \ldots(23)$$

provided the limits exist. For the partial derivative $\partial f/\partial x$, y is held constant and x is considered as a variable. Similarly, for the partial derivative $\partial f/\partial y$, x is held constant and y is considered as a variable.

The differentiation of $\partial f/\partial x$ w.r.t. x or y yields second-order derivatives :

$$\frac{\partial}{\partial x}\left(\frac{\partial f}{\partial x}\right) = \frac{\partial^2 f}{\partial x^2} \text{ and } \frac{\partial}{\partial y}\left(\frac{\partial f}{\partial x}\right) = \frac{\partial^2 f}{\partial y \partial x} \qquad \ldots(24)$$

Similarly, $$\frac{\partial}{\partial x}\left(\frac{\partial f}{\partial y}\right) = \frac{\partial^2 f}{\partial y \partial x}, \text{ and } \frac{\partial}{\partial y}\left(\frac{\partial f}{\partial y}\right) = \frac{\partial^2 f}{\partial y^2} \qquad \ldots(25)$$

If $f(x, y)$ and its partial derivatives (also called *partial differential coefficients*) are continuous, then the order of differentiation is immaterial, *i.e.*,

$$\partial^2 f/\partial x \partial y = \partial^2 f/\partial y \partial x \quad i.e., \quad f_{xy} = f_{yx} \qquad \ldots(26)$$

The **total differential** df of the function $f(x, y)$ is defined as

$$df = \left(\frac{\partial f}{\partial x}\right) dx + \left(\frac{\partial f}{\partial y}\right) dy \qquad \ldots(27)$$

Euler Reciprocal (Reciprocity) Relation

Let $z = f(x, y)$ be the state function of the two independent variables x and y. A state function depends upon the initial and the final states of a system and is independent of the path via which the state is reached. The differential of z, called an *exact or total differential*, is given by

$$dz = \left(\frac{\partial z}{\partial x}\right)_y dx + \left(\frac{\partial z}{\partial y}\right)_x dy \qquad \ldots(28)$$

$$= M(x, y)\,dx + N(x, y)\,dy \qquad ...(29)$$

where $$M(x, y) = (\partial z/x)_y \text{ and } N(x, y) = (\partial z/\partial y)_x \qquad ...(30)$$

Since $M(x, y)$ and $N(x, y)$ are assumed to have continuous partial derivatives,

$$\frac{\partial^2 z}{\partial x \partial y} = \frac{\partial^2 z}{\partial y \partial x} \qquad ...(31)$$

Taking mixed second derivatives of Eq. 30, we have

$$\left(\frac{\partial M}{\partial y}\right)_x = \frac{\partial^2 z}{\partial y \partial x}; \quad \text{and} \quad \left(\frac{\partial N}{\partial x}\right)_y = \frac{\partial^2 z}{\partial x \partial y} \qquad ...(32)$$

From Eqs. 31 and 32, we obtain

$$\left(\frac{\partial M}{\partial y}\right)_x = \left(\frac{\partial N}{\partial x}\right)_y \qquad ...(33)$$

Eq. 33 is called the *Euler reciprocity relation*. It corresponds to an *exact differential*.

Euler Chain Relation (Cyclic Rule). From Eq. 28 we see that if the change occurs at constant z, then $dz = 0$ so that

$$0 = \left(\frac{\partial z}{\partial x}\right)_y dx + \left(\frac{\partial z}{\partial y}\right)_x dy \qquad ...(34)$$

Hence, $$\left(\frac{\partial x}{\partial y}\right)_z = -\frac{(\partial z/\partial y)_x}{(\partial z/\partial x)_y} \qquad ...(35)$$

or $$\left(\frac{\partial z}{\partial x}\right)_y \left(\frac{\partial x}{\partial y}\right)_z \left(\frac{\partial y}{\partial z}\right)_x = -1 \qquad ...(36)$$

Eq. 36 is called the *Euler chain relation* (or the cyclic rule), applicable only for state functions.

Leonhard Euler (1707-1783), the Swiss mathematician, was the most prolific mathematician of all time, who made important contributions to mathematical analysis, algebra and hydrodynamics.

INTEGRATION

If $f(x) = dy/dx$ on a certain interval of the x-axis, then y is called the *antiderivative* or *indefinite integral* of x and is denoted by

$$y = \int f(x)dx = \int \frac{dy}{dx}dx \qquad ...(37)$$

The indefinite integral of a given function is note unique. It differs by an integration constant, c. The *definite integral* of $f(x)$ with respect to x between the interval $a \le x \le b$ is defined as

$$\int_a^b f(x)dx = \lim_{h\to 0} h[f(a) + f(a + h) + f(a + 2h) + \cdots\cdots + f(a + (n - 1)h] \qquad ...(38)$$

provided the limit exists. The quantities a and b are called the *lower* and the *upper* limits of the integral. Eq. 38 can be written symbolically as

$$\int_a^b f(x)dx = \lim_{h\to 0} h \sum_{k=0}^{k=n-1} f(a + kh) \qquad ...(39)$$

If $f(x)$ is continuous over the interval $a \le x \le b$, then the definite integral 39 represents the area under the curve $y = f(x)$ bounded by x-axis and the coordinates at $x = a$ and $x = b$. The process of finding integrals is called *integration*. Below are given some important theorems for both the definite and the indefinite integrals :

(i) If $g(x) = \int_a^b f(x)\,dx$, then $\frac{dg(x)}{dx} = f(x)$ ...(40)

(ii) If $f(x) = \frac{dg(x)}{dx}$ is continuous in the interval $a \le x \le b$, then

$$\int_a^b f(x)\,dx = g(x)\Big|_a^b = g(b) - g(a) \qquad ...(41)$$

Methods of Integration. For the discussion of methods of integration, the reader should refer to books on calculus.

Integration Formulas. Below are listed some integration formulas for both the indefinite and the definite integrals, the arbitrary constants of integration have been omitted (these constants must be included for indefinite integrals). These formulas have been derived in standard text books of calculus.

a. Indefinite Integrals

1. $\int \frac{df(x)}{dx}dx = f(x)$
2. $\int [f(x) \pm g(x)]\,dx = \int f(x)dx \pm \int g(x)dx$
3. $\int c\,f(x)\,dx = c\int f(x)\,dx$
4. $\int x^n\,dx = \frac{x^{n+1}}{n+1}; \; n \ne -1$
5. $\int \sin x\,dx = -\cos x$
6. $\int \cos x\,dx = \sin x$
7. $\int \tan x\,dx = \log_e(\sec x)$
8. $\int \cot x\,dx = \log_e(\sin x)$
9. $\int \sec x\,dx = \log_e(\sec x + \tan x)$
10. $\int \operatorname{cosec} x\,dx = \log_e(\operatorname{cosec} x - \cot x)$
11. $\int \sec^2 x\,dx = \tan x$
12. $\int \operatorname{cosec}^2 x\,dx = -\cot x$
13. $\int e^x\,dx = e^x$
14. $\int \frac{dx}{x} = \log_e x$
15. $\int e^{ax}\sin bx\,dx = \frac{e^{ax}(a\sin bx - b\cos bx)}{a^2 + b^2}$
16. $\int e^{ax}\cos bx\,dx = \frac{e^{ax}(a\cos bx + b\sin bx)}{a^2 + b^2}$
17. $\int \frac{dx}{\sqrt{a^2 - x^2}} = \sin^{-1}\frac{x}{a}$
18. $\int \frac{dx}{\sqrt{a^2 + x^2}} = \tan^{-1}\frac{x}{a}$
19. $\int \sinh x\,dx = \cosh x$
20. $\int \cosh x\,dx = \sinh x$

b. Definite Integrals

21. $\int_0^\infty e^{-ax^2}dx = \frac{1}{2}\left(\frac{\pi}{a}\right)^{\frac{1}{2}}$
22. $\int_0^\infty x^n e^{-ax}\,dx = \frac{n!}{a^{n+1}}$
23. $\int_0^\infty x^{2n} e^{-ax^2}dx = \frac{(1)(3)(5)\ldots(2n-1)}{2^{n+1}a^n}\left(\frac{\pi}{a}\right)^{1/2}$

24. $\int_0^\infty x\,e^{-ax^2}dx = \frac{1}{2a}$ 25. $\int_0^a f(x)\,dx = \int_0^a f(x-a)\,dx$

26. $\int_{-a}^{a} f(x)\,dx = \begin{cases} 0, \text{when } f(x) \text{ is odd} \\ 2\int_0^a f(x)dx, \text{when } f(x) \text{ is even} \end{cases}$

Example 6. Evaluate the following integrals :

(i) $\int_0^{\pi/2} \sin^2 x\,dx$ *(ii)* $\int_0^{\pi/2} \cos^2 x\,dx$

Solution :

(i) $\int_0^{\pi/2} \sin^2 x\,dx = \int_0^{\pi/2} \frac{1-\cos 2x}{2}dx = \frac{1}{2}\left[x - \frac{\sin 2x}{2}\right]_0^{\pi/2} = \frac{\pi}{4}$

(ii) $\int_0^{\pi/2} \cos^2 x\,dx = \int_0^{\pi/2} \frac{1+\cos 2x}{2}dx = \frac{1}{2}\left[x + \frac{\sin 2x}{2}\right]_0^{\pi/2} = \frac{\pi}{4}$

Example 7. Evaluate the following integrals :

(i) $\int \tan^2 x\,dx$ *(ii)* $\int e^{-\log x}\,dx$

Solution : *(i)* $\int \tan^2 x\,dx = \int (\sec^2 x - 1)\,dx = \int \sec^2 x\,dx - \int 1\,dx$

$= \tan x - x + c$, where c is the constant of integration

(ii) $\int e^{-\log x}\,dx = \int e^{\log(x^{-1})}\,dx = \int x^{-1}\,dx = \int \frac{dx}{x} = \log|x| + c$,

where c is the constant of integration.

Example 8. Evaluate the integral $\int_{-\infty}^{\infty} x e^{-ax^2}dx$

Solution : $\int_{-\infty}^{\infty} x e^{-ax^2}dx = \int_{-\infty}^{0} x e^{-ax^2}dx + \int_0^{\infty} x e^{-ax^2}dx = -\int_0^{\infty} x e^{-ax^2}dx + \int_0^{\infty} x e^{-ax^2}dx$

$= 0$ [since xe^{-ax^2} is an odd function]

Example 9. Show that $\int u\,dv = uv - \int v\,du$

Solution : Since $d(uv) = u\,dv + v\,du$, we have

$\int d(uv) = \int u\,dv + \int v\,du$ or $uv = \int u\,dv + \int v\,du$

Hence, $\int u\,dv = uv - \int v\,du$

Example 10. Evaluate $\int \log x\,dx$

Solution : $\int \log x\,dx = \int 1 \times \log x\,dx = (\log x)x - \int \frac{1}{x} x\,dx + c$,

$= x \log x - x + c = x(\log x - 1) + c$,

where c is an arbitrary constant.

Factorial Notation. The factorial $n!$ of a natural number n is defined as the product of the first n natural numbers :

$n! = n(n-1)(n-2)\cdots\cdots(2)(1)$ ...(42)

Thus, $4! = (4)(3)(2)(1) = 24$

Also, $n! = n(n-1)!$ and $0! = 1$, *i.e.*, zero factorial = 1 ...(43)

PERMUTATIONS AND COMBINATIONS

Permutations mean arrangements whereas combinations mean selections (or forming groups). We shall summarize some basic concepts here.

1. Fundamental Theorem. If there are m ways of doing a thing and for each of these m ways there are associated n ways of doing a second thing, then the total number of ways of doing both the things is $m \times n$.

2. Permutations

(i) The number of permutations of n dissimilar things taken r at a time is given by

$${}^nP_r = \frac{n!}{(n-r)!} = n(n-1)(n-2)\cdots\cdots(n-r+1) \quad ...(44)$$

(ii) Number of permutations of n dissimilar things, taken all at a time is ${}^nP_n = n!$

(iii) Number of circular permutations of n different things taken all at a time is $(n-1)!$.

(iv) Number of permutations of n things, taken all at a time, when p_1 are alike of one kind, p_2 are alike of second kind,....., p_r are alike of rth kind, is given by

$$\frac{n!}{(p_1!)(p_2!)\ldots(p_r!)} \quad ...(45)$$

3. Combinations

(i) Number of combinations of n different things, taken r at a time, is given by

$${}^nC_r = \frac{n!}{(n-r)!(r!)} = \frac{{}^nP_r}{r!} \quad ...(46)$$

(ii) ${}^nC_o = 1, {}^nC_n = 1$ ...(47)

(iii) ${}^nC_p = {}^nC_q \Rightarrow p + q = n$ or $p = q$ ...(48)

(iv) ${}^nC_r = {}^nC_{n-r}$ ...(49)

(v) ${}^nC_{r-1} + {}^nC_r = {}^{n+1}C_r$ ...(50)

(vi) Number of combinations of n different things, taken r at a time when p particular things always occur is given by

$$= {}^{n-p}C_{r-p} \quad ...(51)$$

(vii) Number of combinations of n different things taken r at a time when p particular things never occur is given by

$${}^{n-p}C_r \quad ...(52)$$

Example 11. In how many ways can 4 letters be mailed if there are 3 boxes available ?

Solution : Each of the 4 letters may be mailed in any of the 3 mail boxes. Hence, the required number of ways is

$(3)(3)(3)(3) = 3^4 = 81$

Example 12. If ${}^4P_r = 3024$ **and** ${}^nC_r = 126$, **find** r.

Solution : ${}^nP_r = r!\,({}^nC_r)$ [From Eq. 46]

$\therefore \quad r! = \frac{{}^nP_r}{{}^nC_r} = \frac{3024}{126} = 24$

$\therefore \quad r = 4$

Example 13. How many diagonals are there in a polygon of n sides ?

Solution : A polygon having n sides has n vertices. On joining any two vertices at a time, we obtain either a side or a diagonal. Thus, the number of all such line sigments is ${}^nC_2$. These contain n sides.

Hence, number of diagonals $= {}^nC_2 - n = \frac{n(n-1)}{2} - n = \frac{1}{2}n(n-3)$

Example 14. What is the number of diagonals in a decagon ?

Solution : Number of diagonals $= \frac{1}{2}n(n-3) = \frac{1}{2}(10)(10-3) = 35$

PROBABILITY

Let us consider an experiment which involves random drawing of one card from a well-shuffled pack of 52 playing cards. Each drawing of a card is called an *event*. There will be 52 events if we draw one card at a time from a pack of 52 cards. These events are designated as E_1, E_2,....., E_{52}. Other examples of events include throwing a dice and tossing a coin. The result of a single performance of the experiment is called the *outcome* of the event.

1. Random Experiment. If in each trial of an experiment conducted under identified conditions, the *outcome* is not always the same but may be any of the possible outcomes, then that experiment is called a *random experiment*. Thus, tossing a fair coin, rolling an unbiased dice, drawing a card from a well-shuffled pack of cards are all examples of random experiment.

2. Sample space. The set of all possible outcomes in a random experiment is called a *sample space* S . Let us consider the following examples :

(i) In tossing a fair coin we have

$$S = \{H, T\}, \quad i.e., \{head, tail\}$$

where the head H and tail T are enclosed in braces.

(ii) In a throw of a dice, we have

$$S = \{1, 2, 3, 4, 5, 6\}$$

(iii) When two coins are tossed together,

$$S = \{HH, HT, TH, TT\}$$

(iv) When two dices are thrown together,

$$\begin{aligned} S = \{&(1,1), (1,2), (1,3), (1,4), (1,5), (1,6)\\ &(2,1), (2,2), (2,3), (2,4), (2,5), (2,6),\\ &(3,1), (3,2), (3,3), (3,4), (3,5), (3,6),\\ &(4,1), (4,2), (4,3), (4,4), (4,5), (4,6),\\ &(5,1), (5,2), (5,3), (5,4), (5,5), (5,6),\\ &(6,1), (6,2), (6,3), (6,4), (6,5), (6,6)\} \end{aligned}$$

4. Simple Event. Each outcome of an experiment is called a *simple event.*

5. Event. Any combination of simple events is called an *event* denoted by the upper case letter E. (Other uppercase letters such as A, B, C, etc., can also be used to denote an event.) Thus, for example, when a die is thrown, then each one of 1, 2, 3, 4, 5, 6 is a simple event. However, getting a prime number is an event : $E = \{2, 3, 5\}$.

6. Mutually Exclusive Event. A set of events is called *mutually exclusive* if the happening of one event excludes the happening of the other. Thus, E_1 and E_2 are mutually exclusive if

$$E_1 \cap E_2 = \phi \text{ where } \phi \text{ is an empty set.}$$

If $E_1 \cap E_2 \neq \phi$, then E_1 and E_2 are called *compatible events.*

Let us consider throwing a dice ; we have

$$S = \{1, 2, 3, 4, 5, 6\}$$

Let E_1 be the event of getting a number less than 3; clearly, $E_1 = \{1, 2\}$. Also, let E_2 be the event of getting a number greater than 4. Clearly, $E_2 = \{5, 6\}$. We see that $E_1 \cap E_2 = \phi$.

7. Exhaustive Events. The events E_1, E_2,.....,E_k such that $E_1 \cup E_2 \cup ..... \cup E_k = S$ are called *exhaustive events.*

8. Equally Likely Events. Events are said to be equally likely if none of them is expected to occur in preference to the other. Thus, drawing a card from a pack of well-shuffled cards results in 52 *equally likely events.*

9. Probability. In a random experiment let S be the sample space and let E be a subset of S, *i.e.*, $E \subseteq S$. Then E is an event. Then

$$P(E) = \frac{\text{Number of distinct elements in } E}{\text{Number of distinct elements in } S} = \frac{n(E)}{n(S)} \quad ...(53)$$

$$= \frac{\text{Number of outcomes favourable to } E}{\text{Number of all possible outcomes}} \quad ...(54)$$

10. Odds in favour of an Event and Odds Against it. If m is the number of ways an event can occur and n is the number of ways in which it does not occur, then

(i) Odds in favour of the event $= m/n$ ...(55)

(ii) Odds against the event $= n/m$ ...(56)

11. Complementary Event. Let S be the sample space and let $E \subseteq S$. Then, E is an event. Also, $E^c \subseteq S$. Hence, E^c is also an event, called the *complementary event,* sometimes denoted by $\bar{E}$ or E'.

12. Addition Theorem :

$$P(E_1 \cup E_2) = P(E_1) + P(E_2) - P(E_1 \cap E_2) \quad ...(57)$$

Note that if $E_1 \cap E_2 = \phi$ (*i.e.*, an empty set), then

$$P(E_1 \cup E_2) = P(E_1) + P(E_2) \quad ...(58)$$

13. Independent Events. Two events are said to be *independent* if the occurrence of one does not depend on the occurrence of the other. For example, suppose two coins are tossed. Let E_1 be the event of getting a head on the first coin and let E_2 be the event of getting a head on the second coin. Evidently, the occurrence of head on the second coin does not depend on the occurrence of head on the first coin. Thus, E_1 and E_2 are *independent events.*

14. Multiplication Theorem. If E_1 and E_2 are independent events, then

$$P(E_1 \cap E_2) = P(E_1) \cdot P(E_2) \quad ...(59)$$

15. Conditional Probability. The probability of the occurrence of an event E_1 when an event E_2 has already occurred, is called the *conditional probability,* $P(E_1/E_2)$. It can be shown that

(i) $$P(E_1/E_2) = \frac{P(E_1 \cap E_2)}{P(E_2)} \quad ...(60)$$

(ii) $$P(E_2/E_1) = \frac{P(E_1 \cap E_2)}{P(E_1)} \quad ...(61)$$

16. Binomial Theorem of Probability. Let there be n independent trials of an experiment with p as the probability of success and $q = (1 - p)$ as the probability of failure. Then,

$$P(r \text{ successes}) = {}^nC_r\, p^r\, q^{n-r} \quad ...(62)$$

17. Mathematical Expectation. If x is a random variable having values $x_1, x_2, x_3, \ldots\ldots, x_n$ with corresponding probabilities $p_1, p_2, p_3, \ldots\ldots, p_n$, then the mathematical expectation of x is defined as

$$E(x) = x_1p_1 + x_2p_2 + \ldots\ldots + x_np_n = \sum_{i=1}^{n} x_ip_i \qquad \ldots(63)$$

Example 15. A fair coin is tossed twice. Calculate the probability of getting heads in both trials.

Solution : $S = \{HH, HT, TH, TT\}$; $E = \{HH\}$

$$\therefore \quad P(\text{both heads}) = \frac{n(E)}{n(S)} = \frac{1}{4} \qquad \text{[Eq. 53]}$$

Example 16. A card is drawn from a well shuffled pack of 52 cards. What is the probability of getting a king of heart or a queen of club ?

Solution : Total number of ways = 52

Since there is one king of heart and one queen of club, therefore, number of favourable ways = 1 + 1 = 2

$$\therefore \quad \text{The required probability} = \frac{2}{52} = \frac{1}{26}.$$

Example 17. What is the probability that a card drawn from a well-shuffled pack of 52 playing cards is a black card or an ace ?

Solution : Total number of ways = 52.

There are 26 black cards and 4 aces but two aces are black.

$$\therefore \quad \text{Number of favourable ways} = 26 + 4 - 2 = 28$$

$$\therefore \quad \text{The required probability} = \frac{28}{52} = \frac{7}{13}$$

Example 18. What is the probability that a card drawn at random from a well-shuffled pack of 52 playing cards will be a diamond or a king ?

Solution : There are 13 cards of diamond and 4 kings but one of them is a king of diamond.

Number of favourable ways = 13 + 4 - 1 = 16. The required probability $= \frac{16}{52} = \frac{4}{13}$.

Example 19. A pair of dice is thrown. What is the probability of getting a total of 7 ?

Solution : Total number of possible outcomes = $6 \times 6 = 36$

Let E be the event of getting a total of 7. Then,

$$E = \{(1, 6), (2, 5), (3, 4), (4, 3), (5, 2), (6, 1)\}$$

$$\therefore \quad P \text{ (a total of 7)} = \frac{n(E)}{n(S)} = \frac{6}{36} = \frac{1}{6}$$

OTHER MATHEMATICAL RELATIONS

We summarize other concepts in mathematics which are needed to understand wave mechanics and statistical mechanics. No details will be given here.

1. Vectors. A vector in three-dimensional space can be represented in terms of the unit vectors $\hat{i}, \hat{j}, \hat{k}$ in the x, y and z directions :

$$A = A_x\hat{i} + A_y\hat{j} + A_z\hat{k}$$

where A_x, A_y and A_z are the projections on the x, y and z axes. Using the Pythagorus theorem, the length of A is given by

$$|A| = A = (A_x^2 + A_y^2 + A_z^2)^{1/2}$$

The **dot product** (scalar product) $A.B$ of two vectors is defined by

$$A.B = |A||B| \cos\theta = B.A$$

where θ is the angle between the vectors. The dot product is a scalar. In terms of the components,

$$A.B = A_xB_x + A_yB_y + A_zB_z$$

The cross product (vector product) is a vector with the magnitude

$$|A \times B| = |A||B| \sin\theta$$

pointed perpendicular to the plane defined by A and B in the direction such that A, B and $A \times B$ form a right-handed system. The vector product can be conveniently expressed in terms of the components of the individual vectors in the determinantal form :

$$A \times B = \begin{vmatrix} \hat{i} & \hat{j} & \hat{k} \\ A_x & A_y & A_z \\ B_x & B_y & B_z \end{vmatrix}$$

In terms of the components, we have

$$A \times B = (A_yB_z - A_zB_y)\,\hat{i} + (A_zB_x - A_xB_z)\,\hat{j} + (A_xB_y - A_yB_x)\,\hat{k}$$

2. Matrices. A matrix is an array of numbers. If a matrix has m rows and n columns it may be represented as

$$A = \begin{vmatrix} a_{11} & a_{12} & a_{13} & \ldots. & a_{1n} \\ a_{21} & a_{22} & a_{23} & \ldots. & a_{2n} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ a_{m_1} & a_{m_2} & a_{m_3} & & a_{mn} \end{vmatrix}$$

The sum of two matrices is defined by

$$C = A + B$$

where $c_{ij} = a_{ij} + b_{ij}$ for every i and j.

The product of a scalar c and a matrix is defined by

$$B = cA$$

where $b_{ij} = ca_{ij}$ for every i and j.

The product of two matrices is similar to the scalar product of two vectors :

$$C = AB \text{ where}$$

$$c_{ij} = \sum_{k=1}^{n} a_{ik}\, b_{kj}$$

where n is the number of columns in A.

If we want to multiply B by A, then B must have as many rows as A has columns. For example,

$$AB = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \\ a_{31} & a_{32} \end{bmatrix} \begin{bmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{bmatrix} = \begin{bmatrix} a_{11}b_{11} + a_{12}b_{21} & a_{11}b_{12} + a_{12}b_{22} \\ a_{21}b_{11} + a_{22}b_{21} & a_{21}b_{12} + a_{22}b_{22} \\ a_{31}b_{11} + a_{32}b_{21} & a_{31}b_{12} + a_{32}b_{22} \end{bmatrix}$$

Matrix multiplication is not *commutative* ; for example, let

$$A = \begin{bmatrix} 2 & 1 \\ 3 & -2 \end{bmatrix} \text{ and } B = \begin{bmatrix} 1 & 4 \\ 0 & 2 \end{bmatrix}$$

Then,

$$AB = \begin{bmatrix} 2 & 1 \\ 3 & -2 \end{bmatrix} \begin{bmatrix} 1 & 4 \\ 0 & 2 \end{bmatrix} = \begin{bmatrix} 2\times1+1\times0 & 2\times4+1\times2 \\ 3\times1-2\times0 & 3\times4-2\times2 \end{bmatrix} = \begin{bmatrix} 2 & 10 \\ 3 & 8 \end{bmatrix}$$

$$BA = \begin{bmatrix} 1 & 4 \\ 0 & 2 \end{bmatrix}\begin{bmatrix} 2 & 1 \\ 3 & -2 \end{bmatrix} = \begin{bmatrix} 1\times 2 + 4\times 3 & 1\times 1 - 4\times 2 \\ 0\times 2 + 2\times 3 & 0\times 1 - 2\times 2 \end{bmatrix} = \begin{bmatrix} 14 & -7 \\ 6 & -4 \end{bmatrix}$$

We see that since $AB \neq BA$, the two matrices A and B do not commute.

One of the best applications of matrices is in the solution of the simultaneous linear equations. For example, consider the set of simultaneous linear equations :

$$a_{11}x_1 + a_{12}x_2 + a_{13}x_3 = c_1$$
$$a_{21}x_1 + a_{22}x_2 + a_{23}x_3 = c_2$$
$$a_{31}x_1 + a_{32}x_2 + a_{33}x_3 = c_3$$

These equations can be written in the matrix notation as

$$\begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix}\begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} c_1 \\ c_2 \\ c_3 \end{bmatrix}$$

or $$AX = C$$

The inverse of a matrix A^{-1} is defined such that

$$A^{-1}A = AA^{-1} = E$$

where E is the identity matrix :

$$E = \begin{bmatrix} 1 & 0 & 0 & .... & 0 \\ 0 & 1 & 0 & .... & 0 \\ 0 & 0 & 1 & .... & 0 \\ 0 & 0 & 0 & & 1 \end{bmatrix}$$

Multiplying both sides of $AX = C$ by A^{-1}, we obtain

$$A^{-1}AX = X = A^{-1}C$$

Thus, the solution X of the simultaneous equations is obtained by multiplying C by the inverse of A. Small matrices may be *inverted* by hand by the Gaussian elimination and large matrices may be inverted with a computer to obtain the solution of the simultaneous linear equations.

3. Determinants. A determinant is a *square array* of numbers. Its value is defined as a certain sum of products of sub sets of elements. If the determinant has n rows and columns, each term in the sum has n factors in it. For a determinant of order 2,

$$\begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix} = a_1b_2 - a_2b_1$$

The value of a large determinant can be obtained by expanding by *minors*. For a determinant of order 3,

$$\begin{vmatrix} a_1 & b_1 & c_1 \\ a_2 & b_2 & c_2 \\ a_3 & b_3 & c_3 \end{vmatrix} = a_1\begin{vmatrix} b_2 & c_2 \\ b_3 & c_3 \end{vmatrix} - b_1\begin{vmatrix} a_2 & c_2 \\ a_3 & c_3 \end{vmatrix} + c_1\begin{vmatrix} a_2 & b_2 \\ a_3 & b_3 \end{vmatrix}$$

Determinants of higher order are defined by an analogous row (or column) expansion.

4. Complex Numbers. A complex number z can be written as

$$z = x + iy$$

where $i = \sqrt{-1}$, and x and y are *real* numbers. A complex number can be represented as a point in

the **Argand diagram** in the complex plane (Fig. 4).

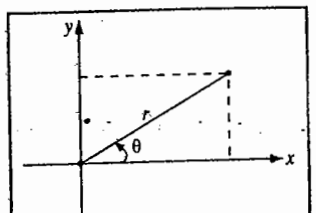

Fig. 4. The Argand diagram for a complex number.

The real part of z is plotted on the horizontal axis and the imaginary part on the vertical axis. The distance r is called the absolute value or **modulus** of z :

$$|z| = r = (x^2 + y^2)^{1/2}$$

Since $$x = r\cos\theta \text{ and } y = r\sin\theta,$$
$$z = r\cos\theta + ir\sin\theta = re^{i\theta}$$

where the last relation is obtained using

$$e^{i\theta} = \cos\theta + i\sin\theta$$

The **complex conjugate** of z is defined by

$$z^* = x - iy = re^{-i\theta}$$

The product of z and its complex conjugate z^* is

$$zz^* = x^2 + y^2 = r^2 = |z|^2$$

which is a real number.

5. Series. Some commonly used series are :

$$(i) \quad e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + ... \qquad [\text{for all } x]$$

$$(ii) \quad \ln(1+x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + ... \qquad [x^2 < 1]$$

$$(iii) \quad (1+x)^{-1} = 1 - x + x^2 - x^3 + ... \qquad [x^2 < 1]$$

$$(iv) \quad (1-x)^{-1} = 1 + x + x^2 + x^3 + ... \qquad [x^2 < 1]$$

$$(v) \quad (1-x)^{-2} = 1 + 2x + 3x^2 + 4x^3 + ... \qquad [x^2 < 1]$$

$$(vi) \quad \sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - ....$$

$$(viii) \quad \cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - ....$$

6. Stirling Approximation. We know that

$$\int_1^n \ln x\,dx = [x\ln x - x]_1^n = n\ln n - n + 1 \qquad ...(i)$$

If we plot the curve $y = \ln x$ versus x (Fig. 5) and draw ordinates to it for $x = 2, 3, 4, ... n-1, n$, then the sum of the areas of the strips is approximately equal to

$$\ln 2 + \ln 3 + \ln 4 + ... + \ln n = \ln(1\times 2\times 3\times ..... n) = \ln n! \qquad ...(ii)$$

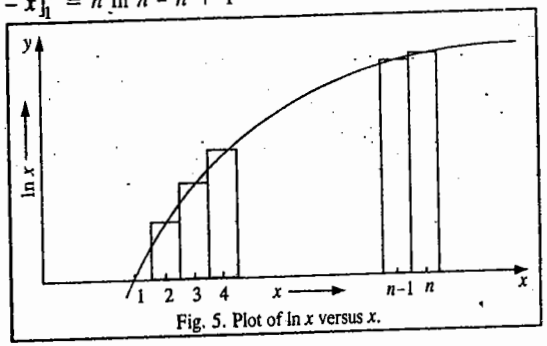

Fig. 5. Plot of $\ln x$ versus x.

For large n, the error incurred in regarding the strips as rectangles is regligible so that the sum of the areas of the reactangles given by Eq. *(ii)* can be equated to the area of the curve [Eq. *(i)*] Thus,

$$\ln n! \simeq n\ln n - n$$

or $$n! = (n/e)^n \qquad ...(iii)$$

where 1 on the right hand side of Eq. *(i)* has been neglected in comparison with n. Eq. *(iii)* is the Stirling approximation in its simple form.

Example 20. Test the Stirling approximation that $\ln n ! = n \ln n - n$, for $n = 5$, 10 and 15 by comparing its predictions with the exact values. Repeat the comparison for the more exact form of the approximation :

$$\ln n ! = \left(n + \tfrac{1}{2}\right) \ln n - n + \tfrac{1}{2} \ln 2\pi$$

Solution. The exact and approximate values are as follows :

n	5	10	15
$\ln n !$	4·7875	15·1044	27·8993
Approximation 1	3·0472	13·0259	25·6208
Approximation 2	4·7708	15·0961	27·8937

We see that for the largest value of $n(=15)$, the second approximation gives a very good agreement with the exact value.

7. Evaluation of Integrals of the Type $\int_0^\infty x^n e^{-ax^2} dx$

***(i)* Reduction of the Integrals.** Integration by parts, using the expression

$$\int u\,dv = uv - \int v\,du$$

can be carried out with

$$dv = x\,e^{-ax^2} dx \text{ and thus } v = -\frac{1}{2a} e^{-ax^2}$$

and

$$u = x^{n-1} \text{ and thus } du = (n-1)x^{n-2}\,dx$$

Using these substitutions, integration by parts gives

$$\int_0^\infty x^n e^{-ax^2} dx = \frac{x^{n-1}}{2a} e^{-ax^2} \Big]_0^\infty - \int_0^\infty \left[-\frac{1}{2a}(n-1)x^{n-2} e^{-ax^2}\right] dx$$

$$= 0 + \frac{n-1}{2a} \int_0^\infty x^{n-2} e^{-ax^2} dx$$

In this way integrals of the general type can be reduced either to one involving the integrand $x\,e^{-ax^2}$ or to one involving the integrand e^{-ax^2}.

***(ii)* For n odd.** In this case the method used in *(i)* leads to the integral $\int_0^\infty x\,e^{-ax^2} dx$ which can be integrated directly to give

$$-\frac{1}{2a} e^{-ax^2} \Big]_0^\infty = \frac{1}{2a}.$$

***(iii)* For n even.** Here, the method used in *(i)* leads to the integral $\int_0^\infty e^{-ax^2} dx$.

Evaluation of this integral is accomplished by writing the product of two such integrals based on two independent coordinates x and y which can be pictured as being cartesian coordinates. We thus investigate

$$\int_0^\infty e^{-ax^2} dx \int_0^\infty e^{-ay^2} dy = \int_0^\infty \int_0^\infty e^{-a(x^2+y^2)}\,dx\,dy$$

The coordinates x and y can now be related to two new coordinates r and θ by the relations which associate cartesian coordinates with *polar coordinates* :

$$x^2 + y^2 = r^2 \text{ and } dx\,dy = r\,dr\,d\theta$$

Again, since in the xy coordinate system the integration is over the first quadrant, the corresponding limits of integration involving r and θ are 0 to ∞ and 0 to $\pi/2$. We thus have the problem, in r and θ, of the double integral $\int_0^{\pi/2} \int_0^\infty e^{-ar^2}\,r\,dr\,d\theta$

The two integrations can be performed to give $(\pi/2)[1/(2a)]$, and thus the original integral is evaluated as

$$\int_0^\infty e^{-ax^2} dx = \frac{1}{2}\left(\frac{\pi}{2}\right)^{1/2}$$

***(iv)* Even and odd character and the limits of integration.** Functions of the type $x^n e^{-ax^2}$ are *even* if n is even and *odd* if n is odd. Integration from $-\infty$ to $+\infty$ will, therefore, give zero for n odd and will give twice the value of the integral from 0 to ∞ for n even.

***(v)* Values of the most often used integrals :**

$$\int_{-\infty}^\infty e^{-ax^2} dx = \left(\frac{\pi}{2}\right)^{1/2} \qquad \int_0^\infty x e^{-ax^2} dx = \frac{1}{2a} \qquad \int_{-\infty}^\infty x^2 e^{-ax^2} dx = \frac{1}{2a}\left(\frac{\pi}{a}\right)^{1/2}$$

$$\int_0^\infty x^3 e^{-ax^2} dx = \frac{1}{2a^2} \qquad \int_{-\infty}^\infty x^4 e^{-ax^2} dx = \frac{3}{4a^2}\left(\frac{\pi}{a}\right)^{1/2}$$

MEMORABILIA PHYSICO-MATHEMATICA

Nature, and Nature's laws, lay hid in night,
God said, Let Newton be, and all was light. *–Alexander Pope*

Maxwell could say, when he was finished with his discovery, *"Let there be electricity and magnetism, and there is light".* *–Richard P. Feynman*

Experiments are the only means of knowledge at our disposal. The rest is poetry, imagination. *–Max Planck*

It seems that if one is working from the point of view of getting beauty in one's equations, and if one has a really sound insight, one is on a sure line of progress. *–P.A.M. Dirac*

Number rules the universe. *–Pythagorus*

God ever geometrizes. *–Plato*

God ever arithmetizes. *–Jacobi*

In questions of science the authority of a thousand is not worth the humble reasonings of a single individual. *–Galileo*

It is remarkable to what extent Indian mathematics enters into the science of our time. Both the form and the spirit of arithmetic and algebra of modern times are essentially Indian and not Grecian. *–F. Cajori*

The greatest mathematicians Archimedes, Newton and Gauss always united theory and applications in equal measure. *–Felix Klein*

There is an astonishing imagination even in the science of mathematics... We repeat, there was far more imagination in the head of Archimedes than in that of Homer. *–Voltaire*

Mathematicians are like Frenchmen : whatever you say to them they translate into their own language and forthwith it is something entirely different. *–Goethe*

An old French geometer used to say that a mathematical theory was never to be considered complete till you had made it so clear that you could explain it to the first man you met in the street. *-H.J.S. Smith*

Everybody praises the incomparable power of the mathematical method, but so is everybody aware of its incomparable unpopularity. *-J. Rosanes*

Archimedes who combined a genius for mathematics with a physical insight, must rank with Newton, who lived nearly two thousand years later, as one of the founders of mathematical physics... The day (when having discovered his famous principle of hydrostatics he ran through the streets shouting Eureka ! Eureka !) ought to be celebrated as the birthday of mathematical physics ; the science came of age when Newton sat in his orchard. *-A.N. Whitehead*

Euler could repeat the Aeneid from the beginning to the end, and he could even tell the first and last lines in every page of the edition which he used. In one of his works there is a learned memoir on a question in mechanics, of which, as he himself informs us, a verse of the Aeneid gave him the first idea. *-David Brewster*

All the results of nature are only mathematical results of a small number of immutable laws. *-Laplace*

As the sun eclipses the stars by his brilliancy, so the man of knowledge will eclipse the fame of others in assemblies of people if he proposes algebraic problems, and still more if he solves them. *-Brahmagupta*

Mathematics is the queen of science, and arithmetic the queen of mathematics. *-Gauss*

The infinite ! No other question has ever moved so profoundly the spirit of man. *-David Hilbert*

A monument to Newton ! A monument to Shakespeare ! Look up to the Heaven, look into the human heart. Till the planets and the passions, the affections and the fixed stars, are extinguished their names cannot die. *-John Wilson*

Newton was the greatest genius that ever lived, and the most fortunate, for we cannot find more than once a system of the world to establish. *-Lagrange*

The aim of research is the discovery of the equations which subsist between the elements of phenomena. *-Ernst Mach*

If my theory of relativity is proven successful, Germany will claim me as a German and France will declare that I am a citizen of the world. Should my theory prove untrue, France will say that I am a German and Germany will declare that I am a Jew. *-Einstein*

Dirac to whom in my opinion we owe the most logical presentation of quantum mechanics..... *-Einstein*

One may be a mathematician of the first rank without being able to compute. It is possible to be a great computer without having the slightest idea of mathematics. *-Novalis*

There is a largeness about mathematics that transcends race and time... The greatest mathematics has the simplicity and inevitableness of supreme poetry and music, standing on the borderland of all that is wonderful in Science and all that is beautiful in Art. Mathematics transfigures the fortuitous concourse of atoms into the tracery of the finger of God. *-H.W. Turnbull*

He [Ramanujan] had an extraordinary memory. He could remember the idiosyncracies of numbers in an almost uncanny way. It was Mr. Littlewood (I believe) who remarked that "every positive integer was one of his personal friends." I remember once going to see him when he was lying ill... I had ridden a taxi-cab number 1729, and remarked that the number seemed to be rather a dull one, and that I hoped it was not an unfavorable omen. "No," he replied, "It is a very interesting number ; it is the smallest number expressible as a sum of two cubes in two different ways." *-G.H. Hardy*

Symmetry, as wide or as narrow as you may define it, is one idea by which man, through the ages has tried to comprehend order, beauty, and perfection. *-Hermann Weyl*

But elements of symmetry are either present or absent ; no intermediate case is possible. *-L.D. Landau*

Fermi's aversion to mathematical technicalities is well known. Even when a mathematical argument had played a role in his initial thinking of a problem, he was careful to erase all its traces from his final account. I was once to talk to a seminar and when I expressed my doubts as to what I should talk about, he advised, "If I were you, I would not be technical," And I asked, "Do you mean, if I were you or you were me ?" This baffled him ; it was the only occasion I got the better of him. *-S. Chandrasekhar*

If a book is to be published at a time T and if it is supposed to be up-to-date to a time $T - t$, then it will certainly be out-of-date at the time $T + t$. *-Freeman J. Dyson*

QUANTUM MECHANICS–I. WAVE MECHANICAL TREATMENT OF SIMPLE SYSTEMS

Electron and the Old Quantum Theory (1900–1926)

John Dalton (1766-1844), the great British propounder of atomic theory, regarded the atom as a hard, dense and smallest indivisible particle of matter. However, the emission of negatively and positively charged particles from radioactive elements as well as from gases on the passage of electricity through them at very low pressures convinced the scientists that atom is not indivisible but consists of much smaller fundamental particles. Thus, if electric discharge from a high potential source is passed through a discharge tube evacuated to pressures around 0·01 mm or less, rays are emitted from the cathode. These are called **cathode rays.** These rays travel in straight lines at right angles to the cathode surface. They produce mechanical motion in a small paddle wheel placed in their path indicating that they are material particles. These particles are deflected from their path by electric and magnetic fields showing that they are electrically charged. The direction of deflection indicates that they are negatively charged. These particles are called **electrons.** The British physicist J.J.Thomson (1856–1940) determined the **ratio e/m of electron** by subjecting the beam of electrons produced in a discharge tube to magnetic as well as electric fields. The magnetic field is applied at right angles to the direction of the beam. Under the influence of magnetic force which is equal to Beu (where B is the strength of the magnetic field, e is the charge on electron and u is its velocity), the electron starts moving in a circular path of radius r. The centrifugal force mu^2/r arising from this circular motion is equal and opposite to the magnetic force. *i.e.*, .

$$Beu = mu^2/r \quad \text{or} \quad e/m = u/rB; \quad \text{where } m \text{ is the electron mass.} \qquad ...(1)$$

Now suppose an electric field of strength E is also applied to the electron beam. The electrical force experienced by each electron is given by Ee. The magnetic and electric fields are so adjusted as to produce equal and opposite effects in such a way that there is no deflection of the electron beam from its original position. Thus,

$$Beu = Ee \quad \text{or} \quad u = E/B \qquad ...(2)$$

Substituting the above value of u in Eq. 1, we have

$$e/m = E/rB^2 \qquad ...(3)$$

The value of r is obtained from the deflection of a spot of light on a fluorescent screen when magnetic field alone is applied. Knowing the strengths of electric and magnetic fields (E and B) for no deflection, the value of e/m can be easily calculated. Thomson found the value of e/m to be the same ($=1{\cdot}75875 \times 10^{11}$ C kg^{-1}) irrespective of the nature of the gas taken in the cathode ray tube or the material constituting the cathode. J.J. Thomson was awarded the Physics Nobel Prize in 1906 for his work on the conduction of electricity by gases.

Robert Millikan determined the charge on electron by using his famous **oil drop technique.** In this technique, an oil spray consisting of microscopic droplets of an oil produced by an atomizer is injected into a chamber containing air at a controlled pressure. The air is ionized by exposing to X-rays. The

electrons produced as a result of ionization of air get attached to oil droplets. The charged oil droplets move down under the action of gravity and acquire a constant velocity u_1 when the force of gravity ($= Mg$) is balanced by the viscous resistance of air. The droplets moving with uniform velocity u_1 enter a region in between two parallel plates held at a suitable distance from each other. These plates can act as electrodes. An electric field of strength E is then applied through the two metal plates in such a way that it acts against the action of gravity. The total force which acts on the falling droplet would thus be $(Mg - Ee)$ where M is the mass and e is the charge on the droplet. If the rate of fall of the droplet is now u_2, then

$$u_1/u_2 = Mg/(Mg - Ee) \qquad ...(4)$$

The velocities u_1 and u_2 are determined by means of a travelling microscope.

When the droplets move only under the action of gravity, their velocity (u_1) is also given by Stokes' law, that is,

$$u_1 = 2gr^2 \rho/9\eta \qquad ...(5)$$

where r, ρ and η are, respectively, the radius of the droplet, the density of the droplet and the coefficient of viscosity of air. Assuming that the particle is spherical, its mass $M=(4/3)\pi r^3\rho$. The radius r is determined with the help of Eq. 5, assuming that density of the droplet is the same as the density of the oil. Thus, knowing the mass of the droplet, M, the charge on the droplet, e, can be easily calculated with the help of Eq. 4.

Millikan carried out a number of experiments by varying the value of E and found that charge e was always equal to a simple multiple of $1{\cdot}6022\times10^{-19}$ coulomb. This indicates that oil droplet had captured one, two, three or more electrons, each carrying a charge equal to $1{\cdot}6022\times10^{-19}$ C. The American physicist Robert Millikan (1868–1953) was awarded the Physics Nobel Prize in 1923 for determining the charge on electron.

In recent years, the viscosity of air has been redetermined more accurately and the charge on electron is taken as $1{\cdot}60206\times10^{-19}$ C.

Since $e = 1{\cdot}60206\times10^{-19}$ C and $e/m = 1{\cdot}75875\times10^{11}$ C kg^{-1}, hence

$$\text{mass of electron} = \frac{e}{e/m} = \frac{1{\cdot}60206\times10^{-19}\ \text{C}}{1{\cdot}75875\times10^{11}\ \text{C kg}^{-1}} = 9{\cdot}109\times10^{-31}\ \text{kg}. \qquad ...(6)$$

This is called the rest mass of the electron, *i.e., the mass which it possesses when it is moving with a speed much smaller than that of light.* The rest mass of electron is now taken as $9{\cdot}1095\times10^{-31}$ kg. On the atomic mass scale, the rest mass of electron=0·0005486 u, where u. is the atomic mass unit. At high speeds, the mass of a particle, according to Einstein's theory of relativity, is given by

$$m = \frac{m_0}{(1-u^2/c^2)^{1/2}} \qquad ...(7)$$

where m is the mass of the particle moving with velocity u, c is the speed of light and m_0 is the *rest mass* of the particle. Evidently, as u approaches c, m becomes infinity.

Careful experiments with discharge tubes containing perforated cathode reveal the emission of another type of radiations which start from the side of the anode and pass through the holes of the cathode. These radiations, which carry positive charge, are called **positive rays** or **anode rays.** Further studies reveal that these rays consist of **positively charged particles** whose e/m ratio varies with the nature of the gas taken in the discharge tube. The positive particles are, in fact, the positive residues of the gas left when one or more electrons are knocked out of the atoms of the gas. The smallest positive

particle given out by the lightest element hydrogen is called the **proton.** It is another fundamental particle whose charge has been found to be equal in magnitude but opposite in sign to that of electron. Its mass is $1{\cdot}6726\times10^{-27}$ kg or 1·00722 u. The charge on an electron or a proton is the smallest charge of electricity. It is usual to speak of the charge on an electron as **unit negative charge** and the charge on a proton as **unit positive charge.**

The Rutherford's Scattering Experiments. In 1911, the British physicist Ernest Rutherford (1871–1937) and the two eminent experimenters Geiger and Marsden directed a narrow beam of alpha particles obtained from polonium at an extremely thin sheet of a metal like silver and gold. After passing through the metal sheet, the alpha particles were made to strike a fluorescent screen. These experiments suggested that

1. Most of the alpha particles pass through the metallic sheet without suffering any change in their path showing that the atom consists predominantly of empty space.

2. An extremely small number of alpha particles get deflected through wider angles or even backwards showing the presence of a heavy positively charged body in each atom and that the volume of this body is only a minute fraction of the total volume of the atom.

The Rutherford's Atomic Model. Based on his scattering experiments, Rutherford suggested that an atom consists of :

1. A minute positively charged body located at the centre, called the *nucleus,* in which almost the entire mass of the atom is concentrated. Since the mass of an atom is almost entirely due to protons, all the protons are present in the nucleus.

2. An equal number of extremely small negatively charged electrons distributed around the nucleus to balance its positive charge.

In order to explain why the electrons do not fall into the nucleus on account of the mutual electrostatic attraction, Rutherford proposed that the electrons are revolving round the nucleus at extremely high speeds at great distances from the nucleus. The centrifugal force arising from this motion balances the force of electrostatic attraction. The electrons, therefore, do not fall into the nucleus. The Rutherford's **nuclear atomic model** was fully confirmed in 1913 by further experiments performed by Geiger and Marsden. Rutherford was awarded the 1908 Chemistry Nobel Prize for contributions to the chemistry of radioactive substances.

James Chadwick (1891—1974), the British physicist, discovered in 1932 that when beryllium or boron is bombarded by alpha particles, new particles which carry no charge but have mass almost equal to that of a proton, are emitted. These particles are called **neutrons.** Chadwick won the Physics Nobel Prize in 1935 for the discovery of neutron.

All the neutrons are present in the nucleus alongwith protons. Because of the presence of protons, the nucleus carries a positive charge, as mentioned above. The number of unit positive charges carried by the nucleus of an atom is called the **atomic number** of the element. In other words, atomic number is equal to the number of protons present in the nucleus of the atom. The sum of the number of protons and neutrons present in the nucleus of an atom is called the **mass number** of the element.

It was pointed out by Niels Bohr (1885–1962), the Danish physicist, that Rutherford's atom should be highly unstable. J.C.Maxwell (1831–1879), the great Scottish mathematical physicist, the pioneer of electromagnetic theory, had shown that whenever an electric charge is subjected to acceleration, it emits radiation and loses energy. Bohr argued, therefore, that if an electron (a charged particle) moves round the nucleus in an orbit, as in Rutherford's model, it should be subjected to acceleration The electron should, therefore, continuously emit radiation and lose energy. Thus, its orbit should become smaller and smaller and finally it should drop into the nucleus. This, however, does not happen. Bohr

solved this problem on the basis of the quantum theory of radiation put forth by the German physicist Max Planck (1858-1947) in 1900 to explain the observed distribution of energy in the spectrum of the heat radiations emitted by a hot body. The *energy density, i.e.,* the amount of energy radiated per unit volume, by a black body depends upon the temperature. However, the energy radiated at a particular temperature is not of a single frequency (or wave length). The correlation between energy density and wave length at different temperatures is depicted in Fig. (1). These curves have the following characteristics:

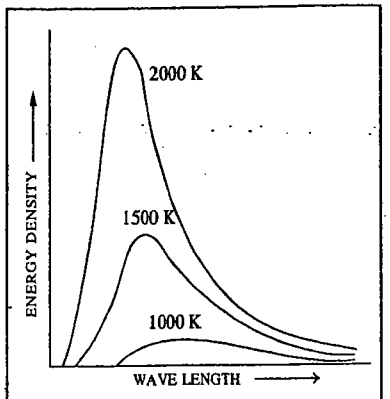

Fig. 1. Emission of radiation from a black body at different temperatures.

1. For each temperature, there is a particular wave length at which the energy radiated is the maximum.

2. The position of the maximum shifts towards lower wave lengths with increase in temperature.

3. The higher the temperature, the more pronounced is the maximum.

These curves are referred to as the black body radiation curves. A **black body** is defined as an object that absorbs all the radiations falling on it. A perfect absorber is also a perfect emitter of radiation. Thus, of all bodies heated to a given temperature, maximum energy is radiated by a black body.

According to **Wien's displacement law**, $\lambda_m T = b$, where λ_m is the wave length corresponding to the maximum in the curve. The Wien constant $b = 0{\cdot}0029$ m K. Wilhelm Wien (1864—1928), the German physicist, was awarded the 1911 Physics Nobel Prize for his discoveries concerning the laws governing the heat radiations.

Quantum Theory of Radiation. The energy distribution in black body radiations could not be explained by the application of classical physics. The correct expression was derived by Planck on the basis of the quantum theory of radiation. According to this theory,

1. Radiant energy is emitted or absorbed discontinuously in the form of tiny bundles of energy known as **quanta.**

2. Each quantum is associated with a definite amount of energy $E(=h\nu)$ where E is the energy in joules, ν is the frequency of radiation in reciprocal seconds (s^{-1}) and h is a fundamental constant known as **Planck's constant**. The numerical value of h is $6{\cdot}626\times10^{-34}$ J s.

The value of a quantum of energy is also given by $hc\bar{\nu}$ where $\bar{\nu}$ is the **wave number** defined as the reciprocal of wave length *i.e.,* $\bar{\nu} = (1/\lambda)$. Evidently, $\nu = c/\lambda = c\bar{\nu}$ and $E = hc\bar{\nu}$.

3. A body can emit or absorb energy only in whole number multiples of quantum, *i.e.,* $1h\nu$, $2h\nu$, $3h\nu$....., $nh\nu$. Energy in fractions of a quantum cannot be lost or absorbed. This is known as **quantization of energy**.

Based on his theory, Planck obtained the following expression for energy density of black body radiation :

$$E(\nu)d\nu = \frac{8\pi h\nu^3}{c^3} \times \frac{d\nu}{\exp(h\nu/kT)-1} \qquad ...(8)$$

Eq. 8 adequately accounts for the black body radiation curves at all wave lengths obtained at different temperatures, as shown in Fig. 1. Planck was awarded the Physics Nobel Prize in 1918 for propounding the quantum theory of radiation.

Photoelectric Effect. J.J. Thomson, in some of his famous experiments, observed that when light of a *certain frequency* strikes the surface of a metal, electrons are ejected from the metal. This phenomenon is known as the photoelectric effect. A few metals show this effect under the action of

visible light but many more show it under the action of more energetic ultraviolet light. Cesium, which amongst the alkali metals has the lowest ionisation energy, is also the metal from which electrons are ejected most easily by light. This metal is, therefore, used largely in **photoelectric cells.**

After making careful studies of photoelectric effect under different conditions, the following observations were made :

1. For each metal, a certain minimum frequency of incident light is needed to eject electrons. This is known as **threshold frequency,** ν_0. A light of smaller frequency than this cannot eject electrons no matter how long it falls on the metal surface or how high is its intensity. The threshold frequency is different for different metals.

2. The kinetic energy of ejected electrons is independent of the intensity of the incident light but varies linearly with its frequency.

3. The number of ejected electrons from the metal surface depends upon the intensity of the incident radiation. The greater the intensity, the larger is the number of ejected electrons.

The photoelectric effect cannot be explained on the basis of the classical wave theory of light. According to this theory, energy of light depends on its *intensity.* If this view is correct, then light of *any frequency,* if made sufficiently intense, can cause ejection of electrons. But this does not happen. The quantum theory of radiation affords an easy explanation for the photoelectric effect. According to this theory, light consists of bundles of energy called **photons,** the energy of each photon being equal to $h\nu$ where ν is the frequency of the light. When a photon of light of frequency ν_0 (threshold frequency) strikes an electron in a metal, it imparts its entire energy ($= h\nu_0$) to the electron. This energy enables the electron to break away from the atom by overcoming the attractive influence of the nucleus. Thus, each photon can eject one electron. If the frequency of the light is less than ν_0, there will be no ejection of electron. Now suppose the frequency of the light falling on a metal surface is higher than the threshold frequency. Let it be ν. When photon of this light strikes a metal surface, some of its energy (which is equal to the energy binding the electron with the nucleus) is consumed to separate the electron from the metal and the remaining energy will be imparted to the ejected electron to give it certain velocity u (*i.e.,* kinetic energy $= \frac{1}{2}mu^2$). Einstein, applying quantum theory, showed that

$$h\nu = \phi + \tfrac{1}{2}mu^2 \qquad ...(9)$$

where ϕ is the threshold energy (or the **work function**) of the metal and $\frac{1}{2}m_e u^2$ is the kinetic energy imparted to the ejected electron. Evidently,

$$\phi = h\nu_0 \qquad ...(10)$$

Substituting the above value of ϕ in Eq. 9 and rearranging, we have

$$\tfrac{1}{2}mu^2 = h(\nu - \nu_0) \qquad ...(11)$$

Eq. 11 is the **Einstein photoelectric equation.** Albert Einstein (1879–1955), the German physicist, won the Physics Nobel Prize in 1921 for explaining the photoelectric effect and other contributions to mathematical physics. It may be mentioned that Einstein's contributions to the Theory of Relativity, considered controversial in those days, were not mentioned in the Nobel Prize citation.

Eq. 11 was tested by Robert Millikan. The kinetic energies of the emitted electrons for various frequencies of light were determined by finding the opposing potential required to stop the photoelectric current. Knowing kinetic energy corresponding to a given incident light of frequency ν and also knowing ν_0, *i.e.,* the threshold frequency required just to cause ejection of electrons, the value of h was calculated. It was found to be $6{\cdot}570\times10^{-34}$ J s. This is in excellent agreement with the value $6{\cdot}626\times10^{-34}$ J s obtained from experiments on black body radiations.

It is evident from the above discussion that photoelectric effect can be explained only on the basis of the corpuscular or particle theory of light. But certain phenomena, such as diffraction, interference and polarisation of light, can be explained only on the basis of the classical wave theory of light. Thus, light is considered to have a **dual character.** It behaves as a *particle* and also as a *wave.*

Example 1. A photon of wave length 4000 Å strikes a metal surface, the work function of the metal being 2·13 eV. Calculate *(i)* the energy of the photon in eV *(ii)* the kinetic energy of the emitted photo-electron and *(iii)* the velocity of the photo-electron. Mass of electron = $9{\cdot}109\times10^{-31}$ kg.

Solution : *(i)* Energy of the photon :

$$\nu = c/\lambda = 3\times10^{8}\ \text{m s}^{-1}/4000\times10^{-10}\ \text{m} = 7{\cdot}5\times10^{14}\ \text{s}^{-1}$$

$$E = h\nu = (6{\cdot}626\times10^{-34}\ \text{J s})\ (7{\cdot}5\times10^{14}\ \text{s}^{-1}) = 4{\cdot}97\times10^{-19}\ \text{J}$$

Since $1\ \text{eV} = 1{\cdot}602\times10^{-19}\ \text{J}$

$$\therefore \quad E = 4{\cdot}97\times10^{-19}\ \text{J}/1{\cdot}602\times10^{-19}\ \text{J/eV} = 3{\cdot}10\ \text{eV}$$

***(ii)* Kinetic energy of emitted photo-electron :**

$\phi = 2{\cdot}13$ eV. Hence, from Eq. 9,

$$\text{K.E.} = h\nu - \phi = 3{\cdot}10\ \text{eV} - 2{\cdot}13\ \text{eV} = 0{\cdot}97\ \text{eV}$$

***(iii)* Velocity of photo-electron :**

$$\text{K.E.} = \tfrac{1}{2}m_e u^2 = 0{\cdot}97\ \text{eV} = 0{\cdot}97\times1{\cdot}602\times10^{-19}\ \text{J}$$

$$\therefore \quad u = \left[\frac{2\times0{\cdot}97\times1{\cdot}602\times10^{-19}\ \text{J}}{9{\cdot}109\times10^{-31}\ \text{kg}}\right]^{1/2} = 5{\cdot}85\times10^{5}\ \text{m s}^{-1} \qquad (\text{J} = \text{kg m}^2\ \text{s}^{-2})$$

The Bohr's Model of the Atom

Niels Bohr, a Danish physicist, proposed his model of the atom in 1913. He retained Rutherford's model of a very small positively charged nucleus at the centre which contains all the protons and neutrons present in an atom. Bohr also agreed that the negatively charged electrons are revolving round the nucleus in the same way as the planets are revolving round the sun. But he took a bold step forward by applying Planck's quantum theory to the electron revolving round the nucleus. The important postulates of Bohr's theory are :

1. The electrons in an atom revolve around the nucleus only in certain selected circular orbits. As long as the electron remains in a particular orbit, it neither loses nor gains energy. In other words, the energy of an electron remains constant in a particular orbit. This leads to the idea that each orbit is associated with a definite energy, *i.e.*, with a definite whole number of quanta of energy. The orbits, therefore, are also known as energy levels or energy shells. Bohr gave numbers 1, 2, 3, 4, etc., (starting from the nucleus) to these energy levels. These numbers are now termed as principal quantum numbers. The various energy levels are also designated by letters *K, L, M, N,* etc. The farther the energy level from the nucleus, the greater is the energy associated with it.

2. The energy of an electron cannot change continuously. It changes only abruptly as the electron jumps from one energy level to another. The same idea has been expressed by the statement that for a change of electronic energy, the electron has to jump and not to 'flow' from one energy level to another.

3. The angular momentum of an electron moving round the nucleus is quantised. An electron, like any other body moving in a circular orbit, has an angular momentum given by *mur* where *m* is the mass, *u* is the linear velocity of the electron and *r* is the radius of the orbit. Bohr postulated that the angular momentum of an electron in an atom can have only definite or discrete values given by the expression

$$\text{Angular momentum} = mur = n(h/2\pi)$$

where *n* is any integer (1, 2, 3, etc.) Thus, the angular momentum of an electron may be $h/2\pi$ or a simple whole number multiple of $h/2\pi$ such as $2h/2\pi$, $3h/2\pi$,.....nh/π. This principle is known as quantisation of angular momentum.

Bohr Equation for the Energy of Electron in Hydrogen and Hydrogen-like Atoms. Working on the above postulates, Bohr was able to calculate the energy of the electron moving in different orbits round the nucleus in hydrogen or hydrogen-like atoms such as He^+, Li^{2+}, etc. He assumed, as had been

suggested by Rutherford, that the electron remains in its orbit because the electrostatic force of attraction exerted by the nucleus is exactly balanced by the centrifugal force arising from its circular motion.

Let the charge on the nucleus be $+Ze$. For hydrogen atom, $Z=1$ and for hydrogen-like atoms such as He^+ and Li^{2+}, $Z=2$ and 3, respectively. A hydrogen atom, having one proton in the nucleus and one electron outside the nucleus, is represented in Fig. 2. The electron with charge $-e$ revolves round the nucleus in an orbit of radius *r*. Let *u* be the tangential velocity and *m* be the mass of the electron.

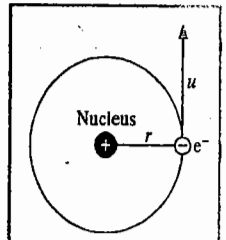

Fig. 2. Bohr's hydrogen atom.

According to the laws of classical mechanics, the centripetal force acting on the electron in a hydrogen-like atom, given by $Ze\times e/r^2$, tends to pull the electron towards the nucleus. However, the centrifugal force acting on the electron, given by mu^2/r tends to take it away from its orbit. Under the influence of these two opposing forces, the electron keeps on revolving in its orbit. When the two force balance,

$$Ze^2/r^2 = mu^2/r$$

Hence, $$u^2 = Ze^2/mr \qquad ...(12)$$

According to Bohr's postulate, the angular momentum, *mur*, is an integral multiple of $h/2\pi$, *i.e.*,

$$mur = n(h/2\pi)$$

or $$u = nh/2\pi mr \qquad ...(13)$$

Squaring Eq. 13, $$u^2 = n^2h^2 / 4\pi^2m^2r^2 \qquad ...(14)$$

Eliminating u^2 from Eqs. 12 and 14, we have

$$Ze^2/mr = n^2h^2 / (4\pi^2m^2r^2)$$

or $$Ze^2 = n^2h^2 / (4\pi^2mr) \qquad ...(15)$$

From Eq. 15, the radius *r* of the orbit is given by

$$r \equiv r_n = \frac{n^2h^2}{4\pi^2Zme^2} \qquad ...(16)$$

Since, for hydrogen atom, $Z=1$, hence,

$$r \equiv r_n = \frac{n^2h^2}{4\pi^2me^2} \qquad ...(17)$$

For hydrogen atom in the ground state ($n=1$), the radius of the orbit (r_1) is designated as the **Bohr radius**, a_0. Thus,

$$r_1 \equiv a_0 = \frac{h^2}{4\pi^2me^2} \qquad ...(18)$$

The total energy *E* of electron revolving in the *n*th orbit is equal to the sum of the kinetic energy ($= 1/2\ mu^2$) and the potential energy ($= -Ze^2/r_n$). Accordingly,

$$E = 1/2\ mu^2 - Ze^2/r_n \qquad ...(19)$$

From Eq. 12, $$mu^2 = Ze^2/r_n$$

Substituting the above value of mu^2 in Eq. 19, we have

$$E = \frac{Ze^2}{2r_n} - \frac{Ze^2}{r_n} = -\frac{Ze^2}{2r_n} \qquad ...(20)$$

Substituting the value of r_n from Eq. 16 in Eq. 20, we get

$$E = -\frac{Ze^2}{2} \times \frac{4\pi^2Zme^2}{n^2h^2} \qquad ...(21)$$

Thus, the **energy of electron in the *n*th orbit,** which we may designate as E_n, is given by

$$E_n = -\frac{2\pi^2 Z^2 me^4}{n^2h^2} \qquad ...(22)$$

This is the famous **Bohr equation** applicable to hydrogen and hydrogen-like atoms.

Niels Bohr (1885-1962), was awarded the 1922 Physics Nobel Prize for his investigations on the structure of the atom.

In **SI system,** Eqs. 16 and 22 take the forms

$$r_n = \frac{(4\pi\varepsilon_0)n^2h^2}{4\pi^2 Zme^2} \qquad ...(23)$$

$$E_n = -\frac{2\pi^2 Z^2 me^4}{(4\pi\varepsilon_0)^2 n^2h^2} \qquad ...(24)$$

The factor $4\pi\varepsilon_0$ is called the **permittivity factor,** its numerical value being $1{\cdot}11264\times10^{-10}$ C^2 N^{-1} m^{-2}.

Bohr Radius. According to Eq. 23, the Bohr radius of hydrogen atom (a_0) is given by

$$a_0 \equiv r_1 = \frac{(4\pi\varepsilon_0)h^2}{4\pi^2 me^2} = \frac{(1{\cdot}11264\times10^{-10}\,C^2\,N^{-1}\,m^{-2})(6{\cdot}626\times10^{-34}\,J\,s)^2}{4\pi^2(9{\cdot}109\times10^{-31}\,kg)(1{\cdot}602\times10^{-19}\,C)^2}$$

$$= 0{\cdot}529\times10^{-10}\ m$$

Velocity of Electron. According to Eq. 13, the velocity of electron, in the *first orbit* of hydrogen atom, is given by

$$u_1 = \frac{nh}{2\pi mr} = \frac{(1)(6{\cdot}626\times10^{-34}\,J\,s)}{2\pi(9{\cdot}109\times10^{-31}\,kg)(0{\cdot}529\times10^{-10}\,m)} = 2{\cdot}186\times10^{6}\ m\,s^{-1}$$

It may be noted that this velocity is about (1/150)th of the velocity of light.

The energy of electron in hydrogen atom ($Z=1$) in ground state, *i.e.*, when it is revolving in the first orbit ($n=1$), is easily obtained from Eq. 24. Thus,

$$E_1 = -\frac{(2\pi^2)(1)^2(9{\cdot}109\times10^{-31}\,kg)(1{\cdot}602\times10^{-19}\,C)^4}{(1{\cdot}11264\times10^{-10}\,C^2\,N^{-1}\,m^{-2})^2(1)^2(6{\cdot}626\times10^{-34}\,J\,s)^2} \qquad (J = kg\,m^2\,s^{-2})$$

$$= -2{\cdot}179\times10^{-18}\,J\ (\text{per atom}) = -1312{\cdot}19\ kJ\ mol^{-1}$$

$$= -\frac{2{\cdot}179\times10^{-18}\,J}{1{\cdot}602\times10^{-19}\,J/eV} = -13{\cdot}6\ eV\ (\text{per atom})$$

The energy of electron in excited states can be obtained by putting n = 2, 3, 4, etc., in Eq. 24.

Evidence for the Bohr quantization came from the celebrated **Franck-Hertz experiment** involving the impact of an electron on an atom. The German physicists James Franck (1882-1964) and Gustav Hertz (1887-1975) were awarded the 1926 Physics Nobel Prize for this work.

Bohr's Theory and the Origin of Hydrogen Spectrum. Hydrogen atom contains only one electron. But its spectrum consists of a large number of lines. Bohr supplied the reason. A given sample of hydrogen contains a very large number of atoms, of the order of several millions. Suppose energy is supplied to this sample of the gas. Now different atoms will absorb different amounts of energy. The

solitary electron in different atoms will, therefore, shift to different energy levels depending upon the energy absorbed by the atoms. Some of the hydrogen atoms, for example, may absorb sufficient energy to shift their electrons to the second energy level only while some others may absorb more energy and may be able to shift their electrons to third or even to one of the higher energy levels. The electrons then tend to fall back, almost immediately, to one or other of the lower energy levels. The various possibilities by which the electrons fall back from various excited state energy levels to lower energy levels (called electronic transitions), are depicted in Fig. 3. During each transition, energy is released which appears in the form of radiation of specific frequency and hence of specific wave length.

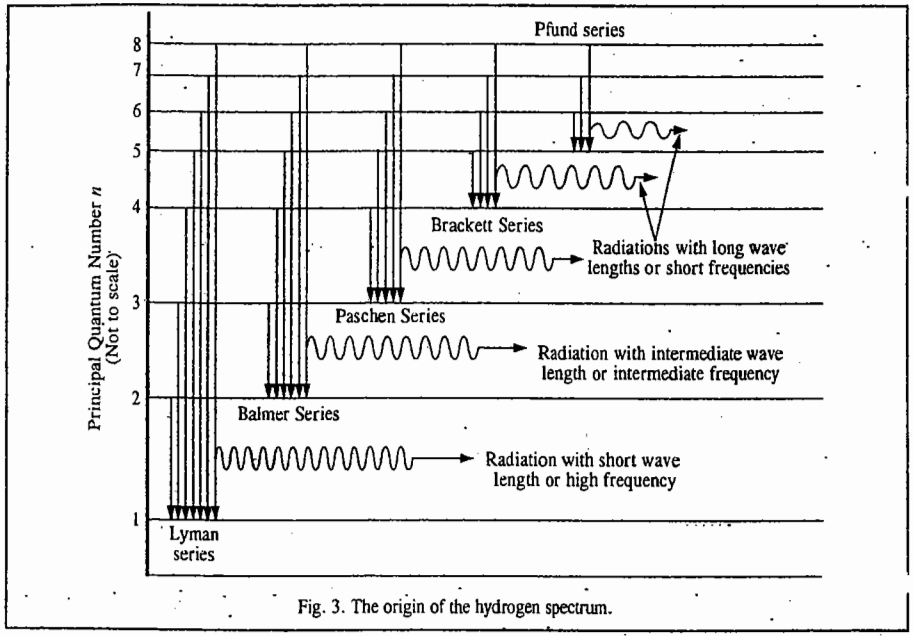

Fig. 3. The origin of the hydrogen spectrum.

Suppose an electron lying in energy level n_2 where its energy is E_2, jumps to a lower energy level n_1 where its energy is E_1. The energies in these two states, are

$$E_2 = -\frac{2\pi^2 me^4}{(4\pi\varepsilon_0)^2 n_2^2h^2} \quad \text{and} \quad E_1 = -\frac{2\pi^2 me^4}{(4\pi\varepsilon_0)^2 n_1^2h^2}$$

The difference in energy, $\Delta E = E_2 - E_1$, would be emitted in the form of radiation of a specific frequency and hence of a specific wave length. The emission spectrum of hydrogen would thus show a line at the frequency of the emitted radiation. If ν is the frequency of the spectral line, then

$$\Delta E = E_2 - E_1 = -\frac{2\pi^2 me^4}{(4\pi\varepsilon_0)^2 n_2^2h^2} + \frac{2\pi^2 me^4}{(4\pi\varepsilon_0)^2 n_1^2h^2} = h\nu \qquad ...(25)$$

or $$\nu = \frac{\Delta E}{h} = \frac{2\pi^2 me^4}{(4\pi\varepsilon_0)^2 h^3}\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right)$$

or $$\bar{\nu} = \frac{1}{\lambda} = \frac{\nu}{c} = \frac{2\pi^2 me^4}{(4\pi\varepsilon_0)^2 h^3 c}\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right) \qquad ...(26)$$

$$= R_H\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right) \qquad ...(27)$$

where R_H is called the **Rydberg constant of the hydrogen atom**. Thus,

$$R_H = \frac{2\pi^2 me^4}{(4\pi\varepsilon_0)^2 h^3 c}\ \text{cm}^{-1} = \frac{2\pi^2 me^4}{(4\pi\varepsilon_0)^2 h^2}\ \text{J} \qquad ...(28)$$

(Frequency in cm^{-1} is multiplied by hc to get energy in joules)

Numerical value of $R_H = 109690{\cdot}8\ \text{cm}^{-1} = 21{\cdot}79 \times 10^{-19}\ \text{J} = 13{\cdot}6\ \text{eV}$

The appearance of various series of spectral lines in the emission spectrum of hydrogen can be easily explained with the help of Eq. 27. The **Lyman** series are produced when the electron jumps from the second, third, fourth or a higher energy level to the first energy level. The frequencies of the various spectral lines of this series can thus be obtained by substituting $n_1 = 1$ and $n_2 = 2, 3, 4$, etc., in Eq. 27. The Balmer series result when the electron jumps from third, fourth, fifth, etc., energy levels to the second energy level. The frequencies of the various spectral lines of the Balmer series can, thus, be obtained by substituting $n_1 = 2$ and $n_2 = 3, 4, 5, 6$, etc. In the same way, the Paschen series originate from the electronic jumps from the fourth, fifth, sixth, etc., energy levels to the third energy level. The frequencies of these spectral lines can be obtained by substituting $n_1 = 3$ and $n_2 = 4, 5, 6$, etc., in Eq. 28, and so on.

The frequencies (in wave numbers m^{-1}) of the spectral lines of the three series calculated from Eq. 27 and those determined experimentally, are given in Table 1.

TABLE 1

Frequencies in Wave Numbers (m^{-1}) of Various Lines of Hydrogen Spectrum

Lyman Series		Balmer Series		Paschen Series	
Experimental	**Calculated**	**Experimental**	**Calculated**	**Experimental**	**Calculated**
$82{\cdot}2 \times 10^5$	$82{\cdot}2 \times 10^5$	$15{\cdot}2 \times 10^5$	$15{\cdot}21 \times 10^5$	$5{\cdot}3 \times 10^5$	$5{\cdot}30 \times 10^5$
97·5	97·6	20·6	20·60	7·8	7·80
102·8	102·7	23·0	23·05	9·1	9·12
105·2	105·2	24·3	24·35	9·2	9·25
106·3	106·2	25·2	25·18	10·5	10·45
107·2	107·1	25·7	25·55		
108·0	107·9				

The agreement between the experimental and the calculated values is excellent. This offered a very strong support to Bohr's theory of the hydrogen atom.

Combining Eqs. 24 and 28, we get

$$E_n = -R_H Z^2/n^2 \qquad ...(29)$$

Example 2. Calculate the value of the Rydberg constant of hydrogen atom in eV.

Solution : $$R_H = \frac{1}{(4\pi\varepsilon_0)^2}\frac{2\pi^2 me^4}{ch^3}$$

Substituting the various values and remembering that $1\text{eV} = 8{\cdot}0655 \times 10^5\ \text{m}^{-1}$, we have

$$R_H = \frac{2(3{\cdot}14)^2(9{\cdot}1\times10^{-31}\text{kg})(1{\cdot}6\times10^{-19}\text{C})^4}{(1{\cdot}11265\times10^{-10}\text{N}^{-1}\text{C}^2\text{m}^{-2})^2(3\times10^8\text{ms}^{-1})(6{\cdot}626\times10^{-34}\text{Js})^3(8{\cdot}0655\times10^5\text{m}^{-1}/\text{eV})}$$

$(\text{J} = \text{kg m}^2\text{s}^{-2})$

$$= 13{\cdot}59\ \text{eV} \approx 13{\cdot}60\ \text{eV}$$

Example 3. Calculate the ground state energies of the electron (in eV) in the case of *(i)* H *(ii)* He^+ *(iii)* Li^{2+} (iv) Be^{3+} species, assuming that their Rydberg constants are equal.

Solution : From Eq. 29, $E_n = -R_H Z^2/n^2$. For ground state ($n = 1$), $R_H = 13{\cdot}60$ eV (from example 2)

(i) For H $(Z = 1)$: $E_1 = -13{\cdot}60$ **eV**

(ii) For H^+ $(Z = 2)$: $E_1 = -(13{\cdot}60)\,(2)^2 = -54{\cdot}40$ **eV**

(iii) For Li^{2+} $(Z = 3)$: $E_1 = -(13{\cdot}60)\,(3)^2 = -122{\cdot}40$ **eV**

(iv) For Be^{3+} $(Z = 4)$: $E_1 = -(13{\cdot}60)\,(4)^2 = -217{\cdot}60$ **eV**

Example 4. Show that the ground state energy of electron in hydrogen atom is equal to the first excited state energy of electron in He^+ ion, assuming that their Rydberg constants are equal.

Solution : $E_n = -R_H Z^2/n^2$; $(n = 1, 2, 3, \ldots.) = -13{\cdot}60\ Z^2/n^2$ eV (from Example 2)

For hydrogen atom in ground state, $Z = 1$, $n = 1$, $\therefore E_1 = -13{\cdot}60$ **eV**

For He^+ ion in first excited state, $Z = 2$, $n = 2$, $\therefore E_2 = -13{\cdot}60$ **eV**

Hence the result.

Example 5. Calculate the short and the long wave length limits of Lyman series in the spectrum of hydrogen. Given $R_H = 109{,}691\ \text{cm}^{-1}$.

Solution : From Eqs. 26 and 27,

$$\bar{\nu} = \frac{1}{\lambda} = R_H\left[\frac{1}{n_1^2} - \frac{1}{n_2^2}\right]$$

For short wave length limit, $\lambda = \lambda_s$, $n_1 = 1$ $n_2 = \infty$. Hence, we find that $\lambda_s = 91{\cdot}16$ **nm**

For long wave length limit, $\lambda = \lambda_l$, $n_1 = 1$ $n_l = 2$. Hence, we find that $\lambda_l = 0{\cdot}1215$ **nm**

Example 6. Calculate the value of the Bohr radius.

Solution : The Bohr radius, *i.e.*, radius of the electron in the first orbit of hydrogen atom, is given by

$$a_0 = \frac{(4\pi\varepsilon_0)h^2}{4\pi^2 me^2} = \frac{1{\cdot}11265\times10^{-10}\,\text{N}^{-1}\text{C}^2\text{m}^{-2}\left(6{\cdot}626\times10^{-34}\ \text{Js}\right)^2}{(4)(3{\cdot}14)^2\,(9{\cdot}1\times10^{-31}\,\text{kg})(1{\cdot}6\times10^{-19}\,\text{C})^2}$$

$$= 5{\cdot}29\times10^{-11}\ \text{m} = 52{\cdot}9\ \text{pm}$$

Example 7. Calculate the radii of the second, third and fourth orbits of hydrogen atom ($a_0 = 0{\cdot}53$Å).

Solution : The radius of the *nth* orbit is given by

$$r_n = n^2 a_0\ ;\ n = 1, 2, 3.....$$

(1) $n = 2$, $r_2 = 2^2\,(0{\cdot}53\ \text{Å}) = 2{\cdot}12\ \text{Å} = 212$ **pm**

(2) $n = 3$, $r_3 = 3^2\,(0{\cdot}53\ \text{Å}) = 4{\cdot}77\ \text{Å} = 477$ **pm**

(3) $n = 4$, $r_4 = 4^2\,(0{\cdot}53\ \text{Å}) = 8{\cdot}48\ \text{Å} = 848$ **pm**

Example 8. Which state of the triply ionized beryllium (Be^{3+}) has the same orbital radius as that of the ground state of hydrogen atom ?

Solution : For hydrogen atom, $r_1 = (4\pi\varepsilon_0)h^2/(4\pi^2 me^2)$ ...*(i)*

For hydrogen-like atom, $r_n' = (4\pi\varepsilon_0)\,n^2h^2/(4\pi^2 mZe^2)$ ...*(ii)*

Dividing Eq. *(ii)* by Eq. *(i)*, we get $r_n'/r_1 = n^2/Z = n^2/4$ $(\because Z = 4$ for $Be^{3+})$

Since $r_n' = r_1$, hence $n = 2$

Thus, the second energy level of Be^{3+} ion has the same radius as that of the ground state of hydrogen atom.

Sommerfeld's Extension of the Bohr Theory

Bohr theory of hydrogen atom enabled calculation of radii and energies associated with the permissible orbits in the hydrogen atom. The calculated values were found to be in good agreement with the experimental values. This theory could also explain successfully the positions of various series of spectral lines in the hydrogen spectrum. The theory was, therefore, largely accepted. However, a few

years later, the use of spectroscopes of high resolving powers revealed the presence of *fine structures* (*i.e.*, groups of closely spaced spectral lines) in the spectrum of hydrogen. Bohr's theory could not explain the occurrence of groups of these closely spaced spectral lines. The theory was, therefore, extended by Arnold Sommerfeld (1868–1951), the German mathematical physicist, by putting forward the idea of *elliptical orbits*.

According to Sommerfeld, an electron revolving around a central positively charged nucleus is so influenced by the nuclear charge that it is set into motion in elliptical orbits with the nucleus situated at one of the foci (Fig. 4). Thus, while according to Bohr's theory, electrons move in circular orbits, according to Sommerfeld's modification, electrons move in elliptical orbits. In the latter case, there will be a major axis and a minor axis having different lengths. As the orbit broadens, the lengths of the two axes become closer and they become equal when the orbit becomes circular, as shown in Fig. 4. Thus, the circular orbit is only a special case of elliptical orbits.

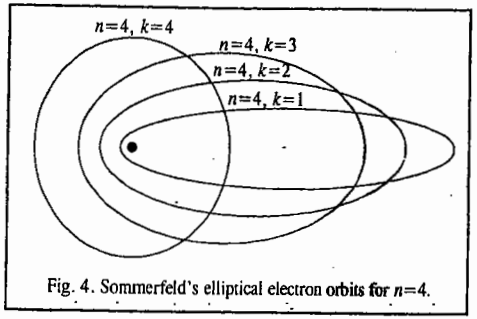

Fig. 4. Sommerfeld's elliptical electron orbits for $n=4$.

The electron travelling in an elliptical orbit will have its angular momentum. The momentum, according to the quantum theory, must also be quantised and thus can have only a limited number of values given by the factor $kh/2\pi$ where k is an integer known as the *azimuthal quantum number*. It can be shown that n, the principal quantum number, used by Bohr and k, the azimuthal quantum number used by Sommerfeld, are related to one another as

$$\frac{n}{k} = \frac{\text{length of major axis}}{\text{length of minor axis}} \qquad ...(30)$$

Thus, for any given value of n (except 1), k can have more than a single value. When $k=n$, the orbit must be circular. But, as k becomes smaller, the orbits become elliptical with greater and greater eccentricity (Fig. 4). It may be noted that k cannot be zero because in that case minor axis would be zero which would imply linear motion of the electron passing through the nucleus. The number of possible values of k is equal to the principal quantum number n. Thus, if n is 4, k can have four values; *viz.*, 4, 3, 2 and 1. When n is 1, k can have only one value.

According to Sommerfeld's extension of Bohr theory, also referred to as the **Bohr–Sommerfeld model,** the energy depends not only on n, the principal quantum number, but also, on the azimuthal quantum number, k. Hence, the transition of an electron from one energy level n_2 to another energy level n_1 will be different as it would also depend upon the various possible values of k in the two states. This explains the occurrence of groups of very closely spaced spectral lines observed in the hydrogen spectrum by using highly refined spectroscopes. The frequencies of some of these spectral lines were found to be in agreement with the frequencies calculated from the Bohr–Sommerfeld model.

Alternative Explanation for the Emission of Fine Hydrogen Spectrum. The emission of fine structure hydrogen spectrum referred to above can be explained more satisfactorily by taking into consideration the role of angular momentum of the electron, as discussed below.

Electron moving around the nucleus in a particular orbit will have a particular angular momentum called the *orbital angular momentum*. A portion of the energy of the electron will be associated with its angular momentum which is described by the quantum number l, called the **orbital angular momentum quantum number.** This is related to the principal quantum number n as $l = n - 1$. Electrons in an atom are thus grouped together not only into major energy shells given by n but also into energy subshells given by l.

Since $l=n-1$, hence the value of l will be 0, 1, 2, 3 ... according as the value of n = 1, 2, 3, ... respectively. The subshells corresponding to $l=0$, 1, 2, 3 ... are designated as *s, p, d, f,* ... subshells, respectively

If $n=1$, l will have only one value, *i.e.*, 0. There will, therefore, be only one subshell, *viz.*, *s* subshell. Thus, the first major shell will have only one subshell.

If $n=2$, l will have two values, *i.e.*, 0 and 1. Thus, the second energy shell will have two subshells, *viz.*, *s* and *p* subshells.

If $n=3$, l will have three values, *i.e.*, 0, 1 and 2. There would thus be three subshells, *viz.*, *s, p* and *d* subshells according as the value of $l=0$, 1 and 2, respectively. Thus, the third energy shell will have three subshells.

Similarly, the fourth energy shell will have four subshells, *s, p, d* and *f* and so on.

Suppose in a spectral study, on excitation of hydrogen atoms, the solitary electrons move to the fourth energy shell. The fourth major energy shell will have four subshells, *viz., s, p, d* and *f* subshells. The electrons will thus be present in the *s, p, d* and *f* subshells of the fourth energy shell. Electronic transitions would thus take place from these four subshells to the lower levels. The energies released during these transitions would appear in the form of a group of four spectral lines differing only slightly in their frequencies because the energies of the *s, p, d* and *f* subshells differ only slightly from one another. This explains the occurrence of a group of four closely spaced lines in the spectrum of hydrogen. If, however, the spectroscope is not powerful enough to resolve these frequencies, the electronic transitions would appear in the form of a single spectral line of a composite frequency as was observed by Bohr.

According to the **Heisenberg uncertainty principle**, (discussed later in details), it is impossible to determine simultaneously the exact position and velocity (momentum) of a minute moving particle like an electron. Therefore, the postulate of Bohr theory that electrons revolve round the nucleus in *well defined orbits* with *will defined velocities* is untenable.

In order to overcome this shortcoming, the use of the term orbit in electronic motion has been dispensed with. In its place, we make use of the term **energy level** or **energy shell** only. This is because energy of an electron can be known with certainty but *not* its position.

Wave-Particle Duality of Electron. Einstein had suggested, in 1905, that light has a *dual character ; as wave* and also as '*particle*'. The French physicist Louis de Broglie (1892–1987) proposed that *matter also has a dual character;* as wave and as particle. The name *wavicle* was suggested for such a particle. de Broglie was awarded the Physics Nobel Prize in 1929.

In Bohr's theory, electron is treated as a particle. But, de Broglie's theory suggested that matter and, therefore, electron also, has a dual character, both as a material particle and as a wave. He derived an expression for calculating the wave length λ of a particle of mass m moving with velocity u according to which

$$\lambda = h/mu \qquad ...(31)$$

Eq. 31 is known as the **de Broglie equation.**

The de Broglie equation can be easily derived by using the Einstein's mass-energy relationship, *viz.*, $E=mc^2$.

Equating this energy with the energy of a photon associated with frequency ν, we have

$$h\nu = mc^2 \qquad ...(32)$$

Since $\nu=c/\lambda$, hence $hc/\lambda = mc^2$ so that

$$\lambda = h/mc \qquad ...(33)$$

Replacing c by the velocity of the electron, u, we have

$$\lambda = h/mu = h/p \qquad ...(34)$$

where p is the linear momentum of the particle.

Example 9. Calculate the de Broglie wave length of electron moving with a velocity of $1{\cdot}20\times10^5$ m s^{-1}.

Solution : $\lambda = \dfrac{h}{m_e u} = \dfrac{(6{\cdot}626\times10^{-34}\ \text{J s})}{(9{\cdot}1\times10^{-31}\ \text{kg})(1{\cdot}20\times10^5\ \text{m s}^{-1})} = 6{\cdot}068\times10^{-9}$ m. $\quad (\text{J} = \text{kg m}^2\ \text{s}^{-2})$

Example 10. Calculate the de Broglie wave length of a body of mass 1 kg moving with a velocity of 2000 m s^{-1}.

Solution : $\lambda = \dfrac{h}{mu} = \dfrac{6{\cdot}626\times10^{-34}\ \text{J s}}{(1\ \text{kg})(2000\ \text{m s}^{-1})} = 3{\cdot}313\times10^{-37}$ m $\quad (\text{J} = \text{kg m}^2\ \text{s}^{-2})$

It may be noted that the above wave length is too small to be measured by any conceivable technique.

Distinction between matter waves and electromagnetic waves. It should be carefully noted that matter waves are distinctly different from electromagnetic waves. The speed of these waves is not the same as that of light ; it is, understandably, much less. These waves cannot be radiated in empty space. They are certainly not emitted by the particle under consideration ; they are simply associated with it. The wave lengths of matter waves are generally very small as compared to the wave lengths of electromagnetic waves.

Derivation of the Bohr Angular Momentum Postulate from de Broglie's Relation. Consider an electron moving in a circular orbit of radius r around a nucleus. The wave train would be as shown in Fig. 5. Evidently, if the wave is to remain continually in phase (Fig. 5 *a*), the circumference of the circular orbit must be an integral multiple of wave length λ, that is,

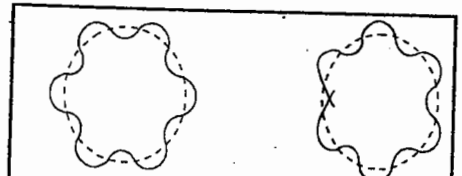
$$2\pi r = n\lambda = nh/mu \qquad ...(35)$$

Thus, the angular momentum,

$$L = mur = nh/2\pi \qquad ...(36)$$

This is the Bohr postulate.

Evidently, if the circumference is bigger or smaller than the value $nh/2\pi$ given in Eq. 36, the wave will no longer remain in phase (Fig. 5 *b*).



(a) Wave continually in phase *(b)* Wave not in phase

Fig. 5. The wave trains of an electron moving in a circular path around a nucleus.

Experimental verification of de Broglie's equation. The verification of de Broglie's equation is possible only by deriving from it certain consequences which may then be tested experimentally.

Let an electron of charge e be accelerated by a potential $\Delta\phi$. Then its kinetic energy is $e\Delta\phi$. The kinetic energy is also equal to $\frac{1}{2}mu^2$ where u is velocity of the electron. Thus,

$$\tfrac{1}{2}mu^2 = e\Delta\phi \quad \text{or} \quad u = (2e\Delta\phi/m)^{1/2} \qquad ...(37)$$

Substituting this value of u into de Broglie's equation, we have

$$\lambda = h/(2me\Delta\phi)^{1/2} \qquad ...(38)$$

Incorporating the numerical values of various quantities, we have

$$\lambda = \frac{6{\cdot}626\times10^{-34}\ \text{J s}}{[(2)(1{\cdot}602\times10^{-19}\ \text{C})(9{\cdot}109\times10^{-31}\ \text{kg})(\Delta\phi\ \text{volt})]^{1/2}}$$

$$= 12{\cdot}26\times10^{-10}\,\Delta\phi^{-1/2}\ \text{m} \qquad ...(39)$$

where $\Delta\phi$ is the numerical value of potential in volts.

If an electron is accelerated through a potential of 100 volts, its wave length should be $1{\cdot}226\times10^{-10}$ m. If potentials are varied between 10 and 10,000 volts, λ should vary between $3{\cdot}877\times10^{-10}$ m and $0{\cdot}1226\times10^{-11}$ m. It is well known that X-rays have wave lengths of this order. It is also well known that crystalline solids can act as diffraction gratings for X-rays having wavelengths

of the above order. Therefore, if de Broglie's view regarding wave-particle duality of electron is correct, the crystalline solids should act as diffraction gratings for a beam of electrons as well. This has been verified experimentally.

Davisson-Germer Experiment. The de Broglie hypothesis regarding wave character of electron received first experimental support from C.J. Davisson and L.H. Germer. In their experiment, electrons were emitted from a hot filament and were accelerated by a potential ranging between 40 and 68 volts before striking a nickel plate, as shown in Fig. 6.

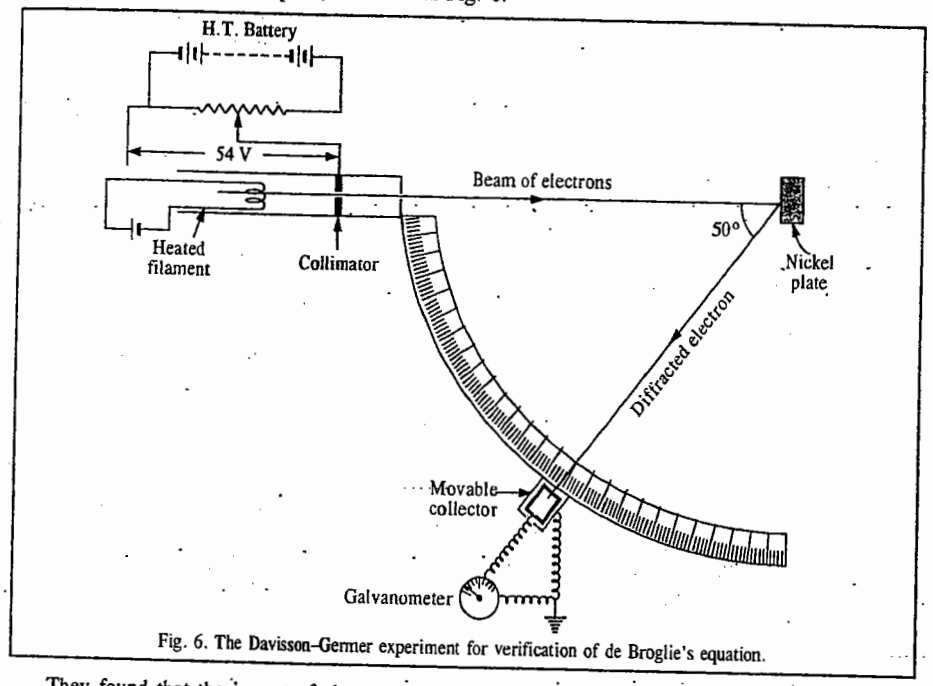


Fig. 6. The Davisson–Germer experiment for verification of de Broglie's equation.

They found that the impact of electrons resulted in the production of diffraction patterns which were similar to those given by X-rays under similar conditions. Since X-rays possess wave character, the experiment gave direct evidence for wave character of electron as well.

The intensities of electron waves scattered by the nickel plate at different angles were measured. It was found that the reflection was most intense and took place at an angle of 50° when electrons were accelerated through 54 volts. Substituting the value of $\Delta\phi$ as 54 V in Eq. 39, it can be shown that the value of λ, the wave length of the electron wave, comes out to be 1·668 Å. This wave length also lies in the range of X-rays. This is another point of similarity between electron waves and X-rays. It should be possible, therefore, to apply the Bragg equation derived for X-ray diffraction, to electron diffraction as well. According to this equation

$$2d\sin\theta = n\lambda \qquad ...(40)$$

when n is a whole number (1, 2, 3, etc.) of wave length λ for a reflection of maximum intensity, d is the distance between successive lattice planes of the crystal (nickel crystal in the present case) and θ is the grazing angle of the waves. This provided an independent experimental method for determining wave length of electron waves. Davisson and Germer found the value of λ to be very close to that obtained by de Broglie's equation. The Davisson–Germer experiment thus offered full support to de Broglie's views and his equation. The American physicist C.J. Davisson (1881–1958) shared the 1937 Physics Nobel Prize with the British physicist G.P. Thomson (1892–1975) for the investigation of electron diffraction by crystals. It has been remarked that J.J. Thomson was awarded the Nobel

Prize for showing that the electron is a *particle* and G.P. Thomson, his son, was awarded the Nobel Prize for showing that the electron is a *wave*.

Heisenberg's Uncertainty Principle. It states that *it is not possible to determine precisely both the position and the momentum (velocity) of a small moving particle.*

Consider a photon incident on a particle. If the particle is of reasonable size, its position or velocity will not be altered by the impact of light photons. Hence it will be possible to know exactly both the position and velocity of the particle. But, this cannot be so when the particle is extremely minute, such as an electron. It will suffer a change in its velocity and path due to the impact of even a single photon of light used to observe it. The path and velocity of an electron, after the impact of light photons, may be quite different from the original path and velocity. For an electron moving in x-direction, the Heisenberg uncertainty principle is expressed mathematically as

$$(\Delta x)(\Delta p_x) \geq h/4\pi \qquad \ldots(41)$$

where Δx is uncertainty with regard to its position and Δp_x is the corresponding uncertainty with regard to its momentum. Evidently, if Δx is very small, *i.e.*, the position of a particle is known more or less exactly, Δp would be large, *i.e.*, uncertainty with regard to momentum will be large. Similarly, if an attempt is made to measure exactly the momentum of the particle, the uncertainty with regard to position will become large. Werner Heisenberg (1900–1976), the German physicist, won the Physics Nobel Prize in 1932.

Example 11. A microscope using suitable photons is employed to locate an electron in an atom within a distance of 0·1 Å. What is the uncertainty involved in the measurement of its velocity ? Mass of electron = $9{\cdot}1\times10^{-31}$ kg.

Solution : From Eq. 41,

$$\Delta x \times \Delta p_x \geq h/4\pi \quad \text{or} \quad \Delta x \times m\Delta u_x \geq h/4\pi$$

$$\therefore \quad 0{\cdot}1\times10^{-10}\ \text{m}\times9{\cdot}1\times10^{-31}\ \text{kg}\times\Delta u_x = 6{\cdot}626\times10^{-34}\ \text{J s}/4\pi$$

$$\Delta u_x = 0{\cdot}579\times10^{7}\ \text{m s}^{-1} \qquad (\text{J} = \text{kg m}^2\ \text{s}^{-2})$$

Example 12. A cricket ball weighing 100 g is to be located within 0·1 Å. What is the uncertainty in its velocity ? Comment on your result.

Solution : From Eq. 41,

$$\Delta x \times \Delta p_x \geq h/4\pi \quad \text{or} \quad \Delta p_x \geq h/4\pi\Delta x$$

$$\therefore \quad \Delta u_x = \Delta p_x/m = h/4\pi\Delta x m = 6{\cdot}626\times10^{-34}/4\pi(10^{-11}\ \text{m})\ (0{\cdot}1\ \text{kg}) = 0{\cdot}527\times10^{-22}\ \text{m s}^{-1}$$

Comparing this value with the typical velocity of a cricket ball, we find that this uncertainty in velocity is completely negligible. This means that we can disregard the uncertainty principle for the motion of *macroscopic bodies*. We can thus say that for such cases, both the position and velocity can be determined to a reasonable degree of precision.

Compton Effect. Arthur Compton found that if monochromatic X-rays (*i.e.*, X-rays having one particular wave length) are allowed to fall on carbon or some other light element, the scattered X-rays have wave lengths larger than the incident rays. In other words, the scattered X-rays have lower frequency, *i.e.*, lower energy than the incident X-rays. Since scattering is caused by electrons, it is evident that some interaction between X-rays and electrons has taken place and this has resulted in decrease in energy of the former. This decrease in energy or increase in wave length of X-rays after scattering from the surface of an object is known as the **Compton effect.**

By applying the law of conservation of energy and the law of conservation of momentum and assuming X-rays to consist of photons, each possessing energy equal to $h\nu$, Compton showed that

$$\Delta\lambda = (2h/mc)\sin^2(\theta/2) \qquad \ldots(42)$$

where $\Delta\lambda$ is the increase in the wave length (termed as **Compton shift**) produced as a result of the collision, m is the rest mass of the electron, c is the velocity of light and θ is the angle between the incident and the scattered X-rays.

According to this equation, Compton shift should be independent of the wavelength of the incident X-rays. This has been found to be so experimentally. Further, the values of Compton shift, as obtained from the above equation, by substituting the known values of h, c, m and θ, have been found to be in close agreement with the experimental values. Arthur Compton (1892–1962), the American physicist, shared the 1927 Physics Nobel Prize with C.T.R. Wilson (1869-1959).

Compton effect provides a good illustration of the uncertainty principle. Suppose X-rays are used to determine the position and momentum of an electron. As a result of mutual interaction of X-rays and the electron, the wave length of X-rays increases, *i.e.*, the frequency or energy of the X-rays decreases. This energy must have been transferred to the electron and, therefore, the momentum of the electron must have changed during the process. Consequently, the momentum of the electron cannot be determined with certainty. Compton effect also provides evidence for the corpuscular or photon nature of radiation. The Compton equation (42) can also be written as

$$\Delta\lambda = \lambda' - \lambda = \frac{h}{mc}(1 - \cos\theta) \qquad \ldots(43)$$

We see that the wave length λ' of scattered X-rays is always greater than the wave length λ of incident X-rays. The wave length shift is independent of the nature of the substance and the wave length of incident X-rays. It depends only on the scattering angle θ. The following three cases may be considered :

Case 1. $\theta = 0°$, *i.e.*, the scattered radiation is parallel to the incident radiation. In this case, $\cos\theta = 1$ so that $\Delta\lambda = 0$, *i.e.*, there is no wave length shift.

Case 2. $\theta = 90°$, *i.e.*, the scattered radiation is perpendicular to the incident radiation. In this case, $\cos\theta = 0$ so that

$$\Delta\lambda = h/mc = 6{\cdot}626\times10^{-34}\ \text{J s}/(9{\cdot}109\times10^{-31}\ \text{kg})(3\times10^{8}\ \text{m s}^{-1})$$
$$= 0{\cdot}02422\times10^{-10}\ \text{m}$$

In the present case, $\Delta\lambda$ is referred to as the **Compton wave length.**

Case 3. $\theta = 180°$, *i.e.*, the radiation is scattered in a direction opposite to the incident radiation. In this case, $\cos\theta = -1$ so that

$$\Delta\lambda = 2h/mc = 0{\cdot}0484\times10^{-10}\ \text{m}$$

This is twice the value of the Compton wave length.

QUANTUM MECHANICS (WAVE MECHANICS)

Introduction to Quantum Mechanics. Classical mechanics, as formulated by Sir Isaac Newton (1642—1727) in the seventeenth century, is obeyed by *macroscopic* 'particles' such as planets and rigid bodies. However, since the *microscopic* particles such as electrons, protons, atoms and molecules show wave-particle duality, they do not obey Newtonian dynamics. They, however, obey **quantum mechanics** (or **wave mechanics**) a key feature of which is the quantization of energy and angular momentum. The laws of quantum mechanics were formulated in 1925 by the German physicists M. Born, W. Heisenberg and P. Jordan (in the formulation known as **matrix mechanics**) and in 1926 by the Austrian physicist E. Schrödinger. The Schrödinger formulation of quantum mechanics is more familiar to chemists than the Born–Heisenberg–Jordan formulation of matrix mechanics, though both the forms are equivalent. We shall not discuss matrix mechanics in this book. In 1928, P.A.M. Dirac, the British physicist, formulated his celebrated **relativistic quantum mechanics** and showed that the electron spin emerges as a natural consequence of his theory whereas in the Schrödinger non-relativistic quantum mechanics, it has to be imposed later. Again, we shall not discuss the Dirac theory though it has become indispensable in the physics of elementary particles whose velocities approach that of light when accelerated in a cyclotron and other high energy accelerators.

Now we shall dwell on the reason why the Heisenberg uncertainty principle forces us to abandon Newtonian mechanics. We know that the motion of a one-particle, one-dimensional classical system

is governed by Newton's second law of motion, *i.e.*, $F = ma = md^2x/dt^2$. In order to obtain the position x as a function of time, this differential equation is to be integrated twice with respect to time. The first integration yields dx/dt and the second integration gives x. Each integration, however, introduces an arbitrary integration constant. Hence, the integration of $F=ma$ gives an equation for x that contains two unknown constants c_1 and c_2. We thus have

$$x = f(t, c_1, c_2) \qquad ...(44)$$

where f is some function. To evaluate c_1 and c_2 we require two pieces of information about the system. If we know that at a certain time t_0, the particle is at the position x_0 and has speed u_0, then c_1 and c_2 can be calculated from the equations

$$x_0 = f(t_0, c_1, c_2) \quad \text{and} \quad u_0 = f'(t_0, c_1, c_2), \qquad ...(45)$$

where f' is the derivative of f with respect to t. Thus, if we know the force F and the initial position and velocity (or linear momentum) of the particle, we can use Newton's second law of motion to predict the position of the particle at any future time. The same argument holds for a three-dimensional, many-particle system.

In classical mechanics, the *state of a system* is defined by specifying all the forces acting and all the positions and velocities (or momenta) of the particles. Thus, as stated above, a knowledge of the present state of a classical mechnical system allows its future state to be predicted with certainty. It is at this stage that the Heisenberg uncertainty (or indeterminacy) principle comes into the picture. It shows that simultaneous specification of position and momentum is impossible for a microscopic particle. The state of a quantum mechanical system necessarily involves less knowledge about the system than in classical mechanics. In other words, the *certainties* of classical mechanics shall have to be abandoned in favour of the *uncertainties* of quantum mechanics. Classical mechanics is a deterministic theory in that it allows us to predict the exact paths (or trajectories) taken by the particles of the system and tells us where they will be at a future time. In contrast, quantum mechanics gives only the probabilities of finding the particles at various locations in space. Besides Newton, contributions to classical mechanics were made by the great French mathematicians Pierre-Simon Laplace (1749–1827) and Joseph L. Lagrange (1736–1813) and by the Irish mathematician William Rowan Hamilton (1805–1865).

As we shall see shortly, in quantum mechanics, the state of a system is defined by the state function or wavefunction ψ which is a function of the coordinates of the particles of the system and is also a function of time (since the state may change with time). Thus, for a two-particle system, the wavefunction can be written as

$$\psi = f(x_1, y_1, z_1, x_2, y_2, z_2, t) \qquad ...(46)$$

where x_1, y_1, z_1 are the coordinates of particle 1, etc. For an n-particle system, the equation governing the time-dependence of ψ is given by

$$\sum_{i=1}^{n} -\frac{\hbar^2}{2m_i}\left(\frac{\partial^2\psi}{\partial x_i^2}+\frac{\partial^2\psi}{\partial y_i^2}+\frac{\partial^2\psi}{\partial z_i^2}\right) + V(x_i, y_i, z_i, t)\psi = i\hbar\frac{\partial\psi}{\partial t} \qquad ...(47)$$

where m_i is the mass and V is the potential energy of the particle.

The above equation is the celebrated *time-dependent second-order differential equation*, known as the Schrödinger wave equation. Notice that this equation contains the first derivative of ψ with respect to time. Therefore, a single integration with respect to time gives us ψ. Integration of this equation thus introduces only one integration constant which can be evaluated if ψ is known at the initial time t_0. Thus, knowing the initial quantum mechanical state, we can use this equation to predict the future quantum mechanical state. The time-dependent Schrödinger wave equation is the quantum mechanical analogue of Newton's second law which allows the future state of a classical mechanical system to be predicted from its present state. However, the knowledge of the state in quantum mechanics usually involves a knowledge of only *probabilities* rather than *certainties*.

We may ask, "what is the relation between quantum mechanics and classical mechanics ?" It is known experimentally that when $v \ll c$, *i.e., the velocity v of a macroscopic body is far less than the velocity of light c*, relativistic mechanics gives the same results as Newton's classical mechanics. Similarly, it was shown by P. Ehrenfest that in the classical limit of taking $h \to 0$ (where h is the Planck's constant), the time-dependent Schrödinger wave equation reduces to Newton's second law. This is a very remarkable result. Also, the Bohr correspondence principle (also called the principle of complementarity) states that classical mechanics and quantum mechanics tend to give the same results when systems are in highly excited quantum states.

It is interesting to point out that the probabilistic nature of quantum mechanics disturbed many physicists, including Schrödinger, de Broglie and Einstein. In 1926, Einstein wrote : "Quantum mechanics says a lot but does not really bring us closer to the secret of God. I, at any rate, am convinced that He does not throw dice." These and many other scientists believed that quantum mechanics does not furnish a complete description of physical reality. However, all attempts to replace quantum mechanics by an underlying causal deterministic theory, have failed. There appears to be some fundamental randomness at the microscopic level. As S. Hawking said, "Quantum mechanics allows us in principle to predict nearly everything around us, within the limits set by the uncertainty principle."

Postulates of Quantum Mechanics. The formulation of quantum mechanics or wave mechanics for the wave mechanical treatment of the structure of atom rests upon a few postulates which, for a system moving in one dimension, say, along the x-coordinate, are given below.

First Postulate. The physical state of a system at time t is described by the wavefunction $\psi(x, t)$.

Second Postulate. The wavefunction $\psi(x, t)$ and its first and second derivatives $\partial\psi(x,t)/\partial x$ and $\partial^2\psi(x,t)/\partial x^2$ are continuous, finite and single valued for all values of x. Also, the wavefunction $\psi(x, t)$ is *normalized, i.e.*,

$$\int_{-\infty}^{\infty} \psi^*(x,t)\,\psi(x,t)dx = 1 \qquad ...(48)$$

where ψ^* is the *complex conjugate* of ψ formed by replacing i with $-i$ wherever it occurs in the function $\psi(i = \sqrt{-1})$.

Third Postulate. A physically observable quantity can be represented by a *Hermitian operator.* An operator $\hat{A}$ is said to be Hermitian if it satisfies the following condition :

$$\int \psi_i^* \hat{A}\psi_j\,dx = \int \psi_j\,(\hat{A}\psi_i)^*\,dx \qquad ...(49)$$

where ψ_i and ψ_j are the wavefunctions representing the physical states of the quantum system, such as a particle, an atom or a molecule.

Fourth Postulate. The allowed values of an observable A are the eigenvalues, a_i, in the operator equation

$$\hat{A}\,\psi_i = a_i\psi_i \qquad ...(50)$$

Eq. 50 is known as an **eigenvalue equation.** Here $\hat{A}$ is the operator for the observable (physical quantity) and ψ_i is an eigenfunction of $\hat{A}$ with eigenvalue a_i. In other words, measurement of the observable A yields the eigenvalue a_i.

Fifth Postulate. The average value (or, the expectation value), $< A >$, of an observable A, corresponding to the operator $\hat{A}$, is obtained from the relation

$$< A > = \int_{-\infty}^{\infty} \psi^* \hat{A}\,\psi\,dx \qquad ...(51)$$

where the function ψ is assumed to be normalized in accordance with Eq. 48. Thus, the average value

of, say, the x-coordinate is given by

$$< x > = \int_{-\infty}^{\infty} \psi^* \hat{x} \psi \, dx \qquad ...(52)$$

Sixth Postulate. The quantum mechanical operators corresponding to the observables are constructed by writing the classical expressions in terms of the variables and converting the expressions to the operators, as shown in Table 2.

TABLE 2

Wave Mechanical Operators for Evaluating Various Classical Variables

Classical variable	Quantum mechanical operator	Operator	Operation
x	$\hat{x}$	x	Multiplication by x
p_x	$\hat{p}_x$	$-i\hbar\frac{\partial}{\partial x}$	Taking derivative with respect to x and multiplying by $-i\hbar$
x^2	$\hat{x}^2$	x^2	Multiplication by x^2
p_x^2	$\hat{p}_x^2$	$-\hbar^2\frac{\partial^2}{\partial x^2}$	Taking second derivative with respect to x and multiplying by $-\hbar^2$
t	$\hat{t}$	$\hat{t}$	Multiplying by t
E	$\hat{E}$	$i\hbar\frac{\partial}{\partial t}$	Taking derivative with respect to t and multiplying by $i\hbar$

Seventh Postulate. The wave function $\psi(x,t)$ is a solution of the time-dependent Schrödinger equation

$$\hat{H}\psi(x,t) = i\hbar\frac{\partial\psi(x,t)}{\partial t} \qquad ...(53)$$

where $\hat{H}$ is the Hamiltonian operator of the system.

The Schrödinger Wave Equation

Erwin Schrödinger, in 1926, gave a wave equation to describe the behaviour of electron waves in atoms and molecules. In Schrödinger's wave model of an atom, the discrete energy levels or orbits proposed by Bohr are replaced by mathematical functions, ψ, which are related to the probability of finding electrons at various places around the nucleus.

Consider a simple wave motion as that of the vibration of a stretched string. Let y be the amplitude of this vibration at any point whose coordinate is x at time t. The equation for such a wave motion may be expressed

$$\frac{\partial^2 y}{\partial x^2} = \frac{1}{u^2}\times\frac{\partial^2 y}{\partial t^2} \qquad ...(54)$$

where u is the velocity with which the wave is propagating. There are two variables, x and t, in the above differential equation, *i.e.*, the amplitude y depends upon two variables x and t.

In order to solve the above differential equation, it is necessary to separate the two variables. Thus, y may be expressed as

$$y = f(x)\, g(t) \qquad ...(55)$$

where $f(x)$ is a function of the coordinate x only and $g(t)$ is a function of the time t only. For stationary waves, such as occur in a stretched string, the function $g(t)$ is represented by the expression

$$g(t) = A \sin(2\pi\nu t) \qquad ...(56)$$

where ν is the vibrational frequency and A is a constant known as the maximum amplitude. Hence, for

stationary waves, the equation for y may be written as

$$y = f(x)\, A \sin(2\pi\nu t) \qquad ...(57)$$

Hence,
$$\frac{\partial^2 y}{\partial t^2} = -f(x)\, 4\pi^2\nu^2 A \sin(2\pi\nu t) \qquad ...(58)$$

$$= -4\pi^2\nu^2 f(x)\, g(t) \qquad ...(59)$$

Similarly, it follows from Eq. 57 that

$$\frac{\partial^2 y}{dx^2} = \frac{\partial^2 f(x)}{\partial x^2} g(t) \qquad ...(60)$$

Combining Eqs. 54, 59 and 60, we have

$$\frac{\partial^2 f(x)}{\partial x^2} = -\frac{4\pi^2\nu^2}{\nu^2} f(x) \qquad ...(61)$$

As is well known, the frequency of the vibrations ν is related to the velocity u by the expression $u=\nu\lambda$, where λ is the corresponding wave length. Hence, from Eq. 61, we have

$$\frac{\partial^2 f(x)}{\partial x^2} = -\frac{4\pi^2}{\lambda^2} f(x) \qquad ...(62)$$

Eq. 62 is valid for the wave motion in one dimension only. We may now extend it to three dimensions represented by the coordinates x, y and z. Evidently, $f(x)$ will then be replaced by the amplitude function for the three coordinates, say, $\psi(x, y, z)$. For the sake of simplicity, it may be put merely as ψ. Hence, Eq. 62 takes the form

$$\frac{\partial^2\psi}{\partial x^2}+\frac{\partial^2\psi}{\partial y^2}+\frac{\partial^2\psi}{\partial z^2} = -\frac{4\pi^2}{\lambda^2}\psi \qquad ...(63)$$

Following de Broglie's ideas, Schrödinger, the Austrian physicist, applied the above treatment to material waves associated with all particles including electrons, atoms and molecules.

Incorporating de Broglie's relationship, *viz.*, $\lambda = h/mu$, in Eq. 63, we have

$$\frac{\partial^2\psi}{\partial x^2}+\frac{\partial^2\psi}{\partial y^2}+\frac{\partial^2\psi}{\partial z^2} = -\frac{4\pi^2 m^2 u^2}{h^2}\psi \qquad ...(64)$$

where m is the mass and u is the velocity of the particle.

The kinetic energy of the particle given by $\frac{1}{2}mu^2$, is equal to the total energy E *minus* the potential energy V of the particle, *i.e.*,

$$K.E. = \tfrac{1}{2}mu^2 = E - V \quad \text{or} \quad mu^2 = 2(E - V) \qquad ...(65)$$

Combining this result with Eq. 64, we get

$$\frac{\partial^2\psi}{\partial x^2}+\frac{\partial^2\psi}{\partial y^2}+\frac{\partial^2\psi}{\partial z^2}+\frac{8\pi^2 m(E-V)}{h^2}\psi = 0 \qquad ...(66)$$

Eq. 66 is the well-known **Schrödinger wave equation** proposed by him in 1926. It is the most celebrated equation in wave mechanics. It is customarily written in the following form:

$$\left[-\frac{\hbar^2}{2m}\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right)+V\right] = E\psi \qquad ...(67)$$

or
$$\left[-\frac{\hbar^2}{2m}\nabla^2 + V\right]\psi = E\psi \qquad (\hbar = h/2\pi) \qquad ...(68)$$

where ∇^2 (read as 'del squared') is the **Laplacian operator,** defined as

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \quad ...(69)$$

Defining the **Hamiltonian operator** $\hat{H}$ as

$$\hat{H} = \frac{-\hbar^2}{2m}\nabla^2 + V, \quad ...(70)$$

the **time-independent Schrödinger equation** (Eq. 68) becomes

$$\hat{H}\psi = E\psi \quad ...(71)$$

It may be noted that Eq. 71 can also be derived from Eq. 53.

E. Schrödinger (1887-1961) shared the 1933 Physics Nobel Prize with P.A.M. Dirac (1902-1984) for the discovery of new productive forms of atomic theory.

The Schrödinger equation can have several solutions, not all of which correspond to any physical or chemical reality. Such solutions or wave functions are, therefore, not acceptable. The acceptable wave functions must satisfy the following conditions :

1. The wave function ψ is *single-valued, i.e.,* for each value of the variables x, y, z, there is only one value of ψ. Suppose one of the variables is an angle θ. Then, single-valuedness of ψ requires that $\psi(\theta) = \psi(\theta + 2n\pi)$ where n is an integer.

2. The wave function ψ and its first derivative with respect to its variables must be *continuous, i.e.,* there must not be any sudden change in ψ when its variables are changed.

3. For bound states, ψ must vanish at infinity. If ψ is a complex function, then $\psi^*\psi$ must vanish at infinity (ψ^* is the complex conjugate of ψ).

Satisfying the above conditions, the Schrödinger equation yields *significant solutions for certain definite values of the total energy E.* These values are called eigenvalues. Eq. 71 is, thus, an eigenvalue equation and we can write it as

$$\hat{H}\psi_n = E_n\psi_n \qquad (n = 1, 2, 3, ...) \quad ...(72)$$

where n is the quantum number. We express Eq. 72 by saying that ψ_n are the eigenfunctions and E_n are the eigenvalues. For an atom, these eigenvalues correspond to discrete sets of energy values postulated by Bohr.

4. The eigenfunctions are said to form an **orthonormal set** if

$$\int \psi_n^* \psi_m \, d\tau = \begin{cases} 0, & n \neq m \\ 1, & n = m \end{cases} = \delta_{nm} \text{ (called the Kronecker delta)} \quad ...(73)$$

They are **orthogonal** when $\int \psi_n^* \psi_m \, d\tau = 0$ ...(74)

and **normalized** when $\int \psi_n^* \psi_m \, d\tau = 1$ ...(75)

It is possible to identify regions of space around the nucleus where there is *high probability* of locating an electron associated with a specific energy. This space is called an atomic orbital. An **atomic orbital,** thus, represents a definite region in three-dimensional space around the nucleus where there is high probability of finding an electron of a specific energy E.

Statistical interpretation of ψ. It was Max Born (1882–1970), the German physicist, who gave statistical interpretation of the function ψ, calling it the **probability amplitude function.** Born won the 1954 Physics Nobel Prize for this interpretation. If $\psi(x)$ is the wavefunction of a particle, then, the probability of finding the particle within the range from x to $x+dx$ is given by

$$P(x)dx = \psi^*\psi \, dx = |\psi|^2 dx \quad ...(76)$$

where ψ^* is the **complex conjugate** of ψ. Note that $P(x)dx$ is the **probability** and $P(x)$ is the **probability density.**

We know that in the case of light waves, the intensity of the electromagnetic field is proportional to the square of the amplitude of the wave at that point. Likewise, in the case of a particle, the probability of its being found between the region x and $(x+dx)$ is proportional to the square of the wavefunction, *i.e.,* the square of the probability amplitude function at that point. Since the total probability of locating the particle must be unity, we have

$$\int_{-\infty}^{\infty} P(x)dx = \int_{-\infty}^{\infty} \psi^*\psi \, dx = \int_{-\infty}^{\infty} |\psi|^2 dx = 1 \quad ...(77)$$

For motion in three dimensions,

$$\int P(\vec{r})d^3r = \int |\psi(\vec{r})|^2 d^3r = 1 \quad ...(78)$$

where the integration is carried over the three-dimensional volume element $d^3r = dx\,dy\,dz$.

It may be noted that in Bohr's theory, the electron associated with a definite energy is considered to be located at a definite distance from the nucleus. In wave mechanics, the equation for calculating the *exact energy* of the electron has been derived but there is a considerable uncertainty with regard to its exact location. This is in conformity with the Heisenberg uncertainty principle.

Operators in Quantum Mechanics

The concept of operators is very important in wave mechanics. We have already listed a few operators in the sixth postulate of quantum mechanics. Here we shall briefly deal with the algebra of operators. If $\hat{A}$ and $\hat{B}$ are two operators and f is a function upon which they operate, then

$$(\hat{A} + \hat{B})f = \hat{A}f + \hat{B}f \quad ...(79)$$

and $$(\hat{A} - \hat{B})f = \hat{A}f - \hat{B}f \quad ...(80)$$

Thus, we can generate new operators $\hat{A}+\hat{B}$ and $\hat{A}-\hat{B}$ by adding and subtracting $\hat{A}$ and $\hat{B}$. Also,

$$\hat{A} + \hat{B} = \hat{B} + \hat{A} \quad ...(81)$$

$$\hat{A} - \hat{B} = -\hat{B} + \hat{A} \quad ...(82)$$

The multiplication of operators can be carried out by doing successive operations with two or more operators on a function. If $\hat{A}$ and $\hat{B}$ are two operators and f is their **operand,** then we can obtain the quantity $\hat{A}\hat{B}f$ as follows : We first operate on f with $\hat{B}$ to obtain f', that is, $\hat{B}f = f'$. Then, f' is operated upon by $\hat{A}$ to obtain f'', that is, $\hat{A}f' = f''$. Thus, we have

$$\hat{A}\hat{B}f = f'' \quad ...(83)$$

It should be remembered that the order of application of operators is always from right to left as they are written. Application of the same operator several times in succession is written with a power. Thus, we have

$$\hat{A}\hat{A}f = \hat{A}^2 f \quad ...(84)$$

Commutation of Operators. The algebra of operators should be distinguished from the algebra of ordinary numbers. If a and b are two numbers, then we know that

$$a \times b = b \times a \quad ...(85)$$

However, if $\hat{A}$ and $\hat{B}$ are two operators, then their product $\hat{A}\hat{B}$ may or may not be equal to $\hat{B}\hat{A}$.

If $\hat{A}\hat{B} = \hat{B}\hat{A}$, then the **commutator** of the two operators is defined as

$$[\hat{A}, \hat{B}] = \hat{A}\hat{B} - \hat{B}\hat{A} = 0 \qquad ...(86)$$

Example 13. Show that

(a) $[\hat{A}, \hat{B}] = -[\hat{B}, \hat{A}]$ *(b)* $[\hat{A}^2, \hat{B}] = \hat{A}[\hat{A}, \hat{B}] + [\hat{A}, \hat{B}]\hat{A}$

Solution : *(a)* $[\hat{A}, \hat{B}] = (\hat{A}\hat{B} - \hat{B}\hat{A}) = -(\hat{B}\hat{A} - \hat{A}\hat{B}) = -[\hat{B}, \hat{A}]$

(b) R.H.S. $= \hat{A}[\hat{A}, \hat{B}] + [\hat{A}, \hat{B}]\hat{A} = \hat{A}(\hat{A}\hat{B} - \hat{B}\hat{A}) + (\hat{A}\hat{B} - \hat{B}\hat{A})\hat{A}$

$= \hat{A}^2\hat{B} - \hat{A}\hat{B}\hat{A} + \hat{A}\hat{B}\hat{A} - \hat{B}\hat{A}^2 = \hat{A}^2\hat{B} - \hat{B}\hat{A}^2 = [\hat{A}^2, \hat{B}]$ = L.H.S.

Expressions for Operators. Expressions for operators can be obtained by operating with the operators on an operand and removing the operand at the end of the operation.

Example 14. Find expressions for the following operators :

(a) $\left(\frac{d}{dx} + x\right)^2$ *(b)* $\left(\frac{d}{dx} + x\right)\left(\frac{d}{dx} - x\right)$ *(c)* $\left(\frac{d}{dx} - x\right)\left(\frac{d}{dx} + x\right)$

Solution : Let $\psi(x)$ be the operand.

(a) $\left(\frac{d}{dx} + x\right)^2 \psi(x) = \left(\frac{d}{dx} + x\right)\left(\frac{d}{dx} + x\right)\psi(x) = \left(\frac{d}{dx} + x\right)\left(\frac{d\psi}{dx} + x\psi\right)$

$= \frac{d^2\psi}{dx^2} + 2x\frac{d\psi}{dx} + x^2\psi + \psi = \left(\frac{d^2}{dx^2} + 2x\frac{d}{dx} + x^2 + 1\right)\psi$

Removing ψ from both sides of this equation, we have

$$\left(\frac{d}{dx} + x\right)^2 = \frac{d^2}{dx^2} + 2x\frac{d}{dx} + x^2 + 1$$

(b) $\left(\frac{d}{dx} + x\right)\left(\frac{d}{dx} - x\right)\psi(x) = \left(\frac{d}{dx} + x\right)\left(\frac{d\psi}{dx} - x\psi\right)$

$= \frac{d^2\psi}{dx^2} - \frac{d}{dx}(x\psi) + x\frac{d\psi}{dx} - x^2\psi = \frac{d^2\psi}{dx^2} - \left(x\frac{d\psi}{dx} + \psi\frac{dx}{dx}\right) + x\frac{d\psi}{dx} - x^2\psi$

$= \frac{d^2\psi}{dx^2} - \psi - x^2\psi = \left(\frac{d^2}{dx^2} - 1 - x^2\right)\psi$ $\qquad (\because\ dx/dx = 1)$

Removing ψ from both sides of the equation, we have

$$\left(\frac{d}{dx} + x\right)\left(\frac{d}{dx} - x\right) = \frac{d^2}{dx^2} - 1 - x^2$$

(c) $\left(\frac{d}{dx} - x\right)\left(\frac{d}{dx} + x\right)\psi(x) = \left(\frac{d}{dx} - x\right)\left(\frac{d\psi}{dx} + x\psi\right) = \frac{d^2\psi}{dx^2} + \frac{d}{dx}(x\psi) - x\frac{d\psi}{dx} - x^2\psi$

$= \frac{d^2\psi}{dx^2} + \left(x\frac{d\psi}{dx} + \psi\frac{dx}{dx}\right) - x\frac{d\psi}{dx} - x^2\psi$

$= \frac{d^2\psi}{dx^2} + \psi - x^2\psi = \left(\frac{d^2}{dx^2} + 1 - x^2\right)\psi$

Removing ψ from both sides of the equation, we have

$$\left(\frac{d}{dx} - x\right)\left(\frac{d}{dx} + x\right) = \frac{d^2}{dx^2} + 1 - x^2$$

Example 15. If $\hat{A}$ and $\hat{B}$ are two operators such that $[\hat{A}, \hat{B}] = 1$, show that $[\hat{A}, \hat{B}^2] = 2\hat{B}$.

Solution : $[\hat{A}, \hat{B}] = \hat{A}\hat{B} - \hat{B}\hat{A} = 1$

$[\hat{A}, \hat{B}^2] = \hat{A}\hat{B}^2 - \hat{B}^2\hat{A} + \hat{B}\hat{A}\hat{B} - \hat{B}\hat{A}\hat{B} = (\hat{A}\hat{B}^2 - \hat{B}\hat{A}\hat{B}) + (\hat{B}\hat{A}\hat{B} - \hat{B}^2\hat{A})$

$= (\hat{A}\hat{B} - \hat{B}\hat{A})\hat{B} + \hat{B}(\hat{A}\hat{B} - \hat{B}\hat{A}) = (1)\hat{B} + \hat{B}(1) = 2\hat{B}$

Example 16. Show that the commutator $\left[x, \frac{d}{dx}\right] = -1$.

Solution : By definition, $\left[x, \frac{d}{dx}\right] = x\frac{d}{dx} - \frac{d}{dx}x$

Let $\psi(x)$ be the operand, then operating on $\psi(x)$ by the right-hand side expression, we have

$$\left(x\frac{d}{dx} - \frac{d}{dx}x\right)\psi = x\frac{d\psi}{dx} - \frac{d}{dx}(x\psi) = x\frac{d\psi}{dx} - x\frac{d\psi}{dx} - \psi\frac{dx}{dx} = -\psi \qquad (\because\ dx/dx = 1)$$

Removing ψ from both sides of this equation, we have

$$\left[x, \frac{d}{dx}\right] = -1.$$

Example 17. Show that the commutator $[\hat{x}^n, \hat{p}_x] = i\hbar n x^{n-1}$ where n is a positive integer.

Solution : The operators for the x-coordinate and the x-component of the linear momentum, p_x are :

$$\hat{x} \to x \quad \text{and} \quad \hat{p}_x \to -i\hbar\frac{d}{dx}$$

$$[\hat{x}^n, \hat{p}_x] = x^n\left(-i\hbar\frac{d}{dx}\right) - \left(-i\hbar\frac{d}{dx}\right)x^n = -i\hbar x^n\frac{d}{dx} + i\hbar\frac{d}{dx}x^n$$

Operating on the arbitrary operand $\psi(x)$ by this operator, we have

$$-i\hbar x^n\frac{d\psi}{dx} + i\hbar\frac{d}{dx}(x^n\psi) = -i\hbar x^n\frac{d\psi}{dx} + i\hbar x^n\frac{d\psi}{dx} + i\hbar n x^{n-1}\psi = i\hbar n x^{n-1}\psi$$

Hence, $[\hat{x}^n, \hat{p}_x] = i\hbar n x^{n-1}$ [Removing ψ from both sides of this equation]

Solution of the Schrödinger Wave Equation for Some Simple Systems

The Schrödinger wave equation can be solved exactly for the following simple systems :

1. Particle in a One-Dimensional Box.
2. Particle in a Three-Dimensional Box.
3. One-Dimensional Simple Harmonic Oscillator (S.H.O.)
4. The Rigid Rotor (or Rotator).
5. The Hydrogen Atom.

Note that since the solutions of the Schrödinger equation, subject to boundary conditions, yield quantized (integral) energy eigenvalues and eigenfunctions, wave mechanics is also called quantum mechanics.

1. Particle in a One-Dimensional Box. This is the simplest quantum mechanical problem which represents **translational motion.** Here a particle of mass m is confined to move in a one-dimensional box of width a, having infinitely high walls (Fig. 7). It is assumed, for the sake of simplicity, that the potential energy of the particle is zero everywhere inside the box, that is

$$V(x) = 0 \qquad ...(87)$$

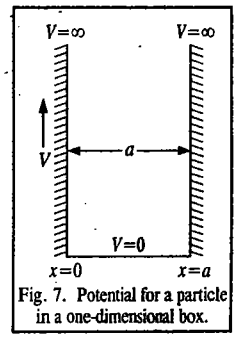

Fig. 7. Potential for a particle in a one-dimensional box.

Thus, inside the box the Schrödinger equation, *viz.*,

$$\left[-\frac{\hbar^2}{2m}(d^2/dx^2)+V(x)\right]\psi(x) = E\psi(x) \quad ...(88)$$

takes the form $$-\frac{\hbar^2}{2m}(d^2\psi/dx^2) = E\psi(x) \quad ...(89)$$

Our problem is to solve this equation for energy E and the wave function $\psi(x)$.

Mathematically, Eq. 89 may be rewritten as

$$\frac{d^2\psi}{dx^2}+(2mE/\hbar^2)\psi = 0 \quad ...(90)$$

or as $$\frac{d^2\psi}{dx^2}+k^2\psi = 0 \quad ...(91)$$

where k^2 $(= 2mE/\hbar^2)$ is a constant, independent of x.

Eq. 91 is an ordinary second-order differential equation which has solution of the form

$$\psi = A\cos kx + B\sin kx \quad ...(92)$$

where A and B are constants. Before we proceed further, it should be pointed out that *outside* the box where $V(x) = \infty$, the Schrödinger equation (88) is

$$\left[-\frac{\hbar^2}{2m}(d^2/dx^2)+\infty\right]\psi(x) = E\psi(x) \quad ...(93)$$

or $$\frac{d^2\psi}{dx^2}+\frac{2m}{\hbar^2}(E-\infty)\psi = 0 \quad ...(94)$$

This equation is satisfied if ψ is zero everywhere *outside* the box. This is another way of saying that the particle cannot be found outside the box ; it is confined within the box. This implies that ψ must be zero at the walls of the box, *i.e.*, at $x=0$ and at $x=a$. Since the postulate of quantum mechanics requires that ψ must be a continuous function of x, we are forced to conclude that in Eq. 92, A must be zero. Thus, the solution of Eq. 91 is of the form

$$\psi = B\sin kx \quad ...(95)$$

Since $\psi = 0$ at $x = 0$ and at $x = a$, we have

$$B\sin ka = 0 \text{ or } \sin ka = 0 \text{ or } ka = n\pi \text{ so that } k = n\pi/a \quad ...(96)$$

where $n(=0, 1, 2, 3, 4.....,)$ is the quantum number. Hence, the allowed solutions of Eq. 91 are

$$\psi \equiv \psi_n = B\sin(n\pi x/a) ; \quad (n = 1, 2, 3, ...) \quad ...(97)$$

Notice that the $n=0$ value of the quantum number, though allowed, is not *acceptable* since it implies that the wave function ψ is zero everywhere inside the box. This is not correct since the particle is taken to be inside the box, to begin with. From Eqs. 91 and 96, we have

$$(2mE/\hbar^2) = n^2\pi^2/a^2 \quad ...(98)$$

or $$E \equiv E_n = n^2\hbar^2\pi^2/2ma^2 = n^2h^2/8ma^2 ; \quad n = 1, 2, 3,.....\text{and } \hbar = h/2\pi \quad ...(99)$$

Note that $\hbar$ is called **reduced Planck's constant** and also **Dirac's constant.**

Eq. 99 gives the expression for the energy of the particle in a one-dimensional box. Since energy depends upon the quantum number n, the energy levels are quantized. Let us determine the coefficient B in the wavefunction given by Eq. 97. This can be done by normalizing the wave function.

Normalization of ψ. Since the total probability of finding the particle within the box is 1,

$$\int_0^a \psi_n^2\,dx = 1 \text{ [Born's interpretation of wave function]} \quad ...(100)$$

$$\int_0^a (B\sin n\pi x/a)^2\,dx = 1 \text{ [Using } \psi_n \text{ from Eq. 97]} \quad ...(101)$$

... or $$B^2\int_0^a \sin^2(n\pi x/a)\,dx = 1 \quad ...(102)$$

Since $\sin^2\theta = \frac{1}{2}(1-\cos 2\theta)$, hence from Eqs. 100 and 102, we have

$$\int_0^a \psi_n^2\,dx = B^2\left[\frac{1}{2}\int_0^a dx - \frac{1}{2}\int_0^a \cos\left(\frac{2n\pi x}{a}\right)dx\right] \quad ...(103)$$

$$= B^2[a/2 - 0] = 1 \quad ...(104)$$

Hence, $B = (2/a)^{1/2}$ ...(105)

Thus, the normalized wave functions for the particle are :

$$\psi_n(x) = (2/a)^{1/2}\sin(n\pi x/a) ; \quad n = 1, 2, 3, ... \quad ...(106)$$

Note that the quantization arises naturally from the boundary conditions. We have gone beyond the stage of Planck and Bohr where quantum numbers are introduced in an *ad hoc* manner.

A few normalized wave functions and the corresponding probability functions for a particle in a box are given in Fig. 8. The most probable position for a particle in the $n = 1$ energy level is the centre of the box. Note that $\psi_n(x)$ are waves with wave length $\lambda_n = 2a/n$. This means that ψ_n is zero at values of x equal to an integral number of $\lambda_n/2$. These zeros are called nodes of the wave function. In one-dimensional problems, the more nodes in an eigenfunction, the higher its eigenvalue of energy. For this problem, the number of nodes is $n - 1$.

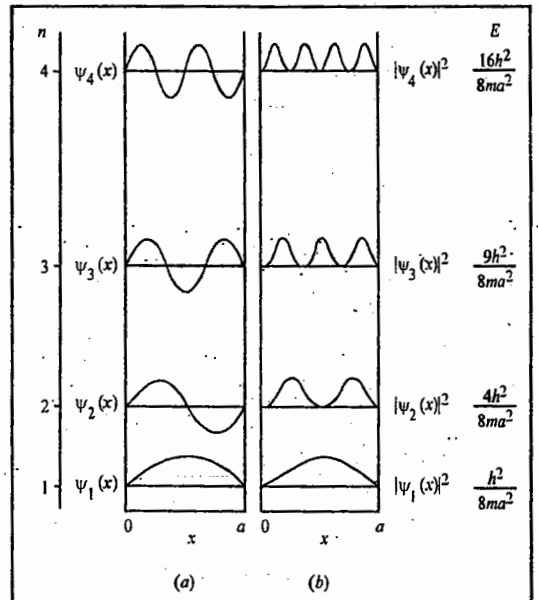

Fig. 8. The energy levels, wavefunctions (*a*) and (*b*) probability densities for the particle in a one-dimensional box.

Example 18. Calculate the energies (in eV) of an electron constrained to move in a one-dimensional box of width 1 Å and exhibit them on an energy level diagram.

Solution :

$$E_n = \frac{n^2(6{\cdot}626\times10^{-34}\text{ J s})^2}{(8)(9{\cdot}109\times10^{-31}\text{ kg})(10^{-10}\text{ m})^2(1{\cdot}602\times10^{-19}\text{ J/eV})}$$

$$= 37{\cdot}6n^2\text{ eV} \approx 38n^2\text{ eV}$$

Energies of the electron corresponding to different values of n are :

$n = 1, \quad E_1 = 38$ eV
$n = 2, \quad E_2 = 38\,(2)^2 = 152$ eV
$n = 3, \quad E_3 = 38\,(3)^2 = 342$ eV
$n = 4, \quad E_4 = 38\,(4)^2 = 608$ eV, and so on.

The above energies are shown in the form of an energy level diagram in Fig. 9. Notice that the energy levels are sufficiently far apart; their quantization is thus distinctly evident.

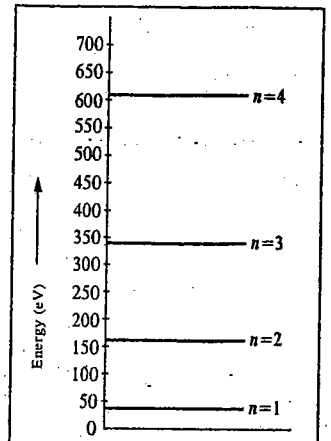

Fig. 9. Energies of an electron moving in a one-dimensional box.

Notice that as a gets large, the energy levels get closer together. In the limit of a very large box (or a very heavy particle), the energy levels are so close together that the quantization may be unnoticeable. In the limit that a becomes very large, all energies become allowed (*i.e.*, the allowed energies get very close together so that any energy is an eigenvalue), so the perfectly free particle can have any energy.

Example 19. An electron is confined in a one-dimensional box of length 1 Å. Calculate its ground state energy in electron volts (eV). Is quantization of energy levels observable ?

Solution : From Eq. 99, the ground state energy of the electron is

$$E_1 = \frac{n^2h^2}{8ma^2} = \frac{(1)^2(6{\cdot}626\times10^{-34}\text{ J s})^2}{(8)(9{\cdot}109\times10^{-31}\text{ kg})(10^{-10}\text{ m})^2(1{\cdot}602\times10^{-19}\text{ J/eV})}$$
$$= 37{\cdot}6 \text{ eV}$$

Let us calculate the energy of the first excited state with $n=2$.

$$E_2 = \frac{(2)^2(6{\cdot}626\times10^{-34}\text{ J s})^2}{(8)(9{\cdot}109\times10^{-31}\text{ kg})(10^{-10}\text{ m})^2(1{\cdot}602\times10^{-19}\text{ J/eV})} = 150{\cdot}4 \text{ eV}$$

Therefore, $\Delta E = E_2 - E_1 = 150{\cdot}4 - 37{\cdot}6 = 112{\cdot}8$ eV

This energy corresponds to that of a quantum of X-rays which can be readily observed. Thus, we conclude that it is possible to observe quantization in the energy levels of microscopic systems.

Example 20. A ball of mass 1 g, confined to a one-dimensional box of length 0·1 m, moves with a velocity of 0·01 m s^{-1}. Calculate the quantum number n. Is it possible to observe the quantization of energy levels of the ball ?

Solution : The kinetic energy of the ball equals the total energy. In the ground state, $n=1$.

$$\therefore \quad E_1 = \tfrac{1}{2}mu_x^2 = \tfrac{1}{2}(0{\cdot}001\text{ kg})\,(0{\cdot}01\text{ m s}^{-1})^2 = 5\times10^{-8}\text{ J} \quad [\text{since } V_{(x)}=0] \quad (\text{J}=\text{kg m}^2\text{ s}^{-2})$$

Since from Eq. 99, $E_n = n^2h^2/8ma^2$, hence, $n^2 = 8ma^2E_n/h^2$

$$\therefore \quad n = [8ma^2E_n/h^2]^{1/2} = (8mE_n)^{1/2}a/h$$

Substituting the various values, we have

$$n = [8(0{\cdot}001\text{ kg})\,(5\times10^{-8}\text{ J})]^{1/2}\left[\frac{0{\cdot}1\text{ m}}{6{\cdot}626\times10^{-34}\text{ J s}}\right] = 3\times10^{27}$$

Notice the fantastically high value of the quantum number n.

Let us calculate ΔE between energy levels characterized by the quantum numbers n and $n+1$:

$$\Delta E = E_{n+1} - E_n = [(n+1)^2 - n^2]\,h^2/(8ma)^2 = (2n+1)\,E_0$$

where $E_0 = h^2/8ma^2 = (6{\cdot}626\times10^{-34})^2/8ma^2 = 5{\cdot}48\times10^{-68}/ma^2$ J

Since, $n = 3\times10^{27}$, $n+1 = 3\times10^{27}+1 = 3\times10^{27}$

(We can safely neglect 1 in comparison with 3×10^{27})

$$\therefore \quad \Delta E = (2n+1)\,E_0 = [2(3\times10^{27})+1]\,\frac{5{\cdot}48\times10^{-68}}{(0{\cdot}001\text{ kg})(0{\cdot}1\text{ m})^2}\text{ J} = 3{\cdot}3\times10^{-35}\text{ J}$$

This implies that $E_1 = 5\times10^{-8}$ J and $E_2 = 5\times10^{-8}\text{ J} + 3{\cdot}3\times10^{-35}\text{ J} \approx 5\times10^{-8}$ J

Since E_1 and E_2 are practically the same, it is not possible to observe quantization in the energy levels of macroscopic systems like the ball.

Example 21. Calculate the expectation (average) value of the energy of a particle of mass m confined to move in a one-dimensional box of width a and infinite height with potential energy zero inside the box. The normalized wavefunction of the particle is $\psi_n(x)=(2/a)^{1/2}\sin(n\pi x/a)$ where $n=1, 2, 3,\ldots$

Solution : Total energy E of a particle is the sum of kinetic energy T and potential energy V. Since the potential energy inside the box is zero, *i.e.*, $V=0$, hence,

$$E = T$$
$$T = \tfrac{1}{2}mu^2 = m^2u_x^2/2m = p_x^2/2m$$

As shown in Table 1, the operator of p_x^2 is $-\hbar^2\,\partial^2/\partial x^2$, hence

$$\hat{H} = -(\hbar^2/2m)\,d^2/dx^2$$

$$\therefore \langle E \rangle = \int_0^a \psi_n(x)\hat{H}\psi_n(x)dx$$

$$= -\frac{\hbar^2}{2m}\int_0^a\left(\frac{2}{a}\right)^{1/2}\sin\left(\frac{n\pi x}{a}\right)\frac{d^2}{dx^2}\left[\left(\frac{2}{a}\right)^{1/2}\sin\left(\frac{n\pi x}{a}\right)\right]dx$$

$$= -\frac{\hbar^2}{ma}\int_0^a\sin\left(\frac{n\pi x}{a}\right)\left[\frac{-n^2\pi^2}{a^2}\sin\left(\frac{n\pi x}{a}\right)\right]dx = \frac{n^2h^2}{4ma^3}\int_0^a\sin^2\left(\frac{n\pi x}{a}\right)dx \qquad (\because \hbar = h/2\pi)$$

$$= \frac{n^2h^2}{4ma^3}\int_0^a\frac{1-\cos(2n\pi x/a)}{2}dx = \frac{n^2h^2}{8ma^3}\left\{[x]_0^a - \frac{a}{2n\pi}\left[\sin\left(\frac{2n\pi x}{a}\right)\right]_0^a\right\}$$

$$= \frac{n^2h^2}{8ma^3}(a-0) = n^2h^2/8ma^2$$

Note that this is also the value obtained by solving the Schrödinger equation for this system.

Example 22. Verify that the wavefunctions of a particle in a one-dimensional box of width a and infinite height are orthogonal.

Solution : $\psi_n(x) = \left(\frac{2}{a}\right)^{1/2}\sin\left(\frac{n\pi x}{a}\right)$; $n = 1, 2, 3.....$

The orthogonality condition requires that $\int_0^a \psi_m^*(x)\psi_n(x)dx = 0$ (cf. Eq. 74)

Since the wavefunctions are real,

$$\psi_m^*(x) = \psi_m(x) = (2/a)^{1/2}\sin(m\pi x/a)$$

Hence, $$\int_0^a\psi_m^*\psi_n dx = \int_0^a\left(\frac{2}{a}\right)^{1/2}\sin\left(\frac{m\pi x}{a}\right)\left(\frac{2}{a}\right)^{1/2}\sin\left(\frac{n\pi x}{a}\right)dx$$

$$= \left(\frac{2}{a}\right)\int_0^a\sin\left(\frac{m\pi x}{a}\right)\sin\left(\frac{n\pi x}{a}\right)dx \qquad \ldots(i)$$

Since $\sin A \sin B = \frac{1}{2}[\cos(A-B) - \cos(A+B)]$,

Eq. *(i)* can be written as

$$\int_0^a\psi_m^*\psi_n\,dx = \frac{1}{a}\int_0^a\left(\cos(m-n)\frac{\pi x}{a} - \cos(m+n)\frac{\pi x}{a}\right)dx$$

$$= \frac{1}{a}\left\{\frac{a}{(m-n)\pi}\sin\left[(m-n)\frac{\pi x}{a}\right]_0^a - \frac{a}{(m+n)\pi}\sin\left[(m+n)\pi\frac{x}{a}\right]_0^a\right\} = 0$$

Hence the result. ($\because$ m and n are integers)

Example 23. Calculate the average values of x, x^2, p_x and p_x^2 for a particle in a one-dimensional box of width a and infinite height and verify that $\Delta p_x \Delta x = \hbar/2$, where Δx is the uncertainty in the positional coordinate x and Δp_x is the uncertainty in the linear momentum along the x-coordinate.

Solution : We know that for the given system, the normalized wavefunctions are

$$\psi_n(x) = \left(\frac{2}{a}\right)^{1/2}\sin\left(\frac{n\pi x}{a}\right);\ n = 1,2,3,..... \qquad \text{(Eq. 106)}$$

and $$< x > = \int_0^a \psi_n \hat{x}\, \psi_n dx \qquad \text{(From Eq. 52)}$$

$$= \int_0^a \left(\frac{2}{a}\right)^{1/2}\sin\left(\frac{n\pi x}{a}\right) x \left(\frac{2}{a}\right)^{1/2}\sin\left(\frac{n\pi x}{a}\right)dx$$

$$= \frac{2}{a}\int_0^a x\sin^2\left(\frac{n\pi x}{a}\right)dx = \frac{2}{a}\int_0^a x\left[\frac{1-\cos(2n\pi x/a)}{2}\right]dx = (2/a)(a^2/4) = a/2$$

$$< x^2 > = \frac{2}{a}\int_0^a x^2\sin^2\left(\frac{n\pi x}{a}\right)dx = \frac{2}{a}\int_0^a x^2\left[\frac{1-\cos(2n\pi x/a)}{2}\right]dx$$

$$= \frac{1}{a}\left[\int_0^a x^2 dx - \int_0^a x^2\cos\left(\frac{2n\pi x}{a}\right)dx\right] = \frac{1}{a}\left[\frac{a^3}{3} - \frac{a^3}{2n^2\pi^2}\right] = \frac{a^2}{3} - \frac{a^2}{2n^2\pi^2}$$

Since the operator of p_x is $-i\hbar d/dx$ (Table 1), hence,

$$< p_x > = \int_0^a \psi_n\left[\left(-i\hbar\frac{d}{dx}\right)^2\right]\psi_n dx = -\hbar^2\int_0^a\left(\frac{2}{a}\right)^{1/2}\sin\left(\frac{n\pi x}{a}\right)\frac{d^2}{dx^2}\left[\left(\frac{2}{a}\right)^{1/2}\sin\left(\frac{n\pi x}{a}\right)\right]dx$$

$$= -(i\hbar)\left(\frac{2}{a}\right)\left(\frac{n\pi}{a}\right)\int_0^a \sin\left(\frac{n\pi x}{a}\right)\cos\left(\frac{n\pi x}{a}\right)dx = 0$$

$$<p_x^2> = \int_0^a \psi_n\left[\left(-i\hbar\frac{d}{dx}\right)^2\right]\psi_n dx = -\hbar^2\int_0^a\left(\frac{2}{a}\right)^{1/2}\sin\left(\frac{n\pi x}{a}\right)\frac{d^2}{dx^2}\left[\left(\frac{2}{a}\right)^{1/2}\sin\left(\frac{n\pi x}{a}\right)\right]dx$$

$$= \hbar^2\left(\frac{n\pi}{a}\right)^2\int_0^a\left(\frac{2}{a}\right)\sin^2\left(\frac{n\pi x}{a}\right)dx \qquad ...(i)$$

The integral on the R.H.S. of Eq. *(i)* equals E_n, the energy of the particle so that

$$<p_x^2> = \hbar^2\,(n\pi/a)^2 E_n = n^2h^2/4a^2 = 2mE_n \text{ where } E_n = n^2h^2/8ma^2$$

We know that $$(\Delta p_x)^2 = <p_x^2> - <p_x>^2 = <p_x^2> = n^2h^2/4a^2 \qquad (\because < p_x >^2 = 0)$$

Again, $$(\Delta x)^2 = <x^2> - <x>^2 = \frac{a^2}{3} - \frac{a^2}{2n^2\pi^2} - \left(\frac{a}{2}\right)^2 = \frac{a^2}{12} - \frac{a^2}{2n^2\pi^2}$$

Hence, $$(\Delta p_x)^2(\Delta x)^2 = \left(\frac{n^2h^2}{4a^2}\right)\left(\frac{a^2}{12} - \frac{a^2}{2n^2\pi^2}\right) = \frac{n^2h^2}{4}\left(\frac{1}{12} - \frac{1}{2n^2\pi^2}\right) = \frac{\hbar^2}{4}\left(\frac{n^2\pi^2}{3} - 2\right)$$

$$\therefore \quad \Delta p_x \Delta x = (\hbar/2)\,[(n^2\pi^2/3) - 2]^{1/2}$$

or $$\Delta p_x\,\Delta x > \hbar/2 \qquad (\because n^2\pi^2/3 \text{ is always gteater than 2})$$

The reader will recognize that here we have **verified the Heisenberg uncertainty principle** for the particle in a one-dimensional box.

Example 24. What will happen if the walls of the one-dimensional box are suddenly removed ?

Solution : When the walls for the particle in a one-dimensional box are suddenly removed, it becomes free to move without any restriction on the value of the potential energy. If the potential energy is taken to be zero, then the solution of Schrödinger equation (94) is given by Eq. 96. However, the arbitrary constants A or B and k in Eq. 96 can have any values which may be assigned to them. Thus, the energy eigenvalues given by $E = k^2h^2/8\pi^2m$ are not quantized. Hence we conclude that a freely moving particle (which may be an electron) without any restriction has *continuous energy spectrum.*

Example 25. What is the zero-point energy of a particle in a one-dimensional box of infinite height ? Is the occurrence of zero-point energy in accordance with the Heisenberg uncertainty principle ?

Solution : Since $E_n = n^2h^2/8ma^2$, the energy corresponding to $n=1$, *viz.*, $E_1 = h^2/8ma^2$, is called the zero-point energy (Z.P.E.) of the particle. Since Z.P.E. is finite (and not equal to zero) it means that the particle inside the box is not at rest even at 0 K. This being so, the position of the particle cannot be precisely known. Again, since only the expectation (and not exact) value of the kinetic energy $<\frac{1}{2}mu^2>$ is known, the linear momentum of the particle is also not precisely known. Thus, occurrence of Z.P.E. implies uncertainty in the position, Δx and also uncertainty in the x-component of the linear momentum Δp_x. This means that the occurrence of Z.P.E. is in keeping with the Heisenberg uncertainty principle.

Example 26. Set up and solve the Schrödinger wave equation for a particle of mass m moving in a one-diminsional potential with rigid walls, *i.e.*,

$$V(x) = \begin{bmatrix} 0, & -a<x<a \\ \infty, & |x|>a \end{bmatrix}$$

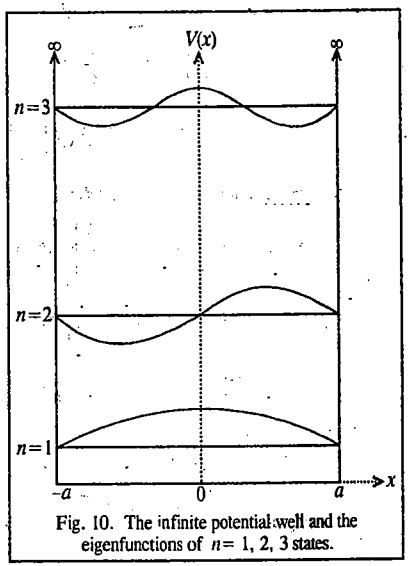

Fig. 10. The infinite potential well and the eigenfunctions of $n = 1, 2, 3$ states.

Solution : See Fig.10 below for the infinite potential well.

The time-independent Schrödinger wave equation for the particle in the region $|x| < a$ is

$$\frac{d^2\psi}{dx^2} + k^2\psi = 0, \qquad \text{where } k^2 = 2mE/\hbar^2 \qquad ...(i)$$

whose solution is

$$\psi(x) = A\sin kx + B\cos kx \qquad ...(ii)$$

Since $V(x) = \infty$ at $x = \pm a$, $\psi(\pm a) = 0$. Using this boundary condition we have

$$A\sin ka + B\cos ka = 0$$

and $$-A\sin ka + B\cos ka = 0$$

From these two equations we find that $B\cos ka = 0$, and $A\sin ka = 0$. Now the solution $A = 0$, $B = 0$ leads to the physically unacceptable solution $\psi = 0$. The other possible cases are $A = 0$, $B \neq 0$ and $A \neq 0$, $B = 0$. The first condition gives,

$$\cos ka = 0, \qquad ka = n\pi/2, \qquad n = 1, 3, 5, ...$$

Thus, $$k^2 = \frac{2mE}{\hbar^2} = \frac{n^2\pi}{4}$$

or, $$E_n = \frac{k^2\hbar^2}{2m} = \frac{\pi^2h^2n^2}{8ma^2}, \quad n = 1, 3, 5, ... \qquad ...(iii)$$

The eigenfunction corresponding to this energy eigenvalue is

or, $$\psi_n(x) = B\cos\frac{n\pi x}{2a}, \quad n = 1, 3, 5, ... \qquad ...(iv)$$

The second condition leads to

$$E_n = \frac{\pi^2\hbar^2 n^2}{8ma^2}, \quad n = 2, 4, 6, \ldots \qquad \ldots(v)$$

with the eigenfunction

$$\psi_n(x) = A\sin\frac{n\pi x}{2a}, \quad n = 2, 4, 6, \ldots \qquad \ldots(vi)$$

Note that quantum number $n = 0$ is not included as it corresponds to a trivial solution $\psi(x) = 0$. In normalization of the wavefunctions gives $A = B = 1/\sqrt{a}$. Thus, the confinement of the particle in the infinite potential well with rigid walls leads to the quantization of energy given by

$$E_n = \frac{\pi^2\hbar^2 n^2}{8ma^2}, \quad n = 1, 2, 3, \ldots \qquad \ldots(vii)$$

The complete set of normalized eigenfunctions are

$$\psi_n(x) = \begin{cases} \frac{1}{\sqrt{a}}\sin\frac{n\pi x}{2a}, & n = 2, 4, 6, \ldots \\ \frac{1}{\sqrt{a}}\cos\frac{n\pi x}{2a}, & n = 1, 3, 5, \ldots \end{cases} \qquad \ldots(viii)$$

These eigenfunctions for the first three states are shown in Fig. 10. From Eq. (*viii*) we see that the wavefunctions corresponding to odd quantum numbers are symmetric with respect to the operation $x \to -x$ (*i.e.*, they are *even functions*), whereas those for even quantum numbers are antisymmetric (*i.e.*, *odd functions*). The energy and the wavefunction of the ground state are

$$E_1 = \frac{\pi^2\hbar^2}{8ma^2} \quad \text{and} \quad \psi_1(x) = \frac{1}{\sqrt{a}}\cos\frac{\pi x}{2a} \qquad \ldots(ix)$$

We see that the particle confined in the box has a certain minimum energy, called the **zero-point energy**, which is a manifestation of the Heisenberg uncertainty principle. This is understandable since an uncertainty, Δx, of order a in position implies an uncertainty, Δp_x, of order $\hbar/2a$ in momentum, which, in turn, gives a minimum kinetic energy of $\hbar^2/(8ma^2)$.

2. Particle in a Three-Dimensional Cubical Box. Let us now consider the motion of a particle of mass m confined to a three-dimensional cubical box with edges of length a and volume equal to a^3. The potential is zero within the box and is infinite outside the box and at its boundaries. The time-independent Schrödinger equation for the particle is

$$\left[-\frac{\hbar^2}{2m}\left(\frac{\partial^2}{\partial x^2} + \frac{\partial}{\partial y^2} + \frac{\partial^2}{\partial z^2}\right)\right]\psi(x, y, z) = E\psi(x, y, z) \qquad \ldots(107)$$

Eq. 107 may be rewritten as

$$\frac{\partial^2\psi}{\partial x^2} + \frac{\partial^2\psi}{\partial y^2} + \frac{\partial^2\psi}{\partial z^2} + \left(\frac{2mE}{\hbar^2}\right)\psi = 0 \qquad \ldots(108)$$

Assuming that the wavefunction ψ is a product of three parts which separately depend on x, y and z, we have

$$\psi(x, y, z) = X(x)\, Y(y)\, Z(z) \qquad \ldots(109)$$

Hence,

$$\frac{\partial^2\psi}{\partial x^2} = YZ\frac{\partial^2 X}{\partial x^2} \qquad \ldots(110)$$

$$\frac{\partial^2\psi}{\partial y^2} = XZ\frac{\partial^2 Y}{\partial y^2} \qquad \ldots(111)$$

$$\frac{\partial^2\psi}{\partial z^2} = XY\frac{\partial^2 Z}{\partial z^2} \qquad \ldots(112)$$

Substituting Eqs. 110–112 in Eq. 108 and dividing throughout by $(2m/\hbar^2)XYZ$, we have

$$\frac{\hbar^2}{2m}\left[\frac{1}{X}\frac{\partial^2 X}{\partial x^2} + \frac{1}{Y}\frac{\partial^2 Y}{\partial y^2} + \frac{1}{Z}\frac{\partial^2 Z}{\partial z^2}\right] + E = 0 \qquad \ldots(113)$$

We notice that the first term is a function of x only and is independent of y and z; the second term is a function of y only and is independent of x and z and the third term is a function of z only and is independent of x and y. The fourth term E is a constant. If energy E is written as the sum of three contributions associated with the three coordinates, then Eq. 113 can be separated into three equations. Thus, for instance, for motion along the X-axis (where X varies while Y and Z remain constant), the second and third terms on the left-hand side of Eq. 113 remain constant. Let this constant be E_x. Accordingly, we can write

$$-\frac{\hbar^2}{2m}\left(\frac{1}{X}\frac{\partial^2 X}{\partial x^2}\right) = E_x \qquad \ldots(114)$$

$$-\frac{\hbar^2}{2m}\left(\frac{1}{Y}\frac{\partial^2 Y}{\partial y^2}\right) = E_y \qquad \ldots(115)$$

$$-\frac{\hbar^2}{2m}\left(\frac{1}{Z}\frac{\partial^2 Z}{\partial z^2}\right) = E_z \qquad \ldots(116)$$

where $E = E_x + E_y + E_z$. $\ldots(117)$

We see that each of the Eqs. 114—116 is of the form of Eq. 89, the solution of which is given by Eq. 106, *i.e.*, we have

$$X(x) = (2/a)^{1/2}\sin(n_x\pi x/a); \quad n_x = 1, 2, 3\ldots. \qquad \ldots(118)$$

and $$E_x = n_x^2\hbar^2/8ma^2 \qquad \ldots(119)$$

Similar solutions exist for $Y(y)$ and $Z(z)$. Hence,

$$\psi(x, y, z) = X(x)\, Y(y)\, Z(z) = (8/a^3)^{1/2}\sin(n_x\pi x/a)\sin(n_y\pi y/a)\sin(n_z\pi z/a) \qquad \ldots(120)$$

and $$E = E_x + E_y + E_z = \frac{(n_x^2 + n_y^2 + n_z^2)h^2}{8ma^2} \qquad \ldots(121)$$

where $n_x, n_y, n_z = 1, 2, 3, 4, \ldots$.

Degeneracy. It is seen from Eq. 121 that the total energy depends upon the sum of the squares of three quantum numbers. It is evident that groups of different states, each specified by a unique set of quantum numbers, can have the *same* energy. In such a case, the energy level and the corresponding independent states are said to be **degenerate.** Consider the energy level having energy $= 14h^2/8ma^2$. There are six combinations of n_x, n_y and n_z which can give this value of energy :

n_x	1	1	2	3	2	3
n_y	2	3	1	1	3	2
n_z	3	2	3	2	1	1

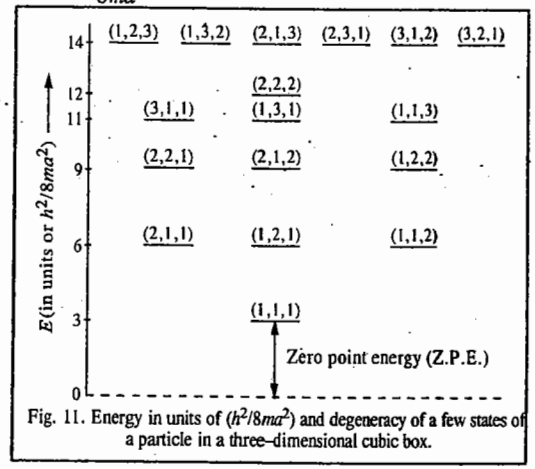

Fig. 11. Energy in units of $(h^2/8ma^2)$ and degeneracy of a few states of a particle in a three-dimensional cubic box.

This energy level is, therefore, 6-*fold degenerate, i.e.,* its degeneracy is equal to 6. Proceeding in this manner we can calculate degeneracy of the energy levels of a particle in a three-dimensional cubical box. The results are shown in Fig. 11.

3. One-Dimensional Simple Harmonic Oscillator. A diatomic vibrating molecule is an example of the so-called simple harmonic oscillator. (S.H.O.). This system represents **vibrational motion.**

According to Hooke's law, the force acting on the molecule is given by $f = -kx$, where x is the displacement from the equilibrium position and k is a constant called the **force constant.** The **Hooke's law potential energy** $V(x)$ of this molecule is given by

$$V(x) = -\int_0^x f dx = \int_0^x kx\,dx = \frac{1}{2}kx^2 \qquad ...(122)$$

Eq. 122 is the equation of a parabola. Thus, if we plot potential energy of a particle executing simple harmonic oscillations as a function of displacement from the equilibrium position, we get a curve as shown in Fig. 12.

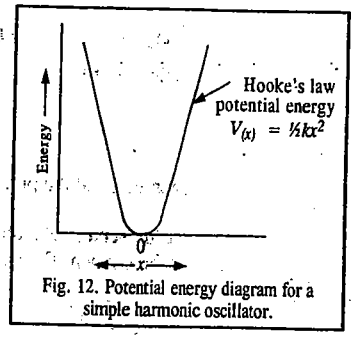

Fig. 12. Potential energy diagram for a simple harmonic oscillator.

The vibrational frequency of the oscillator of mass m is given by

$$\nu = \frac{1}{2\pi}\left(\frac{k}{m}\right)^{1/2} \qquad ...(123)$$

It is more accurate to define the vibrational frequency as

$$\nu = \frac{1}{2\pi}\left(\frac{k}{\mu}\right)^{1/2} \qquad ...(124)$$

where μ is the reduced mass of the diatomic molecule defined as

$$\frac{1}{\mu} = \frac{1}{m_1} + \frac{1}{m_2} \qquad ...(125)$$

where m_1 and m_2 are the atomic masses of the two atoms.

Using the potential energy given by Eq. 122, for one-dimensional S.H.O., the Schrödinger equation (Eq. 67) is represented as

$$\left[-\frac{\hbar^2}{2m}\left(\frac{d^2}{dx^2}\right) + \frac{1}{2}kx^2\right]\psi(x) = E\psi(x) \qquad ...(126)$$

Mathematically, Eq. 126 may be written as

$$\frac{d^2\psi}{dx^2} + \frac{2m}{\hbar^2}\left(E - \frac{1}{2}kx^2\right)\psi = 0 \qquad ...(127)$$

It is convenient to use the mass, rather than the reduced mass, of the S.H.O. in the following discussion ; also bear in mind that the force constant k of the oscillator is given by $k = m\omega^2$, where $\omega(=2\pi\nu)$ is the angular frequency. Thus, Eq. 127 is written as

$$\frac{d^2\psi}{dx^2} + \frac{2m}{\hbar^2}\left(E - \frac{1}{2}m\omega^2x^2\right)\psi = 0 \qquad ...(128)$$

Defining a new variable ξ and a new parameter λ by

$$\xi = (m\omega/\hbar)^{1/2}x \text{ and } \lambda = 2E/\hbar\omega \qquad ...(129)$$

Eq. 128 may be written as

$$\frac{d^2\psi}{d\xi^2} + \left(\lambda - \xi^2\right)\psi = 0 \qquad ...(130)$$

We shall now investigate the **asymptotic solution** of Eq. 130, *i.e.,* to find ψ when $\xi \to \infty$. When ξ is very large, $\lambda - \xi^2 \cong -\xi^2$ so that Eq. 130 becomes

$$\frac{d^2\psi}{d\xi^2} - \xi^2\psi = 0 \qquad ...(131)$$

Its asymptotic solutions are

$$\psi(x) = \exp\left(\pm\xi^2/2\right) \qquad ...(132)$$

since substitution of Eq. 132 in Eq. 131 gives

$$\frac{d^2\psi}{d\xi^2} = \left(\xi^2 + 1\right)\exp\left(\pm\xi^2/2\right) \cong \xi^2\psi$$

Out of the two asymptotic solutions, $\exp\left(\xi^2/2\right)$ is not acceptable since it diverges when $|\xi| \to \infty$. The exact solution of Eq. 130 may thus be written as

$$\psi(x) = e^{-\xi^2/2}H(\xi) \qquad ...(133)$$

where $H(\xi)$ is a function of ξ and the product $e^{-\xi^2/2}H(\xi)$ tends to zero as $|\xi| \to \infty$.

We next carry out the **series solution.** Substituting Eq. 133 into Eq. 131, we obtain the **Hermite equation** (named after the eminent French mathematician Charles Hermite (1822-1901)) :

$$\frac{d^2H(\xi)}{d\xi^2} - 2\xi\frac{dH(\xi)}{d\xi} + (\lambda - 1)H(\xi) = 0 \qquad ...(134)$$

We look for the function $H(\xi)$ as a series solution of the type

$$H(\xi) = \sum_{n=0}^{\infty} a_n\xi^n \qquad ...(135)$$

Substitution of Eq. 135 in Eq. 134 gives

$$\sum_{k=0}^{\infty}\left[(k+1)(k+2)a_{k+2} - (2k + 1 - \lambda)a_k\right]\xi^k = 0 \qquad ...(136)$$

In order that this equation be valid it is essential that the coefficient of each power of ξ must vanish separately. When the coefficient of ξ^k is equated to zero we obtain the so-called **recurrence relation :**

$$a_{k+2} = \frac{2k + 1 - \lambda}{(k+1)(k+2)}a_k \qquad ...(137)$$

This relation allows the calculation of all even coefficients in terms of a_0 and the odd coefficients in terms of a_1. Eq. 135 will have only odd coefficients if $a_0 = 0$ and even coefficients if $a_1 = 0$. Thus, we have two independent solutions of Eq. 135 and the linear combination of the two will give the most general solution. The two solutions are :

$$H_e(\xi) = a_0 + a_2\xi^2 + a_4\xi^4 + ... \qquad ...(138)$$

and

$$H_o(\xi) = \xi(a_1 + a_3\xi^2 + a_5\xi^4 + ...) \qquad ...(139)$$

We now proceed to determine the **energy eigenvalues :**

When $k \to \infty$ in Eq. 137, we obtain

$$\frac{a_{k+2}}{a_k} = \frac{2}{k} \qquad ...(140)$$

Let us consider the Taylor series expansion of exp (ξ^2) :

$$\exp(\xi^2) = \sum_{0,2,4} \frac{1}{(k/2)!}\xi^k \qquad ...(141)$$

The ratio of the coefficients of the successive terms in Eq. 141 is

$$\frac{a_{k+2}}{a_k} = \frac{(k/2)!}{[(k/2)+1]!} = \frac{1}{[(k/2)+1]} \cong \frac{2}{k} \qquad ...(142)$$

where k is large. Thus, for large values of k, $\psi = \exp(-\xi^2/2)\, H(\xi)$ tends to behave like $\exp(-\xi^2/2)$ if the series is even, and $\xi \exp(-\xi^2/2)$ if the series is odd, which is not acceptable. This unrealistic solution can be avoided if the series in Eq. 135 terminates after a finite number of terms. In such a situation, $\psi(\xi) \to 0$ as $\xi \to \infty$ because of the factor $\exp(-\xi^2/2)$. The series can be terminated by choosing λ in such a way that $(2k+1-\lambda)$ vanishes for $k = n$. Thus, one of the series becomes a polynomial and the other can be eliminated by setting the first coefficient equal to zero. Substitution of the value of λ gives

$$2n + 1 - 2E/(\hbar\omega) = 0$$

or,
$$E_n = \left(n + \frac{1}{2}\right)\hbar\omega, \qquad n = 0, 1, 2, \ldots \qquad ...(143)$$

The energy of the S.H.O. , using the old quantum theory, is

$$E_n = n\hbar\omega \qquad n = 0, 1, 2, \ldots \qquad ...(144)$$

From Eqs. 143 and 144 we see that the quantum mechanical energy value (obtained by solving the Schrödinger equation for the oscillator) is higher than the old quantum theory value by $\frac{1}{2}\hbar\omega$, which is the energy possessed by the linear oscillator in the lowest vibrational state ($n = 0$). The oscillator possesses this energy, $\frac{1}{2}\hbar\omega$, called the **zero-point energy**, even at absolute zero of temperature. The occurence of zero-point energy is a manifestation of the Heisenberg uncertainty principle. Note that $E = 0$ implies that both position and the momentum associated with it are well defined, which violates the uncertainty (indeterminacy) principle. We can, in fact, prove that the minimum energy of the oscillator without violating the uncertainty principle is $\frac{1}{2}\hbar\omega$.

We shall now determine the **energy eigenfunctions** of the S.H.O. When the parameter $\lambda = 2n+1$, Eq. 134 reduces to

$$\frac{d^2H_n(\xi)}{d\xi^2} - 2\xi\frac{dH_n(\xi)}{d\xi} + 2nH_n(\xi) = 0 \qquad ...(145)$$

The solutions of Eq. 145 are the **Hermite polynomials.**

The Hermite polynomial of degree n is defined as

$$H_n(\xi) = (-1)^n e^{\xi^2}\left\{\frac{\partial^n(e^{-\xi^2})}{\partial\xi^n}\right\} \qquad ...(146)$$

A few Hermite polynomials are given below :

$$H_0(\xi) = 1 \qquad H_3(\xi) = 8\xi^3 - 12\xi$$
$$H_1(\xi) = 2\xi \qquad H_4(\xi) = 16\xi^4 - 48\xi^2 + 12 \qquad ...(147)$$
$$H_2(\xi) = 4\xi^2 - 2$$

The unnormalized wave functions of the one-dimensional S.H.O. are then written as

$$\psi_n(\xi) = N_n H_n(\xi)\exp\left(-\xi^2/2\right), \quad \xi^2 = (m\omega/\hbar)x^2 \qquad ...(148)$$

The normalization condition leads to

$$|N_n|^2\left(\frac{\hbar}{m\omega}\right)^{1/2}\int_{-\infty}^{\infty} H_n^2(\xi)\exp\left(-\xi^2\right)d\xi = 1 \qquad \text{or} \qquad |N_n|^2\left(\frac{\hbar}{m\omega}\right)^{1/2}\pi^{1/2}2^n(n!) = 1$$

or
$$N_n = \left[\left(\frac{m\omega}{\hbar\pi}\right)^{1/2}\frac{1}{2^n(n!)}\right]^{1/2}$$

The normalized eigenfunctions and the ground state eigenfunction are given by

$$\psi_n(\xi) = \left[\left(\frac{m\omega}{\hbar\pi}\right)^{1/2}\frac{1}{2^n(n!)}\right]^{1/2} H_n(\xi)\exp\left(\frac{-\xi^2}{2}\right) \qquad ...(149)$$

The ground-state ($n = 0$) eigenfunction is

$$\psi_n(x) = \left(\frac{m\omega}{\hbar\pi}\right)^{1/4}\exp\left(-\frac{m\omega x^2}{2\hbar}\right) \qquad ...(150)$$

The wave functions $\psi_n(x)$ and the probability density $|\psi_n(x)|^2$ of the lowest three states are also illustrated in Fig. 13.

We note from Fig.13 that the linear oscillator eigenfunctions are even for even values of the vibrational quantum number n and odd for odd values of n. This is understandable as $\exp(-\xi^2/2)$, which is the Gaussian function, is always even and the Hermite polynomials $H_n(\xi)$ are even or odd according as n is even or odd. We may also note that the quantum oscillator can be *outside* the parabolic Hooke's law potential barrier since the wave function ψ does not vanish at the classical turning points. This implies that the particle can penetrate the barrier to some extent. This barrier penetration, called **quantum mechanical tunnelling,** is a significant feature of quantum mechanics ; classical mechanics does not permit it. A final point to note is the nature of the probability distribution of classical and quantal (quantum

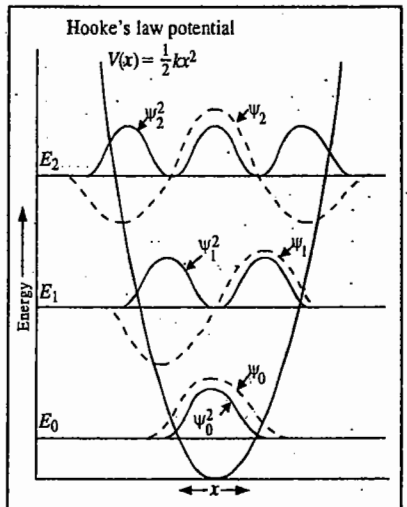

Fig. 13. The wavefunctions, the probability density functions and the energy levels of the three lowest states of a simple harmonic oscillator.

mechanical) oscillators. Classically, the probability of finding an oscillator at a given point is inversely proportional to its velocity at that point. The total energy of the oscillator is

$$E = \text{K.E.} + \text{P.E.} = \tfrac{1}{2}mv^2 + \tfrac{1}{2}kx^2, \text{ or } v = [(2E - kx^2)/m]^{1/2} \quad ...(151)$$

Hence, the classical probability

$$P_c \propto [m/(2E - kx^2)]^{1/2} \quad ...(152)$$

This probability is minimum at the mean position ($x = 0$) and maximum at the extreme positions. For the quantum case, for $n = 0$, the probability is maximum at $x = 0$ and as the quantum number increases the maximum probability moves towards the extreme positions.

Fig. 14 shows the probability density $|\psi_{10}|^2$ and the classical probability distribution (dotted line) for the same energy. Though the two distributions become more and more similar for high quantum numbers, the rapid oscillations of $|\psi_n|^2$ is still a discrepancy. The energy for $n = 0$ is called the **zero point energy** of the oscillator. Classical mechanics predicts that the zero-point energy of the oscillator is zero whereas quantum mechanics predicts that the zero-point energy is non-zero. *The occurrence of the zero-point energy is consistent with the Heisenberg uncertainty principle.*

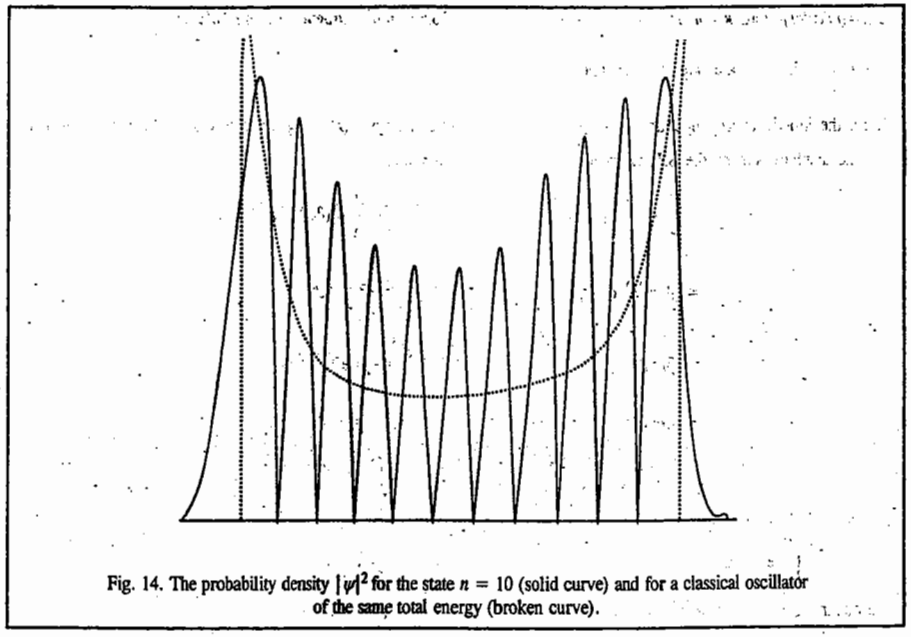

Fig. 14. The probability density $|\psi|^2$ for the state $n = 10$ (solid curve) and for a classical oscillator of the same total energy (broken curve).

It may be mentioned here that the solutions of the time-independent Schrödinger equation are called stationary state wave functions. An atom or a molecule can be in any of the stationary energy states, say, the nth, represented by its own eigenfunction ψ_n with energy, E_n.

Example 27. What is the restriction on α/β if the $n=1$ wave function of a one-dimensional S.H.O. has to satisfy the wave equation $d^2\psi_1/d\xi^2 + (\alpha/\beta - \xi^2)\psi_1 = 0$? Given that $\psi_1 = N\xi\exp(-\xi^2/2)$ where N is a constant.

Solution : $\psi_1 = N\xi e^{-\xi^2/2}$

$$\frac{d\psi_1}{d\xi} = N\xi(-\xi)e^{-\xi^2/2} + Ne^{-\xi^2/2} = -N\xi^2e^{-\xi^2/2} + Ne^{-\xi^2/2}$$

$$\frac{d^2\psi_1}{d\xi^2} = -N\xi^2(-\xi)e^{-\xi^2/2} - 2N\xi e^{-\xi^2/2} - N\xi e^{-\xi^2/2} = N\xi^3e^{-\xi^2/2} - 3N\xi e^{-\xi^2/2}$$

$\frac{d^2\psi_1}{d\xi^2} + \left(\frac{\alpha}{\beta} - \xi^2\right)\psi_1$ will be equal to zero

if $N\xi^3e^{-\xi^2/2} - 3N\xi e^{-\xi^2/2} + \frac{\alpha}{\beta}N\xi e^{-\xi^2/2} - N\xi^3e^{-\xi^2/2} = 0$

or if $-3N\xi e^{-\xi^2/2} + (\alpha/\beta)N\xi e^{-\xi^2/2} = 0$

or if $\alpha/\beta = 3$

which is the **desired restriction.**

Example 28. "According to the virial theorem for a diatomic S.H.O., the expectation (average) value of the kinetic energy, $< T >$, is equal to the expectation value of the potential energy, $< V >$". Verify this statement for the ground state of the S.H.O., given that the ground state wavefunction is

$$\psi_0(x) = (\beta/\pi)^{1/4}\exp(-\beta x^2/2)$$

where $\beta = (mk)^{1/2}/\hbar$ and $k = m\omega^2$; $\omega = 2\pi\nu$ where ν is the vibrational frequency of the S.H.O.

Solution : Let us calculate $<\hat{T}>$ and $<\hat{V}>$.

Here, the kinetic energy operator is $-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2}$ and potential energy $V(x) = \frac{1}{2}kx^2$ where k is the force constant and x is the displacement of the S.H.O. from the equilibrium position.

$$<\hat{T}> = \int_{-\infty}^{\infty}\psi_0^*\hat{T}\psi_0 dx = \int_{-\infty}^{\infty}(\beta/\pi)^{1/4}e^{-\beta x^2/2}\left(-\frac{\hbar^2}{2m}\frac{d^2}{dx^2}\right)(\beta/\pi)^{1/4}e^{-\beta x^2/2}dx$$

$$= (\beta/\pi)^{1/2}\left(-\hbar^2/2m\right)\int_{-\infty}^{\infty}e^{-\beta x^2/2}\left(\frac{d^2}{dx^2}\right)e^{-\beta x^2/2}dx$$

$$= (\beta/\pi)^{1/2}\left(-\hbar^2/2m\right)\int_{-\infty}^{\infty}e^{-\beta x^2/2}\left(\frac{d}{dx}\right)(-\beta x e^{-\beta x^2/2})dx$$

$$= (\beta/\pi)^{1/2}\left(-\hbar^2/2m\right)(-\beta)\int_{-\infty}^{\infty}e^{-\beta x^2/2}[1-\beta x^2]e^{-\beta x^2/2})dx$$

$$= (\beta/\pi)^{1/2}(\hbar^2/2m)\left[\beta\int_{-\infty}^{\infty}e^{-\beta x^2}dx - \beta^2\int_{-\infty}^{\infty}x^2e^{-\beta x^2}dx\right]$$

Using the standard integrals

$$\int_{-\infty}^{\infty}e^{-ax^2}dx = (\pi/a)^{1/2} \quad \text{and} \quad \int_{-\infty}^{\infty}x^2e^{-ax^2}dx = \frac{1}{2a}(\pi/a)^{1/2},$$

we obtain $<\hat{T}> = (\beta/\pi)^{1/2}(\hbar^2/2m)[(\beta)(\pi/\beta)^{1/2} - (\beta^2)(1/2\beta)(\pi/\beta)^{1/2}]$

$$= \frac{\beta\hbar^2}{2m} - \frac{\beta\hbar^2}{4m} = \frac{\beta\hbar^2}{4m} = \frac{\hbar\omega}{4} = \frac{h\nu}{4} \quad (\text{since } \beta = (mk)^{1/2}/\hbar \text{ ; } k = m\omega^2 \text{ and } \omega = 2\pi\nu) \quad ...(i)$$

Again,

$$<\hat{V}> = \int_{-\infty}^{\infty}\psi_0^*\hat{V}\psi_0 dx = \int_{-\infty}^{\infty}(\beta/\pi)^{1/4}e^{-\beta x^2/2}\left(\frac{1}{2}kx^2\right)(\beta/\pi)^{1/4}e^{-\beta x^2/2}dx$$

$$= (\beta/\pi)^{1/2}\left(\frac{1}{2}k\right)\int_{-\infty}^{\infty}x^2e^{-\beta x^2}dx = (\beta/\pi)^{1/2}(k/2)\left(\frac{1}{2\beta}\right)(\pi/\beta)^{1/2}$$

$$= \frac{k}{4\beta} = \frac{m\omega^2}{4(mk)^{1/2}/\hbar} = \frac{m\omega^2\hbar}{4m\omega} = \frac{\hbar\omega}{4} = \frac{h\nu}{4} \qquad ...(ii)$$

From Eqs. *(i)* and *(ii)*, we see that

$$< \hat{T} > = < \hat{V} >, \text{ which is the virial theorem.}$$

Example 29. Verify the Heisenberg uncertainty principle for the ground state of a one-dimensional S.H.O.

Solution : We know that $\Delta x = [< x^2 > - < x >^2]^{1/2}$

$$(\Delta p_x) = [< p_x^2 > - < p_x >^2]^{1/2}$$

For an S.H.O.: $\psi_0(x) = (\beta/\pi)^{1/4} e^{-\beta x^2/2}$

Now, $$< x > = \int_{-\infty}^{\infty} \psi_0^* \hat{x} \, dx = \int_{-\infty}^{\infty} (\beta/\pi)^{1/4} e^{-\beta x^2/2} \hat{x} (\beta/\pi)^{1/4} e^{-\beta x^2/2} dx$$

$$= (\beta/\pi)^{1/2} \int_{-\infty}^{\infty} x e^{-\beta x^2} dx = 0 \text{ (since the integrand is odd)} \qquad ...(i)$$

Again, $$< x^2 > = \int_{-\infty}^{\infty} \psi_0^* \hat{x}^2 \psi_0 dx$$

Proceeding as in Example 28, we find that

$$< x^2 > = 1/2\ \beta \qquad ...(ii)$$

$$< \hat{p}_x > = \int_{-\infty}^{\infty} \psi_0^* (-i\hbar d/dx) \psi_0 \, dx = (\beta/\pi)^{1/2} (-i\hbar) \int_{-\infty}^{\infty} e^{\beta x^2/2} [-\beta x e^{-\beta x^2/2}] dx$$

$$= (\beta/\pi)^{1/2} (-i\hbar)(-\beta) \int_{-\infty}^{\infty} x e^{-\beta x^2} dx$$

$$= 0 \text{ (because the integrand is odd)} \qquad ...(iii)$$

Again, $$< p_x^2 > = \int_{-\infty}^{\infty} \psi_0^* (-\hbar^2 d^2/dx^2) \psi_0 dx = (-\hbar^2)(\beta/\pi)^{1/2} \int_{-\infty}^{\infty} e^{-\beta x^2/2} (d^2/dx^2) e^{-\beta x^2/2} dx$$

Proceeding as in Example 28, where we have evaluated $< \hat{T} >$, we find that

$$< p_x^2 > = \beta\hbar^2/2 \qquad ...(iv)$$

From Eqs. *(i)*, *(ii)*, *(iii)* and *(iv)*, we find on simplification that

$$\Delta x . \Delta p_x = \hbar/2,$$

which is the **Heisenberg uncertainty principle**. A rigorous mathematical derivation gives the inequality

$$\Delta x . \Delta p_x \geq \hbar/2$$

Example 30. For a one-dimensional simple harmonic oscillator in the ground vibrational state,

(*a*) Where is the probability density maximum ?

(*b*) Determine the value of the maximum probability density.

Solution : (*a*) $$\psi_0(x) = \left(\frac{m\omega}{\hbar\pi}\right)^{1/4} \exp\left(-\frac{m\omega x^2}{2\hbar}\right)$$

The probability density is $$P(x) = \psi_0^*(x)\psi_0(x) = \left(\frac{m\omega}{\hbar\pi}\right)^{1/2} \exp\left(-\frac{m\omega x^2}{\hbar}\right)$$

The probability will be a maximum where $dP(x)/dx = 0$

Thus, $$\left(\frac{m\omega}{\hbar\pi}\right)^{1/2} \left(-\frac{m\omega}{\hbar}\right) 2x \exp\left(-\frac{m\omega x^2}{\hbar}\right) = 0$$

which implies that $x = 0$, *i.e.*, the probability is maximum at $x = 0$

(*b*) The maximum probability at $x = 0$ is

$$P(0) = \left(\frac{m\omega}{\hbar\pi}\right)^{1/2}$$

Example 31. Show that the Z.P.E. (zero-point energy), ($\frac{1}{2}\hbar\omega$), of a one-dimensional S.H.O. is a manifestation of the Heisenberg uncertainty principle.

Solution : As we have shown in Example 31, the average position, $<x>$, and average momentum, $<p>$, of an S.H.O., bound to the origin, is zero. Hence,

$$(\Delta x)^2 = \langle x^2 \rangle - \langle x \rangle^2 = \langle x^2 \rangle \quad \text{and} \quad (\Delta p)^2 = \langle p^2 \rangle - \langle p \rangle^2 = \langle p^2 \rangle$$

For the total energy E,

$$<E> = \frac{1}{2m}\langle p^2 \rangle + \frac{1}{2}k\langle x^2 \rangle, \qquad \text{(where } k = m\omega^2\text{)}$$

[where ω is the angular frequency of the oscillator].

or $$<E> = \frac{1}{2m}(\Delta p)^2 + \frac{1}{2}k(\Delta x)^2$$

Replacing $(\Delta p)^2$ with the help of the relation $(\Delta p)^2(\Delta x)^2 \geq \frac{\hbar^2}{4}$ [using the uncertainty principle]

we get $$<E> \geq \frac{\hbar^2}{8m(\Delta x)^2} + \frac{1}{2}k(\Delta x)^2$$

For the right-hand side to be minimum, the differential of $<E>$ with respect to $(\Delta x)^2$ must be zero :

$$\frac{-\hbar^2}{8m(\Delta x)^4_{\min}} + \frac{1}{2}k = 0, \quad \text{or} \quad (\Delta x)^2_{\min} = \frac{\hbar}{2m\omega}$$

and $$<E>_{\min} = \frac{\hbar^2}{8m}\frac{2m\omega}{\hbar} + \frac{1}{2}m\omega^2\frac{\hbar}{2m\omega} = \frac{1}{2}\hbar\omega.$$ Hence proved.

[Note : (Δx) is also called **standard deviation**, and $(\Delta x)^2$ is the **variance**, σ_x^2, which measures the spread around the mean value of the observable x.]

Example 32. Show that the probability density of the linear (simple) harmonic oscillator, S.H.O., in an arbitrary superposition state is periodic with the period equal to the period of the oscillator.

Solution : The time-dependent wave function of the S.H.O. in a superposition state is

$$\psi(x,t) = \sum_n c_n \psi_n(x) \exp\left(-\frac{iE_n t}{\hbar}\right)$$

where $\psi_n(x)$ is the time-independent wave function of the harmonic oscillator in the nth state. Now, the probability density

$$P(x,t)=|\Psi(x,t)|^2 = \sum_m\sum_n c_m^* c_n \psi_m^* \psi_n \exp\left[\frac{i(E_m-E_n)t}{\hbar}\right]$$

It is obvious that $P(x, t)$ is dependent on time. Let us investigate what happens to $P(x, t)$ if t is replaced by $t + (2\pi/\omega)$. We see that

$$\exp\left[\frac{i(E_m-E_n)}{\hbar}\left(t+\frac{2\pi}{\omega}\right)\right] = \exp\left[\frac{i(E_m-E_n)t}{\hbar}\right]\exp\left[\frac{i(E_m-E_n)}{\hbar}\frac{2\pi}{\omega}\right]$$

$$= \exp\left[\frac{i(E_m-E_n)t}{\hbar}\right]$$

as $(E_m - E_n)$ is an integral multiple of $\hbar\omega$. That is, $P(x, t)$ is periodic with period $2\pi/\omega$, the period of the linear harmonic oscillator.

Example 33. Solve the time-independent Schrödinger equation for a three-dimensional harmonic oscillator whose potential energy is

$$V(x, y, z) = \frac{1}{2}\left(k_1x^2+k_2y^2+k_3z^2\right)$$

Solution : The theory developed for a linear harmonic oscillator can easily be extended to the case of three-dimensional oscillator. The Schrödinger equation for the system is

$$\frac{-\hbar}{2m}\nabla^2\psi(x,y,z)+V\psi(x,y,z) = E\psi(x,y,z)$$

This equation can be separated into three equations by writing the wave funciton

$$\psi(x,y,z) = X(x)\,Y(y)\,Z(z)$$

The Schrödinger equation now separates into three equations of the form

$$\frac{d^2X(x)}{dx^2}+\frac{2m}{\hbar}\left(E_x-\frac{1}{2}m\omega_x^2x^2\right)X(x) = 0$$

$$\frac{d^2Y(y)}{dy^2}+\frac{2m}{\hbar}\left(E_y-\frac{1}{2}m\omega_y^2y^2\right)Y(y) = 0$$

$$\frac{d^2Z(z)}{dz^2}+\frac{2m}{\hbar}\left(E_z-\frac{1}{2}m\omega_z^2z^2\right)Y(z) = 0$$

where $E_x + E_y + E_z = E$, the total energy of the system, and

$$\omega_x=\sqrt{\frac{k_1}{m}}, \qquad \omega_y=\sqrt{\frac{k_2}{m}}, \qquad \omega_z=\sqrt{\frac{k_3}{m}}$$

Using the results of the one-dimensional S.H.O.,

$$E_x = \left(n_x+\frac{1}{2}\right)\hbar\omega_x, \qquad n_x = 0, 1, 2, ...$$

$$E_y = \left(n_y+\frac{1}{2}\right)\hbar\omega_y, \qquad n_y = 0, 1, 2, ...$$

$$E_z = \left(n_z+\frac{1}{2}\right)\hbar\omega_z, \qquad n_z = 0, 1, 2, ...$$

The eigenfunctions are given by

$$\psi_{n_xn_yn_z} = NH_{n_x}(\xi x)H_{n_y}(\eta y)H_{n_z}(\zeta z)\exp\left[-\frac{1}{2}\left(\xi^2x^2+\eta^2y^2+\zeta^2z^2\right)\right]$$

where N is the normalization constant and

$$\xi=\left(\frac{m\omega_x}{\hbar}\right)^{1/2}, \qquad \eta=\left(\frac{m\omega_y}{\hbar}\right)^{1/2}, \qquad \zeta=\left(\frac{m\omega_z}{\hbar}\right)^{1/2},$$

The normalization constant is given by

$$N = \frac{\xi^{1/2}\eta^{1/2}\zeta^{1/2}}{\pi^{3/4}\left(2^{n_x+n_y+n_z}n_x!n_y!n_z!\right)^{1/2}}$$

4. Rigid Rotor (or Rotator). A diatomic molecule rotating about an axis perpendicular to the internuclear axis and passing through the centre of gravity of the molecule, constitutes an example of a rigid rotor, it being assumed that the internuclear distance does not change during rotation. This system represents **rotational motion.** The kinetic energy (K.E.) of the molecule is given by

$$\text{K.E.} \equiv T = \tfrac{1}{2}I\omega^2 = L^2/2I \qquad ...(153)$$

where ω is the angular velocity and I is the moment of inertia of the rotating molecule. The angular momentum $L=I\omega$. If no force acts on the rotor, we can set the potential energy $V=0$. Hence, the Hamiltonian is expressed as

$$H = T + V = L^2/2I \qquad ...(154)$$

The expression for L^2 in spherical polar coordinates (r, θ, ϕ) is given by

$$L^2 = -\hbar^2\left[\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial}{\partial\theta}\right)+\frac{1}{\sin^2\theta}\frac{\partial^2}{\partial\phi^2}\right] \qquad ...(155)$$

The Schrödinger equation $\hat{H}\psi = E\psi$ may thus be written as

$$\frac{1}{2I}\left[-\hbar^2\left\{\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial\psi}{\partial\theta}\right)+\frac{1}{\sin^2\theta}\frac{\partial^2\psi}{\partial\phi^2}\right\}\right] = E\psi \qquad ...(156)$$

The above equation may be written as

$$\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial\psi}{\partial\theta}\right)+\frac{1}{\sin^2\theta}\frac{\partial^2\psi}{\partial\phi^2}+\frac{8\pi^2I}{h^2}E\psi = 0 \qquad ...(157)$$

Eq. 157 contains two angular variables θ and ϕ. It can be solved by the method of separation of variables, *i.e.*, we look for a solution of the form

$$\psi(\theta,\phi) = \Theta(\theta)\,\Phi(\phi) \qquad ...(158)$$

Substituting Eq. 158 into Eq. 157, we obtain

$$\frac{\sin\theta}{\Theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial\Theta}{\partial\theta}\right)+\frac{8\pi^2IE}{h^2}\sin^2\theta=-\frac{1}{\Phi}\frac{\partial^2\Phi}{\partial\phi^2} \qquad ...(159)$$

We can set both sides of Eq. 159 equal to a constant, say m^2, thereby obtaining two differential equations each in one variable. These equations are :

$$\frac{\partial^2\Phi}{\partial\phi^2}+m^2\Phi=0 \text{ and} \qquad ...(160)$$

$$\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial\Theta}{\partial\theta}\right)+\left(\lambda-\frac{m^2}{\sin^2\theta}\right)\Theta=0 \qquad (\text{where } \lambda=8\pi^2IE/h^2) \qquad ...(161)$$

Eq. 160 has the solution

$$\Phi(\phi)=N\exp(\pm im\phi), \qquad i=\sqrt{-1} \qquad ...(162)$$

where N is the normalization constant. This wavefunction is acceptable provided m is an integer. This condition arises because Φ must be single-valued. Thus,

$$\Phi(\phi)=\Phi(\phi+2\pi) \qquad ...(163)$$

Hence, $\exp(2\pi im)=1$ ...(164)

Since $e^x=\cos x+i\sin x$ **(Euler's relation)** ...(165)

$\therefore$ $\cos 2\pi m+i\sin 2\pi m=1$ ...(166)

This can be true only if $m=0, \pm 1, \pm 2, \pm 3, \ldots$, etc. Let us now normalize the wave function $\Phi(\phi)$ to determine the normalization constant N.

$$\int_0^{2\pi}\Phi^*\Phi\,d\phi=1 \quad (0\le\phi\le 2\pi) \qquad ...(167)$$

or $$N^2\int_0^{2\pi}e^{im\phi}\times e^{-im\phi}d\phi=1 \qquad ...(168)$$

or $N^2\int_0^{2\pi}d\phi=1$, *i.e.*, $N^2(2\pi)=1$ so that $N=(2\pi)^{-1/2}$ ...(169)

Hence, the normalized wave functions become

$$\Phi_{\pm m}(\phi)=(2\pi)^{-1/2}\exp(\pm im\phi)\,;\ m=0,1,2,3,\ldots \qquad ...(170)$$

We shall not attempt to give a complete solution of Eq. 161 (which also occurs in the hydrogen atom problem) but will merely state that if $\lambda=l(l+1)$ where l is the **rotational quantum number,** then this equation becomes a standard mathematical equation whose solutions are known to be **associated Legendre polynomials** $P_l^{|m|}(\cos\theta)$ where l is either zero or a positive integer and $l>|m|$. The normalized solutions are given by

$$\Theta(\theta)=\Theta_{l,\pm m}(\theta)=\left[\frac{2l+1}{2}\times\frac{(l-|m|)!}{(l+|m|)!}\right]^{1/2}P_l^{|m|}\cos\theta \qquad ...(171)$$

The eigenfunctions of the rigid rotor are the **spherical harmonics,** obtained by the product of the angular functions :

$$Y_{l,m}(\theta,\phi)=\Theta_{l,m}(\theta)\,\Phi_m(\phi)\equiv Y_l^m(\theta,\phi) \qquad ...(172)$$

The energy eigenvalues of the rigid rotor are obtained as follows :

$$\lambda=8\pi^2IE/h^2=l(l+1) \qquad ...(173)$$

Thus, $$E=\frac{l(l+1)h^2}{8\pi^2I};\ l=0,1,2,3,\ldots \qquad ...(174a)$$

In spectroscopy it is customary to use the symbol J rather than l for the rotational quantum number so that the rotational energy levels are given by the expression,

$$E_J=\frac{J(J+1)h^2}{8\pi^2I};\ J=0,1,2,3,\ldots \qquad ...(174b)$$

5. The Schrödinger Equation for Hydrogen Atom. Hydrogen atom is the simplest of all atoms. It is a three-dimensional system and the Schrödinger equation for this system is

$$\hat{H}\psi=E\psi \qquad ...(175)$$

where $$\hat{H}=-\frac{\hbar^2}{2m}\nabla^2+V(x,y,z) \qquad ...(176)$$

and where the Laplacian operator in Cartesian coordinates is given by

$$\nabla^2=\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2} \qquad ...(177)$$

The potential energy of interaction between the electron and the nucleus is given by

$$V(r)=-Ze^2/4\pi\varepsilon_0 r \qquad ...(178)$$

Since this attractive potential has spherical symmetry depending only upon r, it is convenient to express the Schrödinger equation in terms of polar coordinates (r,θ,ϕ), rather than Cartesian coordinates (x, y, z). The Cartesian coordinates are related to polar coordinates (see Fig. 15) as follows :

$$x=r\sin\theta\cos\phi$$

$$y=r\sin\theta\sin\phi$$

$$z=r\cos\theta$$

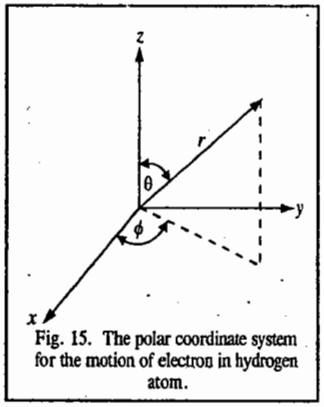

Fig. 15. The polar coordinate system for the motion of electron in hydrogen atom.

The Schrödinger equation for hydrogen atom in terms of polar coordinates becomes

$$\frac{1}{r^2}\frac{\partial}{\partial r}\left(\frac{r^2\partial\psi}{\partial r}\right)+\frac{1}{r^2\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial\psi}{\partial\theta}\right)+\frac{1}{r^2\sin^2\theta}\frac{\partial^2\psi}{\partial\phi^2}+\frac{2\mu}{\hbar}(E-V(r))\,\psi=0 \qquad ...(179)$$

where μ is the reduced mass of the electron and the nucleus, that is, $\mu=m_em_n/(m_n+m_e)$. Assuming that $V(r)$ is a function of r only, the above wave equation can be solved by separating the variables :

$$\psi(r,\theta,\phi)=R(r)\,\Theta(\theta)\,\Phi(\phi) \qquad ...(180)$$

where $R(r)$ is the **radial function** which is a function of r only, and $\Theta(\theta)$ and $\Phi(\phi)$ are **angular functions.**

Substituting Eq. 180 in Eq. 179 and multiplying by $r^2\sin^2\theta/R\Theta\Phi$, we have

$$\frac{\sin^2\theta}{R}\frac{d}{dr}\left(r^2\frac{dR}{dr}\right)+\frac{\sin\theta}{\Theta}\frac{d}{d\theta}\left(\sin\theta\frac{d\Theta}{d\theta}\right)+\frac{2\mu}{\hbar^2}[E-V(r)]r^2\sin^2\theta=-\frac{1}{\Phi}\frac{d^2\Phi}{d\phi^2} \qquad ...(181)$$

The left-hand side of Eq. 181 is a function of r and θ and the right side is a function of ϕ alone. This is possible only when each side is a constant, say m^2. Thus, we can write

$$\frac{d^2\Phi(\phi)}{d\phi^2} = -m^2\Phi(\phi) \qquad ...(182)$$

and

$$\frac{\sin^2\theta}{R}\frac{d}{dr}\left(r^2\frac{dR}{dr}\right)+\frac{\sin\theta}{\Theta}\frac{d}{d\theta}\left(\sin\theta\,\frac{d\Theta}{d\theta}\right)+\frac{2\mu}{\hbar^2}[E-V(r)]r^2\sin^2\theta=m^2 \qquad ...(183)$$

Dividing both sides of Eq. (183) by $\sin^2\theta$ and rearranging, we get

$$\frac{1}{R}\frac{d}{dr}\left(r^2\frac{dR}{dr}\right)+\frac{2\mu}{\hbar^2}(E-V)r^2=-\frac{1}{\Theta\sin\theta}\frac{d}{d\theta}\left(\sin\theta\frac{d\Theta}{d\theta}\right)+\frac{m^2}{\sin^2\theta}$$

This is possible when both sides are equal to a constant, say λ. Consequently, we get the Θ-equation and the radial equation :

$$\frac{1}{\sin\theta}\frac{d}{d\theta}\left(\sin\theta\frac{d\Theta}{d\theta}\right)+\left(\lambda-\frac{m^2}{\sin^2\theta}\right)\Theta = 0 \qquad ...(184)$$

and

$$\frac{1}{r^2}\frac{d}{dr}\left(r^2\frac{dR}{dr}\right)+\frac{2\mu}{\hbar^2}[E-V(r)]R-\frac{\lambda}{r^2}R = 0 \qquad ...(185)$$

We see that the three-dimensional Schrödinger wave equation in spherical polar coordinates (Eq. 179) has been separated into three one-dimensional equations (182, 184 and 185). These are called, respectively, the Φ-equation, the Θ-equation and the R-equation.

Solution of the Φ-equation : This equation also occurs in the Schrödinger equation for the rigid rotator and has already been solved (see Eq. 170), which we rewrite as

$$\Phi_m(\phi) = \frac{1}{\sqrt{2\pi}}e^{im\phi}, \quad m = 0, \pm1, \pm2, ... \qquad ...(186)$$

A few of the normalized $\Phi_{\pm m}(\phi)$ are given in Table 1. Since $\sin(|m|\phi)$ and $\cos(|m|\phi)$ are also solutions of Eq. 182, the real forms of the solutions are also given in this Table 1.

Table 1. The First-few Normalized $\Phi(\phi)$ functions

$\lvert m\rvert$	Complex form	Real form
0	$\Phi_0 = \frac{1}{\sqrt{2\pi}}$	$\Phi_0 = \frac{1}{\sqrt{2\pi}}$
1	$\Phi_1 = \frac{1}{\sqrt{2\pi}}e^{i\phi}$	$\Phi_{1\cos} = \frac{1}{\sqrt{\pi}}\cos\phi$
	$\Phi_{-1} = \frac{1}{\sqrt{2\pi}}e^{-i\phi}$	$\Phi_{1\sin} = \frac{1}{\sqrt{\pi}}\sin\phi$
2	$\Phi_2 = \frac{1}{\sqrt{2\pi}}e^{i2\phi}$	$\Phi_{2\cos} = \frac{1}{\sqrt{\pi}}\cos(2\phi)$
	$\Phi_{-2} = \frac{1}{\sqrt{2\pi}}e^{-i2\phi}$	$\Phi_{2\sin} = \frac{1}{\sqrt{\pi}}\sin(2\phi)$

Solution of the Θ-equation. We define a new variable $z = \cos\theta$, so that $dz = -\sin\theta d\theta$. We can also write

$$\frac{d}{d\theta} = -\sin\theta\frac{d}{dz} = -\left(1-z^2\right)^{1/2}\frac{d}{dz}$$

In terms of z, Eq. 184 becomes

$$\frac{d}{dz}\left[\left(1-z^2\right)\frac{d\Theta(z)}{dz}\right]+\left(\lambda-\frac{m^2}{1-z^2}\right)\Theta(z) = 0 \qquad ...(187)$$

which is **associated Legendre equation** (in honour of the French mathematician A.M. Legendre (1752-1833)). Equation (187) has poles at $z = \pm1$. For physically acceptable solution,

$$\lambda = l(l+1), \qquad l = 0, 1, 2, ... \qquad m = 0, \pm1, \pm2, ..., \pm l$$

The solution of Eq. (187) is the **Legendre polynomial** $P_l(z)$ for $m = 0$ and the **associated Legendre polynomials** $P_l^{|m|}(z)$ for $m \neq 0$. The normalized solution is then

$$\Theta(\theta) = N_{lm}P_l^{|m|}(z) \qquad ...(188)$$

where N_{lm} is the normalization constant. The normalization condition is

$$|N_{lm}|^2\int_{-1}^{+1}P_k^{|m|}(z)P_l^{|m|}(z)dz = 1$$

The orthogonality relation for the associated Ligendre polynomials

$$\int_{-1}^{+1}P_k^{|m|}(z)P_l^{|m|}(z)dz = \frac{2}{(2l+1)}\frac{(l+|m|!)}{(l-|m|!)}\delta_{lk} \qquad ...(189)$$

leads to

$$\Theta_l^m(\theta) = \varepsilon\sqrt{\frac{(2l+1)(l-|m|)!}{2(l+|m|)!}}P_l^m(\cos\theta) \quad \text{(see Eq. 171)} \qquad ...(190)$$

where $\varepsilon = (-1)^m$ for $m > 0$ and $\varepsilon = 1$ for $m \leq 0$ as per the established phase convention.

Spherical Harmonics : The solution of the angular part of the equation, called the *spherical harmonics*, is independent of the energy, E, and the potential energy, $V(r)$. Combining the expressions for $\Phi_m(\phi)$ (Eq. 186) and $\Theta_l^m(\theta)$ (Eq. 190), the normalized expression for the spherical harmonics is

$$Y_{l,m}(\theta,\phi) = \varepsilon\sqrt{\frac{(2l+1)(l-|m|)!}{4\pi(l+|m|)!}}P_l^m(\cos\theta)e^{im\phi} \qquad ...(191)$$

where $l = 0, 1, 2, ...$ $m = 0, \pm1, \pm2, ..., \pm l$ ...(192)

The spherical harmonics are mutually orthogonal and the first-few of them are given in Table 2.

Table 2. The First few Spherical Harmonics

Complex form	Real form
$Y_{0,0} = \frac{1}{(4\pi)^{1/2}}$	$Y_{0,0} = \frac{1}{(4\pi)^{1/2}}$
$Y_{1,0} = \left(\frac{3}{4\pi}\right)^{1/2} \cos\theta$	$Y_{1,0} = \left(\frac{3}{4\pi}\right)^{1/2} \cos\theta = \left(\frac{3}{4\pi}\right)^{1/2} \frac{z}{r}$
$Y_{1,1} = \left(\frac{3}{8\pi}\right)^{1/2} (\sin\theta) e^{i\phi}$	$Y_{1,1\cos} = \left(\frac{3}{4\pi}\right)^{1/2} \sin\theta\cos\phi = \left(\frac{3}{4\pi}\right)^{1/2} \frac{x}{r}$
$Y_{1,-1} = \left(\frac{3}{8\pi}\right)^{1/2} (\sin\theta) e^{-i\phi}$	$Y_{1,1\sin} = \left(\frac{3}{4\pi}\right)^{1/2} \sin\theta\cos\phi = \left(\frac{3}{4\pi}\right)^{1/2} \frac{y}{r}$
$Y_{2,0} = \left(\frac{5}{16\pi}\right)^{1/2} (3\cos^2\theta - 1)$	$Y_{2,0} = \left(\frac{5}{16\pi}\right)^{1/2} (3\cos^2\theta - 1) = \left(\frac{5}{16\pi}\right)^{1/2} \left(\frac{3z^2}{r^2} - 1\right)$
$Y_{2,1} = -\left(\frac{15}{8\pi}\right)^{1/2} (\sin\theta\cos\theta) e^{i\phi}$	$Y_{2,1\cos} = \left(\frac{15}{4\pi}\right)^{1/2} \sin\theta\cos\theta\cos\phi = \left(\frac{15}{4\pi}\right)^{1/2} \frac{xz}{r^2}$
$Y_{2,-1} = \left(\frac{15}{8\pi}\right)^{1/2} (\sin\theta\cos\theta) e^{-i\phi}$	$Y_{2,1\sin} = \left(\frac{15}{4\pi}\right)^{1/2} \sin\theta\cos\theta\sin\phi = \left(\frac{15}{4\pi}\right)^{1/2} \frac{yz}{r^2}$
$Y_{2,2} = \left(\frac{15}{32\pi}\right)^{1/2} (\sin^2\theta) e^{2i\phi}$	$Y_{2,2\cos} = \left(\frac{15}{16\pi}\right)^{1/2} \sin^2\theta\cos(2\phi) = \left(\frac{15}{16\pi}\right)^{1/2} \frac{x^2 - y^2}{r^2}$
$Y_{2,-2} = \left(\frac{15}{32\pi}\right)^{1/2} (\sin^2\theta) e^{-2i\phi}$	$Y_{2,2\sin} = \left(\frac{15}{16\pi}\right)^{1/2} \sin^2\theta\sin(2\phi) = \left(\frac{15}{16\pi}\right)^{1/2} \frac{xy}{r^2}$

It may be noted that the presence of the $\exp(im\phi)$ factor makes the spherical harmonics complex, in general. It is, in fact, advantageous to work with the real form. We know that a linear combination of degenerate eigenfunctions of a degenerate energy level is also an eigenfunction with the same eigenvalue. Thus, for example, we can express $Y_{1\,1}$ and $Y_{1,-1}$ in the real form by taking a suitable linear combination of them. Similar linear combinations can also be taken for other spherical harmonics. The real forms of the first few spherical harmonics are listed in Table 2.

The evaluation of the spherical harmonics listed in Table 2 can be carried out as shown below :

The spherical harmonics of a point A (x, y, z) in the Cartesian coordinate system are defined as

$$Y_n^{m_A} = \Theta_{n,m_A} \Phi_{m_A} \qquad ...(193)$$

where

$$\Theta_{n,m_A} = \sqrt{\frac{(2n+1)}{2} \frac{|n-|m_A|}{|n+|m_A|}} P_n^{m_A}(\cos\theta) \qquad ...(194)$$

and

$$\Phi_{m_A} = \frac{1}{\sqrt{2\pi}} e^{im_A\phi} \qquad ...(195)$$

Here, $P_n^{m_A}$ is the associated Legendre polynomial function and both Θ_{n,m_A} and Φ_{m_A} are normalised. The general form of associated Legendre polynomial $P_n^{m_A}(x)$ is

$$P_n^{m_A}(x) = (1-x^2)^{|m_A|/2} \frac{d^{m_a} P_n(x)}{d_x^{m_a}} \qquad ...(196)$$

where $P_n(x)$ is Legendre polynomial which is given by

$$P_n(x) = \frac{1}{2^n n!} \frac{d^n (x^2-1)^n}{d^n} \qquad ...(197)$$

In Eq. 193 for spherical harmonics we do not assign any specific meaning to n and m_A. These are simply numbers. It is evident from Eq. 194 that the maximum value of $|m_A|$ can be n. In other words, $|m_A|$ can have values $= \pm n, \pm (n-1), \pm (n-2)$ .....0 only.

In order to evaluate the spherical harmonics of point A for different sets of n and $|m_A|$, we need the values of $P(x)$, and $P_n^{m_A}(x)$. Eq. 197 for $P(x)$ yields the following results :

$$P_0(x) = 1 \quad \therefore \quad P_0(\cos\theta) = 1$$

$$P_1(x) = x \quad \therefore \quad P_1(\cos\theta) = \cos\theta$$

$$P_2(x) = \tfrac{1}{2}(3x^2 - 1) \quad \therefore \quad P_2(\cos\theta) = \tfrac{1}{2}(3\cos^2\theta - 1)$$

$$P_3(x) = \tfrac{1}{2}(5x^3 - 3x) \quad \therefore \quad P_3(\cos\theta) = \tfrac{1}{2}(5\cos^3\theta - 3\cos\theta)$$

$$P_4(x) = \tfrac{1}{8}(35x^4 - 30x^2 + 3) \quad \therefore \quad P_4(\cos\theta) = \tfrac{1}{8}(35\cos^4\theta - 30\cos^2\theta + 3)$$

Similarly, Eq. 196 for $P_n^{|m_A|}(x)$ yields the following results :

$$P_0^0(x) = 1 \quad \therefore \quad P_0^0(\cos\theta) = 1$$

$$P_1^0(x) = x \quad \therefore \quad P_1^0(\cos\theta) = \cos\theta$$

$$P_1^{|1|}(x), \textit{ i.e., } P_1^{\pm1}(x) = (1-x^2)^{1/2} \quad \therefore \quad P_1^{\pm1}(\cos\theta) = \sin\theta$$

$$P_2^0(x) = \tfrac{1}{2}(3x^2 - 1) \quad \therefore \quad P_2^0(\cos\theta) = \tfrac{1}{2}(3\cos^2\theta - 1)$$

$$P_2^{|1|}(x), \textit{ i.e., } P_2^{\pm1}(x) = 3x(1-x^2)^{1/2} \quad \therefore \quad P_2^{\pm1}(\cos\theta) = 3\cos\theta\sin\theta$$

$$P_2^{|2|}(x), \textit{ i.e., } P_2^{\pm2}(x) = 3(1-x^2) \quad \therefore \quad P_2^{\pm2}(\cos\theta) = 3\sin^2\theta$$

$$P_3^0(x) = \tfrac{1}{2}(5x^2 - 3)x \quad \therefore \quad P_3^0(\cos\theta) = \tfrac{1}{2}\cos\theta(5\cos^2\theta - 3)$$

$$P_3^{|1|}(x), \textit{ i.e., } P_3^{\pm1}(x) = \tfrac{3}{2}(1-x^2)^{1/2}(5x^2 - 1) \quad \therefore \quad P_3^{\pm1}(\cos\theta) = \tfrac{3}{2}\sin\theta(5\cos^2\theta - 1)$$

$$P_3^{|2|}(x), \textit{ i.e., } P_3^{\pm2}(x) = 15x(1-x^2) \quad \therefore \quad P_3^{\pm2}(\cos\theta) = 15\cos\theta\sin^2\theta$$

$$P_3^{|3|}(x), \textit{ i.e., } P_3^{\pm3}(x) = 15x(1-x^2)^{3/2} \quad \therefore \quad P_3^{\pm3}(\cos\theta) = 15\sin^3\theta$$

$$P_4^0(x) = \tfrac{1}{8}(35x^4 - 30x^2 + 3) \quad \therefore \quad P_4^0(\cos\theta) = \tfrac{1}{8}(35\cos^4\theta - 30\cos^2\theta + 3)$$

$P_4^{|1|}(x)$, *i.e.*, $P_4^{\pm1}(x) = (1-x^2)^{1/2}(7x^3-3x)\frac{5}{2} \therefore P_4^{\pm1}(\cos\theta) = \frac{5}{2}\sin\theta\cos\theta(7\cos^2\theta-3)$

$P_4^{|2|}(x)$, *i.e.*, $P_4^{\pm2}(x) = (1-x^2)(7x^2-1)\frac{15}{2} \therefore P_4^{\pm2}(\cos\theta) = \frac{15}{2}\sin^2\theta(7\cos^2\theta-1)$

$P_4^{|3|}(x)$, *i.e.*, $P_4^{\pm3}(x) = 105\,x(1-x^2)^{3/2} \therefore P_4^{\pm3}(\cos\theta) = 105\sin^3\theta\cos\theta$

$P_4^{|4|}(x)$, *i.e.*, $P_4^{\pm4}(x) = (1-x^2)^2 \times 105 \therefore P_4^{\pm4}(\cos\theta) = 105\sin^4\theta$

With the help of the results reported above and making use of Eqs. 193—195, we can easily arrive at the following values for spherical harmonics, $Y_n^{m_A}$:

$\Theta_{0,0} = \frac{1}{\sqrt{2}}$	$Y_0^0 = \frac{1}{2\sqrt{\pi}}$
$\Theta_{1,0} = \sqrt{\frac{3}{2}}\cos\theta$	$Y_1^0 = \sqrt{\frac{3}{2}}\frac{1}{\sqrt{2\pi}}\cos\theta$
$\Theta_{0,\pm1} = \sqrt{\frac{3}{4}}\sin\theta$	$Y_1^{\pm1} = \sqrt{\frac{3}{4}}\sin\theta\frac{1}{\sqrt{2\pi}}e^{\pm i\phi}$
$\Theta_{2,0} = \sqrt{\frac{5}{8}}(3\cos^2\theta-1)$	$Y_2^0 = \sqrt{\frac{5}{8}}(3\cos^2\theta-1)\frac{1}{\sqrt{2\pi}}$
$\Theta_{2,\pm1} = \sqrt{\frac{15}{4}}\sin\theta\cos\theta$	$Y_2^{\pm1} = \sqrt{\frac{15}{4}}\sin\theta\cos\theta\frac{1}{\sqrt{2\pi}}e^{\pm i\phi}$
$\Theta_{2,\pm2} = \sqrt{\frac{15}{16}}\sin^2\theta$	$Y_2^{\pm2} = \sqrt{\frac{15}{16}}\sin^2\theta\frac{1}{\sqrt{2\pi}}e^{\pm i2\phi}$
$\Theta_{3,0} = \sqrt{\frac{7}{8}}\cos\theta(5\cos^2\theta-3)$	$Y_3^0 = \sqrt{\frac{7}{8}}\cos\theta(5\cos^2\theta-3)\frac{1}{\sqrt{2\pi}}$
$\Theta_{3,\pm1} = \sqrt{\frac{21}{32}}\sin\theta(5\cos^2\theta-1)$	$Y_3^{\pm1} = \sqrt{\frac{21}{32}}\sin\theta(5\cos^2\theta-1)\frac{1}{\sqrt{2\pi}}e^{\pm i\phi}$
$\Theta_{3,\pm2} = \sqrt{\frac{105}{16}}\sin^2\theta\cos\theta$	$Y_3^{\pm2} = \sqrt{\frac{105}{16}}\sin^2\theta\cos\theta\frac{1}{\sqrt{2\pi}}e^{\pm i2\phi}$
$\Theta_{3,\pm3} = \sqrt{\frac{35}{32}}\sin^3\theta$	$Y_3^{\pm3} = \sqrt{\frac{35}{32}}\sin^3\theta\frac{1}{\sqrt{2\pi}}e^{\pm i3\phi}$
$\Theta_{4,0} = \sqrt{\frac{9}{128}}(35\cos^4\theta-30\cos^2\theta+3)$	$Y_4^0 = \sqrt{\frac{9}{128}}(35\cos^4\theta-30\cos^2\theta+3)\frac{1}{\sqrt{2\pi}}$
$\Theta_{4,\pm1} = \sqrt{\frac{45}{32}}\sin\theta\cos\theta(7\cos^2\theta-3)$	$Y_4^{\pm1} = \sqrt{\frac{45}{32}}\sin\theta\cos\theta(7\cos^2\theta-3)\frac{1}{\sqrt{2\pi}}e^{\pm i\phi}$
$\Theta_{4,\pm2} = \sqrt{\frac{45}{64}}\sin^2\theta(7\cos^2\theta-1)$	$Y_4^{\pm2} = \sqrt{\frac{45}{64}}\sin^2\theta(7\cos^2\theta-1)\frac{1}{\sqrt{2\pi}}e^{\pm i2\phi}$
$\Theta_{4,\pm3} = \sqrt{\frac{315}{32}}\sin^3\theta\cos\theta$	$Y_4^{\pm3} = \sqrt{\frac{315}{32}}\sin^3\theta\cos\theta\frac{1}{\sqrt{2\pi}}e^{\pm i3\phi}$
$\Theta_{4,\pm4} = \sqrt{\frac{315}{256}}\sin^4\theta$	$Y_4^{\pm4} = \sqrt{\frac{315}{256}}\sin^4\theta\frac{1}{\sqrt{2\pi}}e^{\pm i4\phi}$

While expressing angular wave functions of hydrogen-like systems in terms of spherical harmonics, we use symbols l and m in place of n and m_A, respectively, in Eqs. 193—195. Accordingly, we write :

$$Y_l^m = \Theta_{l,m}\Phi_m \quad ...(198)$$

$$\Theta_{l,m} = \sqrt{\frac{(2l+1)}{2}\frac{|l-|m|}{|l+|m|}}P_l^m\cos\theta \quad ...(199)$$

$$\Phi_m = \frac{1}{\sqrt{2\pi}}e^{im\phi} \quad ...(200)$$

The symbols l and m used for hydrogen-like systems are referred to as orbital angular momentum quantum number and magnetic quantum number, respectively. As already mentioned, while the radial wavefunction gives the size of the orbitals, the spherical harmonics give both the size and the shape of the orbitals. We must emphasize that the spherical harmonics are wavefunctions for specific states of orbital angular momentum. More specifically, they are orthogonal functions of the angular coordinates θ and ϕ. These functions are polynomials in sin θ and cos θ. The spherical harmonics are the angular factors in centrosymmetric atomic orbitals ; they are angular momentum eigenfunctions; they are also the eigenfunctions of the rigid diatomic rotor.

Complete Wavefunctions and Shapes of Orbitals. Let us write complete wavefunctions for some of the orbitals and deduce their shapes.

Complete wavefunctions for *s* orbitals and their shapes. For an *s* orbital, $l = 0$, therefore, $m = 0$. The complete wave function is, therefore, written as

$$R_{n,0}(r)Y_0^0 = R_{n,0}(r)\frac{1}{\sqrt{2}}\times\frac{1}{\sqrt{2\pi}} = R_{n,0}(r)\frac{1}{2\sqrt{\pi}} \quad ...(201)$$

Since the complete wavefunction in this case is independent of the angles θ and ϕ, therefore, the orbital is *symmetrical* along all directions for a particular r, *i.e.*, it has a **spherical shape**. The 1*s* orbital has no radial node whereas 2*s* and 3*s* orbitals have one and two radial nodes, respectively, as shown in Fig. 16.

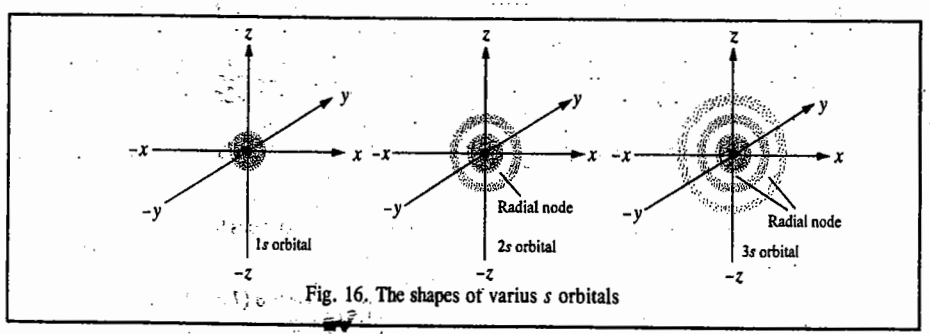

Fig. 16. The shapes of varius *s* orbitals

Complete wavefunctions for *p* orbitals and their shapes. For *p* orbitals, $l=1$. Therefore, $m = 0, +1, -1$. The corresponding complete wave functions are written as (0), (+1) and (-1), respectively. The sets of single electronic wave functions having the same l and the same m but different m_s are written as (m_1), (m_2), etc. Thus,

$$(0) = R_{n,1}(r)\,Y_1^0 = R_{n,1}(r)\sqrt{3/2}\cos\theta\times1/\sqrt{2\pi} = R_{n,1}(r)\sqrt{3/4\pi}\cos\theta \quad ...(202)$$

$$(+1) = R_{n,1}(r)\, Y_1^{+1} = R_{n,1}(r)\sqrt{3/4}\sin\theta \times 1/\sqrt{2\pi}\, e^{+i\phi} \quad ...(203)$$

$$(-1) = R_{n,1}(r)\, Y_1^{-1} = R_{n,1}(r)\sqrt{3/4}\sin\theta \times 1/\sqrt{2\theta}\, e^{-i\phi} \quad ...(204)$$

While the wavefunction represented by Eq. 202 is real, the wavefunctions represented by Eqs. 203 and 204 are not real as they contain the imaginary quantity i and as such cannot be visualised. An acceptable solution of wave equation is that which yields a real wavefunction. In order to obtain real wavefunctions for p orbitals, two linear combinations of angular wavefunctions represented by Eqs. 203 and 204 are taken into consideration. The two normalised linear combinations thus obtained are :

$1/\sqrt{2}\,[(+1) + (-1)]$, *i.e.*, $1/\sqrt{2}\, R_{n,1}(r)(\Theta_{1,+1}\Phi_{+1} + \Theta_{1,-1}\Phi_{-1})$ and

$1/\sqrt{2}\,[(+1) - (-1)]$, *i.e.*, $1/\sqrt{2}R_{n,1}(r)\,(\Theta_{1,+1}\Phi_{+1} - \Theta_{1,-1}\Phi_{-1})$.

These wavefunctions yield the following results :

Combination $1/\sqrt{2}\,[(+1) + (-1)]$ for real p wavefunction $= R_{n,1}(r)\sqrt{3/4\pi}\sin\theta\cos\phi$ ...(205)

Combination $1/\sqrt{2}\,[(+1) - (-1)]$ for real p wavefunction $= R_{n,1}(r)\sqrt{3/4\pi}\sin\theta\sin\phi$ ...(206)

Thus, Eqs. 202, 205 and 206 now represent a set of *real* wave functions for p orbitals.

Let us now investigate the **shapes of the 2p orbitals** represented by the real wavefunctions as given by Eqs. 202, 205 and 206. Expressing these functions in terms of the Cartesian coordinates, the real p wave function, as given by Eq. 202, is

$$(0) = R_{2,1}(r)\sqrt{3/4\pi}\cos\theta \quad ...(207)$$

$$= R_{2,1}(r)\sqrt{3/4\pi}\times z/r \;[\because z = r\cos\theta \text{ (Fig. 15)}] \quad ...(208)$$

This is, evidently, a function of z and is, therefore, known as p_z wavefunction. The wavefunction p_z when plotted in three-dimensional space yields a dumb-bell shaped curve along the z-axis, as shown in Fig. 17.

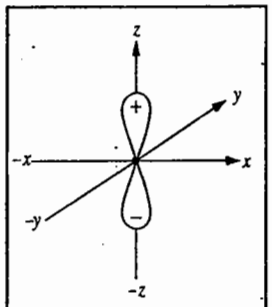

Fig. 17. The shape of p_z orbital

It can be seen from Eq. 208 that the function p_z will be positive when z is positive and negative when z is negative. It may be noted that + and – signs are geometric signs of the plotted wavefunctions only and should not be confused with positive or negative charges.

Let us now consider the real wavefunction given by Eq. 205. Expressing it in terms of Cartesian coordinates, we get

$$1/\sqrt{2}\,[(+1) + (-1)] = R_{2,1}(r)\sqrt{3/4\pi}\,\sin\theta\cos\phi$$

$$= R_{2,1}(r)\,\sqrt{3/4\pi}\times x/r \;[\because \sin\theta\cos\phi = x/r \text{ (Fig. 17)}] \quad ...(209)$$

Evidently, the p wavefunction given by Eq. 209 varies with x only. It is, therefore, referred to as p_x wave function. A plot of p_x wave function in three-dimensional space gives a dumb-bell shaped curve along the x-axis, as shown in Fig. 18.

It can be easily seen from Eq. 209 that the function p_x would be positive when x is positive and negative when x is negative.

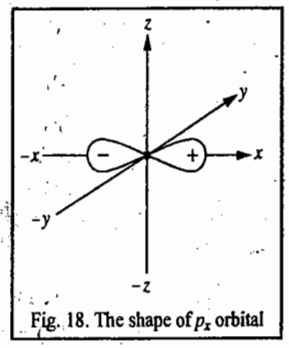

Fig. 18. The shape of p_x orbital

Similarly, the real wave function as given by Eq. 206, when expressed in terms of Cartesian coordinates, yields Eq. 211. Thus,

$$1/\sqrt{2}\,[(+1) - (-1)] = R_{2,1}(r)\sqrt{3/4\pi}\,\sin\theta\sin\phi \quad ...(210)$$

$$= R_{2,1}(r)\sqrt{3/4\pi}\times y/r \;[\because \sin\theta\sin\phi = y/r \text{ (Fig. 15)}] \quad ...(211)$$

Thus, the p wavefunction in this case varies with y only. It is, therefore, called p_y wavefunction.

A plot of p_y wavefunction in three-dimensional space gives a dumb-bell shaped curve along the y-axis, as shown in Fig. 19.

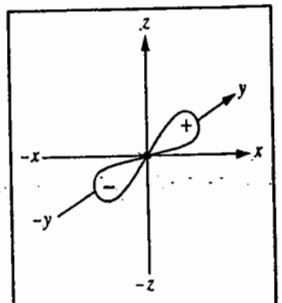

Fig. 19. The shape of p_y orbital

The complete wavefunctions of $2p$, $3p$, $4p$ orbitals would give rise to dumb-bell shaped curves except for the fact that the $4p$ orbital would occupy more space than $3p$ orbital and $3p$ orbital would occupy more space than $2p$ orbital (Fig. 18).

Also, the $4p$ orbital would have *two radial nodes*, the $3p$ orbital would have *one radial node* and $2p$ orbital would have *no radial node* (the number of radial nodes is given by $n - l - 1$).

The shapes of $2p_x$, $3p_x$ and $4p_x$ orbitals with radial nodes are shown in Fig. 20.

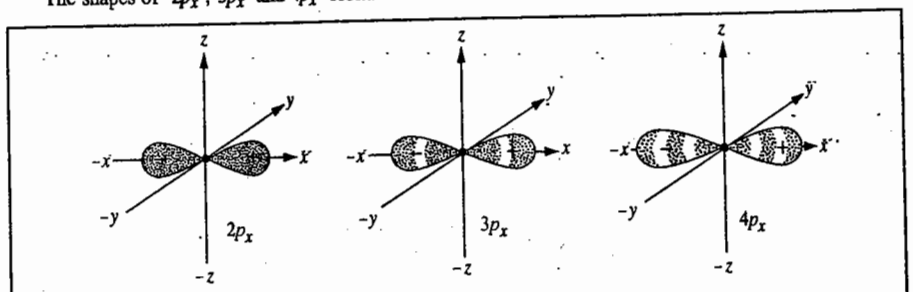

Fig. 20. The shapes of $2p_x$, $3p_x$ and $4p_x$ orbitals.

Complete wave functions for d orbitals and their shapes. For d orbitals, $l = 2$ so that $m = 0, +1, +2, -1, -2$. The complete wave functions for the d orbitals may be written as follows :

$$(0) = R_{n,2}(r)\, Y_2^0 = R_{n,2}(r)\sqrt{5/16\pi}\,(3\cos^2\pi - 1) \quad ...(212)$$

$$(+1) = R_{n,2}(r)\, Y_2^{+1} = R_{n,2}(r)\sqrt{15/8\pi}\,(\sin\theta\cos\theta)e^{i\phi} \quad ...(213)$$

$$(+2) = R_{n,2}(r)\, Y_2^{2+} = R_{n,2}(r)\sqrt{15/32\pi}\,(\sin^2\theta)\,e^{i2\phi} \quad ...(214)$$

$$(-1) = R_{n,2}(r)\, Y_2^{-1} = R_{n,2}(r)\sqrt{15/8\pi}\,(\sin\theta\cos\theta)e^{-i\phi} \quad ...(215)$$

$$(-2) = R_{n,2}(r)\, Y_2^{-2} = R_{n,2}(r)\sqrt{15/32\pi}\,(\sin^2\pi)\,e^{-i2\phi} \quad ...(216)$$

Of the above five wave functions, only one wave function given by Eq. 212 is real. All other wave functions contain the imaginary quantity i for d orbitals. We obtain real d orbital wave functions by the procedure similar to the one we adopted for obtaining p orbital wave functions. The real d orbital wave functions obtained from linear combination of Eqs. 213 and 215 are : (*i*) $1/\sqrt{2}\,[(+1) + (-1)]$, *i.e.*, $1/\sqrt{2}\,R_{n,2}(r)\,(\Theta_{2,1}\Phi_1 + \Theta_{2,-1}\Phi_{-1})$ and (*ii*) $1/\sqrt{2}\,[(+1) - (-1)]$, *i.e.*, $1/\sqrt{2}R_{n,2}(r)(\Theta_{2,1}\Phi_1 - \Theta_{2,-1}\Phi_{-1})$ and the d orbital wave functions obtained from linear combination of Eqs. 214 and 216 are :

(*i*) $1/\sqrt{2}\,[(+2) + (-2)]$, *i.e.*, $1/\sqrt{2}R_{n,2}(r)(\Theta_{2,2}\Phi_2 - \Theta_{2,-2}\Phi_{-2})$ and (*ii*) $1/\sqrt{2}\,[(+2) - (-2)]$, *i.e.*, $1/\sqrt{2}\,R_{n,2}(r)\,(\Theta_{2,2}\,\Phi_2 - \Theta_{2,-2}\Phi_{-2})$.

From these wavefunctions, the five real d orbital wavefunctions obtained are as follows :

$$\text{Real } d \text{ wavefunction (0)} = R_{n,2}(r)\ \sqrt{5/16\pi}\ (3\cos^2\theta - 1) \quad ...(217)$$

$$\text{Real } d \text{ wavefunction } 1/\sqrt{2}\ [(+1) + (-1)] = R_{n,2}(r)\ \sqrt{15/4\pi}\ \sin\theta\cos\theta\cos\phi \quad ...(218)$$

$$\text{Real } d \text{ wavefunction } 1/\sqrt{2}\ [(+1) - (-1)] = R_{n,2}(r)\ \sqrt{15/4\pi}\ \sin\theta\cos\theta\sin\phi \quad ...(219)$$

$$\text{Real } d \text{ wavefunction } 1/\sqrt{2}\ [(+2) + (-2)] = R_{n,2}(r)\ \sqrt{15/16\pi}\ \sin^2\theta\cos 2\phi \quad ...(220)$$

$$\text{Real } d \text{ wavefunction } 1/\sqrt{2}\ [(+2) - (-2)] = R_{n,2}(r)\sqrt{15/16\,\pi}\ \sin^2\theta\sin 2\phi \quad ...(221)$$

Expressing the above wavefunctions in terms of Cartesian co-ordinates, we get

(*i*)
$$(0) = R_{n,2}(r)\sqrt{15/16\,\pi}\ (3\cos^2\theta - 1)$$

$$= R_{n,2}(r)\sqrt{15/16\,\pi}\ (3z^2 - r^2)\times 1/r^2 \quad ....(222)$$

As can be seen, the above d wavefunction *varies as* z^2. Hence, it is called d_z^2 wavefunction.

(*ii*)
$$1/\sqrt{2}\ [(+1) + (-1)] = R_{n,2}(r)\sqrt{15/4\pi}\ \sin\theta\cos\theta\cos\phi$$

$$= R_{n,2}(r)\sqrt{15/4\pi}\times xz/r^2 \quad ...(223)$$

Since the d wavefunction *varies as* xz, it is called d_{xz} wavefunction.

(*iii*)
$$1/\sqrt{2}\ [(+1) - (-1)] = R_{n,2}(r)\sqrt{15/4\,\pi}\ \sin\theta\cos\theta\sin\phi$$

$$= R_{n,2}(r)\sqrt{15/4\,\pi}\times yz/r^2 \quad ...(224)$$

Since the d wavefunction *varies as* yz, it is called d_{yz} wavefunction.

(*iv*)
$$1/\sqrt{2}\ [(+2) + (-2)] = R_{n,2}(r)\sqrt{15/16\pi}\ \sin^2\theta\cos 2\phi$$

$$= R_{n,2}(r)\sqrt{15/16\pi}\sin^2\theta(\cos^2\phi - \sin^2\phi)$$

$$= R_{n,2}(r)\sqrt{15/16\pi}\,(\sin^2\theta\cos^2\phi - \sin^2\theta\sin^2\phi)$$

$$= R_{n,2}(r)\sqrt{15/16\pi}\,(x^2 - y^2)/r^2 \quad ...(225)$$

Since the d wavefunction *varies as* $x^2 - y^2$, it is called $d_{x^2-y^2}$ wavefunction.

(*v*)
$$1/\sqrt{2}\ [(+2) - (-2)] = R_{n,2}(r)\sqrt{15/16\pi}\ \sin^2\theta\sin 2\phi$$

$$= R_{n,2}(r)\sqrt{15/16\,\pi}\sin^2\theta\,2\sin\phi\cos\phi$$

$$= R_{n,2}(r)\sqrt{15/4\pi}\ \sin\theta\sin\phi\sin\theta\cos\phi$$

$$= R_{n,2}(r)\sqrt{15/4\pi}\ xy/r^2 \quad ...(226)$$

Since the d wavefunction *varies as* xy, it is called d_{xy} wavefunction.

Thus, the five real wavefunctions of d orbitals are d_{z^2}, d_{xz}, d_{yz}, $d_{x^2-y^2}$ and d_{xy}. These wavefunctions when plotted in three-dimensional space yield curves as shown in Fig. 21. It may be remembered that all these are solid curves, *i.e., these are three-dimensional* because of their dependence on $r\,(=\sqrt{x^2+y^2+z^2})$.

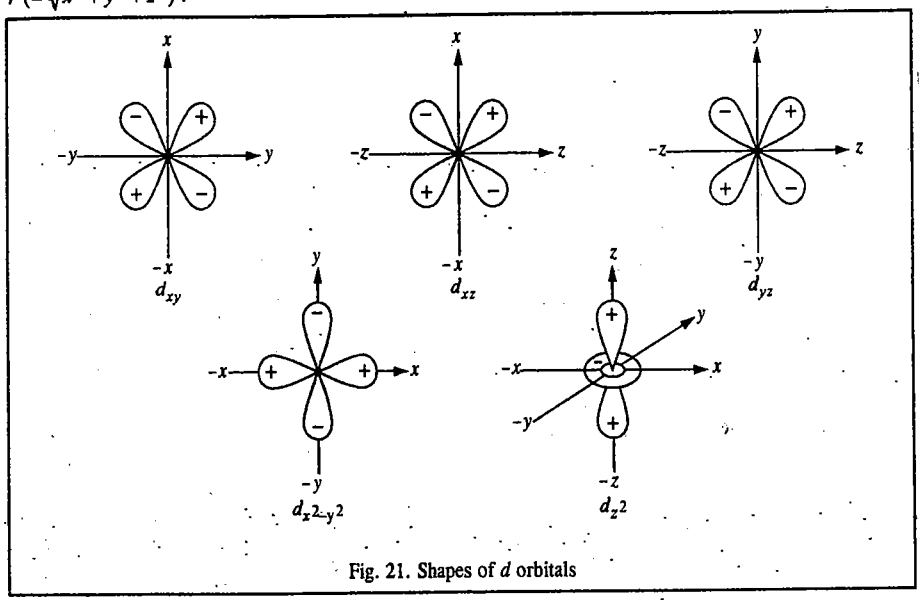

Fig. 21. Shapes of d orbitals

The orbital d_{z^2} has a dumb-bell shaped curve symmetric about the z-axis, having a ring-like collar in xy plane. The dumb-bell shaped part of the curve has a *positive geometric sign* (because whatever be the sign of z, positive or negative, its square is always positive) whereas the collar in the xy plane has a *negative geometric sign.*

The orbital d_{xy} has a double dumb-bell shape. The quantity xy will be positive when both x and y are positive or when both are negative. However, xy will be negative when either of x or y is negative. Thus, the sign of the curve is positive in first and third quadrants while it is negative in second and fourth quadrants. The shapes of d_{xz}, d_{yz} orbitals can be explained in a similar manner.

The orbital $d_{x^2-y^2}$ is also double dumb-bell shaped but its lobes lie on x and y axes. The signs of the lobes on x axis will always be positive (because whatever be the sign of x, x^2 will always be positive) whereas the signs of the lobes on y axis will always be negative (because whatever be the sign of y, $-y^2$ will always be negative). The *exact shapes* of d orbitals are obtained by taking into consideration the total wave function. Accordingly, $3d_{x^2-y^2}$ orbital would be similar in shape to $4d_{x^2-y^2}$ orbital or $5d_{x^2-y^2}$ orbital except for the fact that

1. A $5d$ orbital would have *two*, a $4d$ orbital would have *one* and a $3d$ orbital would have *no* radial node.

2. A $5d$ orbital would occupy more space than a $4d$ orbital and a $4d$ orbital would occupy more space than a $3d$ orbital, as shown in Fig. 22.

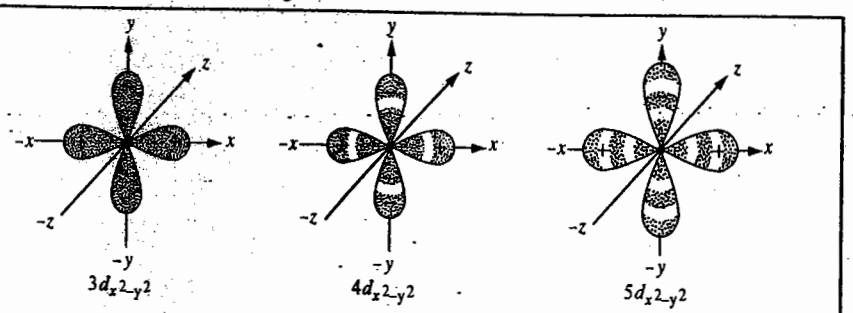

Fig. 22. Curves for $3d_{x^2-y^2}$, $4d_{x^2-y^2}$ and $5d_{x^2-y^2}$ orbitals in three-dimensional space. The curves for the other $3d$, $4d$, $5d$ orbitals can be drawn on similar lines.

In a similar manner, we can determine the shapes of f orbitals

The set of complete wave functions for f orbitals is given below :

$$(0) = R_{n,3}(r)\,Y_3^0$$

$$(\pm 1) = R_{n,3}(r)\,Y_3^{\pm 1}$$

$$(\pm 2) = R_{n,3}(r)\,Y_3^{\pm 2}$$

$$(\pm 3) = R_{n,3}(r)\,Y_3^{\pm 3}$$

The spherical harmonics for the f orbital wave functions have been given earlier. In the set given above, only (0) is real. The rest of the six f orbital wave functions are imaginary. We can derive the real set of f orbital wave functions by following the same procedure as was adopted by obtaining sets of real p and d orbital wave functions. The real f orbital wave functions thus obtained would be desinated as follows :

$f_{z(x^2-y^2)}$, $f_{y(z^2-x^2)}$, $f_{x(y^2-z^2)}$, $f_{z(5z^2-3r^2)}$, $f_{x(5x^2-3r^2)}$, $f_{y(5y^2-3r^2)}$ and $f_{(x,y,z)}$

Solution of the Radial Equation (the R-equation). To solve Eq. 185 we need the explicit form of the potential energy $V(r)$. However, before we attempt the solution, we shall show how the concept of orbital angular momentum arises from this equation. Eq. 185 can be expressed in the form of a one-dimensional equation by writing

$$R(r) = \frac{\chi(r)}{r} \qquad ...(227)$$

The radial equation now reduces to

$$\frac{d^2\chi}{dr^2} + \frac{2\mu}{\hbar^2}\left(E - V(r) - \frac{l(l+1)\hbar^2}{2\mu r^2}\right)\chi = 0 \qquad ...(228)$$

This has the form of a one-dimensional Schrödinger equation of a particle of mass μ moving in the direction of r in a field of effective potential

$$V_{\text{eff}} = V(r) + \frac{l(l+1)\hbar^2}{2\mu r^2} \qquad ...(229)$$

The additional potential energy term $\frac{l(l+1)\hbar^2}{2\mu r^2}$ is a rapulsive one and corresponds to a force $\frac{l(l+1)\hbar^2}{\mu r^3}$. The *centrifugal force* $\mu r\omega^2$ can be written in terms of the orbital angular momentum L as

$$\mu r\omega^2 = \frac{\left(\mu r^2\omega\right)^2}{\mu r^3} = \frac{L^2}{\mu r^3} \qquad ...(230)$$

This form of the centrifugal force and the force corresponding to the additional potential suggests that the square of the orbital angualr momentum, L^2, can be taken as

$$L^2 = l(l+1)\hbar^2 \qquad ...(231)$$

where l is called the orbital angular momentum quantum number. Though orbital angular momentum is equal to $l\hbar$, its exact value is $\left[l(l+1)\right]^{1/2}\hbar$. If $V(r)$, the central field potential, is Coulombic $(-Ze^2/r)$, the additional potential is negligible at large distances. However, this becomes the dominant term at small distances. Fig. 23 shows a plot of the *effective potential*, V_{eff} as a function of r for a Coulombic potential.

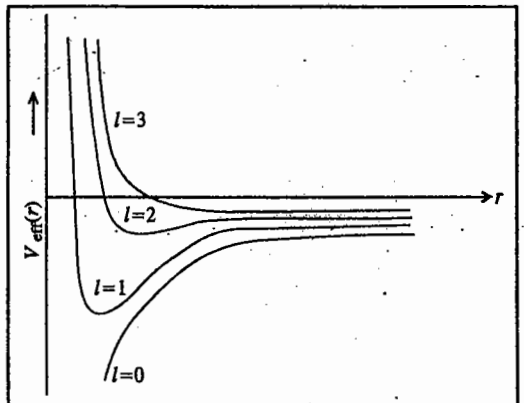

Fig. 23. The effective potential V_{eff} verses r for a Coulomb potential.

We now return to the solution of the radial equation (Eq. 185), which we rewrite as

$$\frac{1}{r^2}\frac{d}{dr}\left(r^2\frac{dR}{dr}\right) + \frac{2\mu}{\hbar^2}\left[E - \frac{l(l+1)\hbar^2}{2\mu r^2} + \frac{Ze^2}{r}\right]R = 0 \qquad ...(232)$$

To solve Eq. (232), let us introduce a variable ρ and a constant λ defined by

$$\rho = \sqrt{\frac{-8\mu E}{\hbar^2}}\,r, \qquad \lambda = \frac{Ze^2}{\hbar}\sqrt{\frac{\mu}{-2E}} \qquad ...(233)$$

As E is negative for bound states, ρ and λ are real quantities. In terms of the new variable, Eq. (232) becomes

$$\frac{d^2R}{d\rho^2} + \frac{2}{\rho}\frac{dR}{d\rho} + \left[-\frac{1}{4} - \frac{l(l+1)}{\rho^2} + \frac{\lambda}{\rho}\right]R = 0 \qquad ...(234)$$

Let us first investigate its asymptotic solution. When $\rho \to \infty$, Eq. 234 reduces to

$$\frac{d^2R}{d\rho^2} - \frac{1}{4}R = 0 \qquad ...(235)$$

Its solutions are $R = \exp(-\rho/2)$ and $\exp(\rho/2)$. out of these only $\exp(-\rho/2)$ is acceptable since $\exp(\rho/2) \to \infty$ as $\rho \to \infty$. The exact solution of Eq. 234 is

$$R(\rho) = e^{-\rho/2}F(\rho) \qquad ...(236)$$

Substitution of Eq. (236) in Eq. (235) gives the differential equation satisfied by $F(\rho)$ as

$$\rho^2\frac{d^2F}{d\rho^2}+\rho(2-\rho)\frac{dF}{d\rho}+\left[\rho\lambda-l(l+1)-\rho\right]F(\rho)=0 \qquad ...(237)$$

When $\rho = 0$, we get

$$l(l+1)\,F(0)=0 \quad \text{or} \quad F(0)=0,\ l\neq 0 \qquad ...(238)$$

Therefore if we try a power series solution for $F(\rho)$ it must not contain a constant term. Hence,

$$F(\rho)=\sum_{k=0}^{\infty}a_k\rho^{c+k} \qquad ...(239)$$

With this value of $F(\rho)$, Eq. (237) reduces to

$$\sum_k a_k(\lambda-1-c-k)\rho^{c+k+1}+\sum_k a_k(c^2+2ck+k^2+c+k-l^2-l)\rho^{c+k}=0 \qquad ...(240)$$

Eq. 240 is valid for all values of ρ only if the coefficient of each power of ρ vanishes separately. Equating the coefficient of ρ^c to zero, we have

$$a_0\left(c^2+c-l^2-l\right)=0$$

or
$$c^2+c-l^2-l=0 \qquad (\text{since } a_0\neq 0)$$

or
$$(c-l)(c+l+1)=0$$

Hence,
$$c=l \quad \text{or} \quad c=-(l+1) \qquad ...(241)$$

If $c = -(l + 1)$, the first term in $F(\rho)$ would be a_0/ρ^{l+1} which tends to infinity as $\rho \to 0$. Hence, $c = l$ is the only acceptable value. Setting the coefficient of ρ^{l+k+1} in Eq. 240 to zero, we obtain

$$a_{k+1}=\frac{l+k+1-\lambda}{(k+1)(k+2l+2)}a_k \qquad ...(242)$$

This recursion relation allows us to determine the coefficients $a_1, a_2, a_3, \ldots$ in terms of a_0 which is quite arbitrary. For large values of k, we get from Eq. (242)

$$\frac{a_{k+1}}{a_k}=\frac{1}{k}$$

In the expansion

$$e^{\rho}=\sum_{k=0}^{\infty}\frac{1}{k!}\rho^k=\sum_{k=0}^{\infty}A_k\rho^k$$

$$\frac{A_{k+1}}{A_k}=\frac{k!}{(k+1)!}=\frac{1}{k+1}\xrightarrow[k\to\infty]{}\frac{1}{k}$$

Hence as $k \to \infty$, the series for $F(\rho)$ behaves like $\rho^l e^{\rho}$ and

$$R(\rho)=e^{-\rho/2}\rho^l e^{\rho}=\rho^l e^{\rho/2}$$

This value of $R(\rho)$ is not acceptable and therefore the series must break off after a certain value of k, say n'. For this to happen $a_{n'+1}$ must be zero. Then, from Eq. 242,

$$l+n'+1-\lambda=0, \qquad n'=0,1,2,\ldots \qquad ...(243)$$

Energy eigenvalues : Defining a new quantum number n by

$$n=l+n'+1=\lambda=\frac{Ze^2}{\hbar}\left(\frac{\mu}{-2E}\right)^{1/2}$$

we have
$$E_n=-\frac{\mu Z^2e^4}{2\hbar^2n^2}, \qquad n=1,2,3,\ldots \qquad ...(244)$$

Since n' and l are integers including zero,

$$n=1,2,3,\ldots \qquad ...(245)$$

As $n \geq l + 1$, the highest possible value of l is $(n - 1)$. Thus,

$$l=0,1,2,\ldots,(n-1) \qquad ...(246)$$

The new quantum number n is called the **principal quantum number** which determines the energy. For hydrogen the atomic number $Z = 1$ and the reduced mass $\mu \approx m$, the mass of the electron.

The energy expression (244) can be written as

$$E_n=-\frac{R_HZ^2}{n^2} \qquad ...(247)$$

where $R_H\left(=\mu e^4/2\hbar^2\right)$ is the Rydberg constant of the hydrogen atom. In atomic units (a.u.) often employed in quantum mechanics, we arbitrarily set $e = \mu = \hbar = a_0 = 1$, so that for the ground state $(n = 1)$, $E_1 = -\frac{1}{2}$(a.u.); the negative sign implies that the electron is attracted to the nucleus.

We note that the energy expression for E_n is the same as the one obtained in the Bohr theory of hydrogen atom, (Eq. 22), the major difference being the occurrence of the concept of **stationary states** and quantization of energy as a consequence of the solution of the Schrödinger wave equation.

Radial wavefunctions : The quantization restriction on energy converts the series for $F(\rho)$ into a polynomial. Writing

$$F(\rho)=\rho^l L(\rho) \qquad ...(248)$$

Eq. 237 reduces to

$$\rho\frac{d^2L(\rho)}{d\rho^2}+(2l+2-\rho)\frac{dL(\rho)}{d\rho}+(n-l-1)L(\rho)=0 \qquad ...(249)$$

The **associated Laguerre polynomial** of order p and degree $(q-p)$, denoted as $L_q^p(\rho)$, satisfies the equation

$$\rho\frac{d^2L_q^p}{d\rho^2}+(p+1-\rho)\frac{dL_q^p}{d\rho}+(q-p)L_q^p(\rho)=0 \qquad ...(250)$$

(The Laguerre polynomials are named after the French mathematician Edmond Laguerre (1834-1886)).

Eqs. (249) and (250) are identical if $L(\rho)$ is taken as $L_{n+l}^{2l+1}(\rho)$. Hence,

$$R_{nl}(r)=Ne^{-\rho/2}\rho^l L_{n+l}^{2l+1}(\rho) \qquad ...(251)$$

The normalization integral

$$\int_0^\infty R_{nl}^2(r)r^2dr=1$$

allows the determination of the normalization constant N. Hence,

$$\frac{n^3\hbar^6}{8\mu^3Z^3e^6}|N|^2\int_0^\infty e^{-\rho}\rho^{2l}\left(L_{n+l}^{2l+1}\right)^2\rho^2d\rho=1$$

Using the orthogonal properties of associated Laguerre polynomials,

$$\frac{n^3\hbar^6}{8\mu^3Z^3e^6}|N|^2\frac{2n[(n+l)!]^3}{(n-l-1)!}=1$$

or

$$|N|=\pm\left\{\left(\frac{2Z\mu e^2}{n\hbar^2}\right)\frac{(n-l-1)!}{2n[(n+l)!]^3}\right\}^{1/2} \qquad ...(252)$$

Thus, the normalized radial wavefunctions are

$$R_{nl}(r)=-\left\{\left(\frac{2Z}{na_H}\right)^3\frac{(n-l-1)!}{2n[(n+l)!]^3}\right\}^{1/2}e^{-\rho/2}\rho^l L_{n+l}^{2l+1}(\rho) \qquad ...(253)$$

where

$$a_H=\frac{\hbar^2}{\mu e^2} \qquad ...(254)$$

The negative sign is selected to make R_{10} positive. As μ is approximately equal to the electron mass, $a_H \approx a_0$, the Bohr radius. Some of the radial wavefunctions are given in Table 3. It may be noted that at the origin the wavefunctions R_{10}, R_{20}, R_{30} are finite whereas R_{21}, R_{31}, R_{32} are zero.

Table 3. The First six Radial Wavefunctions of a Hydrogenic Atom

n	l	$R_{nl}(r)$
1	0	$2\left(\frac{Z}{a_0}\right)^{3/2}e^{-Zr/(a_0)}$
2	0	$\left(\frac{Z}{2a_0}\right)^{3/2}\left(2-\frac{Zr}{a_0}\right)e^{-Zr/(2a_0)}$
	1	$\frac{1}{\sqrt{3}}\left(\frac{Z}{2a_0}\right)^{3/2}\frac{Zr}{a_0}e^{-Zr/(2a_0)}$
3	0	$\frac{2}{27}\left(\frac{Z}{3a_0}\right)^{3/2}\left(27-18\frac{Zr}{a_0}+\frac{2Z^2r^2}{a_0^2}\right)e^{-Zr/(3a_0)}$
	1	$\frac{4\sqrt{2}}{54}\left(\frac{Z}{3a_0}\right)^{3/2}\frac{Zr}{a_0}\left(6-\frac{Zr}{a_0}\right)e^{-Zr/(3a_0)}$
	2	$\frac{4}{27\sqrt{10}}\left(\frac{Z}{3a_0}\right)^{3/2}\left(\frac{Zr}{a_0}\right)^2e^{-Zr/(3a_0)}$

All the radial wavefunctions represent an exponential "decay", and for $n = 2$ the decay is slower than for $n = 1$. We see that radial functions decay as $\exp(-Zr/na_0)$.

Wavefunctions of the hydrogenic atom

The complete wavefunctions for a hydrogen-like atom are given by

$$\psi_{nlm}(r,\theta,\phi)=R_{nl}(r)Y_{lm}(\theta,\phi) \qquad ...(255)$$

where $n = 1, 2, 3, \ldots$, $l = 0, 1, 2, 3, \ldots, (n-1)$, $m = 0, \pm1, \pm2, \ldots, \pm l$

The explicit forms of the wavefunctions for a few states are

$$\psi_{100}=\frac{1}{\pi^{1/2}}\left(\frac{Z}{a_0}\right)^{3/2}e^{-Zr/a_0} \qquad ...(256a)$$

$$\psi_{200}=\frac{1}{\pi^{1/2}}\left(\frac{Z}{2a_0}\right)^{3/2}\left(1-\frac{Zr}{2a_0}\right)e^{-Zr/(2a_0)} \qquad ...(256b)$$

$$\psi_{210}=\frac{1}{\pi^{1/2}}\left(\frac{Z}{2a_0}\right)^{5/2}re^{-Zr/(2a_0)}\cos\theta \qquad ...(256c)$$

$$\psi_{21,\pm1}=\frac{1}{8\pi^{1/2}}\left(\frac{Z}{a_0}\right)^{5/2}re^{-Zr/(2a_0)}(\sin\theta)e^{\pm i\theta} \qquad ...(256d)$$

It may be noted that the expressions for the $l = 1$ state contain the factor r^1. The $l=2$ states will have the factor r^2, and so on. The presence of the factor r^l makes the wavefunction zero at $r = 0$ except for the s-states.

Radial probability density : For the state specified by the wavefunction $\psi_{nlm} \equiv |nlm\rangle$, the probability of finding the electron in a volume element $d\tau$ is

$$|\psi_{nlm}|^2 d\tau = |R_{nl}|^2 |Y_{lm}|^2 r^2 \sin\theta\, dr\, d\theta d\phi$$

The probability of finding the electron in a thin spherical shell bounded by radii r and $(r + dr)$ is then

$$P(r)\, dr = |R_{nl}|^2 r^2 dr \int_0^{\pi} \int_0^{2\pi} |Y_{lm}|^2 \sin\theta\, d\theta d\phi$$

Since the spherical harmonics are normalized to unity

$$P_{nl}(r)\, dr = |R_{nl}|^2 r^2 dr \qquad ...(257)$$

The *radial probability density* $P_{nl}(r)$ is defined as the probability of finding the electron of the hydrogen atom at a distance r from the nucleus. Then

$$P_{nl}(r) = r^2 |R_{nl}|^2 \qquad ...(258)$$

Plots of radial probability density for some of the states are illustrated in Fig. 24.

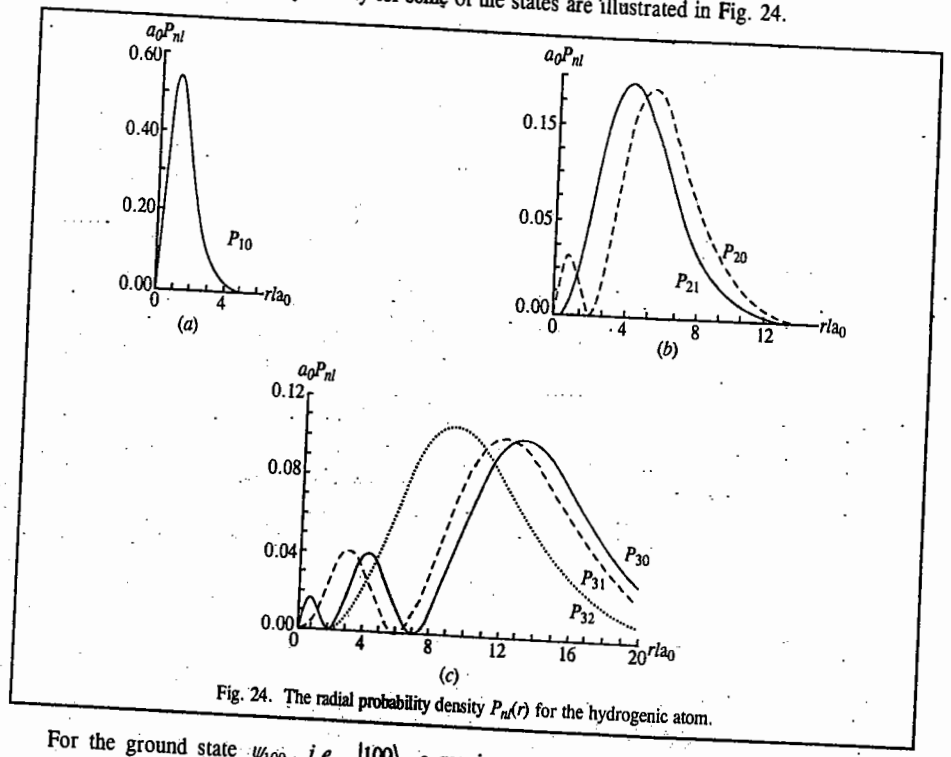

Fig. 24. The radial probability density $P_{nl}(r)$ for the hydrogenic atom.

For the ground state ψ_{100}, *i.e.*, $|100\rangle$, a maximum probability density P_{10} exists at a radial position given by

$$\frac{dP_{10}}{dr} = 0, \quad \text{or} \quad \left(2r - \frac{2r^2}{a_0}\right) e^{-2r/a_0} = 0, \quad \text{or} \quad r = a_0$$

The maximum occurs at a distance equal to the Bohr radius from the origin. Thus, the radial probability density for hydrogen atom in the ground state is maximum at the Bohr radius.

This view of the probability density consists in considering an atom to be composed of "layers" much like an onion and examining the probability of finding the electron in the "layer" which extends from r to $r+dr$ (Fig. 25). The volume of the thin shell may be considered to be dV. Since the volume of the sphere is $V=(4/3)\pi r^3$, $dV=4\pi r^2 dr$, so that $R_{nl}^2 dV = 4\pi r^2 R_{nl}^2 dr$. The essential features of the probability function are that (*i*) at $r = 0$, $4\pi r^2 R_{nl}^2 = 0$; hence the value of the function at the nucleus must be zero; (*ii*) at large values of r, $R_{nl} \to 0$ rapidly and hence $4\pi r^2 R_{nl}^2$ must $\to 0$. Note that although the radial function for the 2s orbital is both positive $(r < 2a_0/Z)$ and negative $(r > 2a_0/Z)$, the probability function is everywhere *positive* (as, of course, it must be to have any physical meaning) as a result of the squaring operation.

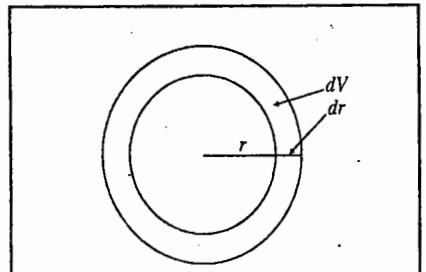

Fig. 25. Volume of a shell of thickness dr.

We may mention here that the presence of a node in the wavefunction indicates a point in space at which the probability of finding the electron has become zero. This raises the interesting question, "How does the electron get from one side of the node to the other if it can never be found exactly at the node?" This is not a valid question as posed, since it presupposes our macroscopically prejudiced view that the electron is a particle. If we consider the electron to exhibit wave-particle duality (as it does according to the de Broglie hypothesis), then the electron behaves as a standing wave, and no problem arises because it simultaneously exists on both sides of the node. We can even imagine that the electron "leaks" or "tunnels" through the node.

The presence of one or more nodes and maxima may have some effect on chemical bonding. Thus, since covalent bonding depends upon the overlap of atomic orbitals on adjacent atoms, it is evident that if one atom had a maximum in its radial wavefunction overlapping with a region with a node (minimum) in the wavefunction of a second atom, the overlap (as determined by the overlap integral $\int \psi_A \psi_B d\tau$ of the two atoms A and B) would be poor. However, accurate quantum mechanical calculations have shown that the nodes lie too close to the nucleus to affect the bonding appreciably. The presence of nodes and small "subnodal maxima" does have a profound effect on the *energy* of electrons in different orbitals. Electrons in an orbital with these subnodal maxima (particularly *s* orbitals with higher values of n) are said to be *penetrating*, *i.e.*, they have considerable electron density in the region of the nucleus. This is the reason for the ordering of the energy levels in polyelectronic atoms : 1s, 2s, 2p, 3s, 3p, etc. We may finally note that the number of radial nodes in a hydrogenic wavefunction is $n - l - 1$; the number of angular nodes (nodal planes) is l. Thus, the total number of nodes is $n - 1$. We see that *n*s orbitals have $n - 1$ radial nodes, *n*p orbitals have $n - 2$ radial nodes, etc.

Quantum Numbers. As discussed earlier, the solution of the Schrödinger wave equation for hydrogen atom yields three quantum numbers n, l and m. Amongst these, n, the principal quantum number, determines, to a large extent, the energy of the electron. It also determines the average distance of an electron from the nucleus. As the value of n increases, the electron gets farther away from the nucleus and its energy increases.

A portion of this energy is, however, associated with the orbital motion of the electron around the nucleus. This orbital motion is described by the angular momentum of the electron which is characterised by the angular momentum quantum number or the azimuthal quantum number, l. This quantum number accounts for the appearance of a group of closely spaced lines in the hydrogen spectra. But *the energy*

associated with the angular momentum of an electron must be well within its total energy determined by n. Thus, the electrons in atoms are grouped not only into main energy levels given by n but also into energy sub-levels given by l. The value of l gives the subshell in which the electron is located. *It also determines the shape of the orbital* in which the electron is located. The number of subshells within a principal shell are determined by the value of n for that principal energy level. Thus, l may have all possible whole number values from 0 to $n-1$. The various sublevels are designated as *s, p, d, f...* according as the value of l=0, 1, 2, 3, respectively.

Since an electron has an angular momentum, its motion may be likened to the flow of an electric current through a loop. Such a flow of current, as is well known, creates a magnetic field. This field can interact with an external magnetic or electric field. As a result of this interaction, *the electrons in a given energy sublevel orient themselves in certain specific regions of space around the nucleus.* These regions of space are called orbitals. The number of orbitals in a given energy sublevel within a principal energy level is given by the magnetic quantum number, m. The number of values allowed to m depends on the values of l. It is known from theory as well as experiment that the possible values of m range from $-l$ through 0 to $+l$, thus, making a total of $2l+1$ values.

The fourth quantum number, *viz.*, the **spin quantum number** does not follow from the wave mechanical treatment. The electron possesses an intrinsic angular momentum or spin, specified by the quantum number $s=\frac{1}{2}$. By analogy with the relation between the angular momentum quantum number l and the orbital angular momentum L (*viz.*, $L=[l(l+1)]^{1/2}\hbar$), the spin angular momentum has a magnitude

$$S = [s(s+1)]^{1/2}\hbar = \left(\sqrt{3}/2\right)\hbar \cdot \text{since } s = \tfrac{1}{2} \qquad ...(259)$$

The components of S in the direction of the magnetic field B are specified by the quantum number m_s, where $m_s=+\frac{1}{2}$ or $-\frac{1}{2}$. The $m_s=+\frac{1}{2}$ component has an upward orientation ($\uparrow$) and the $m_s=-\frac{1}{2}$ component has a downward orientation ($\downarrow$) (Fig. 26).

The spinning electron behaves like a tiny bar magnet. This fact was beautifully demonstrated by the celebrated **Stern–Gerlach experiment.** In alkali metal atoms, the outermost electrons are in an s orbital and the inner electrons are in a closed shell with an inert-gas configuration. The outermost electron has spin-magnetic properties similar to those of an isolated electron. In their experiment, Stern and Gerlach passed a beam of the atoms of an alkali metal through a strong inhomogeneous magnetic field. They found that the beam was split into two separate beams. The field divided the atoms into two beams corresponding to $m_s=+\frac{1}{2}$ and $m_s=-\frac{1}{2}$ for the valence electron. Otto Stern (1888–1969), the American physicist, was awarded the 1943 Physics Nobel Prize for his discovery of the magnetic moment of proton. The electron spin had been postulated in the early 1920s by G. Uhlenbeck and S. Goudsmit. The 1944 Physics Nobel Laureate I.I. Rabi (1898–1988) remarked that it would always remain a mystery why these physicists never won the Nobel prize. The electron spin emerges beautifully from the solution of Dirac's relativistic wave equation for the electron, but this topic is beyond the scope of this book.

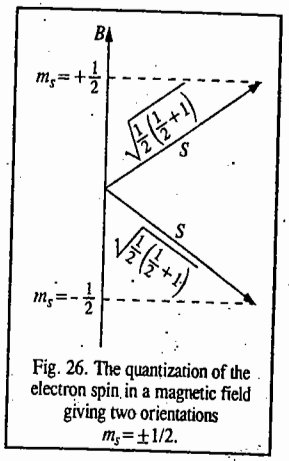

Fig. 26. The quantization of the electron spin in a magnetic field giving two orientations $m_s=\pm 1/2$.

Zeeman Effect. Zeeman, in 1896, found that when a strong magnetic field is applied to a system whose spectrum is being recorded, *each spectral line gets split up into a number of separate lines.* This phenomenon is known as the **Zeeman effect.**

As already stated, there are $(2l+1)$ components of orbital angular momentum vector along any chosen direction, say, the z-direction. The magnitudes of these components are given by $mh/2\pi$. Since the magnetic field generated due to the motion of electron in an orbital has also $(2l+1)$ orientations of

orbital angular momentum vector and since the magnetic field generated depends upon the magnitude of orbital angular momentum, it will also have $(2l+1)$ components along the z-axis whose magnitudes depend on the magnitudes of the z-components of the orbital angular momentum (*i.e.*, $mh/2\pi$).

In the absence of any external magnetic field, all the orientations of the orbital angular momentum (and hence of the magnetic field generated due to the motion of the electron in the orbital) have equal probability to occur. But, if an external magnetic field is applied along the z-axis, the orientation with maximum positive value of m will have maximum magnetic field component *parallel* to the direction of the external field applied. Such an orientation of orbital angular momentum will, therefore, be of lowest energy. Similarly, the orientation with maximum negative value of m will have maximum magnetic field component *antiparallel* to the direction of the external magnetic field applied. Such an orientation will, therefore, be of highest energy. Likewise, the energies of all other orientations of orbital angular momenta having different values of m will be different, ranging between the two extremes mentioned above, in the presence of external magnetic field.

Let us consider the example of a d orbital whose orbital angular momentum is $\sqrt{2(2+1)}\,h/2\pi$. It has five orientations of different energies in the presence of external magnetic field. Each orientation has a different z-component whose value ranges from $+2h/2\pi$ to $-2h/2\pi$, as shown in Fig. 27. Thus, a spectral line obtained in the absence of external magnetic field due to the shift of electron from a higher to a lower d orbital of an atom will be split up into five lines in the presence of the external magnetic field.

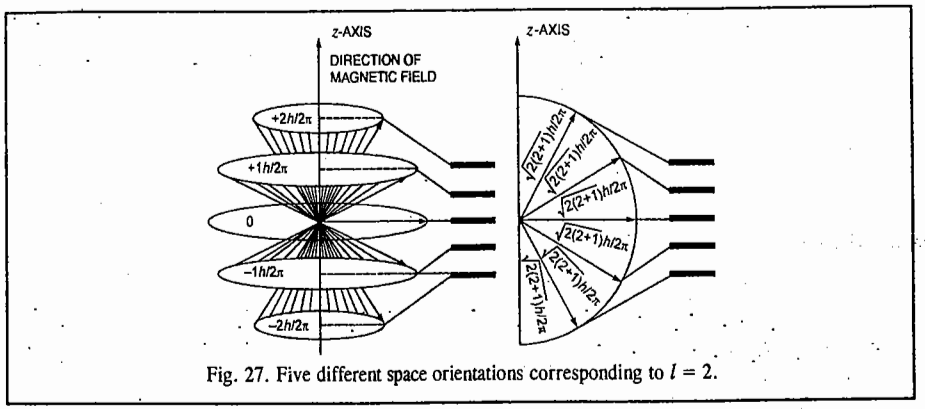

Fig. 27. Five different space orientations corresponding to $l = 2$.

Pauli's Exclusion Principle

This is an important generalisation put forth by Wolfgang Pauli, in 1925, which determines the maximum number of electrons that an energy level can accommodate. Pauli's exclusion principle states that *it is impossible for any two electrons in the same atom to have all the four quantum numbers identical.* Wolfgang Pauli (1900-1958), the Austrian physicist, was awarded the 1945 Physics Nobel Prize for the discovery of the exclusion principle. Thus, in the same atom, any two electrons may have three quantum numbers identical but not the fourth which must be different. This principle is very useful *in determining the maximum number of electrons that can occur in any quantum group.* For K shell, for instance, since $n=1$, l can have only one value (*viz.*, 0) and m can also have only one value (*viz.*, 0). Hence, m_s can be either $+1/2$ or $-1/2$. Thus, there are two combinations of the quantum numbers, as shown:

$$n=1 \quad l=0 \quad m=0 \quad m_s = +1/2$$
$$n=1 \quad l=0 \quad m=0 \quad m_s = -1/2$$

This shows that in the K shell, there is only one subshell $l=0$ and in this only two electrons of opposite spins can be accommodated.

For L shell, since $n = 2$, l can have two values (0 and 1), m can have only one value for $l = 0$ and three values for $l = 1$, *viz.*, -1, 0 and $+1$ and m_s can have two values, *viz.*, $+1/2$ and $-1/2$, for each value of m. These possibilities would give rise to eight combinations of the four quantum numbers, keeping in view the *exclusion principle*. Thus, L shell can accommodate 8 electrons, 2 in the $l = 0$ subshell (s subshell) and 6 in the $l = 1$ subshell (p subshell). Similarly, it can be shown that the M shell can have 18 electrons, 2 in the $l = 0$ subshell (s subshell), 6 in the $l = 1$ subshell (p subshell) and 10 in the $l = 2$ subshell (d subshell) and so on. The *maximum number* of electrons that can be accommodated in the first four principal energy shells as distributed in the various subshells (l values) are given in Table 4.

TABLE 4

Distribution of Electrons in Various Energy Shells and Subshells

Principal energy shell (n)	Subshells (l)	Orbitals (m)	Number of electrons in : Subshell	Number of electrons in : Principal energy shell
1	0 (1s subshell)	0 (one orbital)	2	2
2	0 (2s subshell)	0 (one orbital)	2	8
	1 (2p subshell)	−1, 0, +1 (three orbitals)	6	
3	0 (3s subshell)	0 (one orbital)	2	18
	1 (3p subshell)	−1, 0, +1 (three orbitals)	6	
	2 (3d subshell)	−2, −1, 0, +1, +2 (five orbitals)	10	
4	0 (4s subshell)	0 (one orbital)	2	32
	1 (4p subshell)	−1, 0, +1 (three orbitals)	6	
	2 (4d subshell)	−2, −1, 0, +1, +2 (five orbitals)	10	
	3 (4f subshell)	−3, −2, −1, 0, +1, +2, +3 (seven orbitals)	14	

Physical Interpretation of the Hydrogenic Atomic Orbitals. According to the Bohr theory, the angular momentum L of an electron in an orbital is given by

$$L = n\hbar ; \qquad n = 1, 2, 3,... \qquad ...(260)$$

However, according to wave mechanics, the value of L is given by

$$L = [l(l + 1)]^{1/2}\hbar \qquad ...(261)$$

Thus, while according to the Bohr theory the ground state angular momentum is equal to $\hbar$ since $n=1$ (*i.e.*, it is finite), according to wave mechanics its value is zero (since $l=0$).

It can be shown that, other things being equal, an electron in an orbital of high angular momentum tends to stay farther from the nucleus than an electron in a state of lower angular momentum. Fig. 28 shows the radial parts of the hydrogenic wave functions for the principal quantum number $n = 3$. We see that the higher the value of l, the less likely it is to be found near the nucleus. Thus, for a given value of n, the size of the orbit increases with increase in the azimuthal quantum number, l.

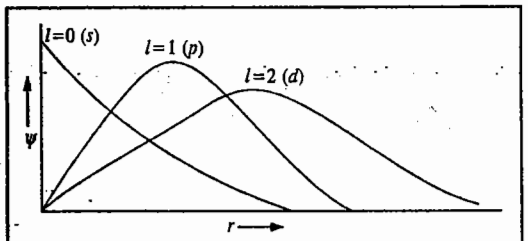

Fig. 28. Radial parts of the hydrogenic wave functions for the principal quantum number n–3.

The increasing order of energy of various orbitals, in general, is as follows :

1s, 2s, 2p, 3s, 3p, 4s, 3d, 4p, 5s, 4d, 5p, 6s, 4f, 5d, 6p, 7s, 5f, 6d.....

Filling of Orbitals. The filling of orbitals in the ground state of an atom is determined by the following rules :

1. The electrons are added one by one to various orbitals as we move from one element to the next in the order of increasing atomic numbers.

2. The electrons enter the various orbitals in the order of increasing energy. This is known as the **aufbau principle**.

3. Electron-pairing in any orbital is not possible until all the available orbitals of a given subshell contain one electron each. This is known as **Hund's rule.**

4. An orbital cannot contain more than two electrons. This is based on Pauli's exclusion principle.

5. Electrons prefer to enter those subshells which, thereby, get either *completely filled* or *just half-filled.*

Electronic configurations of all the known elements based on the above rules are given in the Periodic Table annexed at the beginning of the book.

Fine Structure in the Hydrogen Atomic Spectrum. We have seen that in the Bohr theory of hydrogen atom, the electronic transitions observed in the form of the various spectral series such as Lyman, Balmer, Paschen series, are governed by the selection rule that $\Delta n = 1, 2, 3,....$ *i.e.*, the principal quantum number, n, may change by any integral value. However, observation of the spectrum under conditions of high resolution reveals many additional spectral lines. Bohr's theory cannot explain these additional lines. Schrödinger's quantum mechanics has successfully accounted for these extra lines in the spectrum of hydrogen. It is found that the spectral transitions are governed by the selection rules :

(i) Δn = any integer, *i.e.*, 1, 2, 3,....

(ii) $\Delta l = \pm 1,$

Transitions which obey these selection rules are called **allowed transitions** and transitions which do not obey (or violate) these selection rules are known as **forbidden transitions.**

Angular Momentum in Quantum Mechanics

In quantum mechanics we come across several examples of angular momentum. Thus, angular momentum may be possessed by *(i)* a rotating molecule *(ii)* an electron orbiting around an atom *(iii)* the spinning electrons and *(iv)* certain spinning nuclei. We shall confine ourselves to only a general discussion of angular momentum. For a particle of mass m revolving around a point at a distance r, the

angular momentum L is given by

$$L = mur = mr^2\omega = I\omega \quad ...(262)$$

where u is the linear velocity, ω is the angular velocity ($\omega = u/r$) and I ($=mr^2$) is the moment of inertia of the particle. The particle has kinetic energy E_k given by

$$E_k = \tfrac{1}{2}mu^2 = \tfrac{1}{2}mr^2\omega^2 = \tfrac{1}{2}I\omega^2 \quad ...(263)$$

From Eqs. 262 and 263, kinetic energy can be written in terms of the angular momentum as

$$E_k = L^2/2I \quad ...(264)$$

In three dimensions the angular momentum is represented by a vector, $\vec{L}$. Consider a mass m rotating about a fixed point P with a linear velocity $\vec{u}$. Then, $\vec{L}$ is given by

$$\vec{L} = \vec{r} \times m\vec{u} = \vec{r} \times \vec{p} \quad ...(265)$$

where $\vec{r}$ is the vector from the fixed point P to the mass point and $\vec{p}$ is the linear momentum vector. The vector $\vec{L}$ is perpendicular to the plane defined by $\vec{r}$ and $\vec{p}$. From classical mechanics, the components of the classical angular momentum vector are given by

$$L_x = yp_z - zp_y \quad ...(266)$$

$$L_y = zp_x - xp_z \quad ...(267)$$

$$L_z = xp_y - yp_x \quad ...(268)$$

The square of the angular momentum is given by the scalar product of $\vec{L}$ with itself. Thus,

$$L^2 = \vec{L}.\vec{L} = L_x^2 + L_y^2 + L_z^2 \quad ...(269)$$

The square of the angular momentum is a scalar. If no torque is acting on the particle, its angular momentum remains constant in classical mechanics. Classical mechanics permits all possible values of L.

In quantum mechanics the angular momentum is represented by an operator. The quantum mechanical operators for the components of angular momentum are obtained by replacing the quantities in Eqs. 266, 267 and 268 with their corresponding quantum mechanical operators.

Thus, $\hat{p}_x = -i\hbar\partial/\partial x$, and so on. Hence,

$$\hat{L}_x = -i\hbar\left(y\frac{\partial}{\partial z} - z\frac{\partial}{\partial y}\right) \quad ...(270)$$

$$\hat{L}_y = -i\hbar\left(z\frac{\partial}{\partial x} - x\frac{\partial}{\partial z}\right) \quad ...(271)$$

$$\hat{L}_z = -i\hbar\left(x\frac{\partial}{\partial y} - y\frac{\partial}{\partial x}\right) \quad ...(272)$$

The operator for the square of the momentum is given by

$$\hat{L}^2 = |\vec{L}|^2 = \vec{L}.\vec{L} = \hat{L}_x^2 + \hat{L}_y^2 + \hat{L}_z^2 \quad ...(273)$$

One may now ask if we can measure the angular momentum L and its components L_x, L_y and L_z

simultaneously. It is found from quantum mechanics that, according to Heisenberg's uncertainty principle, only the square of the angular momentum, L^2 and only one of its components can be measured simultaneously, *i.e.*, L^2 and L_x or L^2 and L_y or L^2 and L_z can be simultaneously measured. This fact is expressed by saying that L^2 commutes with one of its components, *i.e.*,

$$[\hat{L}^2, \hat{L}_x] = [\hat{L}^2, \hat{L}_y] = [\hat{L}^2, \hat{L}_z] = 0 \quad ...(274)$$

On the Other hand, $\hat{L}_x$, $\hat{L}_y$; $\hat{L}_y$, $\hat{L}_z$ and $\hat{L}_z$, $\hat{L}_x$ *cannot be simultaneously measured.* In quantum mechanical language, these operators *do not commute with each other, i.e.,*

$$[\hat{L}_x, \hat{L}_y] \neq 0; \quad [\hat{L}_y, \hat{L}_z] \neq 0; \quad [\hat{L}_z, \hat{L}_x] \neq 0 \quad ...(275)$$

Angular momentum is discussed in detail in Chapter 2 ; Eq. 275 is derived there.

Again, in the time-independent Schrödinger equation $\hat{H}\psi = E\psi$, we know that ψ is the eigenfunction and E is the eigenvalue of the Hamiltonian operator, $\hat{H}$. Naturally we want to know the eigenfunctions and eigenvalues of the angular momentum operators. There is another important quantum mechanical result according to which *if two operators commute with each other, they have the same eigenfunctions.* Thus, according to Eq. 274, L^2 and $\hat{L}_z$ (or $\hat{L}^2$ and $\hat{L}_x$, etc.) have the same eigenfunctions, which are spherical harmonics. Keeping in view the above considerations, it can be easily shown that the eigenvalues of $\hat{L}^2$ and $\hat{L}_z$ are

$$|\vec{L}^2| = [l(l+1)]\hbar^2; \quad l = 0, 1\ 2, 3 \quad ...(276)$$

$$|\vec{L}_z| = m_l\hbar; \quad m_l = -l, -l+1, \ldots l-1, l \quad ...(277)$$

where m_l is the component of l along a suitable axis, ; in this case, the z-axis. From Eq. 276,

$$|\vec{L}| = [l(l+1)]^{1/2}\hbar \quad ...(278)$$

Solved Examples in Quantum Mechanics

Example 34. Calculate the magnitude of the angular momentum of an electron that occupies the following atomic orbitals : *(a)* 1*s* *(b)* 3*s* *(c)* 2*p* *(d)* 3*d* *(e)* 3*p*.

Solution : $\vec{L} = [l(l+1)^{1/2}\hbar$; $l = 0,1,2,3$ ($\hbar = 1{\cdot}055 \times 10^{-34}$ J s)

(a) For 1*s* electron : $l = 0$; $|\vec{L}| = 0$

(b) For 3*s* electron : $l = 0$; $|\vec{L}| = 0$

(c) For 2*p* electron : $l = 1$; $|\vec{L}| = [1(1+1)]^{1/2}\hbar = 1{\cdot}414\ \hbar = 1{\cdot}49 \times 10^{-34}$ J s

(d) For 3*d* electron : $l = 2$; $|\vec{L}| = [2(2+1)]^{1/2}\hbar = \sqrt{6}\ \hbar = 2{\cdot}58 \times 10^{-34}$ J s

(e) For 3*p* electron : $l = 1$; $|\vec{L}| = 1{\cdot}414\ \hbar = 1{\cdot}49 \times 10^{-34}$ J s

Example 35. Calculate the angular momentum of a rigid diatomic rotating molecule (say, HCl) in the second rotational energy level. Compare it with the angular momentum of an electron in the 2*p* atomic orbital.

Solution : For a rigid diatomic rotating molecule,

$$|\vec{L}| = [J(J+1)]^{1/2}\ \hbar\ ;\ J = 0,\ 1,\ 2,\ 3....$$

where J is the rotational quantum number. For the second rotational state, $J=1$.

$$\therefore \quad |\vec{L}| = \sqrt{2}\hbar = \sqrt{2}(1{\cdot}055 \times 10^{-34}\ \text{J s}) = 1{\cdot}49 \times 10^{-34}\ \text{J s}.$$

Again, for an electron in an atomic orbital,

$$|\vec{L}| = [l(+1)]^{1/2}\hbar \; ; \; l = 0, 1, 2, 3, \ldots.$$

For the 2*p*-electron, $l = 1$

$$\therefore \quad |\vec{L}| = \sqrt{2}\,\hbar = 1{\cdot}49\times10^{-34} \text{ J s}$$

We see that the two values are the same.

Example 36. The unnormalized angular function, which is a solution of the Φ-equation, is $\Phi(\phi) = N \exp(im\phi)$. Normalize it.

Solution : The wave function is normalized if

$$< \Phi(\phi) \; |\Phi(\phi)> \; = \int_0^{2\pi} \Phi^* \Phi \, d\phi = 1$$

Substituting the value of $\Phi(\phi)$, we have

$$N^2 \int_0^{2\pi} e^{im\phi} e^{-im\phi} d\phi \; = N^2 \int_0^{2\pi} d\phi = N^2(2\pi) = 1$$

$$\therefore \quad N = (1/2\pi)^{1/2}$$

Hence, the normalized angular function is

$$\Phi(\phi) = \frac{1}{\sqrt{2\pi}} . \exp(im\phi)$$

Example 37. Obtain the real functions from the angular functions defined by

$$\Phi_{\pm m}(\phi) = (1/2\pi)^{1/2} \exp(\pm im\phi), \text{ for } m = 1.$$

Solution : $\Phi_{+1}(\phi) = \frac{1}{\sqrt{2\pi}} e^{i\phi}$; $\Phi_{-1}(\phi) = \frac{1}{\sqrt{2\pi}} e^{-i\phi}$

Taking the linear combinations of these functions, we have

$$\Phi_+ = \frac{1}{\sqrt{2\pi}} (e^{i\phi} + e^{-i\phi}) = \frac{1}{\sqrt{2\pi}} (2 \cos \phi)$$

$$\Phi_- = \frac{1}{\sqrt{2\pi}} \left(\frac{e^{i\phi} - e^{-i\phi}}{i} \right) = \frac{1}{\sqrt{2\pi}} (2 \sin \phi)$$

If Φ_+ and Φ_- are further normalized, the normalization constant is found to be $1/\sqrt{2}$. Hence, we have

$$\Phi_+ = \frac{1}{\sqrt{\pi}} \cos \phi \text{ and } \Phi_- = \frac{1}{\sqrt{\pi}} \sin \phi$$

Note : In this problem we have made use of Euler's formula, according to which $e^{\pm i\phi} = \cos \phi \pm i \sin \phi$

Example 38. Determine the radial functions $R_{n,l}(r)$ for *(a)* the 1*s* orbital *(b)* 2*p* orbital.

Solution : *(a)* For the 1*s*-orbital, $n = 1$, $l = 0$. Hence, the associated Laguerre polynomial is

$$L_1^1(\rho) = \frac{d}{d\rho} \left[e^{\rho} \frac{d}{d\rho} (\rho e^{-\rho}) \right] = \frac{d}{d\rho} (1 - \rho) = -1$$

Hence,

$$R_{1,0}(r) = -\left(\frac{2Z}{a_0}\right)^{3/2} \left[\frac{0!}{2(1!)^3} \right]^{1/2} e^{-\rho/2} \rho^0 (-1) = 2\left(\frac{Z}{a_0}\right)^{3/2} e^{-\rho/2} = 2\left(\frac{Z}{a_0}\right)^{3/2} e^{-Zr/a_0}$$

(b) For the 2*p*-orbital, $n = 2$, $l = 1$. Hence, the associated Laguerre polynomial is

$$L_3^3(\rho) = \frac{d^3}{d\rho^3} \left[e^{\rho} \frac{d^3}{d\rho^3} (\rho^3 e^{-\rho}) \right]$$

Now, $\frac{d^3}{d\rho^3} (\rho^3 e^{-\rho}) = \frac{d^2}{d\rho^2} [(3\rho^2 - \rho^3) e^{-\rho}] = (6 - 18\rho + 9\rho^2 - \rho^3) e^{-\rho}$

Hence, we obtain

$$L_3^3(\rho) = \frac{d^3}{d\rho^3} \left[e^{\rho} (6 - 18\rho + 9\rho^2 - \rho^3) e^{-\rho} \right] = \frac{d^3}{d\rho^3} (6 - 18\rho - 9\rho^2 - \rho^3) = -6$$

Hence,

$$R_{2,1}(r) = -\left(\frac{Z}{a_0}\right)^{3/2} \left[\frac{(2-1-1)!}{2\times2[(2+1)!]^2} \right]^{1/2} e^{-\rho/2} \rho(-6) = \left(\frac{Z}{a_0}\right)^{3/2} \frac{1}{2\sqrt{6}} \rho e^{-\rho/2}$$

$$= \frac{1}{2\sqrt{6}} \left(\frac{Z}{a_0}\right)^{5/2} r e^{-Zr/2a_0} \qquad (\because \rho = 2Zr/a_0)$$

Example 39. Show that the 1*s* wavefunction of hydrogen atom given by

$$\psi_{1s} \equiv \psi_{1,0,0} = \frac{1}{\sqrt{\pi}\, a_0^{3/2}} \exp(-r/a_0), \text{ is normalized ; } a_0 \text{ is the Bohr radius.}$$

Solution : For the wavefunction to be normalized the following condition holds :

$$\int \psi_{1s}^* \psi_{1s} d\tau = 1$$

In polar coordinates (r, θ, ϕ), the volume element $d\tau = r^2 \, dr \sin \theta \, d\theta \, d\phi$. Using this expression for $d\tau$ and integrating between appropriate limits, we have

$$\int \psi_{1s}^* \psi_{1s} d\tau \; = \frac{1}{\pi a_0^3} \int_0^{\infty} r^2 e^{-2r/a_0} dr \int_0^{\pi} \sin\theta \, d\theta \int_0^{2\pi} d\phi$$

Each of these integrals can be evaluated separately as follows :

$$\int_0^{2\pi} d\phi \; = 2\pi \text{ and } \int_0^{\pi} \sin\theta \, d\theta = [-\cos\theta]_0^{\pi} \; = -(-1) - (-1) = 2$$

The first integral is evaluated by using the result

$$\int_0^{\infty} x^n e^{-ax} dx = \frac{n!}{a^{n+1}}, \; n \text{ is a positive integer ; } a > 0.$$

Thus, $\int r^2 e^{-2r/a_0} dr \; = \frac{2}{(2/a_0)^3} = \frac{a_0^3}{4}$

$$\therefore \quad \int \psi_{1s}^* \psi_{1s} d\tau = 1$$

Hence, ψ_{1s} is normalized.

Example 40. The un-normalized 1*s* wavefunction for hydrogen atom is given by

$$\psi_{1s} \equiv \psi_{1,0,0} = N \exp(-r/a_0), \text{ where } a_0 \text{ is the Bohr radius.}$$

Determine the normalized wavefunction.

Solution : Here we have to determine the normalization constant, N. For the wavefunction to be normalized, the following condition holds :

$$\int \psi_{1s}^* \psi_{1s} d\tau \; = 1 \qquad \text{(since } \psi_{1s} \text{ is real, } \psi_{1s}^* \text{ is equal to } \psi_{1s})$$

In polar coordinates (r, θ, ϕ), the volume element $d\tau = r^2 \, dr \sin\theta d\theta d\phi$. Using this expression for $d\tau$ and integrating between appropriate limits, we have

$$\int \psi_{1s}^* \psi_{1s} d\tau \; = N^2 \int e^{-2r/a_0} d\tau = N^2 \int_0^{\infty} r^2 e^{-2r/a_0} dr \int_0^{\pi} \sin\theta \, d\theta \int_0^{2\pi} d\phi = 1$$

Each of these integrals can be evaluated separately as follows :

$$\int_0^{2\pi} d\phi \; = 2\pi \text{ and } \int_0^{\pi} \sin\theta \, d\theta = [-\cos\theta]_0^{\pi} \; = -(-1) - (-1) = 2$$

Using the result

$$\int_0^\infty x^n e^{-\alpha x} dx = \frac{n!}{a^{n+1}} \; ; \; n \text{ is a positive integer} \; ; \; a > 0, \text{ we obtain}$$

$$\int_0^\infty r^2 e^{-2r/a_0} dr = \frac{2!}{(2/a_0)^3} = \frac{a_0^3}{4}$$

Hence, $N^2 \, (a_0^3/4) \, (2) \, (2\pi) = 1$

$$\therefore \quad N = 1/\sqrt{\pi} a_0^{3/2}$$

Hence, the normalized ground-state wavefunction is

$$\psi_{1s} = 1/\sqrt{\pi} a_0^{3/2} \exp(-r/a_0)$$

Note : This example is the reverse of the last example.

Example. 41. Show that the 1s and 2s wavefunctions of hydrogen atom, given by

$\psi_{1s} \equiv \psi_{1,0,0} = \dfrac{1}{\sqrt{\pi} a_0^{3/2}} \exp(-r/a_0)$ **and** $\psi_{2s} \equiv \psi_{2,0,0} = \dfrac{1}{4\sqrt{2\pi} \, a_0^{3/2}} \left(2 - \dfrac{r}{a_0}\right) \exp(-r/2a_0)$ **are orthogonal to each other.**

Solution : For the given wavefunctions to be orthogonal, they should satisfy the following condition :

$$\int \psi_{1s} \psi_{2s} \, d\tau = 0$$

Since in polar coordinates, $d\tau = r^2 \, dr \sin\theta \, d\theta \, d\phi$, we have, after integrating between appropriate limits,

$$\int \psi_{1s} \psi_{2s} \, d\tau = \frac{1}{4\sqrt{2\pi} a_0^3} \left[2 \int_0^\infty r^2 e^{-3r/2a_0} dr - \frac{1}{a_0} \int_0^\infty r^3 e^{-3r/2a_0} dr \right] \int_0^\pi \sin\theta \, d\theta \int_0^{2\pi} d\phi$$

Now, $\int_0^\infty \sin\theta \, d\theta \left[-\cos\theta\right]_0^\pi = -(-1) - (-1) = 2$ and $\int_0^{2\pi} d\phi = 2\pi$

Using the standard result $\int_0^\infty x^n e^{-\alpha x} dx = \dfrac{n!}{a^{n+1}}$, we have

$$\int_0^\infty r^2 e^{-3r/2a} a_0 \, dr = \frac{2!}{(3/2a_0)^3} = \frac{16 a_0^3}{27} \text{ and } \int_0^\infty r^3 e^{-3r/2a_0} dr = \frac{3!}{(3/2a_0)^4} = \frac{32 a_0^4}{27}$$

Using the above values of the various integrals we find that

$$\int \psi_{1s} \psi_{2s} \, d\tau = 0$$

Hence, the 1s and 2s wavefunctions of hydrogen atom are orthogonal.

Example 42. Using the normalized wavefunction,

$$\psi_{1s} = (1/\pi a_0^3)^{1/2} \exp(-r/a_0)$$

for the ground state of hydrogen atom, calculate the probability for the electron to be confined in a sphere of radius $r = a_0$, the Bohr radius.

Solution : We know from Born's interpretation of the wave function, the probability is given by

$$P(r) \, dr = \psi^* \, \psi \, d\tau$$

$\therefore$ Integrating, we obtain

$$\int P(r) dr = \int \psi^* \psi d\tau, \quad \text{where } d\tau = r^2 dr \sin\theta \, d\theta \, d\phi$$

or

$$P = \frac{1}{\pi a_0^3} \int_0^{a_0} r^2 e^{-2r} dr \int_0^\pi \sin\theta d\theta \int_0^{2\pi} d\phi = \frac{4}{a_0^3} \int_0^{a_0} r^2 e^{-2r} dr$$

Carrying out integration by parts, we obtain

$$P = \frac{4}{a_0^3} \left\{ \left[\frac{a_0}{2} r^2 e^{-2r/a_0} \right]_0^{a_0} + \left[-\frac{a_0^2}{2} r e^{-2r/a_0} \right]_0^{a_0} + \left[-\frac{a_0^3}{4} e^{-2r/a_0} \right]_0^{a_0} \right\}$$

$$= 5e^{-2} + 1 = \mathbf{0{\cdot}323}$$

Example 43. Calculate the most probable distance, r_{mp}, of the electron from the nucleus in the ground state of hydrogen atom, given that the normalized ground state wavefunction is

$$\psi_{1s} = \frac{1}{\sqrt{\pi} a_0^{3/2}} \exp(-r/a_0)$$

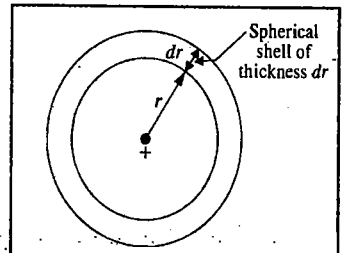

Fig. 29. Spherical shell of thickness dr at a distance r from the nucleus.

Solution : Quantum mechanically, the probability of finding the electron in a spherical shell of thickness dr at a distance r from the nucleus (Fig. 29) is given by

$$P(r)dr = 4\pi \, |\psi_{1s}|^2 \, r^2 dr$$

$$= 4\pi r^2 \, (1/\pi a_0^3) e^{-2r/a_0} \, dr$$

For the probability to be a maximum,

$dP(r)/dr = 0$. Thus,

$$\frac{dP(r)}{dr} = \frac{4}{a_0^3} \left(-\frac{2r^2}{a_0} + 2r \right) e^{-2r/a_0} = 0$$

Since the Bohr radius $a_0 \neq 0$ and the exponential is also $\neq 0$, hence

$$-\frac{2r^2}{a_0} + 2r = 0 \qquad \therefore \; r = r_{mp} = a_0$$

Example 44. Calculate the average distance of the electron from the nucleus in the ground state of hydrogen atom ; given that the normalized ground state wave function is $\psi_{1s} = \dfrac{1}{\sqrt{\pi} a_0^{3/2}} \exp(-r/a_0)$.

Solution : In quantum mechanics, the average (or expectation) value of dynamical variable r is given by

$$< r > = \int \psi_n^* r \psi_n \, d\tau$$

In the present case, the average distance of the electron from the nucleus is given by

$$< r > = \int \psi_{1s}^* r \psi_{1s} \, d\tau$$

Since $d\tau = r^2 \, dr \sin\theta \, d\theta \, d\phi$, hence, integrating between appropriate limits, we get

$$< r > = \frac{1}{\pi a_0^3} \int_0^\infty r^3 e^{-2r/a_0} dr \int_0^\pi \sin\theta \, d\theta \int_0^{2\pi} d\phi = \frac{1}{\pi a_0^3} \left(\frac{3!}{(2/a_0)^4} (2)(2\pi) \right)$$

Note : The results of the last two examples are quite instructive. According to Bohr's theory of hydrogen atom, the distance of the electron from the nucleus in the ground state is exactly equal to a_0, the Bohr radius. But, according to Heisenberg's uncertainty principle, the electron cannot be exactly located in its orbit. Hence, quantum mechanically, while the most probable distance is a_0, the average distance is $3a_0/2$ *i.e.*, the average distance is 50% greater than the Bohr theory result ! The inescapable conclusion we draw from this is that we really do not know where the electron is located in its orbit at a given moment.

Example 45. Show that the average value of $1/r$ for an electron in the 1s-orbital of hydrogen atom is $1/a_0$, where a_0 is the Bohr radius ; given that

$$\psi_{1s} = \frac{1}{\sqrt{\pi} a_0^{3/2}} \exp(-r/a_0)$$

Solution : $< 1/r > = \int \psi_{1s}^* (1/r) \psi_{1s} \, d\tau$

Since $d\tau = r^2\, dr \sin\theta\, d\theta\, d\phi$, hence, integrating between appropriate limits,

$$< 1/r > = \frac{1}{\pi a_0^3}\int_0^\infty r e^{-2r/a_0} dr \int_0^\pi \sin\theta\, d\theta \int_0^{2\pi} d\phi = \frac{1}{\pi a_0^3}\left(\frac{1}{(2/a_0)^2}(2)(2\pi)\right) = \frac{1}{a_0}$$

Example 46. X-rays with λ = 1.0 Å are scattered from a metal block. The scattered radiation is viewed at 90° to the incident radiation. Evaluate the Compton shift.

Solution : Compton shift is $\Delta\lambda = \dfrac{h}{m_e c}(1-\cos\theta)$

or $$\Delta\lambda = \left(\frac{(6.626\times10^{-34}\ \text{Js})(1-\cos 90°)}{(9.109\times10^{-31}\ \text{kg})\,(3\times10^{8}\ \text{m s}^{-1})}\right) = 2.42\times10^{-12}\ \text{m} = 0.024\ \text{Å} \quad [\cos 90° = 0]$$

Example 47. Indicate which of the following functions are acceptable as wave functions :

(*a*) $\psi = x$, (*b*) $\psi = x^2$, (*c*) $\psi = \sin x$, (*d*) $\psi = e^x$, (*e*) $\psi = e^{-x}$,

(*f*) $\psi = e^{-x^2}$, (*g*) $\psi = \tan x$

Solution : (*a*) Not acceptable, as $\psi \to \infty$ as $x \to \infty$;

(*b*) not acceptable,

(*c*) acceptable,

(*d*) not acceptable, as $\psi \to \infty$ as $x \to \infty$;

(*e*) not acceptable, as $\psi \to \infty$ as $x \to -\infty$

(*f*) acceptable, as $\psi \to 0$ as $x \to \pm\infty$;

(*g*) not acceptable, as $\psi \to \infty$ as $x = \pi/2$.

Example 48. Show that the function $\psi(x) = A\exp(ikx)$ represents a de Broglie wave.

Solution : As x changes to $x + \lambda$ (where λ is the wavelength of the de Broglie wave),

$$\psi(x+\lambda) = A\exp(ik(x+\lambda)) = A\exp(ikx).\exp(ik\lambda)$$

$$= A\exp(ikx).\exp(ikh/p) = A\exp(ikx)\exp(2\pi i) \qquad [\because p = k\hbar/2\pi]$$

$$= A\exp(ikx)(\cos 2\pi + i\sin 2\pi) = A\exp(ikx) = \psi$$

Thus, the function $\psi(x)$ repeats after an interval of λ; hence it represents a de Broglie wave.

Example 49. Find the eigenfunctions and eigenvalues of linear momentum operator $\hat{p}_x$. Show that in the absence of any restriction there is a continuous series of eigenvalues of $\hat{p}_x$.

Solution : $\hat{p}_x\psi = \lambda\psi$ [the eigenvalue equation]

Since $\hat{p}_x \to -i\hbar\ (\mathrm{d}/\mathrm{d}x)$, $-i\hbar\dfrac{d\psi}{dx} = \lambda\psi$ where λ is the eigenvalue ψ, or $d\psi/dx = ik\psi$ (where $k = \lambda/\hbar$), whose solution is $\psi = A\exp(ikx)$, which is the required eigenfunction with eigenvalue $\lambda = k\hbar$. If there is no restriction on k there will be no restriction on λ provided ψ is finite, single-valued and continuous for all values of x.

Example 50. What is the Schmidt orthogonalization procedure ?

Solution : We know that eigenfunctions of a Hermitian operator corresponding to different eigenvalues are orthogonal. However, if the eigenfunctions ψ_1 and ψ_2 are degenerate (*i.e.*, they have the same eighnvalues ($\lambda_1 = \lambda_2$), then ψ_1 and ψ_2 may not be orthogonal. However, we can always construct an orthogonal pair ϕ_1 and ϕ_2 by taking suitable linear combinations of ψ_1 and ψ_2 as shown below.

Let ψ_1 and ψ_2 be the two linearly independent degenerate eigenfunctions which are normalized but not orthogonal. Let $\phi_1 = \psi_1$ and $\phi_2 = a_1\psi_1 + a_2\psi_2$. Let $\int\psi_1\psi_2\, d\tau = S$. We have now to determine the coefficients a_1 and a_2 such that

$$\int\phi_1\phi_2\, d\tau = 0 \ ; \text{ and } \int\phi_2\phi_2\, d\tau = 1 \qquad (i)$$

Using the above conditions,

$$\int\psi_1(a_1\psi_1 + a_2\psi_2)\, d\tau = 0 \qquad (ii)$$

or $$a_1\int\psi_1^2\, d\tau + a_2\int\psi_1\psi_2\, d\tau = 0 \ ; \quad \text{or} \quad a_1 + a_2 S = 0 \ ; \text{ or } a_1 = -a_2 S \qquad (iii)$$

Again, $$\int(a_1\psi_1 + a_2\psi_2)^2\, d\tau = 1 \qquad (iv)$$

$$a_1^2\int\psi_1^2\, d\tau + a_2^2\int\psi_2^2\, d\tau + 2a_1a_2\int\psi_1\psi_2\, d\tau = 1 \qquad (v)$$

or $$a_1^2 + a_2^2 + 2a_1a_2 S = 1 \qquad (vi)$$

or $$a_2^2 S^2 + a_2^2 - 2a_2^2 S^2 = 1 \qquad (\because a_1 = -a_2 S \text{ from Eq. (iii)}) \qquad (vii)$$

or $a_2 = (1-S^2)^{-1/2}$, so that $a_1 = -S(1-S^2)^{-1/2}$ (viii)

Hence, the desired orthogonal pair is

$$\phi_1 = \psi_1 ;$$

$$\phi_2 = a_1\psi_1 + a_2\psi_2 = -S(1-S^2)^{-1/2}\psi_1 + (1-S^2)^{-1/2}\psi_2 = (1-S^2)^{-1/2}(\psi_2 - \psi_1 S)$$

This is called the "Schmidt orthogonalization" procedure.

Example 51. Derive the expression for the linear momentum operator of a particle moving in the *x*-direction.

Solution : Consider a particle wave, whose wave function can be represented by the wave function,

$$\psi(x) = A\exp(\pm 2\pi i\, x/\lambda).$$ where λ is the wave length.

Differentiating with respect to x,

$$\frac{d\psi}{dx} = \pm\frac{2\pi i}{\lambda}(A\exp(\pm 2\pi i x/\lambda)) = \pm\frac{2\pi i}{\lambda}\psi \quad (\because \lambda = h/p_x, \text{ by de Broglie's relation})$$

or $$\hat{p}_x\psi = \pm\frac{h}{2\pi i}\frac{d\psi}{dx} = \pm\frac{\hbar}{i}\frac{d\psi}{dx}$$

Removing ψ from both sides, we have

$$\hat{p}_x = \pm(\hbar/i)(d/dx)$$

[+ and − signs refer to positive and negative x-directions, respectively.]

Example 52. Examine if d^2/dx^2 is a Hermitian operator.

Solution : For an operator to satisfy the Hermitian condition we say that if an operator $\hat{A}$ has two eigenfunctions ψ and ϕ, and if

$$\int\psi(\hat{A}\phi)\, d\tau = \int(\hat{A}\psi).\phi\, d\tau \qquad (\psi \text{ and } \phi \text{ are real})$$

or $$\int\psi^*(\hat{A}\phi)\, d\tau = \int(\hat{A}\psi)^*.\phi\, d\tau \qquad (\psi \text{ and } \phi \text{ are complex})$$

then $\hat{A}$ is called the Hermitian operator.

Let $\psi = e^{ix}$, and $\phi = \sin x$ be the two acceptable eigenfunctions. Then,

$$\int\psi(\hat{A}\phi)\, d\tau = \int e^{-ix}\frac{d^2}{dx^2}(\sin x)\, dx = -\int e^{-ix}\sin x\, dx$$

$$\int\phi(\hat{A}\psi)^*\, d\tau = \int\sin x\left[\frac{d^2}{dx^2}(e^{ix})^*\right] dx = \int\sin x\left(i^2 e^{ix}\right)^* dx$$

$$= -\int\sin x\, e^{-ix}\, dx$$

Since the two integrals are the same, d^2/dx^2 is Hermitian.

Example 53. Show that the operator $\hat{p}_x$ for linear momentum is Hermitian.

Solution : It is required to prove that

$$\int_{-\infty}^{\infty} \psi^* \left(-i\hbar \frac{d}{dx}\right) \phi \, dx = \int_{-\infty}^{\infty} \phi \left(-i\hbar \frac{d}{dx}\right)^* \psi^* \, dx$$

Integrating by parts, the left-hand-side is equal to

$$-i\hbar \left[\psi^* \phi\right]_{-\infty}^{\infty} - (-i\hbar) \int_{-\infty}^{\infty} \phi \frac{d\psi^*}{dx} dx = 0 + \int_{-\infty}^{\infty} \phi \left(i\hbar \frac{d}{dx}\right) \psi^* \, dx = \int_{-\infty}^{\infty} \phi \left(-i\hbar \frac{d}{dx}\right)^* \psi^* \, dx = \text{R.H.S.}$$

Hence $\hat{p}_x$ is a Hermitian operator.

Example 54. Show that the Hamiltonian operator for the total energy of a system is Hermitian provided that the eigenfunction is well-behaved.

Solution : $\hat{H} = -\left(\hbar^2/2m\right)\left(d^2/dx^2\right) + \hat{V}(x)$ (in the x-direction)

Assuming the eigenfunctions to be real, it is required to prove that

$$\int_{-\infty}^{\infty} \psi \hat{H} \phi \, dx = \int_{-\infty}^{\infty} \phi \hat{H} \psi \, dx$$

For the potential energy part, we have

$$\int_{-\infty}^{\infty} \psi \hat{V}(x) \phi \, dx = \int_{-\infty}^{\infty} \phi \hat{V}(x) \psi \, dx \qquad (\because \; V(x) \text{ is just a multiplier})$$

For the kinetic energy part,

$$\int_{-\infty}^{\infty} \psi \frac{d^2}{dx^2} \phi \, dx = \left[\psi \frac{d\phi}{dx}\right]_{-\infty}^{\infty} - \int_{-\infty}^{\infty} \frac{d\phi}{dx} \cdot \frac{d\psi}{dx} dx \qquad \text{[integrating by parts]}$$

Also,

$$\int_{-\infty}^{\infty} \phi \frac{d^2}{dx^2} \psi \, dx = \left[\phi \frac{d\psi}{dx}\right]_{-\infty}^{\infty} - \int_{-\infty}^{\infty} \frac{d\psi}{dx} \cdot \frac{d\phi}{dx} dx$$

If the wave functions ψ and ϕ are well-behaved then ψ, $d\psi/dx$, ϕ, $d\phi/dx$ must vanish at infinity, making the first term in each integral zero; the second terms in both the integrals are identical since they differ only in the order of multiplication of $d\psi/dx$ and $d\phi/dx$. Thus, both the potential energy $V(x)$ and the kinetic energy part d^2/dx^2 are Hermitian, while $-(\hbar^2/2m)$ is just a constant factor. Hence proved.

Example 55. Show that if two operators $\hat{A}$ and $\hat{B}$ are Hermitian, then their product $(\hat{A}\hat{B})$ is also Hermitian if and only if $\hat{A}$ and $\hat{B}$ commute.

Solution : Since $\hat{A}\hat{B} = \hat{B}\hat{A}$ (Given),

$$\int \psi^* (\hat{A}\hat{B}) \phi \, d\tau = \int \psi^* (\hat{B}\hat{A}) \phi \, d\tau = \int \psi^* \hat{B} (\hat{A}\phi) \, d\tau$$

Since $\hat{B}$ is Hermitian, the integral is equal to

$$\int (\hat{A}\phi)(\hat{B}\psi)^* \, d\tau = \int (\hat{B}\psi)^* (\hat{A}\phi) \, d\tau = \int \phi \hat{A}^* (B\psi)^* \, d\tau$$

$$= \int \phi (\hat{A}\hat{B})^* \psi^* \, d\tau \qquad (\because \; \hat{A} \text{ is also Hermitian})$$

Hence, $\hat{A}\hat{B}$ is also Hermitian.

Example 56. Calculate the probability that a particle in a one-dimensional box of length a is found to be between 0 and $a/2$.

Solution : The probability that the particle will be found between 0 and $a/2$ is

$$P(0 \le x \le a/2) = \int_0^{a/2} \psi_n^*(x) \psi_n(x) \, dx = \frac{2}{a} \int_0^{a/2} \sin^2 \frac{n\pi x}{a} \, dx$$

Let $n\pi x/a = z$, so that

$$P(0 \le x \le a/2) = \frac{2}{n\pi} \int_0^{n\pi/2} \sin^2 z \, dz = \frac{2}{n\pi} \left| \frac{z}{2} - \frac{\sin 2z}{4} \right|_0^{n\pi/2}$$

$$= \frac{2}{n\pi} \left(\frac{n\pi}{4} - \frac{\sin n\pi}{4}\right) = \frac{1}{2} \quad \text{(for all } n\text{)}$$

Thus, the probability that the particle lies in one-half of the interval $0 \le x \le a/2$ is $\frac{1}{2}$.

Example 57. Assume that a particle of mass m is confined to a cubic box and its energy is 101 $\hbar^2/8ma^2$. What is the degeneracy of this level ?

Solution :

$$E_{n_x, n_y, n_z} = \left(h^2/8ma^2\right)\left(n_x^2 + n_y^2 + n_z^2\right) = \frac{h^2\left(n_x^2 + n_y^2 + n_z^2\right)}{8mV^{2/3}}$$

where V is the volume of the cube. The solution to this problem is to find the sets of quantum numbers that will generate the number 101. By trial and error these are :

10,1,0 ; 10,0,1; 1,10,0; 1,0,10; 0,1,10; 0,10,1; 9,4,2; 9,2,4; 2,9,4; 2,4,9; 4,2,9; 4,9 2; 8,6,1; 8,1,6; 1, 8, 6; 1,6,8; 6,8,1; 6,1,8; 7,6,4; 7,4,6; 6,4,7; 6,7,4; 4,7,6; and 4,6,7. There are thus 24 states in this energy level, so that its degeneracy is **24.**

Example 58. Determine the number of energy states less than $E = 3/2\,kT$ (the translational kinetic energy of an ideal gas molecule) at $T = 298$ K for an N_2 (g) molecule in a container with volume $V = 24{\cdot}8$ dm^3.

Solution : The number of states is given by $N = (\pi V/6h^3)\,(8mE)^{3/2}$. Substituting the data for $N_2(g)$, we have

$$N = \frac{(\pi)(24{\cdot}8\,\text{L})(10^{-3}\,\text{m}^3\,\text{dm}^{-3})}{(6)(6{\cdot}26\times10^{-34}\,\text{J s})^3} \left[(8)\frac{28{\cdot}0\times10^3\,\text{kg mol}^{-1}}{6{\cdot}022\times10^{23}\,\text{mol}^{-1}}\left(\frac{3}{2}\right)(1{\cdot}381\times10^{-23}\,\text{J K}^{-1})(1\,\text{kg m}^2\,\text{s}^{-2}/1\text{J})(298\,\text{K})\right]^{3/2} = 4{\cdot}91\times10^{30}$$

Comment. Notice that the number of energy states is fantastically large! That is why we say that the translational energy is *not* quantized.

Example 59. Show that for a conjugated organic molecule, using the free-electron molecular orbital (FEMO) theory envisaging the particle in a one-dimensional box model, the electronic transition 1→2 is allowed and the transition 1→3 is forbidden.

Solution : An selection rule for an electronic transition states that for allowed transitions the transition moment integral $\langle \psi_n | \mu | \psi_m \rangle \equiv \langle n | \mu | m \rangle \neq 0$, and is zero for forbidden transitions, Now the transition dipole moment $\mu = e\,x$ for motion along the x direction. Using the eigenfunctions $\psi_n(x) = (2/a)^{1/2} \sin(n\pi x/a)$, where a is the width of the box, for1→ 2 transition, $\langle 2|\mu|1\rangle = e \int \psi_2 x \psi_1 \, dx$

$$= \frac{2}{a} e \int \sin\left(\frac{2\pi x}{a}\right) x \sin\left(\frac{\pi x}{a}\right) dx \qquad (i)$$

Recalling that $\sin A \sin B = \frac{1}{2}\cos(A-B) - \frac{1}{2}\cos(A+B)$, we find that

$$\langle 2|\mu|1\rangle \propto \int x \left[\cos(\pi x/a) - \cos(3\pi x/a)\right] dx \qquad (ii)$$

and $$\langle 3|\mu|1\rangle \propto \int \sin\left(\frac{3\pi x}{a}\right) x \sin\left(\frac{\pi x}{a}\right) dx \propto \int x\left[\cos(2\pi x/a) - \cos(4\pi x/a)\right] dx \qquad (iii)$$

Both the integrals (*ii*) and (*iii*) can be evaluated using the standard form

$$\int x(\cos A\,x)\,dx = (1/A^2)\cos Ax + (x/A)\sin A\,x$$

$$\int_0^a x\cos(\pi x/a)\,dx = \frac{1}{(\pi/a)^2}\cos(\pi x/a)\Big|_0^a + \frac{x}{(\pi/a)}\sin(\pi x/a)\Big|_0^a = -2(a/\pi)^2 \neq 0$$

$$\int_0^x x\cos(3\pi x/a)\,dx = \frac{1}{(3\pi/a)^2}\cos(3\pi x/a)\Big|_0^a + \frac{x}{(3\pi/a)}\sin(3\pi x/a)\Big|_0^a = -2(a/3\pi)^2 \neq 0$$

Hence, $<2|\mu|1> \equiv \mu_{21} \neq 0$, so that $1 \rightarrow 2$ electronic transition is allowed. Similarly, $<3|\mu|1> \equiv \mu_{31} = 0$ so that $1 \rightarrow 3$ electronic transition is forbidden.

Example 60. An electron of mass m_e is constrained to move along a circular ring on which the potential energy is constant. Set up and solve the Schrödinger wave equation for this system.

Solution : The Schrödinger equation (assuming that potential energy V is zero) can be written as

$$\frac{d^2\psi}{dx^2} + k^2\psi = 0, \qquad k^2 = 2mE/\hbar^2 \tag{i}$$

The general solution of this equation is

$$\psi = A\cos kx + B\sin kx \tag{ii}$$

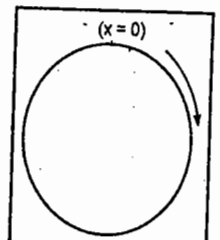

Fig. 30. Electron moving in a ring of constant potential energy.

(See Fig. 30 for the motion of the electron.) In this Figure, an arbitrary point on the ring is chosen as origin (*i.e*, $x = 0$) and the coordinate x varies around the circular ring the length of whose circumference is C. Since the wave functions must be single-valued, we have

$$\psi(x) = \psi(x + C) \tag{iii}$$

The boundary conditions are different from those of a one-dimensional box. From Eq. (*iii*), $\psi(0) = \psi(C)$, so that

$$A = A\cos kC + B\sin kC \tag{iv}$$

Recall that with the particle in a one-dimensional box there was discontinuity in $d\psi/dx$ at the walls of the box because at those points there was a discontinuity in the potential energy. This implied that while ψ was continuous, $d\psi/dx$ was not.

However, in the present case where there is no discontinuity in V, both ψ and $d\psi/dx$ must be continuous. Hence, we have here another condition,

$$\left(\frac{d\psi}{dx}\right)_{x=0} = \left(\frac{d\psi}{dx}\right)_{x=C} \tag{v}$$

This leads to the following equation :

$$Bk = Bk\cos kC - Ak\sin kC \tag{vi}$$

Multiplying Eq. (*iv*) with Ak and Eq. (*vi*) with B and adding, we obtain

$$\cos kC = 1, \text{ or } kC = 2n\pi\,,\ n = 0, \pm1, \pm2, \ldots \quad \text{(because } \cos(-\theta) = \cos\theta) \tag{vii}$$

Hence, the energy levels are given by

$$E_n = \frac{n^2h^2}{2mC^2} \tag{viii}$$

which follows from Eq. (*vii*) and the fact that $k^2 = 2mE/\hbar^2$.

A comparison of these results with those of the electron in a one-dimensional box shows that in the present case the quantum number n can have values of zero, positive or negative integers so that each energy level, except for $n = 0$, is doubly degenerate. The unnormalized wave functions may be written as

$$\psi_n(x) = A\cos(2n\pi x/C) + B\sin(2n\pi x/C) \tag{ix}$$

which follows from Eqs. (*ii*) and (*vii*). For a state with $n = 0$ for which $E = 0$, the wave function is given by

$$\psi_0 = A = \text{constant} \tag{x}$$

Thus, in the ground state the wave function does not vary around the ring. Therefore, the zero point energy is not encountered when the potential energy does not change around the circular ring. This, of course, does not violate the Heisenberg uncertainty principle because the electron can be found anywhere on the ring with equal probability and therefore the uncertainty in its position in infinite.

The relationship between constants A and B can be obtained from the normalization of the eigenfunctions :

$$\int_0^C [A\cos(2n\pi x/C) + B\sin(2n\pi x/C)]^2\,dx$$

$$= A^2\int_0^C \cos^2(2n\pi x/C)\,dx + B^2\int_0^C \sin^2(2n\pi x/C)\,dx + 2AB\int_0^C \cos(2n\pi x/C)\sin(2n\pi x/C)\,dx = 1$$

or $$(A^2 + B^2)C/2 = 1$$

or $$A^2 + B^2 = 2/C \tag{xi}$$

from which it follows that A and B can be written as

$$A = (2/C)^{1/2}\sin\alpha, \qquad B = (2/C)^{1/2}\cos\alpha \tag{xii}$$

where α can have any value. Hence the normalized wave functions are

$$\psi_n(x) = (2/C)^{1/2}\sin\alpha\cos(2n\pi x/C) + (2/C)^{1/2}\cos\alpha\sin(2n\pi x/C)$$

$$= (2/C)^{1/2}\sin((2n\pi x/C) + \alpha) \tag{xiii}$$

Example 61. Confirm that a Gaussian function of the form $\exp(-\beta x^2)$ is an asymptotic solution of the Schrödinger wave equation for the ground state of a one-dimensional S.H.O., and find the expression for β in terms of mass and force constant of the oscillator.

Solution : $-\frac{\hbar^2}{2m}\frac{d^2\psi}{dx^2} + \frac{1}{2}kx^2 = E\psi$ . . [Schrödinger equation for S.H.O.]

In an asymptotic solution the wave function $\psi(x) \rightarrow 0$ as $x \rightarrow \infty$.

$$\psi = e^{-\beta x^2}\,, \text{ so } d\psi/dx = -2\beta x e^{-\beta x^2}$$

$$d^2\psi/dx^2 = -2\beta e^{-\beta x^2} + 4\beta^2x^2e^{-\beta x^2} = -2\beta\psi + 4\beta^2x^2\psi$$

Substituting in the Schrödinger equation, we obtain

$$\left(\frac{\hbar^2\beta}{m}\right)\psi - \left(\frac{2\hbar^2\beta^2}{m}\right)x^2\psi + \frac{1}{2}kx^2\psi = E\psi \quad \text{(where } k \text{ is the force constant)}$$

or, $$\left[\left(\frac{\hbar^2\beta}{m}\right) - E\right]\psi + \left(\frac{1}{2}k - \frac{2\hbar^2\beta^2}{m}\right)x^2\psi = 0$$

The equation is satisfied (since $\psi \neq 0$ for this will imply a trivial solution) if

$$E = \frac{\hbar^2\beta}{m} \text{ and } 2\hbar^2\beta^2 = \frac{1}{2}mk \text{ or } \beta = \frac{1}{2}\left(\frac{mk}{\hbar^2}\right)^{1/2}$$

Therefore, $$E = \frac{1}{2}\hbar\left(\frac{k}{m}\right)^{1/2} = \frac{1}{2}\hbar\omega \quad \text{where } \omega = (k/m)^{1/2} \text{ is the angular fraquency of the oscillator.}$$

Example 62. State and verify Bohr's Correspondence Principle.

Solution : The Bohr correspondence principle states that quantum mechanics reduces to classical mechanics in the limit of large quantum numbers. This can be illustrated by an example Bohr chose from the line spectrum of a hydrogenic atom. Classically, during the periodic motion of an electron in a stationary atom, the frequency of light emitted by the atom is equal to its frequency of revolution, ν_r. Now, from the Bohr theory of hydrogen atom,

$$\nu_r = \frac{v_n}{2\pi r_n} = \frac{me^4}{2\pi n^3 h^3} \quad \text{(in c.g.s. units)}$$

(where v_n is the velocity of the electron in the nth orbit of radius r_n.) For the transition $(n+1) \to n$, the frequency of the emitted radiation is given by

$$\nu = \frac{2\pi^2 me^4}{h^3}\left[\frac{1}{n^2} - \frac{1}{(n+1)^2}\right] = \frac{2\pi^2 me^4}{h^3}\left[\frac{2n+1}{n^2(n+1)^2}\right] \quad \text{(in c.g.s. units)}$$

We see that $\nu \to \nu_r$ when $n \to \infty$, as required by the correspondence principle.

Example 63. Show that the average distance of the electron from the nucleus in hydrogen atom is $6a_0$ in the 2s-state and $5a_0$ in the $2p_z$ state, where a_0 is the Bohr radius.

Solution :

$$\psi_{2s} = \frac{1}{4\sqrt{2\pi}}\left(\frac{Z}{a_0}\right)^{3/2}\left(2 - \frac{Zr}{a_0}\right)\exp(-Zr/a_0) \qquad (Z=1)$$

$$\langle r_{2s}\rangle = \int \psi_{2s}^* r\, \psi_{2s}\, d\tau = \frac{1}{32\pi a_0^3}\int_0^\infty \left(2 - \frac{r}{a_0}\right)^2 \exp(-r/a_0)\, r.r^2\, dr \int_0^\pi \sin\theta \int_0^{2\pi} d\phi$$

$$= \frac{1}{8a_0^3}\int_0^\infty \left(4r^3 - \frac{4r^4}{a_0} + \frac{r^5}{a_0^2}\right)^2 \exp(-r/a_0)\, dr \qquad [d\tau = r^2 dr \sin\theta\, d\theta\, d\phi]$$

$$= \frac{1}{8a_0^3}\left[\frac{4\times 3!}{\left(\frac{1}{a_0}\right)^4} - \frac{4\times 4!}{a_0\left(\frac{1}{a_0}\right)^5} + \frac{5!}{a_0^2\left(\frac{1}{a_0}\right)^6}\right] = 6a_0 \qquad \text{(using standard integrals)}$$

Again,

$$\psi_{2p_z} = \frac{1}{\sqrt{32\pi}}\left(\frac{Z}{a_0}\right)^{5/2}(r)\exp(-Zr/2a_0)\cos\theta \qquad (Z=1)$$

$$\langle r_{2p_z}\rangle = \int \psi^*_{2p_z}\, r\, \psi_{2p_z}\, d\tau = \frac{1}{32\pi a_0^5}\int_0^\infty (r\exp(-r/2a_0))^2\, r.r^2 dr \int_0^\pi \sin\theta\, \cos\theta\, d\theta \int_0^{2\pi} d\phi$$

$$= \frac{1}{32\pi a_0^5}\int_0^\infty r^5 \exp(-r/a_0)\, dr \int_0^\pi \frac{\sin 2\theta}{2} d\theta \int_0^{2\pi} d\phi$$

$$= \frac{1}{24 a_0^5}\frac{5!}{\left(\frac{1}{a_0}\right)^6} = 5a_0$$

Example 64. Show by explicit integration that hydrogenic $2p_x$ and $2p_y$ orbitals are mutually orthogonal.

Given

$$\psi_{2p_x} = \frac{1}{4\sqrt{2\pi}}\left(\frac{Z}{a_o}\right)^{3/2} \rho\, e^{-\rho/2} \sin\theta\cos\phi$$

$$\psi_{2p_y} = \frac{1}{4\sqrt{2\pi}}\left(\frac{Z}{a_0}\right)^{3/2} \rho e^{-\rho/2} \sin\theta\sin\phi; \quad \rho = Zr/a_0$$

Solution : $\psi_{2p_x} = f(r)\sin\theta\cos\phi$; $\psi_{2p_y} = f(r)\sin\theta\sin\phi$

$$\therefore \int_{\text{all space}} \psi_{2p_x}\psi_{2p_z}\, d\tau = \int_{\text{all space}} \psi_{2p_x}\psi_{2p_y} r^2 dr \sin\theta\, d\theta\, d\phi$$

$$= \int_0^\infty f(r)^2 r^2\, dr \int_0^\pi \sin^2\theta\, d\theta \int_0^{2\pi} \cos\phi\, \sin\phi\, d\phi$$

The first factor is non-zero since the radial functions are normalized. The second factor is $\pi/2$. The third factor is zero. Hence, the product of the three integrals is zero and the given wavefunctions are **orthogonal.**

Note : We can also solve the problem by recalling that $p_x \propto x/r$, and $p_y \propto y/r$. Thus,

$$\int_{\text{all space}} p_x p_y\, dx\, dy\, dz = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} (xy/r^2)\, dx\, dy\, dz$$

This is an integral of an odd function of x and y over the entire range of variables from $-\infty$ to $+\infty$. Therefore, the integral is zero.

Example 65. Show that the three $2p$-eigenfunctions of hydrogen atom are orthogonal to each other.

Solution : The three $2p$-eigenfunctions of hydrogen atom are

$$\psi_{200} = \frac{1}{\pi^{1/2}}\left(\frac{Z}{2a_0}\right)^{3/2}(1 - Zr/2a_0)\exp(-Zr/2a_0)$$

$$\psi_{210} = \frac{1}{\pi^{1/2}}\left(\frac{Z}{2a_0}\right)^{5/2} r\exp(-Zr/2a_0)\cos\theta = c_1 r\exp(-r/2a_0)\cos\theta$$

$$\psi_{21\pm1} = \frac{1}{8\pi^{1/2}}\left(\frac{Z}{a_0}\right)^{5/2} r\exp(-Zr/2a_0)\sin\theta\exp(\pm i\phi) = c_2 r\exp(-r/2a_0)\sin\theta\exp(\pm i\phi)$$

where c_1 and c_2 are constants and $Z=1$. The ϕ-dependent part of $\psi^*_{21,1}\psi_{21,-1}$ gives $\exp(-2i\phi)$. The corresponding ϕ-integral becomes

$$\int_0^{2\pi} e^{-2i\phi}\, d\phi = \frac{1}{-2i}\left[e^{-2i\phi}\right]_0^{2\pi} = 0$$

The ϕ-integral of $\int \psi^*_{210}\int \psi_{211}\, d\tau = \int_0^{2\pi} e^{i\phi}\, d\phi = 0$

The ϕ-integral of $\int \psi^*_{210}\, \psi_{21,-1}\, d\tau = \int_0^{2\pi} e^{-i\phi}\, d\phi = 0$

Thus, the three $2p$-eigenfunctions of hydrogen atom are orthogonal to each other. Note that we did not carry out the r-integration and θ-integration, because the ϕ-integration vanishes, so the product of the three integrations vanishes.

Example 66. Prove that $1s$, $2p$ and $3d$ orbitals of a hydrogen-like atom show a single maximum in the radial probability curves. Obtain the values at which these maxima occur.

Solution : The radial probability density $P_{nl} = r^2|R_{nl}|^2$ where

$$R_{10} = (\text{constant})\exp(Zr/a_0)$$

$$R_{21} = (\text{constant})\, r\exp(-Zr/2a_0); \quad R_{32} = (\text{constant})\, r\exp(-Zr/3a_0)$$

P_{nl} will be a maximum when $dP_{nl}/dr = 0$. Therefore,

$$\frac{dP_{10}}{dr} = 0 = (\text{constant})\left(2r - 2Zr^2/a_0\right)\exp(-2Zr/a_0) \text{ or } r = a_0/Z$$

$$\frac{dP_{21}}{dr} = 0 = \text{(constant)}\ (4r^3 - Zr^4/a_0)\exp(-Zr/a_0) \quad \text{or} \quad r = 4a_0/Z$$

Similarly $\frac{dP_{32}}{dr} = 0$ gives $r = 9\ a_0/Z$

In general, $r_{max} = n^2\ a_0/Z$

Comment. The result $r_{max} = a_0/Z$ suggests that the 1*s*- orbital of atoms shrinks in proportion to the increase in *Z*.

Example 67. State the virial theorem and apply it to (*a*) an S.H.O; and (*b*) hydrogen atom.

Solution : Virial theorem states that if the potential energy $V(x)$ of a quantum system moving in the *x*-direction is of the form, $V(x) \propto x^s$, where *s* is constant, then the expectation (mean) value of kinetic energy, $\langle \hat{T} \rangle$, and the expectation value of the potential energy, $\langle \hat{V} \rangle$, are related by

$$\langle \hat{T} \rangle = \frac{1}{2} s \langle \hat{V} \rangle$$

(*a*) S.H.O : $V(x) = \frac{1}{2}kx^2$, where *k* is force constant, so here $s = 2$. Hence, $\langle \hat{T} \rangle = \frac{1}{2}(2)\langle \hat{V} \rangle$, *i.e.*, $\langle \hat{T} \rangle = \langle \hat{V} \rangle$.

(*b*) Hydrogen atom : $V(r) = \frac{-Ze^2}{4\pi\varepsilon_0 r}$; here $x \to r$; $s = -1$

$$\therefore \quad \langle \hat{T} \rangle = \frac{1}{2}(-1)\langle \hat{V} \rangle = -\frac{1}{2}\langle \hat{V} \rangle$$

Example 68. Confirm that function $\psi = \cos ax \cos by \cos cz$ is an eigenfunction of the Laplacian operator ∇^2 and determine its eigenvalue.

Solution : In cartesian coordinates (x,y,z) the Laplacian operator is

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$$

Now, $\frac{\partial^2 \psi}{\partial x^2} = \frac{\partial^2 (\cos ax \cos by \cos cz)}{\partial x^2} = -a^2 \cos ax \cos by \cos cz = -a^2\psi$

Similarly, $\frac{\partial^2 \psi}{\partial y^2} = -b^2\psi$; $\frac{\partial^2 \psi}{\partial z^2} = -c^2\psi$

Thus, $\nabla^2\psi = -(a^2 + b^2 + c^2)\ \psi$

We see that ψ is an eigenfunction of ∇^2 with the eigenvalue $-(a^2+b^2+c^2)$.

Example 69. If the interelectron repulsion in helium atom is ignored, what would be its ground state energy and the wavefunction ?

Solution : He atom has two electrons. For a hydrogen-like atom we know that

$$E_1 = -13.6\,Z^2\ \text{eV}, \text{ and } \psi_{100} = \left(Z^3/\pi a_0^3\right)^{1/2} \exp(-Zr/a_0)$$

When the interelectronic repulsion energy is ignored, the energy of the system is the sum of the energies of two electrons and the wave function is the product of the two 1*s*-wave functions. Thus,

$$E = -13.6\,Z^2 - 13.6\,Z^2 = -108.8\ \text{eV} \qquad [Z = 2 \text{ for helium atom}]$$

$$\psi = \psi_1(r_1)\,\psi_2(r_2) = \frac{1}{\pi}\left(\frac{Z}{a_0}\right)^3 \exp\left[-Z(r_1 + r_2)/a_0\right]$$

where r_1 and r_2 are the radius vectors of electrons 1 and 2, respectively.

Example 70. What is the most probable distance of the electron of hydrogen atom in its 2*p*-state ? What is the radial probability at that distance ?

Solution : Radial probability density $P_{nl}(r) = r^2\ |R_{nl}|^2$, where

$$R_{21} = \left(\frac{1}{2a_0}\right)^{3/2} \frac{1}{a_0\sqrt{3}}\, r \exp\left(-r/2a_0\right)$$

$$\therefore \quad P_{21}(r) = r^2 R_{21}^2 = \frac{1}{24\,a_0^5}\, r^4 \exp(-r/a_0)$$

For $P_{21}(r)$ to be maximum

$$\frac{d\,P_{21}(r)}{dr} = \frac{1}{24\,a_0^5}\left(4r^3 - \frac{r^4}{a_0}\right)\exp\left(-r/a_0\right) = 0$$

or $r_{mp} = 4a_0$. Thus, the most probable distance is four times the Bohr radius ; and $P_{21}(4a_0) = (32/3a_0)\ \exp(-4)$.

Example 71. Calculate the "size" of a hydrogen atom in its ground state by assuming that the size of an atom is measured by the radius of a sphere that contains 90 percent of the charge density of the electrons in the outermost occupied orbital.

Solution : The hydrogen atom has only one electron which occupies the 1*s*-orbital in the ground state,

$\psi_{1s} = \frac{1}{\pi a_0^{3/2}}\ \exp(-r/a_0)$. Hence, the probability of the electron being within a sphere of radius r' is

$$P = \int_0^{r'}\int_0^{\pi}\int_0^{2\pi} \psi_{1s}^2\, r^2\, dr \sin\theta\, d\theta\, d\phi\,.$$

The integral over θ and ϕ gives a factor of 4π, so that

$$0{\cdot}90 = \frac{4}{a_0^3}\int_0^{r'} r^2\, e^{-2r/a_0}\, dr$$

The integral in the above expression is evaluated by integration by parts, giving

$$-\frac{a_0\, r^2\, e^{-2r/a_0}}{2}\Bigg|_0^{r'} + a_0\left[-\frac{a_0\, r\, e^{-2r/a_0}}{2}\Bigg|_0^{r'} + \frac{a_0}{2}\left(-\frac{a_0\, e^{-2r/a_0}}{2}\right)\Bigg|_0^{r'}\right]$$

$$= -\frac{a_0\,(r')^2\, e^{-2r'/a_0}}{2} - \frac{a_0^2\, r'}{2}\, e^{-2r'/a_0} - \frac{a_0^3}{4}\, e^{-2r'/a_0} + \frac{a_0^3}{4}$$

Multiplying by $\left(4/a_0^3\right)$ and factoring $\exp(-2r'/a_0)$, we get

$$0{\cdot}90 = \left[-2\left(\frac{r'}{a_0}\right)^2 - 2\left(\frac{r'}{a_0}\right) - 1\right] e^{-2r'/a_0} + 1$$

or $$2\left(\frac{r'}{a_0}\right)^2 + 2\left(\frac{r'}{a_0}\right) + 1 = 0{\cdot}10\ e^{-2r'/a_0}$$

This equation can be solved numerically to give $r' = 2.66\ a_0$, which is thus the "size" of the hydrogen atom in the ground state.

Example 72. The energy of atoms and molecules, as obtained by solving the Schrödinger equation, is generally expressed in units of 'hartrees' after Hartree who has done fundamental work in quantum mechanics. Verify that 1 hartree=27·2 eV.

Solution : 1 hartree $= e^2/a_0$ where a_0, the Bohr radius, is given by $a_0=\hbar^2/me^2$

$\therefore$ 1 hartree $= me^4/\hbar^2$ (in c.g.s. units)

$$= \frac{me^4}{(4\pi\varepsilon_0)^2\hbar^2} \quad \text{(in SI units)}$$

Let us solve this problem in both the units.

(i) In c.g.s. units :

$$1 \text{ hartree} = \frac{(9{\cdot}107\times10^{-23}\text{g})(4{\cdot}8\times10^{-10}\text{e.s.u.})^4}{(1{\cdot}0545\times10^{-27}\text{ergs})^2(1{\cdot}602\times10^{-12}\text{erg / eV})} = 27{\cdot}2 \text{ eV}$$

(ii) In SI units :

$$1 \text{ hartree} = \frac{(9{\cdot}107\times10^{-31}\text{kg})(1{\cdot}602\times10^{-19}\text{C})^4}{(1{\cdot}11264\times10^{-10}\text{C}^2\text{N}^{-1}\text{m}^{-2})^2(1{\cdot}0545\times10^{-34}\text{Js})^2(1{\cdot}602\times10^{-19}\text{J/eV})} = 27{\cdot}2 \text{ eV}$$

Note : 1 hartree of energy is also called the atomic unit (a.u.) of energy.

1 hartree = 27·2 eV = 2Ry where Ry = Rydberg.

Example 73. Write the Hamiltonian for the following quantum systems: *(a)* Helium atom *(b)* Lithium atom *(c)* H_2^+ *(d)* H_2 *(e)* H_2^-. Which of the terms is hardest to handle in solving the Schrödinger equation in each case ?

Solution : ***(a)* He atom :** It contains one nucleus and two electrons numbered 1 and 2 (Fig. 31). Here r_1 is the distance of electron 1 from the nucleus, r_2 is the distance of electron 2 from the nucleus and r_{12} is the interelectron distance. The charge on the electron is e while that on the nucleus is Ze (Here Z=2).

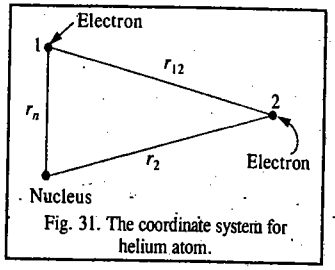

Fig. 31. The coordinate system for helium atom.

The Hamiltonian for the system is given by

$$\hat{H} = -\frac{\hbar^2}{2m}\nabla_1^2 - \frac{\hbar^2}{2m}\nabla_2^2 - \frac{2e^2}{4\pi\varepsilon_0 r_1} - \frac{2e^2}{4\pi\varepsilon_0 r_2} + \frac{e^2}{4\pi\varepsilon_0 r_{12}} \quad \ldots(i)$$

$$= -\frac{\hbar^2}{2m}(\nabla_1^2+\nabla_2^2) + \frac{2e^2}{4\pi\varepsilon_0}\left(\frac{-1}{r_1}-\frac{1}{r_2}\right) + \frac{e^2}{4\pi\varepsilon_0 r_{12}} \quad \ldots(ii)$$

In Eq. *(i)*, the first two terms are the kinetic energy (Laplacian) operators for electrons 1 and 2, respectively ; the third and fourth terms give the attraction of two electrons to the nucleus and the last term gives the repulsion between the two electrons ; it is called the inter-electron repulsion energy term.

***(b)* Lithium atom.** It contains one nucleus and three electrons 1, 2 and 3 (here Z = 3). Hence,

$$\hat{H} = -\frac{\hbar^2}{2m}(\nabla_1^2+\nabla_2^2+\nabla_3^2) + \frac{1}{4\pi\varepsilon_0}\left[-\frac{3e^2}{r_1}-\frac{3e^2}{r_2}-\frac{3e^2}{r_3}+\frac{e^2}{r_{12}}+\frac{e^2}{r_{23}}+\frac{e^2}{r_{31}}\right]$$

The interpretation of these terms is similar to that given in *(a)* above. The last three terms are interelectron repulsion energy terms.

(c) H_2^+. It contains two nuclei A and B and one electron Z = 1(Fig. 32).

The Hamiltonian is given by

$$\hat{H} = -\frac{\hbar^2}{2m}\nabla^2 + \frac{1}{4\pi\varepsilon_0}\left[-\frac{e^2}{r_A}-\frac{e^2}{r_B}+\frac{e^2}{R_{AB}}\right]$$

There is no interelectron repulsion term here because the system contains only one electron. The last term is internuclear repulsion energy term.

(d) H_2 : It contains two nuclei A and B and two electrons 1 and 2. Z=1 (Fig. 33). The Hamiltonian of the system is given by

$$\hat{H} = -\frac{\hbar^2}{2m}(\nabla_1^2+\nabla_2^2) + \frac{1}{4\pi\varepsilon_0}\left[-\frac{e^2}{r_{A_1}}-\frac{e^2}{r_{A_2}}-\frac{e^2}{r_{B_1}}-\frac{e^2}{r_{B_2}}+\frac{e^2}{r_{12}}+\frac{e^2}{R_{AB}}\right]$$

Here the term e^2/r_{12} is the interelectron repulsion term and the last term is the internuclear repulsion.

(e) H_2^-. It contains three electrons 1, 2, 3 and two nuclei A and B. Hence,

$$\hat{H} = -\frac{\hbar^2}{2m}(\nabla_1^2+\nabla_2^2+\nabla_3^2) + \frac{1}{4\pi\varepsilon_0}\left[-\frac{e^2}{r_{A_1}}-\frac{e^2}{r_{A_2}}-\frac{e^2}{r_{A_3}}-\frac{e^2}{r_{B_1}}-\frac{e^2}{r_{B_2}}-\frac{e^2}{r_{B_3}}+\frac{e^2}{r_{12}}+\frac{e^2}{r_{13}}+\frac{e^2}{r_{23}}+\frac{e^2}{R_{AB}}\right]$$

Here the interelectron repulsion terms are (e^2/r_{12}), (e^2/r_{13}) and (e^2/r_{23}) while the last term is internuclear repulsion term.

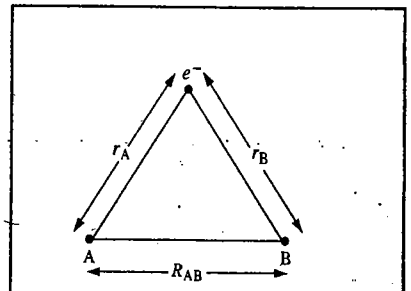

Fig. 32. The coordinate system for H_2^+.

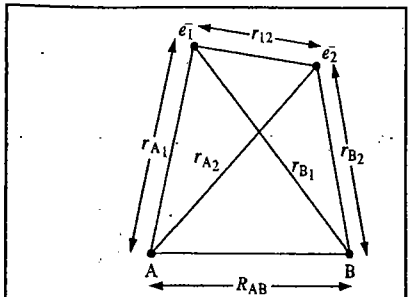

Fig. 33. The coordinate system for H_2.

In all the above cases, the interelectron repulsion term is the most difficult to handle in solving the Schrödinger equation. For molecules, the internuclear term is considered a constant since the nuclei are infinitely heavier than the electrons.

Example 74. Define the term degeneracy of an energy level. Calculate the degeneracies of the following systems : *(i)* third energy level of a particle in a one-dimensional box of infinite height *(ii)* the rigid diatomic rotor in the third rotational energy level *(iii)* the hydrogen atom in the third energy state and *(iv)* the hydrogen atom in the third excited state.

Solution : When two or more wave functions (eigenfunctions) belong to the same energy state, *i.e.*, have the same energy, the energy level is said to be degenerate, *i.e.*, it is said to possess degeneracy, g. Degeneracy is a dimensionless quantity. An energy level with g = 2 is called two-fold degenerate and an energy level with g = 3 is called three-fold degenerate, and so on.

(i) In this case, g = 1, *i.e.*, the energy level is **non-degenerate.** One-dimensional systems are always non-degenerate in all the energy levels.

(ii) For a diatomic molecule rotating as a rigid rotor, the degeneracy is given by

$$g_J = 2J+1 \; ; \; J=0, 1, 2, 3,....$$

where J is the rotational quantum number.

Here J=2 ; hence, $g_2 = 2\times2+1=5$, *i.e*, the energy level is *five-fold degenerate.*

(iii) For hydrogen atom, since the energy is given by

$$E_n = -R_H/n^2 \text{ where } n = 1, 2, 3, 4,....,$$

the degeneracy is given by $g_n = n^2$.

Here n=3, so that $g_3=(3)^2=9$, *i.e.*, the energy level is **nine-fold degenerate.**

(iv) Here n=4, so that $g_4=(4)^2=16$, *i.e.*, the energy level is **16-fold degenerate.**

Example 75. Calculate the degeneracies of a particle of mass m in a three-dimensional cubical box of width a having energies equal to *(i)* 6 *(ii)* 9 *(iii)* 12 and *(iv)* 14 in units of $(h^2/8ma^2)$.

Solution : $E_{n_x, n_y, n_z} = (n_x^2 + n_y^2 + n_z^2)(h^2/8ma^2)$, where $n_x, n_y, n_z = 1, 2, 3, \ldots$

Here we shall tabulate the various combinations of n_x, n_y and n_z which give rise to the energies given above.

(i) $n_x^2 + n_y^2 + n_z^2 = 6$:

Three different combinations of n_x, n_y and n_z, *viz.*, (2, 1, 1), (1, 2, 1) and (1, 1, 2) give energy $= 6(h^2/8ma^2)$.

Hence, $g=3$, *i.e.*, the energy level is **three-fold degenerate.**

n_x	n_y	n_z
2	1	1
1	2	1
1	1	2

(ii) $n_x^2 + n_y^2 + n_z^2 = 9$:

The combinations are (2, 2,1), (2, 1, 2) and (1, 2, 2).

Hence, $g=3$.

n_x	n_y	n_z
2	2	1
2	1	2
1	2	2

(iii) $n_x^2 + n_y^2 + n_z^2 = 12$

$g=1$ because only one combination (2, 2, 2) gives energy$=12(h^2/8ma^2)$. The energy level is **non-degenerate.**

(iv) $n_x^2 + n_y^2 + n_z^2 = 14$:

Here, six combinations, as shown, give energy$=14(h^2/8ma^2)$.

Hence, $g=6$. The energy level is thus **six-fold degenerate**

n_x	n_y	n_z
1	2	3
1	3	2
2	1	3
3	1	2
2	3	1
3	2	1

Hermitian Operators. Hermitian operators, named after the 19th century mathematician Charles Hermite, play a very important role in quantum mechanics. An operator $\hat{A}$ is said to be *Hermitian* if

$$\int \psi_1^* (\hat{A}\psi_2) d\tau = \int (\hat{A}\psi_1)^* \psi_2 d\tau \qquad \ldots(279)$$

where ψ_1 and ψ_2 are the eigenfunctions of the operator $\hat{A}$. The asterisk shown as superscript represents the complex conjugate of the quantity. We shall prove a significant result that a *Hermitian operator has real eigenvalues*. Since $\hat{A}$ is an operator it obeys the eigenvalue equation

$$\hat{A}\psi = \lambda\psi \qquad \ldots(280)$$

where ψ is the eigenfunction of $\hat{A}$ and λ is its eigenvalue. Multiplying both sides of Eq. 280 by the complex conjugate of ψ, *viz.*, ψ^* and integrating over all space, we have

$$\int \psi^* \hat{A}\psi \, d\tau = \lambda \int \psi^* \psi \, d\tau \qquad \ldots(281)$$

Taking the complex conjugate of every quantity in Eq. 280, we obtain

$$\hat{A}^* \psi^* = \lambda^* \psi^* \qquad \ldots(282)$$

Multiplying both sides with ψ and integrating over all space, we obtain

$$\int \psi A^* \psi^* \, d\tau = \lambda^* \int \psi^* \psi \, d\tau \qquad \ldots(283)$$

According to the definition of the Hermitian operator, the left hand sides of Eqs. 281 and 283 are

equal, so that

$$\lambda \int \psi^* \psi d\tau = \lambda^* \int \psi^* \psi d\tau \qquad \ldots(284)$$

i.e., $\lambda = \lambda^*$. This means that the eigenvalue λ is equal to its complex conjugate which is true only if λ is *real*. Since most of the observables (observable quantities) are represented by Hermitian operators in quantum mechanics, they have real eigenvalues.

Important Theorems of Quantum Mechanics

1. Theorem 1. Two eigenfunctions of a Hermitian operator with different eigenvalues are orthogonal.

2. Theorem 2. If two operators commute, they have the same set of eigenfunctions.

3. Theorem 3. A wavefunction which is not an eigenfunction of an operator, $\hat{A}$, can be arbitrarily expanded in a series of orthonormal functions *i.e.*, it can be written as a **linear superposition** of the orthonormal eigenfunctions of $\hat{A}$.

Proof of Theorem 1. Let $\hat{A}$ be the Hermitian operator. Then its eigenvalue equations are

$$\hat{A}\psi_1 = \lambda_1\psi_1 \qquad \ldots(285)$$

$$\hat{A}\psi_2 = \lambda_2\psi_2 \qquad \ldots(286)$$

where ψ_1 and ψ_2 are the eigenfunctions of $\hat{A}$ with λ_1 and λ_2 the corresponding eigenvalues, respectively. Taking the complex conjugate of Eq. 285 and recalling that λ_1 is real,

$$\hat{A}^*\psi_1^* = \lambda_1\psi_1^* \qquad \ldots(287)$$

Multiplying Eq. 287 on the left by ψ_2 and integrating,

$$\int \psi_2 \hat{A}\psi_1^* d\tau = \lambda_1 \int \psi_2 \psi_1^* d\tau \qquad \ldots(288)$$

Again, multiplying Eq. 286 on the left by ψ_1^* and integrating,

$$\int \psi_1^* \hat{A}\psi_2 d\tau = \lambda_2 \int \psi_1^* \psi_2 d\tau \qquad \ldots(289)$$

Since $\hat{A}$ is a Hermitian operator, the left hand sides of Eqs. 288 and 289 are equal so that

$$\lambda_1 \int \psi_2 \psi_1^* d\tau = \lambda_2 \int \psi_1^* \psi_2 d\tau \quad \text{or} \quad (\lambda_1 - \lambda_2) \int \psi_1^* \psi_2 d\tau = 0 \qquad \ldots(290)$$

Since $\lambda_1 \neq \lambda_2$, $\int \psi_1^* \psi_2 d\tau = 0$. Thus, ψ_1 and ψ_2 are orthogonal.

Proof of Theorem 2. Let $\hat{A}$ be the operator whose eigenvalue equation is

$$\hat{A}\psi_i = a_i\psi_i \qquad \ldots(291)$$

where ψ_is are the set of eigenfunctions with a_is as the corresponding eigenvalues.

Since $\hat{A}$ and $\hat{B}$ commute, hence

$$\hat{A}\hat{B} = \hat{B}\hat{A} \qquad \ldots(292)$$

Operating on ψ_i, $\hat{A}\hat{B}\psi_i = \hat{B}\hat{A}\psi_i = \hat{B}(a_i\psi_i) = a_i(\hat{B}\psi_i)$ $\ldots(293)$

This shows that $(\hat{B}\psi_i)$ is an eigenfunction of $\hat{A}$ with eigenvalue a_i. This is possible only if $(\hat{B}\psi_i)$ is a multiple of ψ_i, *i.e.*,

$$\hat{B}\psi_i = b_i\psi_i \qquad \ldots(294)$$

In other words, ψ_i is also an eigenfunction of $\hat{B}$.

Proof of Theorem 3. The proof of this theorem has not been rigorously established but it seems to be valid for Hermitian operators. This theorem states that

$$\psi = \sum_i c_i \phi_i \qquad \ldots(295)$$

where ψ is an arbitrary function and ϕ_i are orthonormal functions, *i.e.*, they are both orthogonal and normalized :

$$\left.\begin{aligned} \int \phi_i^* \phi_j \, d\tau &= 0 \quad \text{(orthogonality condition)} \\ \int \phi_i^* \phi_i \, d\tau &= 1 \quad \text{(normalization condition)} \end{aligned}\right\} \qquad \ldots(296)$$

The two conditions, or criteria, can be summed up by the relation

$$\int \phi_i^* \phi_j \, d\tau = \delta_{ij} = \begin{cases} 1, & i = j \\ 0, & i \neq j \end{cases} \qquad \ldots(297)$$

where δ_{ij} is called the **Kronecker delta** in honour of the 19th century German mathematician Leopold Kronecker (1823–1891).

4. Virial Theorem. According to the virial theorem, if the potential energy $V(x)$ of a quantum mechanical system moving in the x-direction is of the form

$$V(x) \propto x^s, \qquad \ldots(298)$$

where s is a constant, then the expectation (average) value of the kinetic energy, $\langle \hat{T} \rangle$ and the expectation value of the potential energy, $\langle \hat{V} \rangle$ are related by

$$\langle \hat{T} \rangle = \tfrac{1}{2} s \langle \hat{V} \rangle \qquad \ldots(299)$$

Virial theorem is a very important theorem in quantum mechanics and is the real test of the accuracy of the wavefunction of the quantum mechanical system (atom or molecule), obtained by the solution of the Schrödinger wave equation by the Hartree–Fock self-consistent field (SCF) method.

5. Variation Theorem. If ψ is the approximate wave function of a quantum mechanical system described by the Hamiltonian, $\hat{H}$, then the expectation value of the energy, $\langle E \rangle$ given by the integral

$$\langle E \rangle = \int \psi^* \hat{H} \psi \, d\tau \equiv \langle \psi^* | \hat{H} | \psi \rangle \qquad \ldots(300)$$

is an *upper limit* to the ground state energy, E_0, of the system, *i.e.*,

$$E \geq E_0 \qquad \ldots(301)$$

6. Koopmanns' Theorem. The ionization potential (energy) of a molecule is equal to the negative of the energy of the HOMO (highest occupied molecular orbital). This theorem was discovered by T. Koopmanns, the cowinner of the 1975 Nobel Memorial Prize in Economics.

7. Unsöld Theorem. The electron density in a completely filled atomic orbital is spherically symmetric.

8. Hellmann–Feynman Theorem. Discovered independently by H. Hellmann and R.P. Feynman, it states that the force acting on each nucleus of a molecule is exactly that calculated by classical electrostatics from the charges and positions of the other nuclei and the electrons. Since at the equilibrium configuration of a molecule the resultant force acting on each nucleus vanishes, for this

configuration the repulsion of a given nucleus by other nuclei is just balanced by its attraction by the electrons. This important theorem gives deeper insight into molecular electronic structure and has inspired considerable theoretical research activity.

9. Kramers Theorem. It states that in the absence of the external magnetic field, the electronic states of any molecule or ion having an odd number of electrons are at least doubly degenerate. If follows that all complicated interactions (spin–spin interaction, spin–orbit interaction and ligand–field splitting) in transition metal ions cannot remove the degeneracy of a state with total electron spin $S = \frac{1}{2}, \frac{3}{2}, \frac{5}{2}$, etc. (Note that $(2S+1)$ is the **multiplicity** of a state so that the states with $S = \frac{1}{2}, \frac{3}{2}, \frac{5}{2}$, etc. are doublet, quartet and sextet states, respectively.) The spin degeneracy of systems containing odd number of electrons is called **Kramers' degeneracy**. The spin-levels are split even in the absence of the magnetic field, the splitting being referred to as **zero-field splitting** (ZFS).

10. Jahn-Teller Theorem. According to this theorem a non-linear molecule in an electronically degenerate state always distorts itself into a less symmetric but more stable configuration in which the electronic degeneracy has been removed.

11. Bohr's Correspondence (or Complementarity) Principle. It states that classical mechanics and quantum mechanics tend to give the same result when systems are in highly excited quantum states.

Since science is an intellectual edifice based on theories, which must ultimately be tested by experiment, and theories imply the existence of theorems, important theorems such as those mentioned above are a part of the scientist's arsenal and must be on his/her fingertips.

I. Review Questions

1. Describe Planck's quantum theory of radiation. State and explain Einstein's photoelectric equation.
2. Using the Bohr postulates derive the equation for the energy of hydrogen atom.
3. Derive the Brogile relation. How was it verified ?
4. Set up and solve the Schrödinger wave equation for a particle in an infinite one-dimensional box, with potential energy zero inside the box. Normalize the wavefunctions.
5. Show that $\exp(ikx)$ is an eigenfunction of the operator d/dx. Also show that $\exp(kx^2)$ is not an eigenfunction of d/dx.
6. Determine which of the following functions are eigenfunctions of the operator d^2/dx^2 : *(a)* $\exp(ikx)$, *(b)* $\cos kx$, *(c)* $\exp(-\alpha x^2)$? Determine the eigenvalue where appropriate. **[Ans. *(a)*, *(b)*]**
7. Show that for a particle in a one-dimensional box of width a,

   (i) $\langle x \rangle = a/2$ *(ii)* $\langle p_x \rangle = 0$ *(iii)* $\langle x^2 \rangle = a^2 \left[\frac{1}{3} - \frac{1}{2\pi^2 n^2} \right]$

8. Discuss the solution of Schrödinger wave equation for a particle in a three-dimensional cubic box with edges of length a assuming that the potential is zero within the box and infinite outside the box. What is meant by degeneracy of energy levels?
9. Set up the Schrödinger wave equation for a simple harmonic oscillator, and solve it for the energy eigenvalues.
10. Derive an expression for the energy of a rigid rotor using the Schrödinger wave equation.
11. Write the Schrödinger wave equation for hydrogen atom in terms of polar coordinates. Separate the resultant equation in three equations using the technique of separation of variables. How do the quantum numbers n, l and m emerge from the solution of the wave equation ?
12. Show that the following radial wavefunction of hydrogen atom is normalized :

$$R_{1,0}(r) = (2/a_0)^{3/2} \exp(-r/a_0)$$

II. Problems

1. The work function of cesium metal is 2·14 eV. Calculate the kinetic energy and the speed of electrons emitted when the metal is irradiated with light of wave length *(a)* 700 nm *(b)* 300 nm.
[Ans. *(a)* No ejection *(b)* 837 km s^{-1}]

2 Calculate the short and long wave length limits of the Lyman series in the spectrum of hydrogen atom ($R_H = 1{\cdot}09677 \times 10^8\ m^{-1}$). [Ans. λ_s = 911·6 Å, λ_l = 1215 Å]

3. In the Balmer series for hydrogen spectrum what is the wave length of the series limit ? [Ans. 364·7 μ]

4. Calculate the de Brolie wave length of a body of mass 1 mg moving with a velocity of 10 m s^{-1}
[Ans. $6{\cdot}626\times10^{-29}$ m]

5. Calculate the de Broglie wave length of electron that has been accelerated through a potential difference of 100 V. [Ans. 0·1226 nm]

6. An electron has kinetic energy $2{\cdot}8\times10^{-25}$ J. Calculate the Broglie wave length. $m_e = 9{\cdot}1\times10^{-31}$ kg.
[Ans. $\lambda = 9{\cdot}245\times10^{-7}$ m]

7. Calculate the uncertainty in the velocity of an electron if the uncertainty in its position is approximately 1 Å.
[Ans. $5{\cdot}8\times10^{-7}$ m s^{-1}]

8. An electron in a one-dimensional box of width 1 Å undergoes a transition from the ground state (n=1) to the first excited state (n=2). Calculate the transition energy in eV. [Ans. $1{\cdot}128\times10^2$ eV]

9. A proton in a one-dimensional box of width 1 Å undergoes a transition from the ground state to the first excited state. Calculate the transition energy in eV. [Ans. $6{\cdot}141\times10^{-2}$ eV]

10. Calculate the probability (P) of finding a particle between 0·49 a and 0·51 a for the states y_1 and y_2, where a is the width of the one-dimensional infinite box. [Ans. P_1 = 0·0399 ; P_2 = 0·0001]

11. Neglecting the electron spin, calculate the degeneracy, g_n, of the energy levels of hydrogen atom with the following values of the principal quantum number, n : *(a)* 1 *(b)* 2 *(c)* 3 *(d)* 4. [Ans. *(a)* 1 *(b)* 4 *(c)* 9 *(d)* 16]

12. A radio station operates at a frequency of 108·7 MHz. If the power output is 250 kW, what is the rate of emission of the quanta from the station ? [Ans. $3{\cdot}4\times10^{30}$ quanta/second]

13. Calculate the number of times the electron goes around the first Bohr orbit of hydrogen atom per second. The Bohr radius = 0·529 0 Å.

[Hint : $T = 2\pi a_0/v$, where T is the time period and v is the velocity. Also number of revolutions of the electron is $n = 1/T$]. [Ans. $6{\cdot}57\times10^{15}$ s^{-1}]

14. An atom makes a transition from an excited state with lifetime of 1 ns to the ground state by emitting a photon of wave length 600 nm. Calculate the uncertainty in the energy of the excited state. Also calculate the percentage uncertainty if the energy is measured from the ground state. [Hint : $\Delta E.\Delta t \geq h/4\pi$; Also, $E = h\nu$]
[Ans. $5{\cdot}28\times10^{-26}$ J ; $1{\cdot}6\times10^{-5}$ %]

15. Determine which of the following functions are eigenfunctions of the operator d/dx : *(a)* exp (ikx) *(b)* cos kx *(c)* kx *(d)* exp $(-ax^2)$? Determine the eigenvalue where appropriate. [Ans. *(a)*]

16. Which of the functions given in the last problem are eigenfunctions of the operator d^2/dx^2 ? Give the eigenvalue where appropriate. [Ans. *a, b*]

17. Verify that the wave function $\psi(x) = x\,e^{-ax^2}$ is an eigenfunction of the operator $d^2/dx^2 - 4a^2x^2$. What is the corresponding eigenvalue ? [Ans. $-6a$]

18. An electron in a one-dimensional box of width 10 Å undergoes a transition from the ground state to the first excited state. Calculate the wave length of the photon absorbed. [Ans. λ = 10,29999 Å]

19. Calculate the ground state energy (in kJ mol^{-1}) for an electron that is confined to a one-dimensional infinite potential well with a width of 0·2 nm. [Ans. 907 kJ mol^{-1}]

20. Calculate the degeneracies of the first six energy levels for a particle in an infinite cubical box.
[Ans. 1, 3,3, 3, 1, 6]

21. Calculate the degeneracy of the energy level with energy equal to
(i) $11(h^2/8ma^2)$ and *(ii)* $12(h^2/8ma^2)$ for a particle in a cubical box. [Ans. *(i)* 3 *(ii)* 1]

22. Calculate the probability of locating the particle in the ground state one-dimensional box between $a/4$ and $3a/4$, where a is the width of the box. [Ans. 0·83]

23. Calculate the wave lengths of the first three lines of Paschen series for hydrogen atom.

CHAPTER 2

QUANTUM MECHANICS–II. ADVANCED TOPICS AND ATOMIC SPECTRA

After discussing simple applications of quantum mechanics in Chapter 1, we shall deal with advanced topics in quantum mechanics including the solution of Schrödinger equation for quantum mechanics of many-electron atoms, approximation methods, angular momentum, atomic spectra and quantum mechanical tunneling, in this chapter.

Solution of Schrödinger Equation for Multi-Electron Atoms

The Schrödinger wave equation cannot be solved exactly for atoms beyond hydrogen atom in the periodic table. The troublesome term is the interelectron repulsion term in the Hamiltonian because of which the n–electron wave equation cannot be split into n one–electron wave equations. Hence, methods have been developed for the approximate solution of the multi–electron Schrödinger wave equation. In this book we shall deal briefly with these methods omitting mathematical details. One of these methods is based on the time-independent perturbation theory and the other, called the variation method, involves the selection of a trial wave function.

1. The Time–independent Perturbation Theory. The Schrödinger wave equation to be solved is

$$\hat{H}\psi = E\psi \qquad ...(1)$$

The Hamiltonian is decomposed into two parts as

$$\hat{H} = \hat{H}^{(0)} + \lambda\hat{H}' \qquad ...(2)$$

where $\hat{H}^{(0)}$ is the unperturbed part and $\lambda\hat{H}'$ is the **perturbation** where λ is the *perturbation parameter* which measures the deviation of the problem of interest from the unperturbed system. It is further assumed that

$$\lambda\hat{H}' << \hat{H}^{(0)} \qquad ...(3)$$

In general, λ is set equal to unity which means that perturbation is fully applied. Associated with $\hat{H}^{(0)}$ are a set of eigenvalues $E_1^{(0)}$, $E_2^{(0)}$, ..., $E_n^{(0)}$ and the corresponding eigenfunctions $\psi_1^{(0)}$, $\psi_2^{(0)}$, ... $\psi_n^{(0)}$, *i.e.*,

$$\hat{H}\psi_n^{(0)} = E_n^{(0)}\psi_n^{(0)} \qquad ...(4)$$

It is assumed that the eigenfunctions ψ_n and the energy eigenvalues E_n of the total Hamiltonian $\hat{H}$ can be expressed in the form of a power series of λ :

$$\psi_n = \psi_n^{(0)} + \lambda\psi_n^{(1)} + \lambda^2\psi_n^{(2)} + \lambda^3\psi_n^{(3)} + ... \qquad ...(5)$$

$$E_n = E_n^{(0)} + \lambda E_n^{(1)} + \lambda^2 E_n^{(2)} + \lambda^3 E_n^{(3)} + ... \qquad ...(6)$$

The first term in Eq. 5 is the zeroth–order term, the second represents the first order correction ;

the third represents the second-order correction, etc., to the unperturbed zeroth-order term. The eigenfunctions $\psi_n^{(1)}$, $\psi_n^{(2)}$,... and the eigenvalues $E_n^{(1)}, E_n^{(2)}$, ... are independent of λ and $\psi_n^{(1)}$, $\psi_n^{(2)}$, ... are so chosen that they are orthogonal to $\psi_n^{(0)}$ which is assumed to be normalized.

Substituting Eqs. 5 and 6 in Eq. 1, we get

$$\left(\hat{H}^{(0)} + \lambda \hat{H}'\right)\left(\psi_n^{(0)} + \lambda\psi_n^{(1)} + \lambda\psi_n^{(2)} + \ldots\right)$$

$$= \left(E_n^{(0)} + \lambda E_n^{(1)} + \lambda^2 E_n^{(2)} + \ldots\right)\left(\psi_n^{(0)} + \lambda\psi_n^{(1)} + \lambda^2\psi_n^{(2)} + \ldots\right)$$

or $$\left(\hat{H}^{(0)} - E_n^{(0)}\right)\psi_n^{(0)} + \lambda\left(\hat{H}'\psi_n^{(0)} + \hat{H}^{(0)}\psi_n^{(1)} - E_n^{(1)}\psi_n^{(0)} - E_n^{(0)}\psi_n^{(1)}\right) = 0 \quad \ldots(7)$$

Since the perturbation parameter λ is arbitrary, the coefficient of each power of λ must vanish separately and, therefore, we have

$$\hat{H}^{(0)}\psi_n^{(0)} = E_n^{(0)}\psi_n^{(0)} \quad \ldots(8)$$

$$\hat{H}'\psi_n^{(0)} + \hat{H}^{(0)}\psi_n^{(1)} = E_n^{(1)}\psi_n^{(0)} + E_n^{(0)}\psi_n^{(1)} \quad \ldots(9)$$

$$H'\psi_n^{(1)} + \hat{H}^{(0)}\psi_n^{(2)} = E_n^{(2)}\psi_n^{(0)} + E_n^{(1)}\psi_n^{(1)} + E_n^{(0)}\psi_n^{(2)} \quad \ldots(10)$$

We are ordinarily interested only in the terms upto second order ; we, therefore, neglect equations beyond Eq. 10. It may be noted that Eq. 8 is identical with Eq. 4 as expected since it refers to the zero-order perturbation. We shall now consider the following two cases of perturbation theory :

A. Nondegenerate Perturbation Theory

Here we shall consider perturbation on nondegenerate energy levels. It will be convenient to use the wave function itself to label the states.

1. First-order correction to the energy. Multiplying Eq. 9 from the left by $\left\langle\psi_n^{(0)}\right|$, we get

$$\left\langle\psi_n^{(0)}\middle|\hat{H}'\middle|\psi_n^{(0)}\right\rangle + \left\langle\psi_n^{(0)}\middle|\hat{H}^{(0)}\middle|\psi_n^{(1)}\right\rangle = E_n^{(1)}\left\langle\psi_n^{(0)}\middle|\psi_n^{(0)}\right\rangle + E_n^{(0)}\left\langle\psi_n^{(0)}\middle|\psi_n^{(1)}\right\rangle \quad \ldots(11)$$

Since $\hat{H}^{(0)}$ is Hermitian, the second term on the left reduces to $E_n^{(0)}\left\langle\psi_n^{(0)}\middle|\psi_n^{(1)}\right\rangle$ and Eq. 11 gives

$$E_n^{(1)} = \left\langle\psi_n^{(0)}\middle|\hat{H}'\middle|\psi_n^{(0)}\right\rangle \quad \ldots(12)$$

In simplified form, Eq. 12 can be written as

$$E_n^{(1)} = \langle n|\hat{H}'|n\rangle \quad \ldots(13)$$

which is called the **matrix element.** The first order correction to the energy is thus the expectation (average) value of the perturbation Hamiltonian over the corresponding unperturbed states of the system (atom or a molecule).

2. First order correction to the wave function. The first order correction to the wave function is written as a linear combination of the unperturbed eigenfunctions of the system :

$$\psi_n^{(1)} = \sum_{l=1}^{\infty} a_l\psi_l^{(0)} \quad \ldots(14)$$

Substitution of Eq. 14 in Eq. 9 and multiplication from the left by $\left\langle\psi_m^{(0)}\right|$, gives

$$\left\langle\psi_m^{(0)}\middle|\hat{H}'\middle|\psi_n^{(0)}\right\rangle + \sum_{l=1}^{\infty} a_l E_l^{(0)}\left\langle\psi_m^{(0)}\middle|\psi_l^{(0)}\right\rangle = E_n^{(1)}\left\langle\psi_m^{(0)}\middle|\psi_n^{(0)}\right\rangle + \sum_{l=1}^{\infty} a_l E_n^0\left\langle\psi_m^{(0)}\middle|\psi_l^{(0)}\right\rangle$$

or $$\left\langle\psi_m^{(0)}\middle|\hat{H}'\middle|\psi_n^{(0)}\right\rangle + a_m E_m^{(0)} = a_m E_n^{(0)}$$

or $$a_m = \frac{\left\langle\psi_m^{(0)}\middle|\hat{H}'\middle|\psi_n^{(0)}\right\rangle}{E_n^{(0)} - E_m^{(0)}} = \frac{\langle m|\hat{H}'|n\rangle}{E_n^{(0)} - E_m^{(0)}} \quad \ldots(15)$$

All the as except a_n in Eq. 14 can be calculated using Eq. 15. The coefficient a_n is found to be zero from the normalization condition $\langle\psi_n|\psi_n\rangle = 1$. It follows that

$$\psi_n^{(1)} = \sum_m{}' \frac{\langle m|\hat{H}'|n\rangle}{E_n^{(0)} - E_m^{(0)}}\left|\psi_m^0\right\rangle \quad \ldots(16)$$

Consequently, the energy and wave function corrected to first order are

$$E_n = E_n^{(0)} + \langle m|\hat{H}'|n\rangle \quad \ldots(17)$$

and $$\psi_n = \psi_n^{(0)} + \sum_m{}' \frac{\langle m|\hat{H}'|n\rangle}{E_n^{(0)} - E_m^{(0)}}\left|\psi_m^0\right\rangle \quad \ldots(18)$$

where the prime on the sum means that the state $m=n$ should be excluded.

3. Second-order correction to the energy. We use the same procedure to obtain the second-order correction to the energy from Eq. 10. Multiplying Eq. 10 from left by $\left\langle\psi_n^{(0)}\right|$ and using the Hermitian property of the unperturbed Hamiltonian $\hat{H}^{(0)}$, we obtain

$$\left\langle\psi_n^{(0)}\middle|\hat{H}'\middle|\psi_n^{(1)}\right\rangle = E_n^{(2)}\left\langle\psi_n^{(0)}\middle|\psi_n^{(0)}\right\rangle + E_n^{(1)}\left\langle\psi_n^{(0)}\middle|\psi_n^{(1)}\right\rangle \quad \ldots(19)$$

The form of $\psi_n^{(1)}$, Eq. 16, suggests that the second term on the right vanishes. Therefore,

$$E_n^{(2)} = \left\langle\psi_n^{(0)}\middle|\hat{H}'\middle|\psi_n^{(1)}\right\rangle \quad \ldots(20)$$

Substituting the value of $\psi_n^{(1)}$ in Eq. 20, we have

$$E_n^{(2)} = \sum_m{}' \frac{\langle \psi_m^{(0)} | \hat{H}' | \psi_n^{(0)} \rangle \langle \psi_n^{(0)} | \hat{H}' | \psi_m^{(0)} \rangle}{E_n^{(0)} - E_m^{(0)}} = \sum_m{}' \frac{\langle m|\hat{H}'|n\rangle \langle n|\hat{H}'|m\rangle}{E_n^{(0)} - E_m^{(0)}} \quad ...(21)$$

If $\hat{H}'$ is Hermitian $\langle n|\hat{H}'|m\rangle = \langle m|\hat{H}'|n\rangle^*$. Then,

$$E_n^{(2)} = \sum_m{}' \frac{|\langle m|\hat{H}'|n\rangle|^2}{E_n^{(0)} - E_m^{(0)}} \quad ...(22)$$

Since $|\langle m|\hat{H}'|n\rangle|^2$ is always positive, the sign of the correction is determined by the denominator in Eq. 22. The second-order correction to the energy level n due to energy levels for which $E_n^{(0)} > E_m^{(0)}$ is positive, whereas that due to levels for which $E_n^{(0)} < E_m^{(0)}$ is negative.

It can be further shown that

$$E_n^{(3)} = \langle \psi_n^{(0)} | \hat{H}' | \psi_n^{(2)} \rangle \quad ...(23)$$

and

$$E_n^{(n)} = \langle \psi_n^{(0)} | \hat{H}' | \psi_n^{(n-1)} \rangle \quad ...(24)$$

These equations show that the calculation of nth order energy requires a knowledge of $(n-1)$th order eigenfunctions. Since the contribution of second order, third order, etc., terms goes on successively decreasing, we are primarily interested in the first order correction. The above treatment is called the **Rayleigh-Schrödinger perturbation theory.**

4. Second-order correction to the wavefunction. The second-order correction to the wave function, $\psi_n^{(2)}$, is written as a linear combination of the unparturbed wave functions of the system :

$$\psi_n^{(2)} = \sum_k b_k \psi_k^{(0)} \quad ...(25)$$

Substitution of Eq. 25 in Eq. 10 and multiplication from left by $\langle \psi_l^0 |$, gives

$$\sum_m{}' a_m \langle l|\hat{H}'|m\rangle + \sum_k{}' b_k \langle l|\hat{H}^{(0)}|k\rangle = E_n^{(2)} \langle l|n\rangle + \sum_m{}' a_m E_n^{(1)} \langle l|m\rangle + \sum_k b_k E_n^{(0)} \langle l|k\rangle$$

The first term on the right is zero. Rearranging, we get

$$b_l \left(E_l^{(0)} - E_n^{(0)}\right) = E_n^{(1)} a_l - \sum_m{}' a_m \langle l|\hat{H}^{(0)}|m\rangle$$

Substituting the values of the as and $E_n^{(1)}$, we get

$$b_l = \frac{\langle n|\hat{H}'|n\rangle \langle l|\hat{H}'|n\rangle}{\left(E_l^{(0)} - E_n^{(0)}\right)\left(E_n^{(0)} - E_l^{(0)}\right)} - \sum_m{}' \frac{\langle n|\hat{H}'|n\rangle \langle l|\hat{H}'|m\rangle}{\left(E_n^{(0)} - E_m^{(0)}\right)\left(E_l^{(0)} - E_n^{(0)}\right)}$$

$$= \sum_m{}' \frac{\langle n|\hat{H}'|n\rangle \langle l|\hat{H}'|m\rangle}{\left(E_n^{(0)} - E_m^{(0)}\right)\left(E_n^{(0)} - E_l^{(0)}\right)} - \frac{\langle n|\hat{H}'|n\rangle \langle l|\hat{H}'|n\rangle}{\left(E_n^{(0)} - E_l^{(0)}\right)^2} \quad ...(26)$$

The normalization condition of the wave function shows that the coefficient b_n is zero. It follows that the energy and wave function of the system corrected to second order in the perturbation is

$$E_n = E_n^{(0)} + \langle n|\hat{H}'|n\rangle + \sum_m{}' \frac{|\langle n|\hat{H}'|m\rangle|^2}{E_n^{(0)} - E_m^{(0)}} \quad ...(27)$$

$$\psi_n = \psi_n^{(0)} + \sum_m{}' a_m \psi_m^{(0)} + \sum_m{}' b_l \psi_l^{(0)} \quad ...(28)$$

where the coefficients a_m and b_l are given by Eqs. 15 and 26, respectively. The prime on the summation again signifies the omission of the states $m = n$ or $l = n$, as the case may be.

Application of First-Order Perturbation Theory to Helium Atom. We shall solve the Schrödinger wave equation for the ground state of helium atom using the first-order time-independent perturbation theory.

$$\hat{H}\psi = E\psi \quad ...(29)$$

$$\hat{H} = \hat{H}^{(0)} + \hat{H}' \quad ...(30)$$

where the unperturbed Hamiltonian, $\hat{H}^{(0)}$, is given by

$$\hat{H}^{(0)} = -\frac{\hbar^2}{2\mu}(\nabla_1^2 + \nabla_2^2) - \frac{Ze^2}{4\pi\varepsilon_0}\left(\frac{1}{r_1} + \frac{1}{r_2}\right) \quad ...(31)$$

and the perturbation is the interelectron repulsion term :

$$\hat{H}' = e^2/4\pi\varepsilon_0 r_{12} \quad ...(32)$$

Here r_1 and r_2 are the distances of the two electrons from the helium nucleus of charge Ze and r_{12} is the interelectron distance. We shall use atomic units, a.u. ($\hbar = e = \mu \approx m_e = 1/4\pi\varepsilon_0 = a_0 = 1$), so that

$$\hat{H}^{(0)} = -\frac{1}{2}(\nabla_1^2 + \nabla_2^2) - \left(\frac{2}{r_1} + \frac{2}{r_2}\right) \quad (\because Z = 2 \text{ for helium}) \quad ...(33)$$

$$\hat{H}' = 1/r_{12} \quad ...(34)$$

Since $\hat{H}' << \hat{H}^{(0)}$, it is pertinent to use perturbation theory.

Since $\hat{H}^{(0)}$ is the *sum* of two one-electron Hamiltonians, the unperturbed wave function $\psi^{(0)}(r_1, r_2)$ can be written as the *product* of two hydrogenic wave functions :

$$\psi^{(0)}(r_1, r_2) = \psi^{(0)}(r_1)\, \psi^{(0)}(r_2) \quad ...(35)$$

where $\psi^{(0)}(r_i)$ is the wave function of the ith electron in a hydrogenic atom with nuclear charge = Ze. Thus,

$$\psi^{(0)}(r_1, r_2) = \left(\frac{Z^3}{\pi a_0^3}\right)^{1/2} e^{-Zr_1/a_0} \times \left(\frac{Z^3}{\pi a_0^3}\right)^{1/2} e^{-Zr_2/a_0}$$

$$= (Z^3/\pi)e^{-Z(r_1+r_2)} \quad \text{(in a.u.)} \quad ...(36)$$

The unperturbed ground state energy, $E_0^{(0)}$, is equal to the sum of the ground state energies of two hydrogenic atoms :

$$E_0^{(0)} = (-Z^2/2) + (-Z^2/2) = -Z^2 \text{ (in a.u.)} \quad ...(37)$$

The first-order correction to the groundstate energy is

$$E_0^{(1)} = \langle \psi^{(0)} | \hat{H}' | \psi^{(0)} \rangle$$

$$= \iint \psi^{*(0)}(r_1, r_2) \hat{H}' \psi^{(0)}(r_1, r_2) d\tau_1 d\tau_2 \quad ...(38)$$

Substituting the value of $\psi^{(0)}(r_1, r_2)$ from Eq. 36 into Eq. 38, we obtain

$$E_0^{(1)} = \frac{Z^6}{\pi^2} \iint e^{-2Z(r_1+r_2)} (1/r_{12}) d\tau_1 d\tau_2 \quad ...(39)$$

where the volume elements of the two electrons (in spherical polar coordinates) are

$$d\tau_1 = r_1^2 \sin\theta_1 \, dr_1 \, d\theta_1 \, d\phi_1$$
$$d\tau_2 = r_2^2 \sin\theta_2 \, dr_2 \, d\theta_2 \, d\phi_2$$

The evaluation of the interelectron repulsion integral (Eq. 39) is rather tedious ; it can be shown that it is given by

$$E_0^{(1)} = \left(\frac{5}{8}\right) Z \quad ...(40)$$

Notice that $E_0^{(1)}$ is positive, as was to be expected since the repulsion energy between two electrons is always positive.

Adding Eqs. 37 and 40, we have

$$E_0 = E_0^{(0)} + E_0^{(1)} = -Z^2 + \left(\frac{5}{8}\right) Z$$

$$= -\left(Z^2 - \frac{5}{8} Z\right) \text{ (in a.u.)} \quad ...(41a)$$

Reincorporating the original units we find that

$$E_0 = -\left(Z^2 - \frac{5}{8} Z\right) \frac{\mu e^2}{2\hbar^2} \quad \text{(for 2 electrons)} \quad ...(41b)$$

Recalling that the ground state energy of hydrogen atom is $-\frac{1}{2}$ a.u. or $-\mu e^4/2\hbar^2$ or $-13{\cdot}60$ eV, we get for helium atom

$$E_0 = -\left(Z^2 - \frac{5}{8} Z\right)(27{\cdot}2) \text{ eV} = -74{\cdot}80 \text{ eV} = -2{\cdot}75 \text{ a.u.} \quad ...(42)$$

The experimental value is $-2{\cdot}904$ a.u. or $-78{\cdot}986$ eV. The agreement between the theoretical and experimental values is not good. If the second-order and higher order contributions are included, the agreement improves but is still not very good.

Example 1. Show that the first-order Stark effect on the ground state of hydrogen atom is zero.

Solution. This is another interesting application of the perturbation theory. In the Stark effect, named after the German physicist J. Stark, who won the 1919 Physics Nobel Prize, the system, atom or molecule, is placed in an electric field. The energy levels are split by the field. Let ε be the electric field applied in the z-direction, assuming that the hydrogen atom is placed at the origin of the three-dimensional Cartesian coordinate system. Hence, the

perturbation is

$$\hat{H}' = e\varepsilon z = e\varepsilon r \cos\theta \quad \text{(in polar coordinates)} \quad ...(i)$$

$$\hat{H} = \hat{H}^{(0)} + \hat{H}' \quad ...(ii)$$

The eigenfunctions and eigenvalues of the unperturbed Hamiltonian, $\hat{H}^{(0)}$ for the ground state of hydrogen atom, are

$$E_0^{(0)} = -\frac{1}{2} \text{ (a.u.)} \quad ...(iii)$$

$$\psi_0^{(0)} = \psi_{1s}^{(0)} \equiv 1s = \frac{1}{\sqrt{\pi}} e^{-r} \text{ (in a.u.)} \quad ...(iv)$$

$$E_n = E_n^{(0)} + E_n^{(1)} + E_n^{(2)} + ... \quad \text{(assuming } \lambda = 1\text{)}$$

For the ground state, $n = 0$ so that

$$E_0 = E_0^{(0)} + E_0^{(1)} + E_0^{(2)} + ... \quad ...(v)$$

From Eq. 12, $E_0^{(1)} = \langle \psi_0^{(0)} | \hat{H}' | \psi_0^{(0)} \rangle \equiv 1s | \hat{H}' | 1s \rangle$

$$= \langle 1s | e\varepsilon r \cos\theta | 1s \rangle = e\varepsilon \langle 1s | r \cos\theta | 1s \rangle$$

$$= e\varepsilon \int \psi_{1s}^{*(0)} \, r \cos\theta \, \psi_{1s}^{(0)} \, d\tau \quad ...(vi)$$

Recalling that in spherical polar coordinates,

$$d\tau = r^2 \sin\theta \, dr \, d\theta \, d\phi, \quad ...(vii)$$

we have from Eqs. *(iv), (vi) and (vii),*

$$E_0^{(1)} = e\varepsilon (1/\pi) \int_0^\infty r^3 e^{-2r} dr \int_0^\pi \sin\theta\cos\theta \, d\theta \int_0^{2\pi} d\phi$$

$$= 2e\varepsilon \int_0^\infty r^3 e^{-2r} \, dr \int_0^\pi \sin\theta\cos\theta \, d\theta \quad ...(viii)$$

We need not evaluate the first integral in Eq. *(viii)* because the second integral is zero :

$$\int_0^\pi \sin\theta\cos\theta \, d\theta = \frac{1}{2} \int_0^\pi \sin 2\theta \, d\theta = 0 \quad ...(ix)$$

Hence, $E_0^{(1)} = 0$ ...(x)

Thus, we see that there is no first-order Stark effect on the ground state of hydrogen atom.

B. Degenerate Perturbation Theory

We must emphasize here that the unperturbed wave function $\psi_n^{(0)}$ is a unique one in the non-degenerate case. When there is a degeneracy, a linear combination of the degenerate wave functions can be taken as the unperturbed wave function. For simplicity, we shall consider a case in which the unperturbed energy level, $E_n^{(0)}$, is two-fold degenerate. Let $\psi_n^{(0)}$ and be $\psi_l^{(0)}$ be the eigenfunctions corresponding to the eigenvalues $\psi_n^{(0)}$ and be $\psi_l^{(0)}$. Thus, a linear combination of the two is

$$\phi = c_n \psi_n^{(0)} + c_l \psi_l^{(0)} \quad \text{(where } c_n \text{ and } c_l \text{ are constants)} \quad ...(43)$$

Replacing $\psi_n^{(0)}$ in Eq. 9 by ϕ, we get

$$\hat{H}'\left|\left(c_n\psi_n^{(0)}+c_l\psi_l^{(0)}\right)\right\rangle+\hat{H}^{(0)}\left|\psi_n^{(1)}\right\rangle=E_n^{(1)}\left|\left(c_n\psi_n^{(0)}+c_l\psi_l^{(0)}\right)\right\rangle+E_n^{(0)}\left|\psi_n^{(0)}\right\rangle \quad ...(44)$$

Multiplying Eq. 44 from left by $\left\langle\psi_n^{(0)}\right|$, we have

$$c_n\left\langle\psi_n^{(0)}\left|\hat{H}'\right|\psi_n^{(0)}\right\rangle+c_l\left\langle\psi_n^{(0)}\left|\hat{H}'\right|\psi_l^{(0)}\right\rangle+\left\langle\psi_n^{(0)}\left|\hat{H}^{(0)}\right|\psi_n^{(1)}\right\rangle=c_nE_n^{(1)}+E_n^{(0)}\left\langle\psi_n^{(0)}\left|\psi_n^{(1)}\right\rangle \quad ...(45)$$

Since $\hat{H}^{(0)}$ is Hermitian,

$$\left\langle\psi_n^{(0)}\left|\hat{H}^{(0)}\right|\psi_n^{(1)}\right\rangle=E_n^{(0)}\left\langle\psi_n^{(0)}\left|\psi_n^{(1)}\right\rangle$$

and Eq. 45 reduces to

$$\left(H'_{nn}-E_n^{(1)}\right)c_n+\hat{H}'_{nl}\,c_l=0 \quad ...(46)$$

Operating Eq. 44 from left by $\psi_n^{(0)}$, we have

$$H'_{lm}c_n+\left(H'_{ll}-E_n^{(1)}\right)c_l=0 \quad ...(47)$$

Eqs. 46 and 47 together form a set of simultaneous equations for the coefficients c_n and c_l. A nontrivial solution of these equations exists only if the determinant of the coefficients vanish :

$$\begin{vmatrix}H'_{nn}-E_n^{(1)} & H'_{nl}\\ H'_{ln} & H'_{ll}-E_n^{(1)}\end{vmatrix}=0 \quad ...(48)$$

This is called the secular equation and its two solutions are

$$E_{n\pm}^{(1)}=\frac{1}{2}\left(H'_{nn}+H'_{ll}\right)\pm\frac{1}{2}\left[\left(H'_{nn}+H'_{ll}\right)^2+4\left|H'_{nl}\right|\right]^{1/2} \quad ...(49)$$

Thus, the corrected energies are

$$E_n=E_n^{(0)}+E_{n+}^{(1)} \quad \text{and} \quad E_l=E_n^{(0)}+E_{n-}^{(1)} \quad ...(50)$$

Both the energies will be real since the diagonal matrix elements H'_{nn} and H'_{ll} of the Hermitian operator $\hat{H}'$ are real. If $H'_{nn}=H'_{ll}$ and $H'_{nl}=0$, $E_{n+}=E_{n-}$ and the degeneracy is not removed in the first order.

When the two roots of Eq. 48 are distinct, each (say E_{n+}) can be used to calculate the ratio c_n/c_l either from Eq. 46 or from Eq. 47. The normalization condition enables us to calculate the values of the coefficients c_n and c_l. The values of these coefficients give the desired linear combination associated with the energy level $E_n^{(0)}+E_{n+}$. Similarly, the combination associated with the energy level $E_n^{(0)}+E_{n-}$ can also be evaluated.

Stark Effect on the First Excited State of hydrogen Atom

The first excited state of hydrogen atom (with principal quantum number $n=2$) is four-fold degenerate, since it has the (l, m) values (0, 0), (1, 0), (1, 1) and (1, –1). We assume, as before, that the electric field, ε, is applied along the positive z-axis so that the perturbation Hamiltonian is $\hat{H}'=e\varepsilon z=e\varepsilon r\cos\theta$. The four degenerate states (wavefunctions) can be conveniently specified by the quantum numbers (nlm) as

$$|nlm\rangle:\ |200\rangle,\ |210\rangle,\ |211\rangle,\ |21,-1\rangle$$

Since the state is four-fold degenerate ($2s$, $2p_z$, $2p_x$, $2p_y$ being the degenerate orbitals), we have to evaluate sixteen matrix elements of $\hat{H}'$, as required by the degenerate perturbation theory. Of these, the four diagonal matrix elements are zero since they correspond to the same parity ($\hat{H}'$ is of odd parity). The off-diagonal matrix elements between states of different m values (10 in numbers) are zero since

$$\int_0^{2\pi}\exp\left[i\left(m'-m\right)\phi\right]d\phi=0 \quad \text{if } m'\neq m$$

The remaining two matrix elements $\langle 200|\hat{H}'|210\rangle$ and $\langle 210|\hat{H}'|200\rangle$ are the only nonvanishing ones. These can be evaluated using the expressions

and
$$\psi_{200}=\frac{1}{4\sqrt{2\pi}}\frac{1}{a_0^{3/2}}\left(2-\frac{r}{a_0}\right)\exp\left(-\frac{r}{2a_0}\right) \quad ...(51)$$

$$\psi_{210}=\frac{1}{4\sqrt{2\pi}}\frac{1}{a_0^{3/2}}\frac{r}{a_0}\exp\left(-\frac{r}{2a_0}\right)\cos\theta \quad ...(52)$$

Therefore

$$\langle 200|\hat{H}'|210\rangle=\frac{e\varepsilon}{32\pi a_0^4}\int_0^{2\pi}\int_0^{\pi}\int_0^{\infty}\left(2-\frac{r}{a_0}\right)r^2\exp\left(-\frac{r}{a_0}\right)\cos^2\theta\, r^2\sin\theta\, dr\, d\theta\, d\phi$$

$$=\frac{e\varepsilon}{16a_0^4}\int_0^{\pi}\cos^2\theta\sin\theta\, d\theta\int_0^{\infty}\left(2r^4-\frac{r^5}{a_0}\right)\exp\left(-\frac{r}{a_0}\right)dr$$

Using standard integrals, we have

$$\langle 200|\hat{H}'|210\rangle=-3e\varepsilon a_0 \quad ...(53)$$

Similarly,
$$\langle 210|\hat{H}'|200\rangle=-3e\varepsilon a_0 \quad ...(54)$$

The perturbation matrix is, therefore,

$$\hat{H}'=\begin{array}{c}(nlm)\\ \downarrow\\ (200)\\ (210)\\ (211)\\ (21,-1)\end{array}\begin{array}{c}\rightarrow\\ \\ \\ \\ \\ \end{array}\begin{array}{cccc}(200) & (210) & (211) & (21,-1)\\ \hline 0 & -3e\varepsilon a_0 & 0 & 0\\ -3e\varepsilon a_0 & 0 & 0 & 0\\ 0 & 0 & 0 & 0\\ 0 & 0 & 0 & 0\end{array} \quad ...(55)$$

The secular determinant is then

$$\begin{vmatrix} -E_2^{(1)} & -3e\varepsilon a_0 & 0 & 0 \\ -3e\varepsilon a_0 & -E_2^{(1)} & 0 & 0 \\ 0 & 0 & -E_2^{(1)} & 0 \\ 0 & 0 & 0 & -E_2^{(1)} \end{vmatrix} = 0 \quad ...(56)$$

The four roots of this determinantal equation are $3e\varepsilon a_0$, $-3e\varepsilon a_0$, 0 and 0; where a_0 is the Bohr radius. The states $|200\rangle$ and $|210\rangle$ are affected by the applied (external) electric field whereas the states $|211\rangle$ and $|21,-1\rangle$ are not. The four-fold degeneracy is thus lifted partially. Eigenstates (eigenfunctions) corresponding to these eigenvalues can be evaluated using Eq. 46 or Eq. 47 and the normalization condition for the coefficients. For the eigenvalue $3e\varepsilon a_0$, from Eq. 46, $c_n/c_l = -1$ and the condition $c_n^2 + c_l^2 = 1$ gives $c_n = 1/\sqrt{2}$ and $c_l = -1/\sqrt{2}$. The eigenstate corresponding to the eigenvalue $3e\varepsilon a_0$ is then $\left(1/\sqrt{2}\right)\left(|200\rangle - |210\rangle\right)$. Similarly, the eigenstate corresponding to the eigenvalue $-3e\varepsilon a_0$ is $\left(1/\sqrt{2}\right)\left(|200\rangle + |210\rangle\right)$. The energies along with the eigenstates of the $n = 2$ state of hydrogen atom in an electric field ε along the z-direction are shown in Fig. 1.

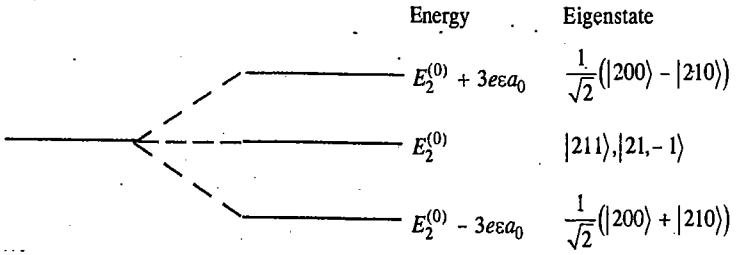

Fig. 1. Energies and wave functions of the first excited state of hydrogen atom in an electric field ε

We thus see that hydrogen atom in the first excited state passess a permanent electric dipole moment of magnitude $3ea_0$ with three different orientations—one state parallel to the external electric field, one state antiparallel to the field and two states with zero component along the field. The states $|211\rangle$ and $|21,-1\rangle$ do not possess dipole moments and, therfore, do not have a first-order interaciton with the electric field.

2. Variation Method (The Variation Theorem). According to the variation method, also called the *variation theorem*, if ψ is an approximate wave function of a quantum mechanical system, an atom or a molecule, described by the Hamiltonian $\hat{H}$, then the energy eigenvalue of the system, approximately given by the integral

$$E = \frac{\langle \psi|\hat{H}|\psi\rangle}{\langle \psi|\psi\rangle} \equiv \frac{\int \psi^* \hat{H} \psi \, d\tau}{\int \psi^* \psi \, d\tau} \quad ...(57)$$

or, if ψ is normalized (so that $\langle \psi|\psi\rangle = 1$), by the integral

$$E = \langle \psi|\hat{H}|\psi|\rangle \equiv \int \psi^* \hat{H} \psi \, d\tau \quad ...(58)$$

is an **upper bound** to the ground state energy, E_0, of the system, *i.e.*,

$$E \geq E_0 \quad ...(59)$$

If the approximate wave function, also called the **trial function**, happens to be exact (true) wave function, then

$$E = E_0 \quad ...(60)$$

However, this is seldom the case since we have no idea of the exact wave function, to begin with. The application of the variation method involves the following steps :

(i) Choose a trial wave function ψ dependent on *variable parameters*.

(ii) Evaluate the integral $\langle \psi|\hat{H}|\psi\rangle$

(iii) Minimise the above integral with respect to the variable parameters.

(iv) The function ψ with the optimum value of the parameters is the best approximation to the true wavefunction and the lowest value of $\langle \psi|\hat{H}|\psi\rangle$ is the nearest approximation to the true energy.

The proof of variation theorem is given later in this chapter.

Application of Variation Method to Helium Atom. The Hamiltonian for He atom (in atomic units) is

$$\hat{H} = -\frac{1}{2}\left(\nabla_1^2 + \nabla_2^2\right) - \left(\frac{2}{r_1} + \frac{2}{r_2}\right) + \frac{1}{r_{12}} \quad ...(61)$$

where the symbols have their usual meanings. As a result of screening, each electron (1 and 2) shields the other from the nucleus so that the two electrons do not "see" the same nuclear charge. Here it is natural to use a wave function with nuclear charge Z less than 2. That is, Z is a **variation parameter** which we shall determine from the variational calculation. It is important to remember that the Hamiltonian in Eq. 61 contains the exact value of $Z = 2$. The variational parameter appears only in the trial wave function :

$$\psi(r_1, r_2) = \left(\frac{Z^3}{\pi}\right)^{\frac{1}{2}} e^{-Zr_1} \times \left(\frac{Z^3}{\pi}\right)^{\frac{1}{2}} e^{-Zr_2} \quad ...(62)$$

$$= (Z^3/\pi) \exp\left[-Z(r_1 + r_2)\right] \quad ...(63)$$

$$E = \langle \psi|\hat{H}|\psi\rangle \quad ...(64)$$

Substituting the value of $\hat{H}$ from Eq. 61 in Eq. 64, we have

$$E = -\frac{1}{2}\langle \psi|\nabla_1^2|\psi\rangle - \frac{1}{2}\langle \psi|\nabla_2^2|\psi\rangle - 2\left\langle \psi\left|\frac{1}{r_1}\right|\psi\right\rangle - 2\left\langle \psi\left|\frac{1}{r_2}\right|\psi\right\rangle + \left\langle \psi\left|\frac{1}{r_{12}}\right|\psi\right\rangle \quad ...(65)$$

The Laplacian operator in spherical polar coordinates (r, θ, ϕ) is given by

$$\nabla^2 = \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2 \frac{\partial}{\partial r}\right) + \frac{1}{r^2 \sin\theta}\frac{\partial}{\partial \theta}\left(\sin\theta \frac{\partial}{\partial \theta}\right) + \frac{1}{r^2 \sin^2\theta}\frac{\partial^2}{\partial \phi^2} \quad ...(66)$$

Since the trial wave function (Eq. 62) does not depend upon angles θ and ϕ, differentiations with respect to θ_1, ϕ_1, θ_2 and ϕ_2 vanish so that for the first kinetic energy operator in Eq. 65, we get

$$-\frac{1}{2}\langle \psi|\nabla_1^2|\psi\rangle = \left(\frac{Z^3}{\pi}\right)^2 \int e^{-Zr_1}\left[-\frac{1}{2r_1^2}\frac{\partial}{\partial r_1}\left(r_1^2 \frac{\partial}{\partial r_1}\right)\right] e^{-Zr_1} \times r_1^2 \sin\theta_1 \, dr_1 \, d\theta_1 \, d\phi_1 \int e^{-2Zr_2} r_2^2 \sin\theta_2 \, dr_2 \, d\theta_2 \, d\phi_2 \quad ...(67)$$

The functions of r_2 are not affected by differentiation. Carrying out the integrations over all angles we obtain

$$-\frac{1}{2} < \psi |\nabla_1^2| \psi > = \left(\frac{Z^3}{\pi}\right)^2 (4\pi)^2 \int_0^\infty e^{-Zr_1}\left[-\frac{1}{2r_1^2}\frac{\partial}{\partial r_1}\left(r_1^2 \frac{\partial e^{-Zr_1}}{\partial r_1}\right)\right] r_1^2 dr_1 \times \int_0^\infty e^{-2Zr_2} \quad ...(68)$$

The second integral in Eq. 68, evaluated using the standard integral, is equal to $2!/(2Z)^3$ so that Eq. 68 becomes

$$(4Z^3)^2\left(-\frac{1}{2}\right)\frac{2!}{(2Z)^3}\int_0^\infty e^{-Zr_1}\left[\frac{\partial}{\partial r_1}(-Zr_1^2 e^{-Zr_1}\right] dr_1$$

$$= (-2Z^3)\int_0^\infty e^{-Zr_1}(-2Zr_1 + Z^2 r_1^2)e^{-Zr_1} dr_1$$

$$= (-2Z^3)\left[-2Z\int_0^\infty r_1 e^{-2Zr_1} dr_1 + Z^2\int_0^\infty r_1^2 e^{-2Zr_1} dr_1\right]$$

$$= (-2Z^3)\left[-\frac{2Z}{(2Z)^2} + \frac{Z^2 2!}{(2Z)^3}\right] = \frac{Z^2}{2} \quad ...(69)$$

Similarly, the second kinetic energy operator term in Eq. 65 gives $Z^2/2$. The third and the fourth electron–nuclear attraction energy terms can be handled easily. The third term, for instance, simplifies to

$$\left(\frac{Z^3}{\pi}\right)^2 \int e^{-Zr_1} e^{-Zr_2}\left[-\frac{2}{r_1}\right] e^{-Zr_1} e^{-Zr_2} r_1^2 \sin\theta_1 \, dr_1 \, d\theta_1 \, d\phi_1 \times r_2^2 \sin\theta_2 \, dr_2 \, d\theta_2 \, d\phi_2$$

$$= (4Z^3)^2 (-2) \int_0^\infty r_1 e^{-2Zr_1} dr_1 \int_0^\infty r_2^2 e^{-2Zr_2} dr_2$$

$$= -32Z^6 \times \frac{1}{(2Z)^2} \times \frac{2!}{(2Z)^3} = -2Z \quad ...(70)$$

Similarly, the fourth term in Eq. 65 gives $-2Z$. The fifth term, the interelectron repulsion energy integral, is somewhat more tedious. So, we will not go into details about its evaluation, merely stating that it evaluates to (5/8) Z. Combining all these contributions,

$$E = 2(Z^2/2) + 2(-2Z) + (5/8)Z = Z^2 - (27/8)Z \quad ...(71)$$

Using the variation method, we minimize the energy with respect to Z, obtaining

$$\partial E/\partial Z = 2Z - 27/8 = 0, \text{ whence } Z = 27/16 = 1{\cdot}69$$

Substituting this value of Z in Eq. 71, we obtain the ground state energy of helium atom :

$$E_0 = (27/16)^2 - (27/8)(27/16) = -2{\cdot}8476 \text{ a.u.}$$
$$= -(2{\cdot}8476)(27{\cdot}21 \text{ eV})$$
$$= -77{\cdot}48 \text{ eV} \qquad [\because 1 \text{ a.u.} = 27{\cdot}21 \text{ eV}] \quad ...(72)$$

This is much better than the first-order perturbation theory result, *viz.*, – 74·80 eV, the experimental value being – 2·904 a.u., *i.e.*, – 78·986 eV. In 1929, the Norwegian physicist E.A. Hyleraas, using a more complicated wave function and the concept of the so-called **electron correlation** which stipulates that electrons try to avoid each other, obtained a result for the ground state energy of helium which is very close to the experimental value. However, this is the realm of electronic computers and we shall not delve into the mathematical details which are beyond the scope of this book.

Example 2. Using the normalized trial wave function $\psi = (\sqrt{30}/a^{5/2})\, x(a - x)$ for a particle of mass m moving inside an infinite one-dimensional box of width a, calculate the upper bound to the ground state energy and compare with the true value $h^2/8ma^2$.

Solution. $$<E> = \int_0^a \psi^* \hat{H} \psi \, dx$$

where $$\hat{H} = (-\hbar^2/2m)\, d^2/dx^2, \quad 0 < x < a$$

Thus, $$<E> = -\frac{30\hbar^2}{2ma^5}\int_0^a (ax - x^2)\frac{d^2}{dx^2}(ax - x^2)\, dx$$

$$= -\frac{30\hbar^2}{ma^5}\int_0^a (x^2 - ax)\, dx = -\frac{30\hbar^2}{ma^5}\left|\frac{x^3}{3} - \frac{ax^2}{2}\right|_0^a = \frac{5h^2}{4\pi^2 ma^2}$$

Since the true value $E_0 = h^2/8ma^2$, we see that $< E >$ **is greater than** E_0, which is as it should be according to the variation theorem.

$$\% \text{ error} = \frac{(5/4\pi^2 - 1/8)(h^2/ma^2)}{(1/8)(h^2/ma^2)} \times 100 = 1{\cdot}3\%.$$

Comment. Though it is not a true variational calculation since it does not use a variation parameter, this example does illustrate the fact that an approximate trial function always yields an *upper bound* to the true ground state energy.

Example 3. The hydrogen atom problem has been solved quantum mechanically, the exact ground state wave function being of the form exp (– r) (in a.u.), neglecting the normalization factor ; here r is the distance of the electron from the nucleus. Introduce a variational parameter α in the exponent to get a trial wave function exp (– αr) (in a.u.). Using variation method, estimate the ground state energy of the electron in hydrogen atom.

Solution. The Schrödinger wave equation is $\hat{H}\psi = E\psi$ ...(*i*)

where $$\hat{H} = -\frac{1}{2}\nabla^2 - \frac{1}{r} \text{ (in a.u.) since in a.u., } \hbar = m_e = e = 1/4\pi\varepsilon_0 = 1 \quad ...(ii)$$

We know that the Laplacian operator ∇^2, in polar coordinates, is given by

$$\nabla^2 = \frac{1}{r^2}\frac{\partial}{\partial r}\left[r^2\frac{\partial}{\partial r}\right] + \frac{1}{r^2\sin\theta}\frac{\partial}{\partial\theta}\left[\sin\theta\frac{\partial}{\partial\theta}\right] + \frac{1}{r^2\sin^2\theta}\frac{\partial^2}{\partial\phi^2}$$

We see that the trial function $\psi(r) = e^{-\alpha r}$ is spherically symmetric since if does not depend upon coordinates θ and ϕ. Hence, the partial derivatives $\partial\psi/\partial\theta$ and $\partial^2\psi/\partial\phi^2$ vanish, giving

$$\nabla^2 = \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right) \quad ...(iii)$$

Substituting in Eq. *(ii)* $$\hat{H} = -\frac{1}{2r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right) - \frac{1}{r} \quad ...(iv)$$

Instead of first normalizing the given trial function and then determining the energy from the relation

$$E = <\hat{H}> = \int \psi^* \hat{H}\psi \, d\tau \equiv <\psi|\hat{H}|\psi> \quad ...(v)$$

we will keep it unnormalized and determine the energy using the relation

$$E \equiv <\hat{H}> = \frac{<\psi|\hat{H}|\psi>}{<\psi|\psi>} \equiv \frac{\int \psi^* \hat{H}\psi \, d\tau}{\int \psi^*\psi \, d\tau} \quad ...(vi)$$

We recall that in spherical polar coordinates (r, θ, ϕ), the volume element $d\tau = r^2 \sin\theta \, dr d\theta d\phi$, where $0 \le r \le \infty$; $0 \le \theta \le \pi$ and $0 \le \phi \le 2\pi$.

Let us first evaluate $\hat{H}\psi$:

$$\hat{H}\psi = -\frac{1}{2r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial e^{-\alpha r}}{\partial r}\right) - \frac{1}{r}e^{-\alpha r}$$

$$\frac{\partial e^{-\alpha r}}{\partial r} = -\alpha e^{-\alpha r}$$

and $$\frac{\partial}{\partial r}(-\alpha r^2 e^{-\alpha r}) = (-\alpha)\frac{\partial}{\partial r}(r^2 e^{-\alpha r}) = (-\alpha)(2r - \alpha r^2)e^{-\alpha r} = (-2\alpha r + \alpha^2 r^2)e^{-\alpha r}$$

Thus, $$\hat{H}\psi = -\frac{1}{2r^2}(-2\alpha r + \alpha^2 r^2)e^{-\alpha r} - \frac{1}{r}e^{-\alpha r} = \left(\frac{\alpha - 1}{r} - \frac{\alpha^2}{2}\right)e^{-\alpha r}$$

Substituting in Eq. *vi*, $$E = \frac{\int_0^\infty e^{-\alpha r}\left[\frac{\alpha-1}{r} - \frac{\alpha^2}{2}\right]e^{-\alpha r} r^2 dr \int_0^\pi \sin\theta\, d\theta \int_0^{2\pi} d\phi}{\int_0^\infty e^{-\alpha r} e^{-\alpha r} r^2 dr \int_0^\pi \sin\theta\, d\theta \int_0^{2\pi} d\phi}$$

Cancelling the common factors in the numerator and the denominator and simplifying, we get

$$E = \frac{(\alpha - 1)\int_0^\infty r\, e^{-2\alpha r} dr - \frac{\alpha^2}{2}\int_0^\infty r^2 e^{-2\alpha r} dr}{\int_0^\infty r^2 e^{-2\alpha r} dr}$$

The integrals occurring in the above equation can be evaluated using the standard integral

$$\int_0^\infty x^n e^{-ax} dx = \frac{n!}{a^{n+1}}, \text{ giving } E = \frac{(\alpha - 1)\frac{1}{4\alpha^2} - \frac{\alpha^2}{2}\frac{2}{(2\alpha)^3}}{2/(2\alpha)^3}$$

$$= \frac{\frac{\alpha - 1}{4\alpha^2} - \frac{1}{8\alpha}}{1/4\alpha^3} = \frac{(2\alpha - 2 - \alpha)/8\alpha^2}{1/4\alpha^3} = \frac{1}{2}(\alpha^2 - 2\alpha) \qquad ...(vii)$$

Using the variation method, differentiating E with respect to α and setting $(\partial E/\partial\alpha)_{\alpha_0} = 0$, we have $\partial E/\partial\alpha = (1/2)(2\alpha - 2) = \alpha - 1 = 0$, whence $\alpha = 1$, as expected. Substituting this value of the variational parameter in Eq. *vii*, we have

$$E_0 = -\frac{1}{2} \text{ (a.u.)}$$

which, we recall, is the exact ground state energy of hydrogen atom corresponding to the exact ground state function $\psi = e^{-r}$ (in a.u.)

Example 4. Using the variation method estimate the ground state energy of a one-dimensional S.H.O. of mass m and anguler frequency ω using a Gaussian trial wave function.

Solution : $$\hat{H} = -\frac{\hbar^2}{2m}\frac{d^2}{dx^2} + \frac{1}{2}m\omega^2 x^2$$

and the Gaussian trial wavefunction is

$$\psi(x) = N \exp(-\alpha x^2)$$

where N is the normalization constant and α is the variation parameter. The normalization condition gives

$$1 = \int_{-\infty}^{\infty} \psi^* \psi dx = |N|^2 \int_{-\infty}^{\infty} \exp(-2\alpha x^2) dx$$

$$= |N|^2 (\pi/2\alpha)^{1/2} \qquad \text{[using the standard integral formula]}$$

so that $N^2 = (2\alpha/\pi)^{1/4}$, and the normalized wave function is

$$\psi(x) = (2\alpha/\pi)^{1/4} \exp(-\alpha x^2) \qquad (i)$$

Hence, $$E = \langle\hat{H}\rangle = \langle\psi|\hat{H}|\psi\rangle = \left\langle\psi\left|-\frac{\hbar^2}{2m}\frac{d^2}{dx^2} + \frac{1}{2}m\omega^2 x^2\right|\psi\right\rangle$$

$$= -\frac{\hbar^2}{2m}\left\langle\psi\left|\frac{d^2}{dx^2}\right|\psi\right\rangle + \frac{1}{2}m\omega^2\langle\psi|x^2|\psi\rangle \qquad (ii)$$

where $$\left\langle\psi\left|\frac{d^2}{dx^2}\right|\psi\right\rangle = -\left(\frac{2\alpha}{\pi}\right)^{1/2} 2\alpha\int_{-\infty}^{\infty}\exp(-2\alpha x^2)dx + \left(\frac{2\alpha}{\pi}\right)^{1/2} 4\alpha^2\int_{-\infty}^{\infty} x^2\exp(-2\alpha x^2)dx$$

$$= -\left(\frac{2\alpha}{\pi}\right)^{1/2} 2\alpha\left(\frac{\pi}{2\alpha}\right)^{1/2} + \left(\frac{2\alpha}{\pi}\right)^{1/2} 4\alpha^2\frac{1}{4\alpha}\left(\frac{\pi}{2\alpha}\right)^{1/2} = -\alpha \qquad (iii)$$

and $$\langle\psi|x^2|\psi\rangle = \left(\frac{2\alpha}{\pi}\right)^{1/2}\int_{-\infty}^{\infty} x^2\exp(-2\alpha x^2)dx = \frac{1}{4\alpha} \qquad (iv)$$

Thus, we have from Eqs. *ii*, *iii* and *iv*

$$E = \langle\hat{H}\rangle = \frac{\hbar^2\alpha}{2m} + \frac{1}{2}m\omega^2\frac{1}{4\alpha} = \frac{\hbar^2\alpha}{2m} + \frac{m\omega^2}{8\alpha} \qquad (v)$$

Using the variation method, differentiating E with respect of α and setting $(\partial E/\partial\alpha)_{\alpha_0} = 0$, we have

$$\partial E/\partial\alpha = \frac{\hbar^2}{2m} - \frac{m\omega^2}{8\alpha^2} = 0, \text{ whence } \alpha_0 = \frac{m\omega}{2\hbar}$$

Substituting this value of α_0 in Eq. *v*

$$E_{min} = \langle H\rangle_{min} = \frac{1}{2}\hbar\omega = \frac{1}{2}h\nu \qquad (\because\ \omega = 2\pi\nu)$$

which, we recall, is the exact ground state energy of the S.H.O. $\left[E_n = \left(n + \frac{1}{2}\right)h\nu,\ n = 0, 1, 2, \ldots\right]$. Hence, the trial wave function we have used is, in fact, the exact eigenfunction.

Example 5. An anharmonic oscillator moves under the potential energy

$$V(x) = \frac{1}{2}kx^2 + \frac{1}{6}\gamma x^3$$

Calculate the first-order correction to the harmonic oscillator energy levels.

Solution : The unperturbed eigenfunctions of the oscillator are

$$\psi_n^{(0)}(x) = \left[\frac{\beta^{1/2}}{2^n n!\sqrt{\pi}}\right]^{1/2} e^{-\beta x^2} H_n(\beta^{1/2}x); \quad \beta = (\mu k)^{1/2}/\hbar$$

Here $H_n(\beta^{1/2}x)$ are the Hermite polynomials.

The unperturbed energies are

$$E_n^{(0)} = \left(n + \frac{1}{2}\right)h\nu$$

where ν is the oscillator frequency : $\nu = (1/2\pi)(k/\mu)^{1/2}$; μ is the reduced mass and k is the force constant.

The perturbation term of the oscillator is

$$\hat{H}^{(1)} = \frac{1}{6}\gamma x^3$$

Hence,

$$E_n^{(1)} \equiv \Delta E = \left[\frac{\beta^{1/2}}{2^n n!\sqrt{\pi}}\right]\frac{\gamma}{6}\int_{-\infty}^{\infty} H_n(\beta^{1/2}x)x^3 H_n(\beta^{1/2}x)\exp(-\beta x^2)\,dx$$

This integral can be evaluated for any value of n by remembering that the Hermite polynomials are either even or odd functions. Thus, the integrand here is overall an odd function, so that the integral itself vanishes, giving $\Delta E=0$. Thus,

$$E_n = \left(n+\frac{1}{2}\right)h\nu + \text{higher order terms.}$$

There is no change in the energy upto first order. Thus, the first-order contribution to energy = 0.

Example 6. The anharmonic oscillator moves under the potential energy which includes quadratic, cubic and quartic terms *viz.*,

$$V(x) = \frac{1}{2}kx^2 + \frac{1}{6}\gamma x^3 + \frac{1}{24}bx^4$$

Calculate the first-order correction to the ground state energy of the oscillator.

Solution : In this case the perturbation is

$$\hat{H}^{(1)} = \frac{1}{6}\gamma x^3 + \frac{1}{24}bx^4$$

The ground state wave function of the harmonic oscillator is

$$\psi_0(x) = \left(\frac{\beta}{\pi}\right)^{1/4}\exp\left(-\beta x^2/2\right); \quad \beta = (\mu k)^{1/2}/\hbar$$

The first-order correction to the ground-state energy is given by

$$E_0^{(1)} \equiv \Delta E = \left(\frac{\beta}{\pi}\right)^{1/2}\int_{-\infty}^{\infty}\left(\frac{1}{6}\gamma x^3 + \frac{1}{24}bx^4\right)\exp\left(-\beta x^2\right)dx$$

The integral involving $\gamma x^3/6$ here vanishes because the integrand is odd. The remaining integral is

$$\Delta E = \frac{b}{12}\left(\frac{\beta}{\pi}\right)^{1/2}\int_0^{\infty} x^4\exp(-\beta x^2)\,dx$$

This integral is found in the tables of integrals, and is equal to $3\pi^{1/2}/8\beta^{5/2}$, and so

$$\Delta E = b/32\beta^2 = b\hbar^2/32k\mu \neq 0$$

The total ground state energy is

$$E = \frac{h\nu}{2} + \frac{b\hbar^2}{32k\mu} + \text{higher-order terms.}$$

We see that there *is* a change in energy upto first-order.

Example 7. Discuss quantum mecheanically the spin-orbit interaction in an atom.

Solution : The electron in an atom moves in a central potential energy $V(r)$ (assumed to be spherically symmetric) that is produced by the nucleus and the other electrons. The interaction between its orbital and spin magnetic moments produces a term in the energy of the system. This phenomenon is called *spin-orbit-interaction.* The spin-orbit Hamillanion $\hat{H}_{so}$ is given by

$$\hat{H}_{so} = \zeta(r)\,L.S., \text{ where } \zeta(r) = \frac{1}{2m_e^2c^2}\frac{1}{r}\frac{dV}{dr}$$

The radial average of the function $\zeta(r)\hbar^2$ is written as $hc\zeta$, where ζ is called the *spin-orbit coupling constant.* Then,

$$hc\zeta = \langle nl|\zeta|nlm\rangle\hbar^2$$

On the basis of this definition, ζ is a wave number and $hc\zeta$ is an energy. For an electron in a hydrogenic atom, the potential energy

$$V(r) = -\frac{Ze^2}{r} \quad \text{or} \quad \frac{dV}{dr} = \frac{Ze^2}{r^2} \qquad \text{(in c.g.s. units)}$$

Hence,

$$\hat{H}_{so} = \zeta(r)\,\text{L.S} = \frac{Ze^2}{2m_e^2c^2}\frac{1}{r^3}\,\text{L.S}$$

The expectation value of $1/r^3$ for the hydrogenic wave functions is

$$\left\langle nlm\left|\frac{1}{r^3}\right|nlm\right\rangle = \frac{Z^3}{n^3a_0^3l(l+\frac{1}{2})(l+1)}$$

where a_0 is the Bohr radius. The spin-orbit coupling constant for a hydrogenic atom is given by

$$hc\zeta_{nl} = \frac{Z^4e^2\hbar^2}{2m_e^2c^2a_0^3n^3l\ (l+\frac{1}{2})(l+1)}$$

It can be written as

$$\zeta_{nl} = \frac{Z^4\alpha^2R^2}{n^3l(l+\frac{1}{2})(l+1)}$$

where the *fine structure constant* $\alpha = e^2/\hbar c = 1/137$ and R is the Rydberg constant $= 2\pi^2m_ee^4/h^3c$.

Thus, we see that the spin-orbit interaction is proportional to Z^4 and is very predominant in heavy elements having large value of the atomic number Z.

After this preliminary discussion of spin-orbit interaction, we proceed to determine its effect on the energy levels. Since $\hat{H}_{so}$ is very weak compared with the energy level separations of the atom, it can be treated as a perturbation on the unperturbed Hamiltonian $\hat{H}^{(0)}$ which has degenerate eigenvalues for a given n and l. However, we can avoid working with degenerate perturbation theory by using the basis $|lsjm\rangle$ since L^2, S^2, J^2 and J_z commute. The first-order correction to the energy of the state $|lsjm\rangle$ is

$$E_{so} = \left\langle lsjm\left|\hat{H}_{so}\right|lsjm\right\rangle = \langle lsjm|\zeta(r)\,\text{L.S}|\,lsjm\rangle$$

The matrix elements of the scaler product L.S can be easily evaluated by writing

$$J^2 = L^2 + S^2 + 2\,L.S \quad \text{or} \quad L.S = \frac{1}{2}\left(J^2 - L^2 - S^2\right)$$

It follows that

$$\langle lsjm|L.S|lsjm\rangle = \frac{1}{2}\hbar^2[j(j+1) - l(l+1) - s(s+1)]$$

Hence, the interaction energy is

$$E_{so} = \frac{1}{2}hc\zeta_{nl}[j(j+1) - l(l+1) - s(s+1)$$

$$= \frac{hcZ^4\alpha^2R}{2} \frac{j(j+1)-l(l+1)-s(s+1)}{n^2l(l+\frac{1}{2})(l+1)}$$

The E_{so} is independent of m_j and, therefore, each level is (2j+1)-fold degenerate. For an s electron, the spin-orbit interaction is zero, since $l=0$ and $j=s$.

Hartree and Hartree-Fock Self-Consistent Field (SCF) Method

We have seen that the application of the above two approximate methods to the solution of the Schrödinger wave equation for helium atom, the simplest two-electron system, does not give very accurate result. For the other atoms in the periodic table, the number of inter-electron repulsion terms in the Hamiltonian will increase thereby rendering the exact solution of the wave equation even more difficult. Thus, we need more powerful methods for the calculation of the ground state energy and wave functions of many-electron atoms or ions. In 1928, the British physicist D.R. Hartree suggested that the wave function of an n-electron atom be written as the ***product*** of n one-electron wave functions :

$$\psi(1, 2, 3, ..., n) = \phi_1(1)\,\phi_2(2)\,\phi_3(3)\,.....\,\phi_n(n) \qquad ...(73)$$

where $\phi(i)$ are normalized and mutually orthogonal one-electron wave functions. Thus, $\phi_1(1)$ means that electron 1 occupies atomic orbital ϕ_1, etc. Hartree proposed the self-consistent field (SCF) method *according to which each electron is assumed to move in a spherically symmetrical potential due to the nucleus and the average potential of all the electrons except the one under consideration.* Thus, potential energy (in a.u.) of electron 1 can be written as

$$V_1 = -\frac{Z}{r_1} + \sum_{i\neq 1} \int \frac{\phi_i^2(i)}{r_{1i}} d\tau_i \qquad ...(74)$$

Similarly, for every other electron i in the atom,

$$V_i = -\frac{Z}{r_i} + \sum_{j\neq i} \int \frac{\phi_j^2(j)}{r_{ij}} d\tau_j \qquad ...(75)$$

where the first term is the attractive potential energy between the ith electron and the nucleus ; it is a negative term. *It is the second term in Eq. 75 which represents the self-consistent field* ; here r_{ij} is the distance between electrons i and j ; the integral is over all space accessible to electron j and the summation is over all j electrons except $j=i$. The quantity $\phi_i^2(i)$ is the probability distribution of electron i. Using Eq. 75 for V_i, the Schrödinger wave equation for the ith electron in an atom is

$$\left(-\frac{1}{2}\nabla_i^2 + V_i\right)\phi_i(i) = \varepsilon_i\phi_i \qquad (i = 1, 2, 3, ... n) \qquad ...(76)$$

where ε_i is the energy of the ith orbital, ϕ_i, assumed to be normalized. The n non-linear simultaneous equations cannot be solved since V_i requires a prior knowledge of all other one-electron wave functions ϕ_j. The SCF method is as follows : First, we choose an arbitrary set of AOs ϕ_j, ϕ_k, etc. The potential energy field V_i arising from all the electrons except the ith electron is calculated from this chosen set of functions and Eq. 76 is solved numerically on the computer to obtain ϕ_i. This procedure is repeated for each of the n electrons in the atom. In general, the calculated set of ϕ_is is not identical with the original chosen set. The calculations are then repeated using the calculated set of orbitals. The process of iteration is continued until the assumed set of ϕ_is and the calculated set are identical. This is expressed by saying that the set of Eq. 76 has been solved by the SCF method.

If $\phi_1'(1)$, $\phi_2'(2)$, $\phi_3'(3)$,.... are the self-consistent orbitals (one-electron wave functions) then the total wave function of the n-electron system is given by

$$\psi'(1, 2, 3, ..., n) = \phi_1'(1)\,\phi_2'(2)\,\phi_3'(3).....\phi_n'(n) \qquad ...(77)$$

The corresponding energy ε associated with this wavefunction is

$$\varepsilon = \langle \psi' | \hat{H} | \psi' \rangle$$

$$= \langle \phi_1'(1)\,\phi_2'(2)....\phi_n'(n) \left| -\frac{1}{2}\sum_i \nabla_i^2 - \sum_i \frac{Z}{r_i} + \frac{1}{2}\sum_{i\neq j}\frac{1}{r_{ij}} \right| \phi_1'(1)\,\phi_2'(2)....\phi_n'(n)\rangle$$

$$= \sum_i \langle \phi_1'(i) \left| -\frac{1}{2}\nabla_i^2 - \frac{Z}{r_i} \right| \phi_1'(i)\rangle + \frac{1}{2}\sum_i\sum_j \langle \phi_i'(i)\phi_j'(j) \left| \frac{1}{r_{ij}} \right| \phi_i'(i)\,\phi_j'(j)\rangle$$

Omitting further mathematical details, the final result is

$$\varepsilon = \sum_i \varepsilon_i' - \frac{1}{2}\sum_{\substack{i\\ i\neq j}}\sum_j \langle \phi_i'(i)\,\phi_j'(j) \left| \frac{1}{r_{ij}} \right| \phi_i'(i)\,\phi_j'(j)\rangle \qquad ...(78)$$

In 1930, the Russian physicist V. Fock proposed that since the Hartree wave function (Eq. 73) was the product of n one-electron *spatial* functions, an improved wave function should include both the spatial part and the electron spin part. This suggestion had also been made by J.C. Slater. Fock solved the many-electron Schrödinger wave equation using such a wave function and the Hartree method. This technique is called the Hartree–Fock SCF method. E. Clementi obtained the SCF wave functions for atoms of various elements in 1965. Hartree-Fock calculations give good agreement with experimental data. Because the Hartree-Fock method uses determinantal wave functions, there is some correlation between electrons with the same spin, because two electrons with the same spin cannot occupy the same orbital. Neverthless, the Hartree-Fock method is not exact, and so we define a correlation energy

$$\text{Correlation energy (CE)} = E_{\text{exact}} - E_{\text{HF}} \qquad ...(79)$$

Though correlation energies appear to be small, they are really very significant.

Slater Determinant for n-Electron Atoms

It was proposed by J.C. Slater in 1930 that for a multielectron atom the total wave function must consist of the *spatial* part and the *spin* part. He showed that the total atomic wave function, which is the product of the spatial wave function and the spin wave function, is *antisymmetric* (A) with respect to the interchange of electrons, *i.e.*,

$$\Psi_{\text{total}} = \psi_{\text{space}} \times \psi_{\text{spin}} \text{ (antisymmetric)} \qquad ...(80)$$

Thus, for helium atom with the ground state electronic configuration $1s^2$,

$$\psi_{\text{space}} = 1s(1)\,1s(2) \qquad ...(81)$$

Interchanging the two electrons,

$$\psi_{\text{space}} = 1s(2)\,1s(1) \qquad ...(82)$$

That is, ψ_{space} is symmetric (S) ; it does not change sign. If α and β are the spin wave functions for

the upward (↑) orientation and the downward (↓) orientation, respectively, then

$$\psi_{spin} = \begin{cases} \alpha(1)\alpha(2); (S) \\ \frac{1}{\sqrt{2}}[\alpha(1)\beta(2)+\alpha(2)\beta(1)]; (S) \\ \frac{1}{\sqrt{2}}[\alpha(1)\beta(2)-\alpha(2)\beta(1)]; (A) \\ \beta(1)\beta(2); (S) \end{cases} \quad ...(83)$$

We see that there are three symmetric (S) and one antisymmetric (A) spin wave functions.

Thus, $\Psi_{total} = \psi_{space} \times \psi_{spin}$

$$= 1s(1)\ 1s(2)\ ;(S) \times \begin{cases} \alpha(1)\alpha(2); (S) \\ \frac{1}{\sqrt{2}}[\alpha(1)\beta(2)+\alpha(2)\beta(1)]; (S) \\ \frac{1}{\sqrt{2}}[\alpha(1)\beta(2)-\alpha(2)\beta(1)]; (A) \\ \beta(1)\beta(2); (S) \end{cases} \quad ...(84)$$

Hence, the only combination which gives total antisymmetric wavefunction is the product of the symmetric spatial wavefunction and the antisymmetric spin function. Thus,

$$\Psi_{total} \equiv \psi(1, 2) = 1s(1)\ 1s(2) \left\{\frac{1}{\sqrt{2}}[\alpha(1)\beta(2) - \alpha(2)\beta(1)]\right\}$$

$$= \frac{1}{\sqrt{2}}\ [1s(1)\ \alpha(1)\ 1s(2)\ \beta(2) - 1s(1)\ \beta(1)\ 1s(2)\ \alpha(2)] \quad ...(85)$$

which can be written as a 2×2 determinant,

$$\Psi(1, 2) = \frac{1}{\sqrt{2!}}\begin{vmatrix} 1s(1)\alpha(1) & 1s(2)\alpha(2) \\ 1s(1)\beta(1) & 1s(2)\beta(2) \end{vmatrix} \quad ...(86)$$

This is called the **Slater determinant** for helium atom.

Interchanging electrons 1 and 2 in Eq. 333, we have

$$\Psi(2, 1) = \frac{1}{\sqrt{2!}}\begin{vmatrix} 1s(2)\alpha(2) & 1s(1)\alpha(1) \\ 1s(2)\beta(2) & 1s(1)\beta(1) \end{vmatrix} = -\Psi(1, 2) \quad ...(87)$$

This result follows from the fact that if in a determinant two rows (or columns) are interchanged, it changes sign. What is true of a two-electron system is also true of polyelectron atoms and molecules. The polyelectron wave function also satisfies the antisymmetry rule. The solution of the Schrödinger wave equation for such systems must start from the appropriate Slater determinant for a given electronic configuration. The Hartree-Fock SCF method, using Slater determinants has been successfully employed by theoretical chemists and physicists. In 1951 the American physicist C.C.J. Roothaan extended it to molecules as well.

Example 8. Write the Slater determinants for the ground states of *(a)* lithium atom ($1s^2\ 2s^1$) and *(b)* carbon atom ($1s^2\ 2s^2\ 2p^2$).

Solution. *(a)* $$\Psi(1, 2, 3) = \frac{1}{\sqrt{3!}}\begin{vmatrix} 1s(1)\alpha(1) & 1s(2)\alpha(2) & 1s(3)\alpha(3) \\ 1s(1)\beta(1) & 1s(2)\beta(2) & 1s(3)\beta(3) \\ 2s(1)\alpha(1) & 2s(2)\alpha(2) & 2s(3)\alpha(3) \end{vmatrix}$$

(b) $\Psi(1, 2, 3, 4, 5, 6) =$

$$\frac{1}{\sqrt{6!}}\begin{vmatrix} 1s(1)\alpha(1) & 1s(2)\alpha(2) & 1s(3)\alpha(3) & 1s(4)\alpha(4) & 1s(5)\alpha(5) & 1s(6)\alpha(6) \\ 1s(1)\beta(1) & 1s(2)\beta(2) & 1s(3)\beta(3) & 1s(4)\beta(4) & 1s(5)\beta(5) & 1s(6)\beta(6) \\ 2s(1)\alpha(1) & 2s(2)\alpha(2) & 2s(3)\alpha(3) & 2s(4)\alpha(4) & 2s(5)\alpha(5) & 2s(6)\alpha(6) \\ 2s(1)\beta(1) & 2s(2)\beta(2) & 2s(3)\beta(3) & 2s(4)\beta(4) & 2s(5)\beta(5) & 2s(6)\beta(6) \\ 2p_{+1}(1)\alpha(1) & 2p_{+1}(2)\alpha(2) & 2p_{+1}(3)\alpha(3) & 2p_{+1}(4)\alpha(4) & 2p_{+1}(5)\alpha(5) & 2p_{+1}(6)\alpha(6) \\ 2p_0(1)\alpha(1) & 2p_0(2)\alpha(2) & 2p_0(3)\alpha(3) & 2p_0(4)\alpha(4) & 2p_0(5)\alpha(5) & 2p_0(6)\alpha(6) \end{vmatrix}$$

We may mention here that the Slater determinant is the quantum mechanical version of the Pauli principle. Thus, for instance, the Slater determinant for the electronic configuration $1s^3$ is zero. This is in accordance with the Pauli principle according to which $1s$ orbital cannot have three electrons. Thus, Pauli's exclusion principle may be stated as follows :

The wave function for any system of electrons must be antisymmetric with respect to the interchange of any two electrons. If a system of electrons in an atom could be symmetric with respect to the interchange of any two electrons, there would be an entirely different set of elements. There is no simple expression for the energy of a many-electron atom. However, in contrast with the energy of the hydrogen atom, the energy of the polyelectronic atom can be written as

$$E_n = -\frac{2\pi^2 Z_{eff}^2\ \mu e^4}{(4\pi\varepsilon_0)^2\ n^2 h^2} \quad ...(88)$$

where n is the effective principal quantum number, μ is the reduced mass and Z_{eff} is the effective nuclear charge, defined as $Z_{eff} = Z - \sigma$ where Z is the atomic number (the true nuclear charge) and σ is the **screening constant** (or, **shielding constant**) which depends upon the quantum numbers n and l.

The American physicist J.C. Slater (1900-1976) formulated the following empirical rules (known as **Slater's rules**) for estimating σ :

1. Electrons farther away from the nucleus than the electron under consideration do not contribute to σ.

2. The electrons in the same group, *i.e.*, *ns*, *np*, *nd* or *nf*-electrons, contribute 0·35 to σ (except $1s$-electron for which σ=0·30).

3. In the case of electrons in the *ns* and *np* orbitals, all electrons in the $(n-1)$ shell contribute 0·85 each and all electrons in the $(n-2)$ shell contribute 1·0 each.

4. For electrons in the *nd* and *nf* orbitals, each electron in the lower groups contributes 1·0 to σ.

Knowing the value of σ Z_{eff} can be calculated.

Example 9. Calculate the effective nuclear charge for *(i)* the 3*s* electron in sulphur (Z=16) *(ii)* the 4*s* electron in potassium (Z=19) *(iii)* a 3*d* and a 4*s* electron in vanadium (Z=23).

Solution : *(i)* Electronic configuration of S atom is : $1s^2\ 2s^2\ 2p^6\ 3s^2\ 3p^4$

For the 3s electron, $\sigma = (5\times0{\cdot}35) + (8\times0{\cdot}85) + (2\times1{\cdot}00) = 10{\cdot}55$

$\therefore$ $Z_{eff} = Z - \sigma = 16 - 10{\cdot}55 = \mathbf{5{\cdot}45}$

(ii) Electronic configuration of K atom is : $1s^2\ 2s^2\ 2p^6\ 3s^2\ 3p^6\ 4s^1$

For the 4*s* electron, $\sigma = 8\times0{\cdot}85 + 1\times 10 = 16{\cdot}80$

$\therefore$ $Z_{eff} = Z - \sigma = 19 - 16{\cdot}80 = \mathbf{2{\cdot}20}$

(iii) Electronic configuration of V atom is : $1s^2\ 2s^2\ 2p^6\ 3s^2\ 3p^6\ 3d^3\ 4s^2$

For the 3*d* electron, $\sigma = 2\times0{\cdot}35 + 18\times1 = 18{\cdot}70$

$\therefore$ $Z_{eff} = Z - \sigma = 23 - 18{\cdot}70 = \mathbf{4{\cdot}30}$

For the 4*s* electron,

$$\sigma = 0{\cdot}35\times1 + 11\times0{\cdot}85 + 10\times1 = 0{\cdot}35 + 9{\cdot}35 + 10 = 19{\cdot}70$$

$$\therefore \quad Z_{eff} = 23 - 19{\cdot}70 = 3{\cdot}30$$

Atomic Term Symbols. (These are discussed in detail later in this chapter). In an atom the electron spin angular momentum may couple with the total angular momentum as follows :

The coupling of spin angular momenta of two electrons, known as *s–s* coupling, gives rise to a quantum number S (called **total spin number**), where

$$S = \tfrac{1}{2} + \tfrac{1}{2} \text{ or } \tfrac{1}{2} - \tfrac{1}{2} \text{ or } -\tfrac{1}{2} - \tfrac{1}{2}, \quad i.e., \ 1, 0 \text{ or } -1 \qquad ...(89)$$

Similarly, the coupling of orbital angular momenta of two electrons, known as *l–l* coupling, gives rise to a quantum number L (called **total orbital angular momentum quantum number**), where

$$L = (l_1 + l_2), (l_1 + l_2 - 1), \ldots |l_1 - l_2| \qquad ...(90)$$

The term $|l_1 - l_2|$ signifies absolute value of $l_1 - l_2$.

The coupling of L and S, known as the **Russell–Saunders coupling**, gives rise to quantum number J where

$$J = (L + S), (L + S - 1), \ldots |L - S| \qquad ...(91)$$

The terms L, S and J collectively constitute an important symbol known as **atomic term symbol** which is generally designated as ${}^{2S+1}L_J$. The superscript represents the multiplicity of the term and subscript is the value of J as given by Eq. 91. Just as $l = 0$, 1, 2, and 3 corresponds to the atomic orbitals s, p, d and f, respectively, similarly, L=0,1,2,3 correspond to *atomic states* S,P,D and F, respectively. (The state S should not be confused with the total spin quantum number S).

THE SCHRÖDINGER EQUATION FOR A FINITE POTENTIAL BARRIER : QUANTUM MECHANICAL TUNNELLING

1. Finite Potential Well

Potential energy barriers are never infinite in a real world and a box with infinitely hard walls has no physical counterpart. However, potential wells with barriers of *finite height* certainly do exist. We shall here investigate the wave functions and energy levels in such a well. Fig. 2 shows potential well with square corners that is V_0 high and a wide. It contains a particle whose *energy is less than* V_0. According to classical mechanics, when the particle strikes the sides of the well, it bounces off without entering regions I and III. In quantum mechanics, however, the particle also bounces back and forth, but now it has a *finite probability* of penetrating into regions I and III even though $E < V_0$.

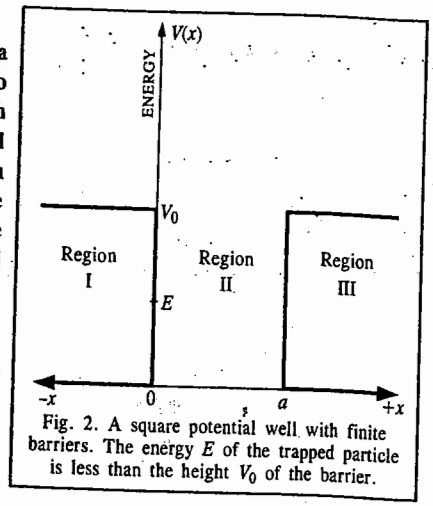

Fig. 2. A square potential well with finite barriers. The energy E of the trapped particle is less than the height V_0 of the barrier.

In regions I and III, the Schrödinger wave equation is

$$\frac{d^2\psi}{dx^2} + \frac{2m}{\hbar^2}(E - V_0)\psi = 0 \qquad ...(92)$$

or

$$\frac{d^2\psi}{dx^2} - k^2\psi = 0 \ ; \ x < 0 \text{ and } x > a \qquad ...(93)$$

where $k = [2m(V_0 - E)]^{1/2}/\hbar$.

The solutions of Eq. 92 are real exponentials, *viz.*,

$$\psi_I = Ae^{kx} + Be^{-kx} \qquad ...(94)$$

$$\psi_{III} = Ce^{kx} + De^{-kx} \qquad ...(95)$$

Both ψ_I and ψ_{III} must be finite everywhere. Since $e^{-kx} \to \infty$ as $x \to -\infty$ and $e^{kx} \to \infty$ as $x \to \infty$, the coefficients B and C must, therefore, be zero. Hence, we have

$$\psi_I = Ae^{kx} \text{ and } \psi_{III} = De^{-kx} \qquad ...(96)$$

These wave functions decrease exponentially inside the barriers at the sides of the well.

Within the well, the Schrödinger wave equation is

$$\frac{d^2\psi}{dx^2} + \frac{2mE}{\hbar^2}\psi = 0 \qquad ...(97)$$

since $V = 0$ there. The solution of Eq. 97 is

$$\psi_{II} = E\sin\frac{(2mE)^{1/2}}{\hbar}x + F\cos\frac{(2mE)^{1/2}}{\hbar}x \qquad ...(98)$$

In the case of a well with *infinitely high barriers*, it is found that $F = 0$ in order that $\psi = 0$ at x=0 and $x = a$. Here, however, $\psi_{II} = A$ at $x = 0$ and $\psi_{II} = D$ at $x = a$; so both the sine and cosine solutions of Eq. 98 are possible.

For either solution, both ψ and $d\psi/dx$ must be continuous at x=0 and x=a. The wave functions inside and outside each side of the well must not only have the same value where they join but also the same slopes so that they match perfectly. When these boundary conditions are taken into account, the result is that exact matching only occurs for certain values of energy (E_n) of the particle. The complete wave functions and their probability densities are shown in Fig. 3.

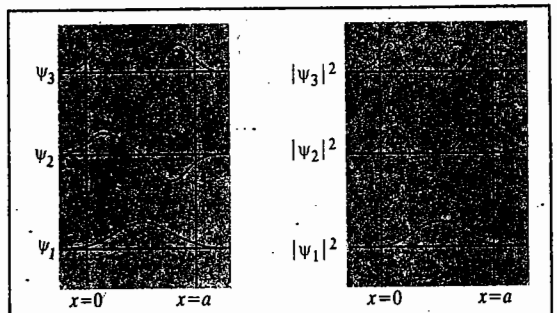

Fig. 3. Wave functions and probability densities of a particle in a finite potential well.
The particle has a certain probability of being found outside the well.

2. Quantum Mechanical Tunnelling

This phenomenon plays a central role in the Gamow-Gurney-Condon theory of the alpha decay of nuclei, the Marcus theory of electron-transfer reactions, hydrogen bonding, semiconductors, superconductors and scanning tunnelling microscopy (STM). Consider a beam of identical particles all of which have the kinetic energy E. The beam is incident from the left on a potential barrier of height V_0 and with width a (Fig. 4). Mathematically, we have

$$V(x) = \begin{cases} 0, & x < 0 \quad \text{(Region I)} \\ V_0, & 0 < x < a \quad \text{(Region II)} \\ 0, & x > a \quad \text{(Region III)} \end{cases}$$

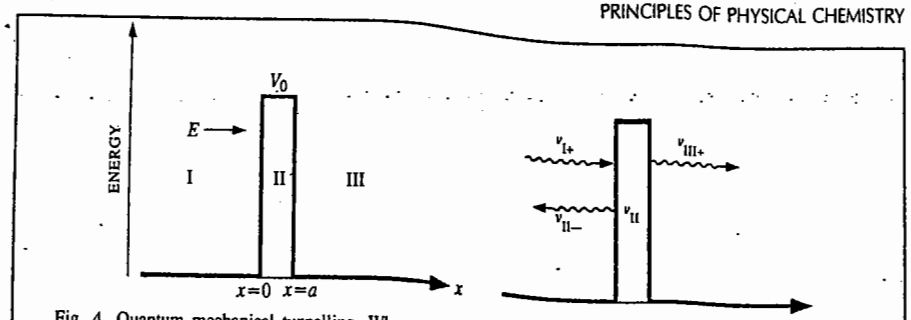

Fig. 4. Quantum mechanical tunnelling. When a particle of energy $E < V_0$ approaches a potential barrier, according to classical mechanics, the particle must be reflected. In quantum mechanics, the de Broglie waves that correspond to the particle are partly reflected and partly transmitted, which means that the particle has a finite probability of *penetrating* the barrier or *tunnelling* through the barrier.

On both sides of the barrier, $V = 0$ which means that no forces act on the particles there. In these regions the Schrödinger wave equation is

$$\frac{d^2\psi_I}{dx^2} + \frac{2mE}{\hbar^2}\psi_I = 0 \qquad ...(99)$$

$$\frac{d^2\psi_{III}}{dx^2} + \frac{2mE}{\hbar^2}\psi_{III} = 0 \qquad ...(100)$$

The solutions to these equations are

$$\psi_I = Ae^{ik_1x} + Be^{-ik_1x} \qquad ...(101)$$

$$\psi_{III} = Fe^{ik_1x} + Ge^{-ik_1x} \qquad ...(102)$$

where

$$k_1 \left(= \frac{(2mE)^{1/2}}{\hbar} = \frac{p}{\hbar} = \frac{2\pi}{\lambda} \right) \qquad ...(103)$$

is the *wave number* of de Broglie waves that represent the particles outside the potential energy barrier. Since according to Euler's formula,

$$e^{i\theta} = \cos\theta + i\sin\theta \text{ and } e^{-i\theta} = \cos\theta - i\sin\theta$$

we find that these solutions (Eqs 101 and 102) are equivalent to those of a particle inside a potential box of infinite height—the values of the coefficients are different in each case, of course—but are in a more suitable form to describe particles that are not trapped. The various terms in Eqs. 101 and 102 are easy to interpret. As shown schematically in Fig. 4, Ae^{ik_1x} is a wave of amplitude A incident from the left on the barrier. Hence, we can write, for the *incoming wave*,

$$\psi_{I+} = Ae^{ik_1x} \qquad ...(104)$$

This wave corresponds to the incident beam of particles in the sense that $|\psi_{I+}|^2$ is their probability density. If v_{1+} is the **group velocity** of the incoming wave, which equals the velocity of the particles, then

$$S = |\psi_{1+}|^2 v_{1+}$$

is the **flux** of particles (*i.e.*, number of particles per square metre per second) that arrive at the barrier.

At $x=0$, the incident wave strikes the barrier and is partially reflected. Thus, for the *reflected wave*, we have

$$\psi_1 = Be^{-ik_1x}$$

Hence,

$$\psi_I = \psi_{I+} + \psi_{I-} \qquad ...(105)$$

$$...(106)$$

On the far side of the barrier ($x > a$), there can be only one wave *viz.*, the transmitted wave,

$$\psi_{III+} = Fe^{ik_1x} \qquad ...(107)$$

travelling in the $+x$ direction at velocity v_{III+} since region III contains nothing that could reflect the wave. Hence, $G = 0$, and

$$\psi_{III} = \psi_{III+} = Fe^{ik_1x} \qquad ...(108)$$

The **transmission probability**, T, for a particle to pass through the barrier is given by

$$T = \frac{|\psi_{III+}|^2 v_{III}}{|\psi_{1+}|^2 v_1} = \frac{FF^* v_{III}}{AA^* v_1} \qquad ...(109)$$

between the flux of particles that emerges from the barrier and the flux that arrives at it. In other words, *T is the fraction of the incident particles that succeed in tunnelling through the barrier.* Classically, $T = 0$ because the particle with energy $E < V_0$ cannot exist inside the barrier. We shall now consider the quantum mechanical result.

In region II, the Schrödinger wave equation for the particles is

$$\frac{d^2\psi_{II}}{dx^2} + \frac{2m}{\hbar^2}(E - V_0)\psi_{II} = \frac{d^2\psi_{II}}{dx^2} - \frac{2m}{\hbar^2}(V_0 - E)\psi_{II} = 0 \qquad ...(110)$$

Since $V_0 > E$, the solution for the *wavefunction inside the barrier* is

$$\psi_{II} = Ce^{-k_2x} + De^{k_2x} \qquad ...(111)$$

where the *wave number inside the barrier is*

$$k_2 = [2m(V_0 - E)]^{1/2}/\hbar \qquad ...(112)$$

Since the exponents are real quantities, ψ_{II} does not oscillate and, therefore, does not represent a moving particle. However, the probability density $|\psi_{II}|^2$ is not zero, so there is a finite probability of finding a particle within the barrier. Such a particle may emerge into region III or it may return to region I.

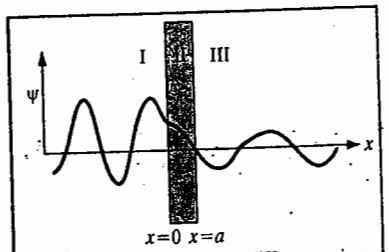

Fig. 5. The wave functions in different regions.

We shall derive the formula for the transmission probability by applying the boundary conditions to ψ_I, ψ_{II} and ψ_{III}. Fig. 5 shows the wave functions in regions I, II and III. Both ψ and its derivative $d\psi/dx$ must be continuous everywhere.

At each wall of the barrier, the wave functions inside and outside it must match up perfectly, which means that they must have the same values and same slopes there.

This implies that for a perfect fit at each side of the barrier, the wave functions inside and outside must have the same value and the same slope. However, at the left hand side of the barrier, we have

$$\left.\begin{aligned}\psi_I &= \psi_{II} \\ d\psi_I/dx &= d\psi_{II}/dx\end{aligned}\right\} \text{ (Boundary conditions at } x = 0) \qquad ...(113)$$

and at the right hand side,

$$\left.\begin{aligned}\psi_{II} &= \psi_{III} \\ d\psi_{II}/dx &= d\psi_{III}/dx\end{aligned}\right\} \text{ (Boundary conditions at } x = a) \qquad ...(114)$$

Substituting for ψ_I, ψ_{II} and ψ_{III} from Eqs. 101, 108 and 111 into the above equations,

we have in the same order

$$A + B = C + D \qquad ...(115$$

$$ik_1A - ik_1B = -k_2C + k_2D \quad ...(116)$$

$$Ce^{-k_2a} + De^{k_2a} = Fe^{ik_1a} \quad ...(117)$$

$$-k_2Ce^{-k_2a} + k_2De^{k_2a} = ik_1Fe^{ik_1a} \quad ...(118)$$

Eqs. 115 to 118 may be solved for (A/F) to give

$$\left(\frac{A}{F}\right) = \left[\frac{1}{2} + \frac{i}{4}\left(\frac{k_2}{k_1} - \frac{k_1}{k_2}\right)\right]e^{(ik_1+k_2)a} + \left[\frac{1}{2} - \frac{i}{4}\left(\frac{k_2}{k_1} - \frac{k_1}{k_2}\right)\right]e^{(ik_1-k_2)a} \quad ...(119)$$

Assume that $V_0 > E$ so that $k_2/k_1 > k_1/k_2$ and

$$\frac{k_2}{k_1} - \frac{k_1}{k_2} \approx \frac{k_2}{k_1} \quad ...(120)$$

We shall further assume that the barrier is wide enough for ψ_{II} to be severely weakened at $x=0$ and $x=a$. This means that $k_2a >> 1$ and $e^{k_2a} >> e^{-k_2a}$. With these assumptions, Eq. 119 can be approximated to

$$\left(\frac{A}{F}\right) = \left(\frac{1}{2} + \frac{ik_2}{4k_1}\right)e^{(ik_1+k_2)a} \quad ...(121)$$

In order to calculate the complex conjugate of (A/F) we replace i by $-i$ wherever it occurs in (A/F) :

$$\left(\frac{A}{F}\right)^* = \left(\frac{1}{2} + \frac{ik_2}{4k_1}\right)e^{(-ik_1+k_2)a} \quad ...(122)$$

Multiplying (A/F) by $(A/F)^*$, we have

$$\frac{AA^*}{FF^*} = \left(\frac{1}{4} + \frac{k_2^2}{16k_1^2}\right)e^{2k_2a}$$

Here $v_{III+} = v_{I+}$ so that $v_{III+}/v_{I+} = 1$ in Eq. 109, which means that the transmission probability is given by

$$T = \frac{FF^*v_{III+}}{AA^*v_{I+}} = \left(\frac{AA^*}{FF^*}\right)^{-1} = \left[\frac{16}{4 + (k_2/k_1)^2}\right]e^{-2k_2a} \quad ...(123)$$

From the definitions of k_1 (Eq. 103) and k_2 (Eq. 112), we find that

$$\left(\frac{k_2}{k_1}\right)^2 = \frac{2m(V_0 - E)/\hbar^2}{2mE/\hbar^2} = \frac{V_0}{E} - 1 \quad ...(124)$$

From this result we see that the quantity in brackets in Eq. 123 varies much less with E and V_0 than does the exponential. Furthermore, the bracketed quantity is always of the order of magnitude of 1 in value. Hence, the approximate formula for the transmission probability is

$$T \approx e^{-2k_2a} \quad ...(125)$$

Thus, we conclude in the words of R.P. Feynman that "it is possible in quantum mechanics to sneak quickly across a region which is illegal energetically."

Example 10. Electrons with energies of 1·0 eV and 2·0 eV are incident on a barrier 10·0 eV high and 0·50 nm wide. *(a)* Calculate their respective transmission probabilities *(b)* How are these affected if the barrier is doubled in width ?

Solution : *(a)* For the 1·0 eV electrons,

$$k_2 = \frac{[2m(V_0 - E)]^{1/2}}{\hbar} = \frac{[(2)(9{\cdot}1 \times 10^{-31}\,\text{kg})[(10{\cdot}0 - 1{\cdot}0)\,\text{eV}]1{\cdot}6 \times 10^{-19}\,\text{J/eV}]^{1/2}}{1{\cdot}504 \times 10^{-34}\,\text{Js}}$$

$$= 1{\cdot}6 \times 10^{10}\,\text{m}^{-1}$$

Since $a = 0{\cdot}50\,\text{nm} = 5{\cdot}0 \times 10^{-10}$ m, $2k_2a = (2)(1{\cdot}6 \times 10^{-10}\,\text{m}^{-1})(5{\cdot}0 \times 10^{-10}\,\text{m}) = 16$ and the approximate transmission probability is given by

$$T_1 \approx \exp(-2k_2a) = e^{-16} = 1{\cdot}1 \times 10^{-7}$$

Thus, we see that one 1·0 eV-electron out of 8·9 million can tunnel through the 10 eV barrier on the average. For the 2·0 eV-electrons, a similar calculation gives $T_2 \approx 2{\cdot}4 \times 10^{-7}$. These electrons are over twice as likely to tunnel through the barrier.

(b) If the barrier is doubled in width to 1·0 nm, the transmission probability becomes

$$T_1' = 1{\cdot}3 \times 10^{-14}, \quad T_2' \approx 5{\cdot}1 \times 10^{-14}$$

Evidently, T is more sensitive to the width of the barrier than to the particle energy.

SIMPLE HARMONIC OSCILLATOR : THE ALGEBRAIC METHOD

Although the Schrödinger wave equation for the simple harmonic oscillator (S.H.O.), which plays a very important role in quantum mechanics and relativistic quantum field theory, can be solved using the brute force solution, *i.e.*, the more traditional tools of differential equations, special functions and the power series method, it is more instructive to treat the S.H.O. (also called linear harmonic oscillator (L.H.O.)) as an application of the diabolically clever algebraic technique, using the so called ladder operators which exploit the commutation relations and operator identities. We shall outline here the algebraic technique.

The time-independent Schrödinger wave equation for the S.H.O. is

$$\hat{H}\psi = E\psi \quad ...(126)$$

or

$$\frac{-\hbar^2}{2m}\frac{d^2\psi}{dx^2} + \frac{1}{2}m\omega^2x^2\psi = E\psi \quad ...(127)$$

where the Hooke's law potential $V(x) = (1/2)\,kx^2 = (1/2)\,m\omega^2x^2$. Here k is the force constant $= m\omega^2$ where m is the mass of the oscillator and $\omega(= 2\pi\nu)$ is the *angular frequency* ; ν being the *frequency* of the S.H.O. Rewriting Eq. 127 in the more suggestive form :

$$\frac{1}{2m}[p^2 + (m\omega x)^2]\psi = E\psi \quad ...(128)$$

where $p = -i\hbar(d/dx)$ is the linear momentum operator. The basic idea is to *factor* the Hamiltonian,

$$H = (1/2m)\,[p^2 + (m\omega x)^2] \quad ...(129)$$

If these were *numbers*, it would be easy :

$$a^2 + b^2 = (ia + b)(-ia + b)$$

Here, however, it's not quite so simple because p and x are *operators* and operators do not, in general, commute (xp is not the same as px). Still, this does motivate us to examine the quantities

$$a_\pm \equiv \frac{1}{\sqrt{\hbar m\omega}}(\mp ip + m\omega x) \quad ...(130)$$

(The factor in front is just there to make the final results look nicer).

Let us evaluate the product a_-a_+ :

$$a_-a_+ = \frac{1}{2\hbar m\omega}(ip + m\omega x)(-ip + m\omega x)$$

$$= \frac{1}{2\hbar m\omega}[p^2 + (m\omega x)^2 - im\omega(xp - px)] \quad ...(131)$$

The extra term in Eq. 131, involving $(xp - px)$ is called the commutator of x and p, written as $[x, p] = xp - px$. Thus,

$$a_- a_+ = \frac{1}{2\hbar m\omega}[p^2 + (m\omega x)^2] - \frac{i}{2\hbar}[x, p] \quad ...(132)$$

To evaluate $[x, p]$, we operate on the test function $f(x)$:

$$[x, p] f(x) = \left[x(-i\hbar)\frac{df(x)}{dx} - (-i\hbar)\frac{d\{xf(x)\}}{dx}\right]$$

$$= -i\hbar\left(x\frac{df}{dx} - x\frac{df}{dx} - f\right) = i\hbar f(x) \quad ...(133)$$

Dropping the test function, which has served its purpose,

$$[x, p] = i\hbar \quad ...(134)$$

This lovely and ubiquitous result is known as the **canonical commutation relation.**

[Theoretical physicists feel that in a deep sense all of the mysteries of quantum mechanics can be traced to the fact that position and momentum do not commute. Eq. 134 is the quantum mechanical version of the Heisenberg uncertainty principle, Indeed, some authors take the canonical commutation relation as an *axiom* and use it to *derive* $p = -i\hbar\, d/dx$.]

Using Eq. 134, Eq. 132 becomes

$$a_- a_+ = \left(\frac{1}{\hbar\omega}\right)H + \frac{1}{2} \quad ...(135)$$

or

$$H = \hbar\omega\left(a_- a_+ - \frac{1}{2}\right) \quad ...(136)$$

Evidently, the Hamiltonian does not *factor* perfectly - there is extra - 1/2 on the right. Notice that the ordering of a_+ and a_- is important here. The same argument with a_+ on the left yields

$$a_+ a_- = \left(\frac{1}{\hbar\omega}\right)H - \frac{1}{2} \quad ...(137)$$

Now, the commutator of a_- and a_+ is

$$[a_-, a_+] = 1 \quad ...(138)$$

So, the Hamiltonian can equally well be written as

$$H = \hbar\omega\left(a_+ a_- + \frac{1}{2}\right) \quad ...(139)$$

In terms of $a_\pm$, the Schrödinger equation for the S.H.O. takes the form

$$\hbar\omega\left(a_\pm a_\mp \pm \frac{1}{2}\right)\psi = E\psi \quad ...(140)$$

(In Eq. 140 we read the upper signs all the way across, or else the lower signs).

Now we proceed to prove the crucial result which states that *if ψ satisfies the Schrödinger equation with energy E (i.e., $H\psi = E\psi$), then $a_+\psi$ satisfies the Schrödinger equation with energy $(E + \hbar\omega)$ i.e., $H(a_+\psi) = (E + \hbar\omega)(a_+\psi)$*. Thus,

$$H(a_+\psi) = \hbar\omega\left(a_+ a_- + \frac{1}{2}\right)(a_+\psi) = \hbar\omega\left(a_+ a_- a_+ + \frac{1}{2}a_+\right)\psi$$

$$= \hbar\omega a_+\left(a_- a_+ + \frac{1}{2}\right)\psi = a_+\left[\hbar\omega\left(a_+ a_- + 1 + \frac{1}{2}\right)\psi\right]$$

$$= a_+(H + \hbar\omega)\psi = a_+(E + \hbar\omega)\psi = (E + \hbar\omega)(a_+\psi)$$

Here we have used Eq. 138 to replace $a_- a_+$ by $(a_+ a_- + 1)$ in the second line. Notice that whereas the ordering of a_+ and a_- *does* matter, the ordering of $a_\pm$ and any *constants*—such as $\hbar$, ω and E—does *not* ; an operator commutes with any constant. Similarly, we can show that $a_-\psi$ is a solution with energy $(E - \hbar\omega)$:

$$H(a_-\psi) = \hbar\omega\left(a_- a_+ - \frac{1}{2}\right)(a_-\psi) = \hbar\omega a_-\left(a_+ a_- - \frac{1}{2}\right)\psi$$

$$= a_-\left[\hbar\omega\left(a_- a_+ - 1 - \frac{1}{2}\right)\psi\right]$$

$$= a_-(H - \hbar\omega)\psi = a_-(E - \hbar\omega)\psi$$

$$= (E - \hbar\omega)(a_-\psi)$$

Here, then, is the wonderful machine for generating new solutions, with higher and lower energies if we could just find *one* solution to get started ! We call $a_\pm$ **ladder operators** because they allow us to climb up and down in energy ; a_+ is the raising operator and a_- is the lowering operator. The ladder of states is illustrated in Fig. 6.

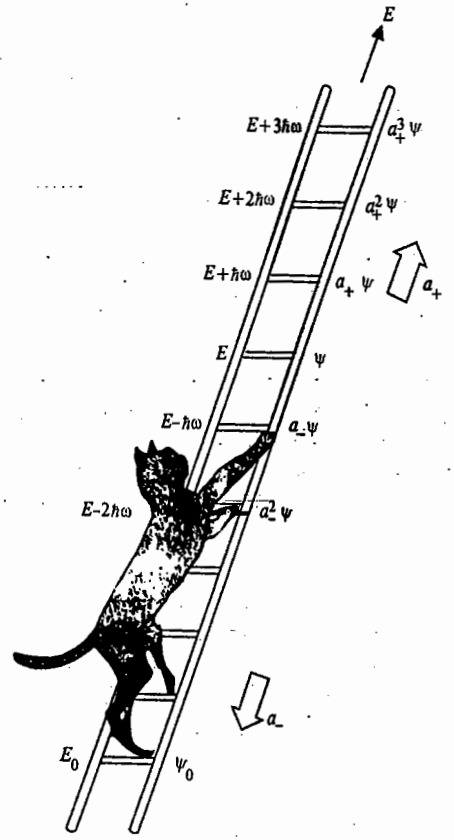

Fig. 6. The "ladder" of states for the harmonic oscillator.

If, however, we apply the lowering operator repeatedly, we eventually reach a state with energy less than zero which does not exist ! At some point the machine must fail. We know that $a_-\psi$ is a new solution to the Schrödinger equation and there occurs a lower rung (call it ψ_0) such that

$$a_-\psi_0 = 0 \qquad ...(141)$$

We can use this to determine $\psi_0(x)$:

$$\frac{1}{\sqrt{2\hbar m\omega}}\left(\hbar\frac{d}{dx} + m\omega x\right)\psi_0 = 0$$

or, $$\frac{d\psi_0}{dx} = -\frac{m\omega}{\hbar}x\psi_0 \qquad ...(142)$$

This differential equation can be solved easily :

$$\int\frac{d\psi_0}{\psi_0} = -\frac{m\omega}{\hbar}\int x\,dx \;;\text{ or } \ln\psi_0 = -\frac{m\omega}{2\hbar}x^2 + \text{constant} \qquad ...(143)$$

so that $$\psi_0(x) = N\exp\left(-\frac{m\omega}{2\hbar}x^2\right) \qquad ...(144)$$

which can be normalized easily :

$$N^2\int_{-\infty}^{\infty}\exp\left(-\frac{m\omega x^2}{\hbar}\right)dx = N^2\left(\frac{\pi\hbar}{m\omega}\right)^{\frac{1}{2}} = 1 \qquad ...(145)$$

so that $$N^2 = (m\omega/\pi\hbar)^{\frac{1}{2}} \qquad ...(146)$$

Hence, $$\psi_0(x) = \left(\frac{m\omega}{\pi\hbar}\right)^{\frac{1}{4}}\exp\left(-\frac{m\omega x^2}{2\hbar}\right) \qquad ...(147)$$

To determine the energy of this state we substitute it into the Schrödinger equation (in the form of Eq. 140), $\hbar\omega\left(a_+a_- + \frac{1}{2}\right)\psi_0 = E_0\psi_0$ and exploit the fact that $a_-\psi_0 = 0$. Accordingly,

$$E_0 = \frac{1}{2}\hbar\omega \qquad ...(148)$$

This is the zero point energy (Z.P.E.) of the S.H.O. With our foot now firmly planted on the bottom rung (the ground state of the S.H.O), we simply apply the raising operator (repeatedly) to generate the excited states, increasing the energy by $\hbar\omega$ with each step :

$$\psi_n(x) = N_n(a_+)^n\psi_0(x), \text{ with } E_n = \left(n + \frac{1}{2}\right)\hbar\omega \qquad ...(149)$$

where N_n is the normalitzation constant and n is the vibrational quantum number. By applying the raising operator (repeatedly) to ψ_0, we can (in principle) construct all the stationary states of the S.H.O. Meanwhile, without even doing that explicitly, we have determined the allowed energies. We can even get N_n algebraically, but it takes some fancy footwork. So we stop here.

ANGULAR MOMENTUM OPERATORS, COMMUTATION RELATIONS, LADDER OPERATORS, EIGENFUNCTIONS AND EIGENVALUES

1. Angular Momentum Operators. The Cartesian components of the angular momentum operators are given by

$$\hat{L}_x = -i\hbar\left[y\frac{\partial}{\partial z} - z\frac{\partial}{\partial y}\right] \qquad ...(150a)$$

$$\hat{L}_y = -i\hbar\left[z\frac{\partial}{\partial x} - x\frac{\partial}{\partial z}\right] \qquad ...(150b)$$

$$\hat{L}_z = -i\hbar\left[x\frac{\partial}{\partial y} - y\frac{\partial}{\partial x}\right] \qquad ...(150c)$$

In order to determine whether L_x, L_y and L_z can be precisely specified simultaneously, we must determine whether each of the pairs of the corresponding operators commute. Let us evaluate the commutator $[\hat{L}_x, \hat{L}_y]$.

$$[\hat{L}_x, \hat{L}_y] = \hat{L}_x\hat{L}_y - \hat{L}_y\hat{L}_x$$

$$\hat{L}_x\hat{L}_y = -i\hbar\left[y\frac{\partial}{\partial z} - z\frac{\partial}{\partial y}\right](-i\hbar)\left[z\frac{\partial}{\partial x} - x\frac{\partial}{\partial z}\right]$$

$$= -\hbar^2\left[y\frac{\partial}{\partial z}\times z\frac{\partial}{\partial x} - y\frac{\partial}{\partial z}x\frac{\partial}{\partial z} - z\frac{\partial}{\partial y}z\frac{\partial}{\partial x} + z\frac{\partial}{\partial y}x\frac{\partial}{\partial z}\right]$$

$$= -\hbar^2\left[y\frac{\partial}{\partial x} + yz\frac{\partial^2}{\partial z\partial x} - yx\frac{\partial^2}{\partial z^2} - z^2\frac{\partial^2}{\partial y\partial x} + zx\frac{\partial^2}{\partial y\partial z}\right]$$

(because terms like $\partial z/\partial x = 0$ and $\partial z/\partial z = 1$)

Again, $$\hat{L}_y\hat{L}_x = -\hbar^2\left[z\frac{\partial}{\partial x} - x\frac{\partial}{\partial z}\right]\left[y\frac{\partial}{\partial z} - z\frac{\partial}{\partial y}\right]$$

$$= -\hbar^2\left[z\frac{\partial}{\partial x}y\frac{\partial}{\partial z} - z\frac{\partial}{\partial x}z\frac{\partial}{\partial y} - x\frac{\partial}{\partial z}y\frac{\partial}{\partial z} + x\frac{\partial}{\partial z}z\frac{\partial}{\partial y}\right]$$

$$= -\hbar^2\left[zy\frac{\partial^2}{\partial x\partial z} - z^2\frac{\partial^2}{\partial x\partial y} - xy\frac{\partial^2}{\partial z^2} + x\frac{\partial}{\partial y} + xz\frac{\partial^2}{\partial z\partial y}\right]$$

Hence, $$\hat{L}_x\hat{L}_y - \hat{L}_y\hat{L}_x = -\hbar^2\left[y\frac{\partial}{\partial x} - x\frac{\partial}{\partial y}\right] = i\hbar\left[i\hbar\left(y\frac{\partial}{\partial x} - x\frac{\partial}{\partial y}\right)\right]$$

$$= i\hbar\left[-i\hbar\left(x\frac{\partial}{\partial y} - y\frac{\partial}{\partial x}\right)\right] = i\hbar\hat{L}_z \text{ (using Eq. 150c)} \qquad ...(151)$$

Thus, $$[\hat{L}_x, \hat{L}_y] = i\hbar\hat{L}_z \qquad ...(152)$$

Similarly, we can show that

$$[\hat{L}_y, \hat{L}_z] = i\hbar\hat{L}_x \text{ and } [\hat{L}_z, \hat{L}_x] = i\hbar\hat{L}_y \qquad ...(153)$$

None of the relations in Eqs. 152 and 153 is zero, which means that the three components L_x, L_y, L_z of angular momentum cannot be specified simultaneously. If we specify one component, the other two become uncertain. By convention, the component L_z is chosen to have a specific value so that L_x and L_y cannot have specific values. However, the z-axis itself is chosen arbitrarily. But when the atom or molecule is placed in a magnetic or electric field, the direction of the field is chosen as the z-axis.

Next we are intersested in knowing whether L (the angular momentum itself) and L_z (its z-component) can be specificed simultaneously or not. To find it out, we recall that L is given by

$$L = (L_x^2 + L_y^2 + L_z^2)^{1/2}$$

This means that the operator $\hat{L}$ has to be defined as the square root of another operator. Ignoring the meaning of the square root of an operator, let us find out whether the operators $\hat{L}^2$ and $\hat{L}_z$ commute.

$$\begin{aligned}[\hat{L}^2, \hat{L}_z] &= [\hat{L}_x^2 + \hat{L}_y^2 + \hat{L}_z^2, \hat{L}_z] \\ &= \hat{L}_x^2\hat{L}_z + \hat{L}_y^2\hat{L}_z + \hat{L}_z^2\hat{L}_z - \hat{L}_z\hat{L}_x^2 - \hat{L}_z\hat{L}_y^2 - \hat{L}_z\hat{L}_z^2 \\ &= (\hat{L}_x^2\hat{L}_z - \hat{L}_z\hat{L}_x^2) + (\hat{L}_y^2\hat{L}_z - \hat{L}_z^2\hat{L}_y) + (\hat{L}_z^2\hat{L}_z - \hat{L}_z\hat{L}_z^2) \\ &= [\hat{L}_x^2, \hat{L}_z] + [\hat{L}_y^2, \hat{L}_z] + [\hat{L}_z^2, \hat{L}_z] \qquad \ldots(154)\end{aligned}$$

The first term in Eq. 154, *viz.*,

$$\begin{aligned}[\hat{L}_x^2, \hat{L}_z] &= \hat{L}_x\hat{L}_x\hat{L}_z - \hat{L}_z\hat{L}_x\hat{L}_x \\ &= \hat{L}_x\hat{L}_x\hat{L}_z - \hat{L}_x\hat{L}_z\hat{L}_x + \hat{L}_x\hat{L}_z\hat{L}_x - \hat{L}_z\hat{L}_x\hat{L}_x \\ &= \hat{L}_x(\hat{L}_x\hat{L}_z - \hat{L}_z\hat{L}_x) + (\hat{L}_x\hat{L}_z - \hat{L}_z\hat{L}_x)\hat{L}_x \\ &= \hat{L}_x[\hat{L}_x, \hat{L}_z] + [\hat{L}_x, \hat{L}_z]\hat{L}_x \\ &= -i\hbar\hat{L}_x\hat{L}_y - i\hbar\hat{L}_y\hat{L}_x \qquad (\because [\hat{L}_x, \hat{L}_z] = -[\hat{L}_z, \hat{L}_x]) \\ &= -i\hbar(\hat{L}_x\hat{L}_y + \hat{L}_y\hat{L}_x) \qquad \ldots(155)\end{aligned}$$

Similarly, it can be shown that

$$[\hat{L}_y^2, \hat{L}_z] = i\hbar(\hat{L}_x\hat{L}_y + \hat{L}_y\hat{L}_x) \qquad \ldots(156)$$

and

$$[\hat{L}_z^2, \hat{L}_z] = 0 \qquad \ldots(157)$$

Adding Eqs. 155, 156 and 157, we have

$$[\hat{L}^2, \hat{L}_z] = 0 \qquad \ldots(158)$$

which means that the square of the angular momentum and its z-component can be specified simultaneously. We can similarly show that $\hat{L}^2$ commutes with $\hat{L}_x$ and $\hat{L}_y$.

Commutation relations (Eqs. 152, 153 and 158) mean that the angular momentum L of a relating particle can be represented by a vector of precise length L with one and only one of its components (conventionally L_z) precisely defined. Since the other two components (L_x and L_y) are uncertain, the vector may lie anywhere on the surface of a cone whose axis coincides with the z-axis. In the classical sense, it corresponds to the vector L precessing around z-axis (Fig. 7).

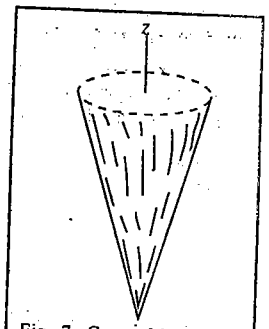

Fig. 7. Cone of location of angular momentum vector.

The relations 152, 153 and 158 constitute the quantum mechanical definition of angular momentum. In fact, any vector J may be called **generalized angular momentum** if it satisfies the following relations:

$$[\hat{J}_x, \hat{J}_y] = i\hbar\hat{J}_z; [\hat{J}_y, \hat{J}_z] = i\hbar\hat{J}_x; [\hat{J}_z, \hat{J}_x] = i\hbar\hat{J}_y \qquad \ldots(159)$$

$$[\hat{J}^2, \hat{J}_k] = 0, \text{ where } k = x, y, z \qquad \ldots(160)$$

and

$$J^2 = (\hat{J}_x^2 + \hat{J}_y^2 + \hat{J}_z^2)^{\frac{1}{2}} \qquad \ldots(161)$$

A rotating system is thus characterized by two operators $\hat{J}^2$ and $\hat{J}_z$ and their eigenvalues. Before we proceed to find the eigenvalues and eigenfunctions, we shall introduce two new operators $\hat{J}_+$ and $\hat{J}_-$, called the **ladder operators** (or **step-up** and **step-down operators, shift operators** and, sometimes, **raising** and **lowering operators**) and examine some of their commutation properties.

2. Ladder Operators. These operators are defined as

$$\left.\begin{aligned}\hat{J}_+ &= \hat{J}_x + i\hat{J}_y \\ \hat{J}_- &= \hat{J}_x - i\hat{J}_y\end{aligned}\right\} \qquad \ldots(162)$$

They are so called because, as we shall see later, they have the effect of raising and lowering eigenvalues, respectively. These operators commute with $\hat{J}^2$ but not with $\hat{J}_z$; they also do not commute between themselves as described below :

$$\begin{aligned}[\hat{J}^2, \hat{J}_+] &= [\hat{J}^2, (\hat{J}_x + i\hat{J}_y)] = \hat{J}^2(\hat{J}_x + i\hat{J}_y) - (\hat{J}_x + i\hat{J}_y)\hat{J}^2 \\ &= \hat{J}^2\hat{J}_x + i\hat{J}^2\hat{J}_y - \hat{J}_x\hat{J}^2 - i\hat{J}_y\hat{J}^2 = (\hat{J}^2\hat{J}_x - \hat{J}_x\hat{J}^2) + i(\hat{J}^2\hat{J}_y - \hat{J}_y\hat{J}^2) \\ &= [\hat{J}^2, \hat{J}_x] + i[\hat{J}^2, \hat{J}_y] = 0 + 0 = 0 \qquad \ldots(163)\end{aligned}$$

Similarly,

$$[\hat{J}^2, \hat{J}_-] = 0 \qquad \ldots(164)$$

Again,

$$[\hat{J}_+, \hat{J}_z] = [(\hat{J}_x + i\hat{J}_y), \hat{J}_z] = (\hat{J}_x + i\hat{J}_y)\hat{J}_z - \hat{J}_z(\hat{J}_x + i\hat{J}_y)$$

$$= \hat{J}_x \hat{J}_z + i \hat{J}_y \hat{J}_z - \hat{J}_z \hat{J}_x - i \hat{J}_z \hat{J}_y$$

$$= (\hat{J}_x \hat{J}_z - \hat{J}_z \hat{J}_x) + i(\hat{J}_y \hat{J}_z - \hat{J}_z \hat{J}_y)$$

$$= [\hat{J}_x, \hat{J}_z] + i[\hat{J}_y, \hat{J}_z] = -i\hbar \hat{J}_y - \hbar \hat{J}_x$$

$$= -\hbar(\hat{J}_x + i \hat{J}_y) = -\hbar \hat{J}_+ \quad ...(165)$$

Similarly, we can show that

$$[\hat{J}_-, \hat{J}_z] = -\hbar \hat{J}_- \quad ...(166)$$

and

$$[\hat{J}_+, \hat{J}_-] = -2\hbar \hat{J}_z \quad ...(167)$$

3. Eigenfunctions and Eigenvalues of $\hat{J}^2$ and $\hat{J}_z$. The commutation relations provide an elegant means of arriving at the eigenvalues of the angular momentum operators $\hat{J}^2$ and $\hat{J}_z$. Since $\hat{J}^2$ and $\hat{J}_z$ commute, they have a common set of eigenfunctions. Denoting these eigenfunctions as $\psi_{j,m}$ (or, in the Dirac notation, as $|j, m>$), the two eigenvalue equations are

$$\hat{J}^2 \mid j,m > = k_j \mid j, m > \quad ...(168)$$

$$\hat{J}_z \mid j,m > = k_m \mid j, m > \quad ...(169)$$

where j and m are the quantum numbers which specify the eigenvalues k_j and k_m, respectively. Operating on both sides of Eq. 169 by $\hat{J}_z$, we obtain

$$\hat{J}_z^2 \mid j,m > = \hat{J}_z(k_m \mid j,m >) = k_m(\hat{J}_z \mid j,m >) = k_m^2 \mid j,m > \quad ...(170)$$

Subtracting Eq. 170 from Eq. 168, we get

$$(\hat{J}^2 - \hat{J}_z) \mid j,m > = (k_j - k_m^2) \mid j,m > \quad ...(171)$$

or

$$(\hat{J}_x^2 + \hat{J}_y^2) \mid j,m > = (k_j - k_m^2) \mid j,m > \quad ...(172)$$

(because $\hat{J}^2 = \hat{J}_x^2 + \hat{J}_y^2 + \hat{J}_z^2$)

Now, $(\hat{J}_x^2 + \hat{J}_y^2)$ is the operator for the physical quantity $(J_x^2 + J_y^2)$ which can never be negative; hence, the eigenvalue $(k_j - k_m^2)$ in Eq. 172 must always be positive, that is,

$$k_j \geq k_m^2 \text{ for any value of } k_m \quad ...(173)$$

Let us now consider the effect of the ladder operators and to know why they are called by this name. We shall first consider the effect of $\hat{J}_+$ on the eigenvalue of $\hat{J}^2$. Since $\hat{J}^2$ commutes with $\hat{J}_+$ (Eq. 163), we have

$$\hat{J}^2 \hat{J}_+ \mid j,m > = \hat{J}_+ \hat{J}^2 \mid j\,m > = \hat{J}_+(k_j \mid j,m >) = k_j(\hat{J}_+ \mid j,m >) \quad ...(174)$$

(in view of Eq. 168)

This means that $\hat{J}_+ \mid j,m >$ is also an eigenfunction of $\hat{J}^2$ with the same eigenvalue (k_j), that is, there is no effect of J_+ on the eigenvalue of $\hat{J}^2$.

Let us now consider the effect on k_m. By adding and subtracting $\hat{J}_+ \hat{J}_z$, we obtain

$$\hat{J}_z \hat{J}_+ \mid j,m > = (\hat{J}_+ \hat{J}_z + \hat{J}_z \hat{J}_+ - \hat{J}_+ \hat{J}_z) \mid j,m > = \{\hat{J}_+ \hat{J}_z + [\hat{J}_z, \hat{J}_+]\} \mid j,m >$$

$$= \{\hat{J}_+ \hat{J}_z \mid j,m > + [\hat{J}_z \hat{J}_+] \mid j,m >\}$$

$$= \hat{J}_+ k_m \mid j,m > + \hbar \hat{J}_+ \mid j,m > = \hat{J}_+(k_m + \hbar) \mid j,m >$$

$$= (k_m + \hbar) \hat{J}_+ \mid j,m > \quad ...(175)$$

(by Eqs. 169 and 165, and from the fact that $[\hat{J}_z, \hat{J}_+] = -[\hat{J}_+, \hat{J}_z]$)

This means that $\hat{J}_+ \mid j,m >$ is also an eigenfunction of $\hat{J}_z$ but its eigenvalue is raised from k_m to $(k_m + \hbar)$, *i.e.*, by one atomic unit. The clue to this derivation is that $\hat{J}_+$ does not commute with $\hat{J}_z$.

Similarly, it can be shown that $\hat{J}_-$ lowers the eigenvalue of $\hat{J}_z$ from k_m to $(k_m - \hbar)$, *i.e.*, by one atomic unit but keeps that of $\hat{J}^2$ unaltered, that is,

$$\hat{J}^2(\hat{J}_- \mid j,m >) = k_j(\hat{J}_- \mid j,m >) \quad ...(176)$$

$$\hat{J}_z(\hat{J}_- \mid j,m >) = (k_m - \hbar)(\hat{J}_- \mid j,m >) \quad ...(177)$$

It is now easy to show that

$$\hat{J}_\pm(\hat{J}_\pm \mid j;m >),\ \hat{J}_\pm[\hat{J}_\pm(\hat{J}_\pm \mid j,m >)],\ldots \quad ...(178)$$

are all eigenfunctions of $\hat{J}_z$ with altered eigenvalues and also of $\hat{J}^2$ with unaltered eigenvalues. Successive applications of the operators $\hat{J}_\pm$ will, therefore, generate a series of eigenfunctions of $\hat{J}_z$ whose eigenvalues constitute the series

$$k_m', k_m' + \hbar, k_m' + 2\hbar, \ldots, k_m'' - 2\hbar, k_m'' - \hbar, k_m''$$

or $k_m', k_m' + 1, k_m' + 2, \ldots, k_m'' - 2, k_m'' - 1, k_m''$ (in atomic units) ...(179)

(recall that in quantum mechanics, we set $e = \hbar = m_e = 1$ arbitrarily, using atomic units)

where for a given value of k_j, k_m' is the lowest and k_m'' is the highest eigenvalue. The lowest and the highest values of k_m are governed by the condition contained in Eq. 173, *viz.*, $k_m^2 \leq k_j$. It also follows that the maximum and minimum values are related as

$$k_n'' = k_m' + n\hbar$$

or

$$k_n'' = k_m' + n \text{ (in a.u.)}$$

where n is a positive integer.

For the maximum value of k_m, *i.e.* k_m'', let $| j'', m'' >$ be the eigenfunctions; then we have the eigenvalue equation

$$\hat{J}_z | j'', m'' > = k_m'' | j'', m'' > \quad ...(180)$$

Since k_m'' is the upper limit of the eigenvalue, further application of the operator will yield zero as the eigenvalue, *i.e.*, $\hat{J}_+ | j'', m'' > = 0$.

Operating with $\hat{J}_-$, we get

$$\hat{J}_- \hat{J}_+ | j'', m'' > = 0$$

or $$(\hat{J}_x - i\hat{J}_y)(\hat{J}_x + i\hat{J}_y) | j'', m'' > = 0$$

or $$(\hat{J}_x^2 + \hat{J}_y^2 + i\hat{J}_x\hat{J}_y - i\hat{J}_y\hat{J}_x) | j'', m'' > = 0$$

or $$(\hat{J}^2 - \hat{J}_z^2 + i^2\hbar\hat{J}_z) | j'', m'' > = 0$$

or $$(k_j - k_m''^2 - \hbar k_m'') | j'', m'' > = 0 \quad \text{(because } k_j'' = k_j\text{)} \quad ...(181)$$

since $| j'', m'' > \neq 0$, $k_j = k_m''(k_m'' + \hbar)$

Similarly, we can show that

$$k_j = k_m'(k_m' - \hbar) \quad ...(182)$$

From Eqs. 181 and 182, we get

$$k_j = k_m''(k_m'' + \hbar) = k_m'(k_m' - \hbar) \quad ...(183)$$

and from Eq. 180,

$$(k_m' + n\hbar)[k_m' + (n+1)\hbar] = k_m'(k_m' - \hbar)$$

or $$2(n+1)\hbar k_m' + n(n+1)\hbar^2 = 0$$

or $$k_m' = -n\hbar/2 = -j\hbar \text{ (where } j = n/2) \quad ...(184)$$

Similarly, $$k_m'' = +n\hbar/2 = +j\hbar \quad ...(185)$$

Eqs. 184 and 185 show that j must be either an integer or a half-integer. Hence, Eq. 183 gives

$$k_j = j(j+1)\hbar^2 \text{ or } j(j+1) \text{ (in a.u.)} \quad ...(186)$$

and $$k_m = m\hbar \text{ or } m \text{ (in a.u.)} \quad ...(187)$$

where for a given value of j, m can take any of the values in the series

$$j, j-1, j-2, \ldots, 0, \ldots -(j-2), -(j-1), -j \quad ...(188)$$

making a total of $2j+1$ values for m.

Eqs. 168 and 169 may, thus, be written as

$$\hat{J}^2 | j, m > = [j(j+1)\hbar^2] | j, m > \quad ...(189)$$

$$\hat{J}_z | j, m > = m\hbar | j, m > \quad ...(190)$$

where m takes any value in the series (Eq. 188). Thus, for $j = 2$, $m = +2, +1, 0, -1$ or -2, and for $j = (3/2)$ m can be $3/2$, $1/2$, $-1/2$ or $-3/2$.

The physical interpretation is that the behaviour of the angular momentum vector J is governed by Eqs. 189 and 190, *i.e.*, the magnitude of J is quantized and given by $[j(j+1)]^{1/2}\hbar$, where j is the angular momentum quantum number. The vector is oriented in space in such a manner that its z-component has the value $m\hbar$, where m is the quantum number corresponding to the z-component of J (Fig. 8.)

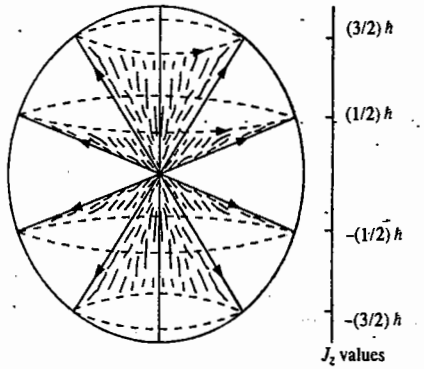

Fig. 8. Quantization of the angular momentum vector J for which $j = 3/2$

4. Orbital and Spin Angular Momentum Operators : Their Eigenfunctions and Eigenvalues.

The electrons (and other elementary particles) execute two types of rotational motion, *viz.*, the motion around the orbit called the *orbital motion*, and the rotation about its own axis, called the *spinning motion*. The corresponding angular momenta are designated L and S, respectively. They obey the same commutation rules and have similar eigenvalue equations. The angular momentum operators for the orbital motion are designed by $\hat{L}^2$ and $\hat{L}_z$ and those for the spinning motion by $\hat{S}^2$ and $\hat{S}_z$. The two quantum numbers needed to characterize the eigenfunctions are denoted as l and m_l for the orbital motion and s and m_s for the spinning motion.

The eigenfunctions of the orbital angular momentum operators are the **spherical harmonics** $Y_{l,m_l}(\theta, \phi)$, written in the Dirac notation as $|l, m_l >$; and the eigenfunctions for the spin angular momentum operators are $| \alpha >$ and $| \beta >$, where $| \alpha > \equiv | \frac{1}{2}, \frac{1}{2} >$ and $| \beta > \equiv | \frac{1}{2}, -\frac{1}{2} >$, *i.e.*, $| s, m_s >$, where for $s = \frac{1}{2}$, $m_s = +\frac{1}{2}$ or $-\frac{1}{2}$.

The eigenvalue equations are

$$\left.\begin{aligned} \hat{L}^2 | l, m_l > &= l(l+1)\hbar^2 | l, m_l > \\ \hat{L}_z | l, m_l > &= m_l\hbar | l, m_l > \end{aligned}\right\} \quad ...(191)$$

and
$$\left.\begin{aligned}\hat{S}^2 \mid s, m_s > &= s(s+1)\hbar^2 \mid s, m_s > \\ \hat{S}_z \mid s, m_s > &= m_s\hbar \mid s, m_s >\end{aligned}\right\} \quad ...(192)$$

Eqs. 192 can be written as

$$\left.\begin{aligned}\hat{S}^2 \mid \alpha > &= \tfrac{3}{4}\hbar^2 \mid \alpha >;\ \hat{S}^2 \mid \beta > = \tfrac{3}{4}\hbar^2 \mid \beta > \\ \hat{S}_z \mid \alpha > &= \tfrac{1}{2}\hbar \mid \alpha >;\ \hat{S}_z \mid \beta > = -\tfrac{1}{2}\hbar \mid \beta >\end{aligned}\right\} \quad ...(193)$$

Physically, the magnitude of the vector S is $(\sqrt{3}/2)\hbar$ and it is oriented only in any of such directions that its z-component is either $\hbar/2$ or $-\hbar/2$ (Fig. 9).

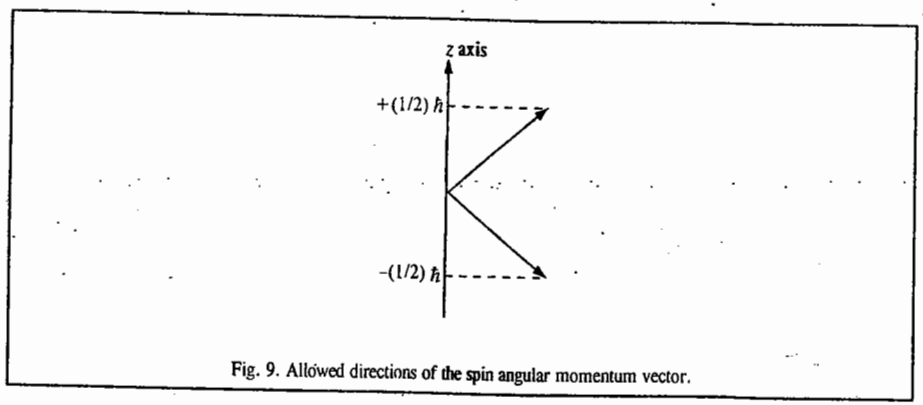

Fig. 9. Allowed directions of the spin angular momentum vector.

Note : Here $\mid \alpha >$ refers to upward ($\uparrow$) spin orientation and $\mid \beta >$ refers to downward ($\downarrow$) spin orientation.
For a detailed treatment of angular momentum see the last section of this chapter.

Derivation of the Variation Theorem

Suppose ψ is an approximate wave function of a quantum system. Then, the energy of the system is given by **Rayleigh ratio**

$$E = \frac{\int \psi^* \hat{H} \psi \, d\tau}{\int \psi^* \psi \, d\tau} = \frac{< \psi \mid \hat{H} \mid \psi >}{< \psi \mid \psi >} \quad ...(194)$$

Let ϕ_n denote the exact set of orthonormal eigenfunctions of the Hamiltonian, $\hat{H}$:

$$\hat{H}\phi_n = E_n\phi_n ;\ (n = 0, 1, 2, 3.....) \quad ...(195)$$

The wave function ψ can be expanded in terms of the eigenfunctions, ϕ_n, of $\hat{H}$:

$$\psi = \sum_n c_n\phi_n \quad ...(196)$$

Substituting for ψ from Eq. 196 into Eq. 194, we get

$$E = \frac{\int (\sum_n c_n^* \phi_n^*) \hat{H} (\sum_m c_m\phi_m) d\tau}{\int (\sum_n c_n^* \phi_n^*)(\sum_m c_m\phi_m) d\tau} \quad ...(197)$$

Using Eq. 195, we obtain

$$E = \frac{\sum_n \sum_m c_n^* \, c_m E_m \int \phi_n^* \, \phi_m \, d\tau}{\sum_n \sum_m c_n^* \, c_m \int \phi_n^* \, \phi_m \, d\tau} = \frac{\sum_n c_n^* c_n E_n}{\sum_n c_n^* c_n} = \frac{\sum_n |c_n|^2 E_n}{\sum_n |c_n|^2} \quad ...(198)$$

Substracting E_0, the ground state energy, from both sides of Eq. 198, we have

$$E - E_0 = \frac{\sum_n |c_n|^2 (E_n - E_0)}{\sum_n |c_n|^2} \quad ...(199)$$

since $\int \phi_n^* \phi_m^* \, d\tau = < \phi_n \phi_m > = \delta_{nm} = \begin{cases} 1, n = m \\ 0, n \neq m \end{cases}$

Further, $E_n \geq E_0$ since, by definition, E_0 is the ground state energy. Again, since $|c_n|^2 \geq 0$ for all n, it follows that

$$E - E_0 \geq 0 \quad \text{or} \quad E \geq E_0 \quad ...(200)$$

This important inequality called **Eckart's inequality** shows that *the approximate energy E, corresponding to the approximate wave function ψ, is always greater than the true energy, E_0.* This is the statement of the **variation theorem.** Using the inequality 200 one can obtain an **upper bound** to the ground state energy E_0. The procedure is to construct a 'trial' wave function which depends upon a set of variation parameters $\{\alpha_i\}$. Thus, we can write

$$\psi = \psi(\alpha_1, \alpha_2, ... \alpha_n) \quad ...(201)$$

The parameters $\{\alpha_i\}$ may, for instance, enter the trial function as exponential factors.

Using this trial function in Eq. 194, the energy E is calculated. We then choose $\{\alpha_i\}$ so as to minimize E, that is,

$$\partial E/\partial \alpha_i = 0 \text{ for } i = 1, 2, 3, ... n \quad ...(202)$$

The minimum energy thus obtained provides an upper bound to E_0 which will be closer to the exact value if the trial function approximates the ground state wave function ϕ_0.

It may be remarked that in Eckart's inequality reside both the power and the weakness of the variation method for seeking approximate solutions to Schrödinger's equation. The power lies in the fact that it is possible to choose the 'best' wave function from several functions on the basis of the lowest energy. The weakness, on the other hand, is that the energy does not turn out to be a sensitive criterion with respect to the 'best' wave function for other physical properties of the quantum system.

ATOMIC STATES AND TERM SYMBOLS

As we have remarked in the discussion of angular momentum of many-electron atoms, as a result of the *spin-orbit interaction*, the term symbol in the Russell-Saunders coupling scheme is designated by the symbol $^{2S+1}L_J$. The term symbol for the ground state of hydrogen atom is $^2S_{1/2}$ whereas the term symbol for the ground state of helium atom is $^1S_0$. For an atom such as boron atom whose electronic configuration is $1s^2\,2s^2 2p^1$, we can make use of the fact that all *closed shells and subshells contribute nothing to the term symbol.* Hence, both $1s^2$ and $2s^2$ electrons give $L = S = J = 0$. The $2p^1$ electron has $L=1$, $S=1/2$ and $J=1 \pm 1/2$, yielding the term symbols $^2P_{1/2}$ and $^2P_{3/2}$. For carbon atom whose electronic configuration is $1s^2\,2s^2 2p^2$, there are two p electrons. The spins may be paired or unpaired, so $L = 2, 1, 0$; $S = 1, 0$; and $J = 3, 2, 1, 0$. To work out the appropriate states for this atom, we require a systematic approach which we shall outline here.

Term Symbols for p^2 Configuration. For determining the term symbols for p^2 configuration we proceed as follows :

1. *Determine the possible values of M_L and M_S.* For the p^2 configuration, L can have a maximum value of 2 and M_L can have values of -2, -1, 0, +1, +2. The electrons can be paired (M_S=0) or parallel (M_S = +1, - 1).

2. *Determine the electronic configurations that are allowed by the Pauli exclusion principle.* The easiest way to do this is to draw up a number of sets of p orbitals as in Fig. 10 (each vertical column represents a set of three p orbitals) and fill in electrons until all possible arrangements have been formed. The M_L value for each arrangement can be found by summing m_l and M_S is evaluated from the sum of m_s (spin-up electrons have arbitrarily been assigned m_s = +1/2). Each microstate consists of one combination of M_L and M_S.

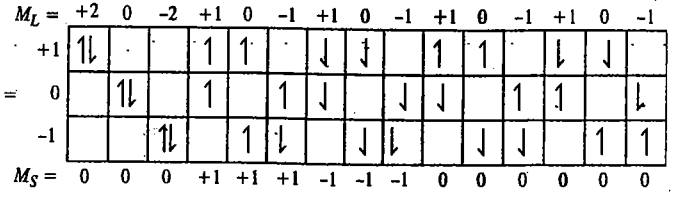

Fig. 10. The fifteen microstates and resultant values of M_L and M_S for the $1s^2 2s^2 2p^2$ electronic configuration of carbon.

3. *Set up a chart of microstates.* For example, the microstate corresponding to the first vertical column in Fig. 1 has M_L = +2 and M_S = 0. It is then entered into the table below under those values. The fifteen microstates of p^2 yield :

		M_S		
		+1	0	-1
	-2		x	
	-1	x	xx	x
M_L	0	x	xxx	x
	+1	x	xx	x
	+2		x	

4. *Resolve the chart of microstates into appropriate atomic states.* An atomic state forms an array of microstates consisting of $2S+1$ columns and $2L+1$ rows. Thus, for instance, a ^{1}D state requires a single column of 5 and a ^{5}D state requires a 5×5 array, etc. Looking at the array of microstates, it is easy to spot the unique third microstate at M_L=0 and M_S= 0 ; this must be a ^1S. A central column of M_S=0 provides a ^{1}D. Removing these two states from the table, one is left with an obvious 3×3 array of a ^{3}P state :

		M_S		
		+1	0	-1
	-2			
	-1	x	x	x
M_L	0	x	x	x
	+1	x	x	x
	+2			

The atomic states of carbon atom are, therefore, ^{1}S, ^{1}D and ^{3}P. The ^{3}P state is further split by differing J values to the terms $^3P_0$, $^3P_1$ and $^3P_2$. The relative magnitudes of splitting are shown in Fig. 11.

It is possible to predict the ground term of an atom by using three empirical rules, known as **Hund's rules.** According to **Hund's first rule**, for a given ground configuration, the term with the greatest multiplicity ($2S+1$) lies lowest in energy. **Hund's second rule** states that for a term of given multiplicity, the greater the value of L, the lower the energy.

Hund's third rule states that for levels with the same S and L, the one with the lowest energy depends on the extent to which the subshell is filled :

(a) If the subshell is less than half-filled, the state with the smallest value of J is most stable.

(b) If the subshell is more than half-filled, the state with the largest value of J is the most stable.

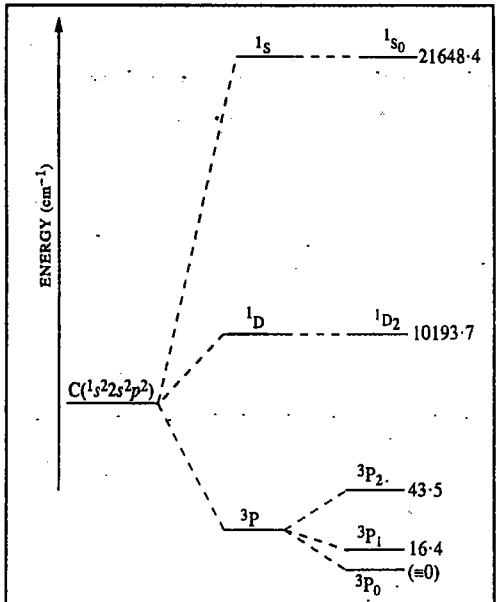

Fig. 11. Term splitting in the ground state ($1s^2 2s^2 2p^2$) configuration of carbon. All energies are in cm^{-1}. The ^{3}P, ^{1}D and ^{1}S terms are split as a result of electron-electron repulsion. The ^{3}P term is further split with J= 0, 1, 2 as a result of spin-orbit coupling. The scale of the latter is exaggerated.

Thus, of the three terms of carbon atom derived above, ^{3}P is the ground state term (from Hund's first rule) because such a system having a maximum number of parallel spins will be stabilized by **exchange energy** resulting from their more favourable spatial distribution compared with that of paired electrons. Using the Hund's second rule, ^{1}D lies lower in energy than ^1S. This is explained by saying that when L is high, each electron can stay clear of its partner and hence have a lower coulombic interaction with it because (in a classical picture of the atom) the electrons are then orbiting in the same direction. If L is low, the electrons are orbiting in the opposite direction and meet more often (and hence repel each other more strongly.

We shall conclude this discussion by briefly mentioning the so-called **Racah parameters.** The different terms of a configuration have different energies on account of the coulombic repulsion between electrons. These inter-electron repulsion energies are given by complicated integrals over the orbitals occupied by the electrons. In the 1940s, Giulio Racah, the Italian physicist, developed theoretical expressions for inter-electron repulsion energies in terms of three combinations of integrals A, B, C, called the Racah parameters. The Racah parameters can, in fact, be treated as empirical quantities obtained from spectroscopy. All the three Racah parameters are positive (they represent inter-electron repulsions); they summarize the energies of all the terms that may arise from a single configuration. The parameters are the quantitative expression of the ideas in Hund's rules and are more powerful than the rules alone since they also account for deviations from them.

Example 11. The term symbol for the ground state of sodium is $3^2S_{1/2}$ and that of the first excited state is $3^2P_{1/2}$. List the possible quantum numbers n, l, j and m_j of the outer electron in each case.

Solution : The electronic configuration of Na atom is $1s^2\ 2s^2\ 2p^6\ 3s^1$. Recall that all closed shells and subshells

do not contribute to the term symbol. Now $2S+1 = 2$ so that $S = 1/2$. Hence,

$$3^2S_{1/2}: \quad n = 3, \quad l = 0 \quad j = \frac{1}{2} \quad m_j = \pm\frac{1}{2} \qquad [J = L \pm S]$$

$$3^2P_{1/2}: \quad n = 3, \quad l = 1 \quad j = \frac{3}{2} \quad m_j = \pm\frac{1}{2}, \pm\frac{3}{2}$$

$$n = 3, \quad l = 1 \quad j = \frac{1}{2} \quad m_j = \pm\frac{1}{2}$$

Example 12. Why is it impossible for a $2^2P_{5/2}$ state to exist ?

Solution : $2S + 1 = 2$, so that $S = 1/2$. A P state has $L = 1$

and $J = L \pm S = 1 \pm \frac{1}{2}$, hence $J = \frac{5}{2}$ is impossible.

Example 13. What is the ground term for the electronic configurations (a) $3d^5$ of Mn^{2+} and (b) $3d^3$ of Cr^{3+} ?

Solution : (*a*) Mn^{2+} (d^5)

↑	↑	↑	↑	↑

$L=2$; $M_L=$ 2 +1 0 -1 -2

We see that $S = 5\times1/2 = 5/2$, and multiplicity $2S+1 = 6$

Also, $M_L = +2+1+0-1-2 = 0$; so $L=0$, an S term.

Hence, the term is a sextet : ^6S

(*b*) Cr^{3+} ($3d^3$)

↑	↑	↑		

$L = 2$; $M_L=$ + 2 + 1 0 - 1 - 2

We see that $S = 3\times1/2 = 3/2$ and multiplicity $2S+1 = 4$

Also, $M_L = 2 + 1 + 0 = 3$; so $L = 3$, an F term.

Hence, the term is a quartet : ^4F

Note : The ground state term symbol can be derived (as illustrated here) by using a method that does not require writing all the permitted microstates.

Example 14. The term symbol for the ground state of N atom is $^4S_{3/2}$. Determine the electronic configuration for this element.

Solution. $2S+1 = 4$. Hence, $S = M_S = 3/2$, implying that there are three unpaired electrons. The S term gives $L = M_L = 0$, which agrees with one electron in each of the p orbitals.

$$M_L = (+ 1) + (0) + (- 1) = 0$$

∴ The configuration is $1s^2\,2s^2\,2p^3$ or $1s^2\,2s^2\,2p_x^1\,2p_y^1\,2p_z^1$

Example 15. The term symbol for the ground state of Nb is $^6D_{1/2}$. Does this agree with the predicted outer electronic configuration of $5s^2\,4d^3$?

Solution : Recall that closed shells or subshells do not contribute to the term symbol; so the d^3 configuration gives

$$M_L = L = (+ 2) + (+ 1) + (0) = + 3; \quad M_S = S = \left(+\frac{1}{2}\right)+\left(+\frac{1}{2}\right)+\left(+\frac{1}{2}\right) = \frac{3}{2}$$

which leads to the incorrect term symbol ^4F. The outer electronic configuration of $5s^1\,4d^4$ gives

$$M_L = L = (0) + (+ 2) + (+ 1) + (0) + (- 1) = + 2$$

$$M_S = S = \left(+\frac{1}{2}\right)+\left(+\frac{1}{2}\right)+\left(+\frac{1}{2}\right)+\left(+\frac{1}{2}\right)+\left(+\frac{1}{2}\right) = \frac{5}{2}$$

which leads to the correct term symbol of ^6D.

Example 16. Determine the term symbol for the ground state of Ni which has the outer electronic configuration $3d^8$.

Solution :

(*a*) Ni $3d^8$

↑↓	↑↓	↑↓	↑	↑

$L = 2$; $M_L =$ +2 +1 0 -1 -2

$$M_L = (+ 2) + (+ 1) + (0) + (- 1) + (- 2) + (+ 2) + (+ 1) + (0) = 3$$

$$M_S = \left(+\frac{1}{2}\right)+\left(+\frac{1}{2}\right)+\left(+\frac{1}{2}\right)+\left(+\frac{1}{2}\right)+\left(+\frac{1}{2}\right)+\left(-\frac{1}{2}\right)+\left(-\frac{1}{2}\right)+\left(-\frac{1}{2}\right) = 1$$

These values are assumed to be L and S, respectively, giving the term ^3F. The values of $L = 3$ and $S = 1$ correspond to $J = 4$, 3 and 2. Choosing the greatest value for J because the subshell is more than half-filled gives $^3F_4$.

The Russell-Saunders coupling (also called LS coupling) which we have used to determine the atomic term symbols, works for lighter atoms with atomic number Z < 30. In heavier atoms (Z > 30), this hierarchy breaks down and the **spin-orbit coupling** eventually becomes stronger than the LS coupling. In this limit a different coupling scheme, the ***jj* coupling** is used in which individual electrons acquire total angular momentum $j_i = l_i + s_i$. The total angular momentum is then given by $J=\Sigma j_i$. In atoms of intermediate Z, neither approximation is valid and the situation is very complicated but the eigenfunction of the Hamiltonian is still an eigenfunction of J^2. However, for heavier atoms it is still convenient to use the Russell-Saunders coupling scheme to determine the term symbols. The complexity of determining the appropriate terms increases with increase in the number of electrons. States for various electronic configurations are shown in Table 1.

TABLE 1

Term Symbols for Various Electronic Configurations

Configurations	Term Symbols for Equivalent Electrons
s^2, p^6 and d^{10}	^1S
p and p^5	^2P
p^2 and p^4	^3P, ^1D, ^1S
p^3	^4S, ^2D, ^2P
d and d^9	^2D
d^2 and d^8	^3F, ^3P, ^1G, ^1D, ^1S
d^3 and d^7	^4F, ^4P, ^2H, ^2G, ^3F, ^2F, ^2D, ^2D, ^2P
d^4 and d^6	^5D, ^3H, ^3G, ^3F, ^3F, ^3D, ^3P, ^3P, ^1I, ^1G, ^1G, ^1F, ^1D, ^1D, ^1S, ^1S
d^5	^6S, ^4G, ^4F, ^4D, ^4P, ^2I, ^2H, ^2G, ^2G, ^2F, ^2F, ^2D, ^2D, ^2D, ^2P, ^2S
	Term Symbols for Nonequivalent Electrons
$s\,s$	^1S, ^3S
$s\,p$	^1P, ^3P
$s\,d$	^1D, ^3D
$p\,p$	^3D, ^1D, ^3P, ^1P, ^3S, ^1S
$p\,d$	^3F, ^1F, ^3D, ^1D, ^3P, ^1P
$d\,d$	^3G, ^1G, ^3F, ^1F, ^3D, ^1D, ^3P, ^1P, ^3S, ^1S
$s\,s\,s$	^4S, ^2S, ^2S
$s\,s\,p$	^4P, ^2P, ^2P
$s\,p\,p$	^4D, ^2D, ^2D, ^4P, ^2P, ^2P, ^2P, ^4S, ^2S, ^2S
$s\,p\,d$	^4F, ^2F, ^2F, ^4D, ^2D, ^2D, ^4P, ^2P, ^2P

Example 17. An atom with orbital angular momentum L and spin angular momentum S often has a term in its Hamiltonian of the form $\lambda L.S$, called the spin-orbit coupling term. Since the angular momentum $J = L + S$ commutes with the Hamiltonian, the states of this atom can be labelled with the eigenvalues of J^2, J_z, L^2 and S_z. Notice that $L.S = (1/2)\ (J^2 - L^2 - S^2)$ so that the eigenvalue of $L.S$ is $(1/2)\ [J\ (J+1) - L\ (L+1) - S\ (S+1)]$. This can lead to observable energy level splittings. Thus, for example, the excited states of an alkali atom with the outermost electron excited from the s to the next higher p orbital will have $L = 1$ and $S = 1/2$. This leads to two possible J values : 3/2 and 1/2. Calculate the energy level splitting due to spin-orbital coupling.

Solution. The energy term due to $\lambda L.S$ will be

$$\lambda\left[J(J+1) - 1(1+1) - \frac{1}{2}\left(\frac{1}{2}+1\right)\right] = A\left[J(J+1) - \frac{11}{4}\right]$$

For $J = 3/2$, the energy term equals λ; for $J = 1/2$ it equals $-2A$, giving a splitting of 3λ.

In Na atom, the observed splitting of the intense yellow fluorescent lines is 17 cm^{-1}. Thus, . $\lambda = 5{\cdot}7\ cm^{-1}$, as shown in Fig. 12. λ is called spin-orbit coupling constant.

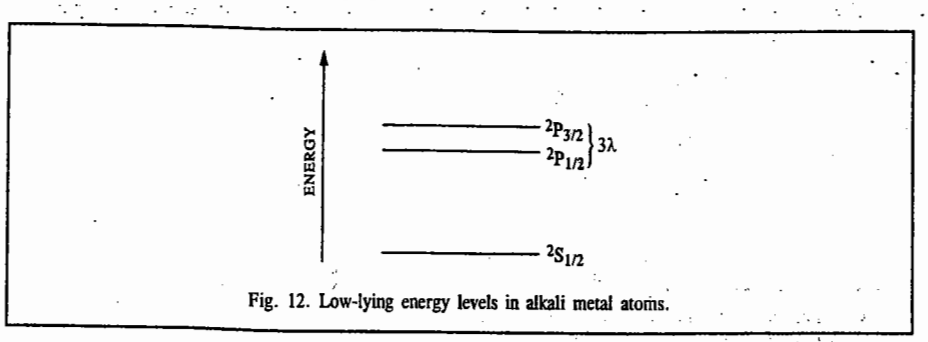

Fig. 12. Low-lying energy levels in alkali metal atoms.

ATOMIC SPECTRA

The spectrum of hydrogen atom is the simplest of all spectra. This spectrum is governed by the selection rule :

$$\Delta n = \text{anything},\quad \Delta l = \pm 1,\quad \Delta m = \pm 1, 0 \qquad ...(203)$$

We may mention here that most intense spectroscopic transitions involve the interaction of the electric vector of the electromagnetic radiation with instantaneous electric dipole moment induced in the atom or molecule. These are called **electric dipole transitions.** Electric dipole transitions are due to the oscillating electric field component of the radiation and **magnetic dipole transitions** are due to oscillating magnetic field component of radiation. Magnetic dipole transitions are generally about 10^5 times weaker (*i.e.*, less probable) than electric dipole transitions.

From the selection rule given in Eq. 203, we see that an electron in the ground state ($1s$ orbital) can undergo a transition to any p state :

$$1s \longrightarrow np\ (n \geq 2)$$

while a $2p$ electron can undergo transitions to either an s state or a d state :

$$2p \longrightarrow ns \text{ or } nd$$

Since s and d orbitals are here degenerate, the energies of both these transitions will be identical. These transitions are shown in Fig. 13. A diagram of the type shown in Fig. 13 which summarises the energies of the atomic states and the transitions between them is called **Grotrian diagram.**

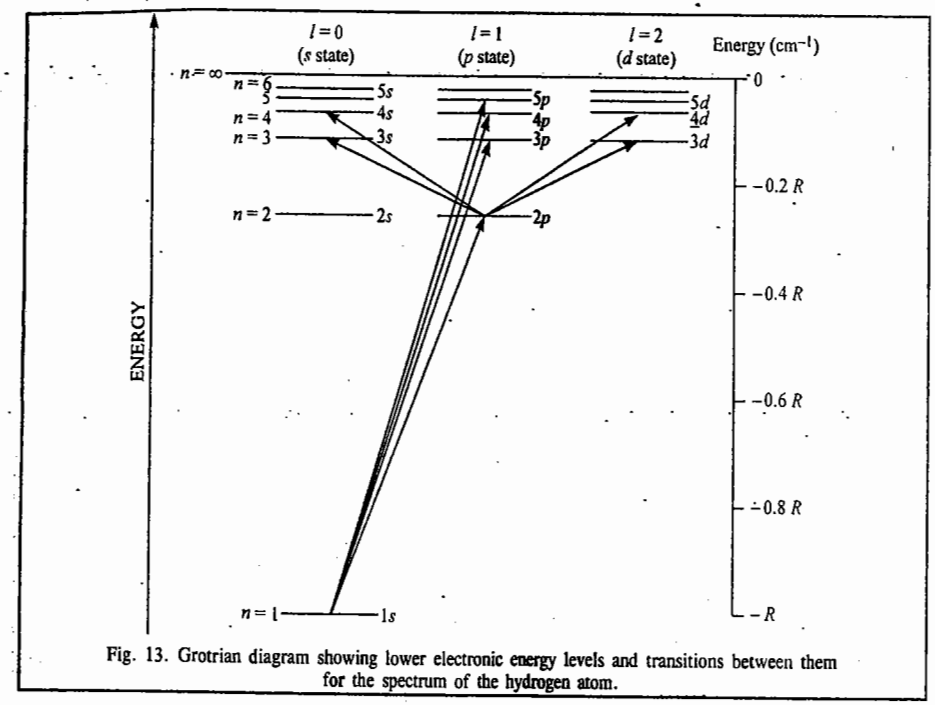

Fig. 13. Grotrian diagram showing lower electronic energy levels and transitions between them for the spectrum of the hydrogen atom.

We shall deal briefly with *(i)* fine structure *(ii)* the Zeeman effect *(iii)* the Stark effect and *(iv)* hyperfine structure in atomic spectra.

A. Fine Structure

This structure arises from **spin-orbit interaction**, *i.e.*, coupling of orbital and spin angular momenta of electrons ; thus,

$$j = l + s \qquad ...(204)$$

where $j = |l + s|, |l + s - 1|, \ldots, |l - s|$

Due to the coupling between the spin angular momentum, s, and the orbital angular momentum, l, to give the total angular momentum j, most of the energy levels shown in Fig. 13 are split into doublets. For example, for the $2p$ case we have $l = 1$, and $s = 1/2$, and hence $j = 3/2$ and $1/2$. These states are labelled by the term symbols $^{2s+1}L_j$, so that we have $^2P_{3/2}$ and $^2P_{1/2}$. On the other hand, the $1s$ orbital remains a singlet since $l = 0$; thus the ground state term symbol for hydrogen atom is $^2S_{1/2}$. The selection rules for n and l are the same as before :

$$\Delta n = \text{anything} ; \Delta l = \pm 1 \text{ only} \qquad ...(205)$$

but there is an additional solution rule for j :

$$\Delta j = 0, \pm 1, \qquad ...(206)$$

Thus, the $1s \rightarrow 2p$ transition in hydrogen atom will give rise to a doublet, *i.e.*, two lines. In other words, the transitions are allowed between any S level and any P level (Fig. 14) :

$$^2S_{1/2} \longrightarrow {}^2P_{1/2}\ (\Delta j = 0)$$

$$^2S_{1/2} \longrightarrow {}^2P_{3/2}\ (\Delta j = +1)$$

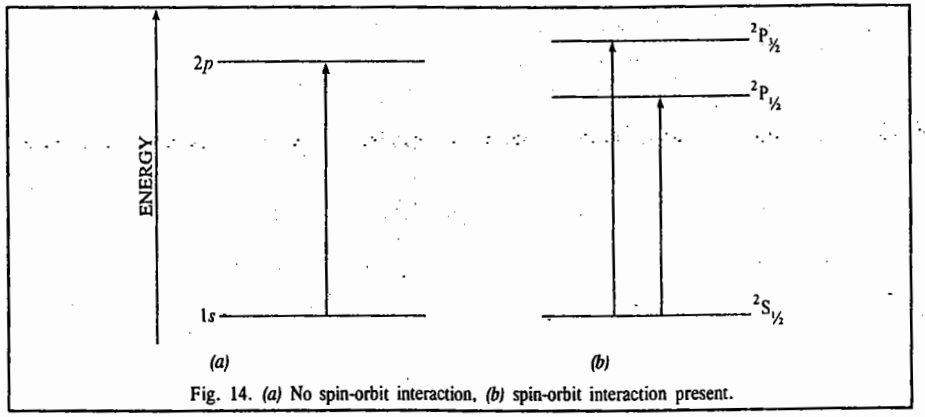

Fig. 14. *(a)* No spin-orbit interaction, *(b)* spin-orbit interaction present.

This coupling is very weak for hydrogen atom and the first few hydrogenic ions. Fig. 15 shows a few lower energy levels of hydrogen atom, showing the *j*-splitting and some transitions. This spectrum showing $^2S_{1/2} \longrightarrow {}^2P_{1/2,3/2}$ gives a simple doublet. However, the spectrum (Fig. 16) showing $^2P \longrightarrow {}^2D$ transition gives the following three allowed transitions :

$$^2P_{3/2} \longrightarrow {}^2D_{3/2} \ (\Delta j = 0)$$

$$^2P_{3/2} \longrightarrow {}^2D_{5/2} \ (\Delta j = +1)$$

$$^2P_{1/2} \longrightarrow {}^2D_{3/2} \ (\Delta j = +1)$$

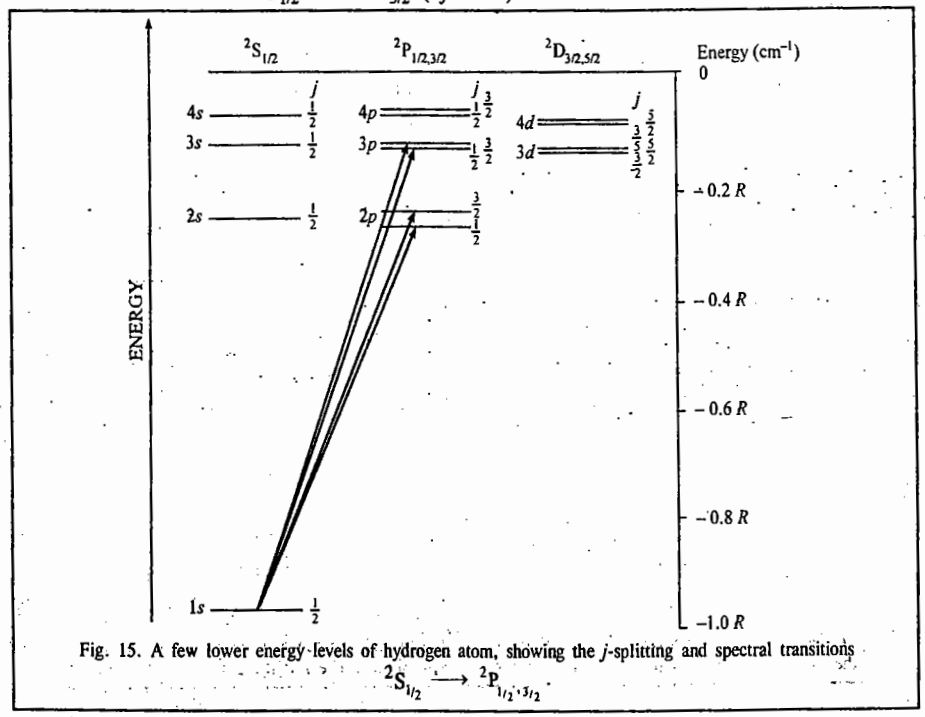

Fig. 15. A few lower energy levels of hydrogen atom, showing the *j*-splitting and spectral transitions $^2S_{1/2} \longrightarrow {}^2P_{1/2,3/2}$.

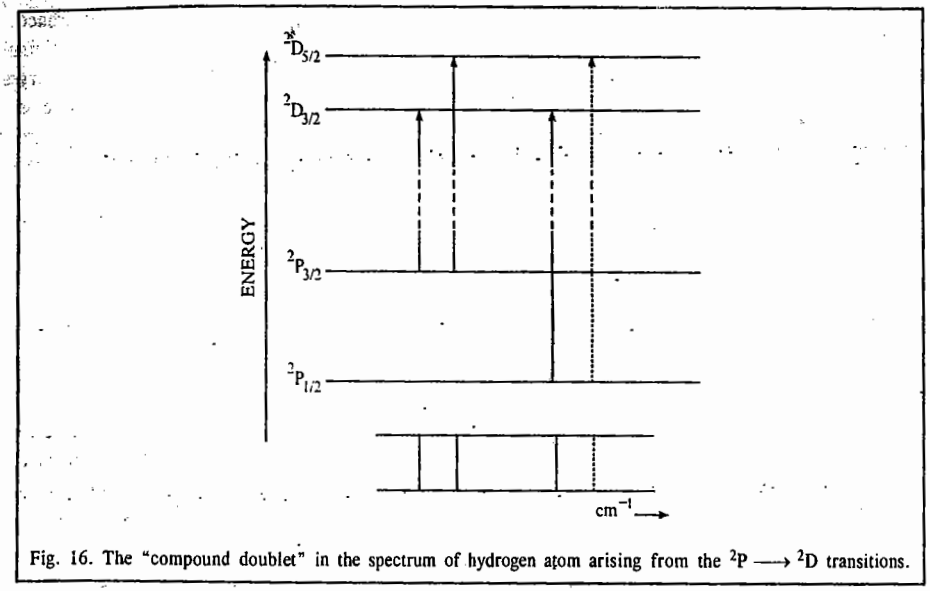

Fig. 16. The "compound doublet" in the spectrum of hydrogen atom arising from the $^2P \longrightarrow {}^2D$ transitions.

Note that the fourth transition (shown dotted), $^2P_{1/2} \longrightarrow {}^2D_{5/2}$, is forbidden for it corresponds it $\Delta j = +2$.

We next consider the spectrum of lithium atom. Fig. 17 shows the energy levels of lithium.

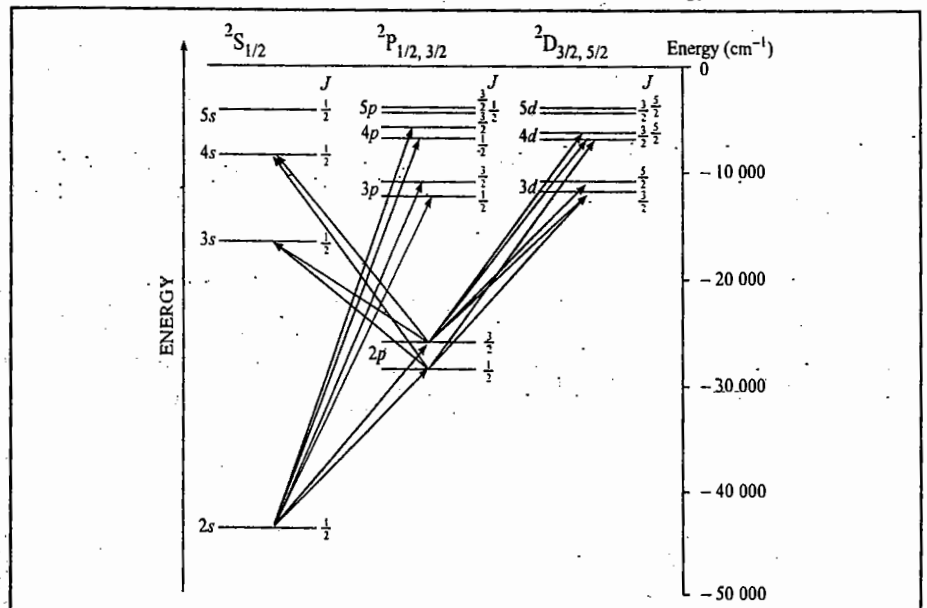

Fig. 17. A few lower energy levels of the lithium atom, showing the difference in energy of *s*, *p*, and *d* states with the same value of *n*. Some allowed transitions are also shown. The *j*-splitting is greatly exaggerated.

Notice that this diagram is similar to that for hydrogen atom (Fig. 3) except for the difference between the *s*, *p* and *d* orbitals of a given *n* in the case of lithium atom and the fact that, for the lithium atom, the 1*s* state is filled with electrons which do not take part in spectral transitions under ordinary conditions. The selection rules for lithium metal (and of course, other Group I metals) are the same as for hydrogen atom, *viz*; Δn = anything, $\Delta l = \pm 1$, $\Delta j = 0, +1$, with the result that the spectra are similar. Contrary to the hydrogen atom case, the fine structure in the spectra of alkali metals can be easily resolved (Fig. 17).

When, however, there is more than one electron, the addition of spin and orbital angular momenta is governed by *(a)* the **Russell-Saunders coupling scheme** (for atoms with $Z \leq 30$) and *(b)* by ***jj*-coupling scheme** (for heavier atoms with $Z > 30$). This we have already discussed while determining the term symbols of many-electron atoms. For many-electron atoms the relevant selection rules are

$$\Delta S = 0,\ \Delta L = \pm 1 \text{ and } \Delta J = 0, \pm 1 \qquad ...(207)$$

Let us consider the spectrum of helium atom. Russell-Saunders coupling scheme shows that the terms of helium are a series of singlets ($^1S_0$, $^1P_1$, $^1D_1$) and a series of triplets ($^3S_1$; $^3P_{2,1,0}$, $^3D_{3,2,1}$). Using the selection rule (1), the spectral transitions in the helium atom spectrum are shown in Fig. 18. Note that transitions between the singlet and the triplet energy levels are forbidden.

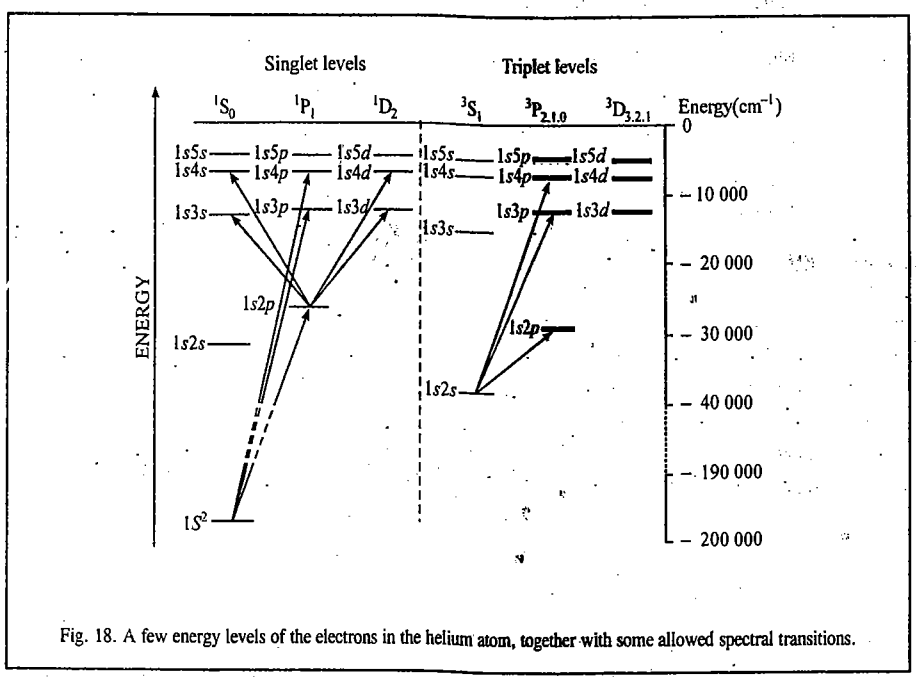

Fig. 18. A few energy levels of the electrons in the helium atom, together with some allowed spectral transitions.

Fig. 19 shows a transition between ^3P and ^3D states ; we see that the spectrum (shown at the foot of the figure) consists of six lines. This spectrum is ordinarily not resolved since the spacing is very close; only three lines are observed ; hence, the spectrum is referred to as a **compound triplet.**

Other atoms containing two outer electrons — as, for instance, alkaline earths, beryllium, magnesium, calcium, etc. — exhibit spectra similar to helium atom.

Example 18. State and prove Lande's interval rule.

Solution : According to the Lande's interval rule the separation between the two *J* levels of a Russell-Saunders term, brought about by spin-orbit interaction, is proportional to the larger *J* value of the pair.

$$J = L + S$$

$$J^2 = J^2 + S^2 + 2L.S$$

whence, the spin-orbit interaction, $L.S$ is

$$L.S = \frac{1}{2}(J^2 - L^2 - S^2)$$

We know that the eigenvalues of the various angular momenta are

$$J^2 = J(J+1)\hbar^2;\ L^2 = L(L+1)\hbar^2;\ S^2 = S(S+1)\hbar^2$$

Hence, the energy of the level characterized by the quantum number J, as a result of the spin-orbit interaction, is

$$E_J = \frac{1}{2}[J(J+1) - L(L+1) - S(S+1)]\hbar^2$$

For a term with the same L and S but with $J = J - 1$, we get

$$E_{J-1} = \frac{1}{2}[J-1)J - L(L+1) - S(S+1)]\hbar^2$$

Thus, $\Delta E = E_J - E_{J-1} = J\hbar^2$

which is **Lande's interval rule.**

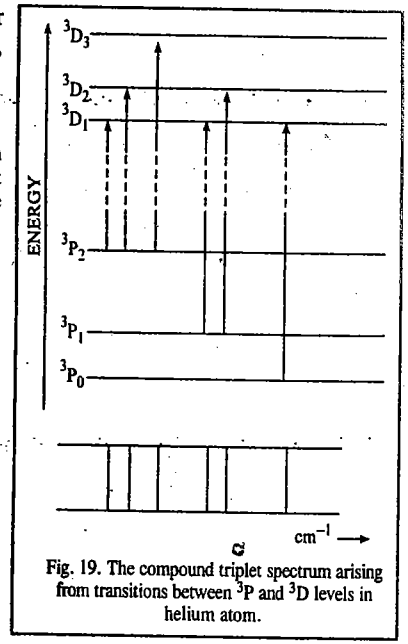

Fig. 19. The compound triplet spectrum arising from transitions between ^3P and ^3D levels in helium atom.

B. Zeeman Effect

The splitting of spectral lines in the presence of an applied magnetic field B (called the magnetic flux density) is called the Zeeman effect, first observed by P. Zeeman in 1896. This effect arises as a result of the interaction between B and the magnetic moment, μ, associated with the electron spin and orbital motion ; thus,

$$E_{int} = -\mu.B \qquad ...(208)$$

The applied magnetic field B splits a term with a given J value into $2J + 1$ sub-levels, characterized by the quantum number M_J, which is the component of J along the direction of the magnetic field (usually chosen as the *z*-axis) ; thus,

$$E(M_J) = g_J \mu_B B_z M_J \qquad ...(209)$$

where g_J is the **Lande' *g*-factor**, defined as

$$g_J = 1 + \frac{J(J+1) + S(S+1) - L(L+1)}{2J(J+1)} \qquad ...(210)$$

μ_B is the Bohr magneton ($= 9{\cdot}273 \times 10^{-24}$ JT^{-1}). The selection rule for the Zeeman effect is $\Delta M_J = 0, \pm 1$. Note that the Zeeman transitions between the singlet terms are referred to as the **normal Zeeman effect** and the Zeeman transitions between terms of higher multiplicity (between, for instance, the doublet terms, or the triplet terms, etc.) are called the **anomalous Zeeman effect**. In fact, the anomalous Zeeman effect, in which the original line splits into more than three components, is much

more common than the normal Zeeman effect, in which the original line splits into three components.

We shall illustrate the Zeeman effect by a few solved examples.

Example 19. Work out the Zeeman pattern for a $^1P_1 \longleftrightarrow {}^1D_2$ transition in atomic spectra.

Solution : The Lande g-factor is

$$g_J = 1 + \frac{J(J+1) + S(S+1) - L(L+1)}{2J(J+1)} \quad \text{[Eq. 210]}$$

Note : 0 divided by 0 in the second term is treated not as indeterminate but as equal to 0.

For the $^1P_1$ and $^1D_2$ terms $J = L$ because $= 0$. Substituting in the expression for g_J, gives $g = 1$, for both the singlet terms. Hence, the $^1P_1$ and $^1D_2$ levels will be split into equally spaced sub-levels. Using the selection rule $\Delta M_J = 0, \pm 1$, we get nine transitions (Fig. 20) but only three lines, each being triply degenerate.

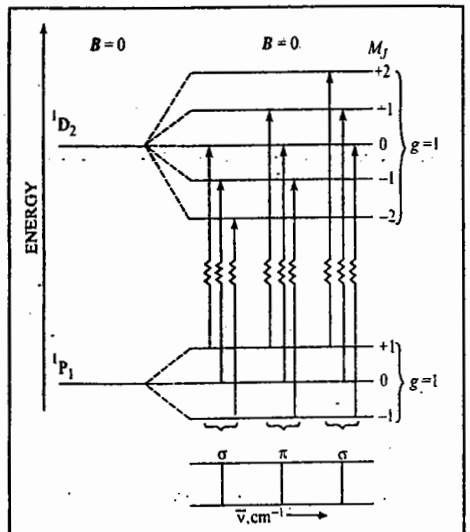

Fig. 20. The Zeeman pattern for a $^1P_1 \longleftrightarrow {}^1D_2$ transition.

It is customary to call the outer components of a Zeeman pattern the σ-components and the inner ones the π-components. In drawing the Zeeman pattern we have ignored the relative intensity of the σ- and π-components, all the components having been drawn equally intense.

Example 20. Work out the Zeeman pattern for a $^1S_0 \longleftrightarrow {}^1P_1$ transition in atomic spectra.

Solution : As shown in the previous example, for the $^1S_0$ and $^1P_1$ terms $J = L$ because $S = 0$. Substituting in the expression for the Lande g-factor g_J gives $g = 1$ for both the singlet terms. The number of states that each term splits into is given by the M_J quantum number. There are $2J + 1$ values of M_J. For the $^1S_0$ term, $M_J = 0$ and no splitting occurs. For $^1P_1$ state, the $2(1) + 1 = 3$ values of M_J are +1, 0 and −1. Using the selection rule $\Delta M_J = 0, \pm 1$, we get three transitions (Fig. 21).

Example 21. Work out the Zeeman pattern for the $^2P_{1/2,3/2} \longleftrightarrow {}^2S_{1/2}$ transition in sodium atom. (This transition corresponds to the 3p ⟷ 3s transition in sodium, which results in the D-lines in the sodium atom spectrum).

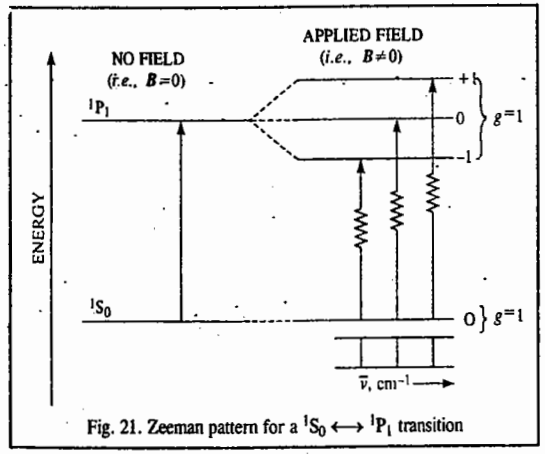

Fig. 21. Zeeman pattern for a $^1S_0 \longleftrightarrow {}^1P_1$ transition

Solution : For the $^2S_{1/2}$ level, $S = \frac{1}{2}$. $L = 0$, $J = \frac{1}{2}$ Hence, $g_J = 2$. For the $^2P_{1/2}$ level, $S = \frac{1}{2}$, $L = 1$, $J = \frac{1}{2}$. Hence, $g_J = 2/3$. Again, for the $^2P_{3/2}$ level, $S = \frac{1}{2}$, $L = 1$, $J = 3/2$; so that $g_J = 4/3$. The Zeeman field splits the $^2P_{3/2}$ level into four equally spaced sub-levels corresponding to $M_J = +3/2, +1/2, -1/2, -3/2$. From the values of g_J we see that the $^2S_{1/2}$, $^2P_{1/2}$ and $^2P_{3/2}$ levels are split by the Zeeman field in the ratio of 3 : 1 : 2. The selection rules for the transitions are

$$\begin{aligned} \Delta S &= 0 \\ \Delta L &= 0, \pm 1 \text{ (but } L = 0 \not\longleftrightarrow L = 0) \\ \Delta J &= 0, \pm 1 \text{ (but } J = 0 \not\longleftrightarrow J = 0) \\ \Delta M_J &= 0, \pm 1 \end{aligned} \quad \ldots(211)$$

Using these selection rules, the energy level diagram and the transitions between the energy levels are shown in Fig. 22. (The resulting spectrum is also shown under the corresponding spectral transitions).

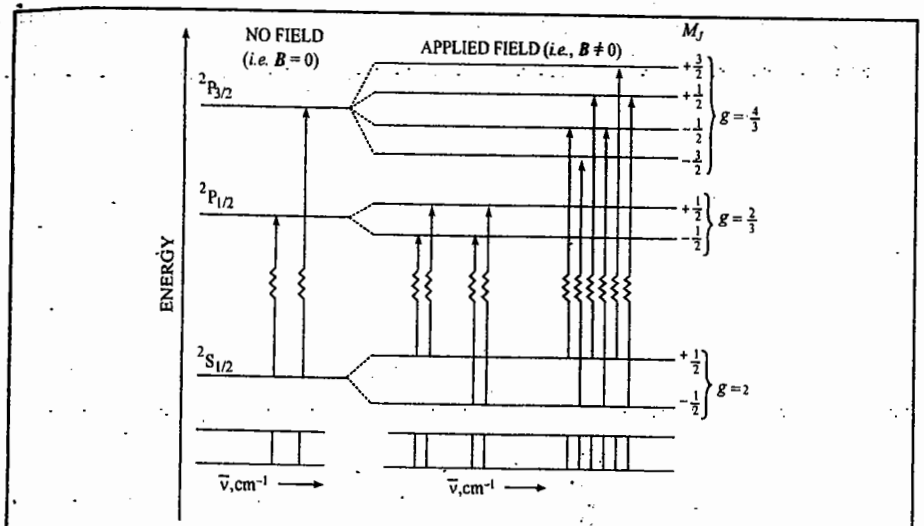

Fig. 22. The Zeeman pattern for a $^2S_{1/2} \longleftrightarrow {}^2P_{1/2,3/2}$ transition.

Example 22. Work out the Zeeman pattern for a $^3S \longleftrightarrow {}^3P$ transition in atomic spectra.

Solution : Proceeding as in Example 21, the Zeeman pattern, showing the energy level diagram and the transitions between them, is drawn in Fig. 23, along with the resulting spectrum.

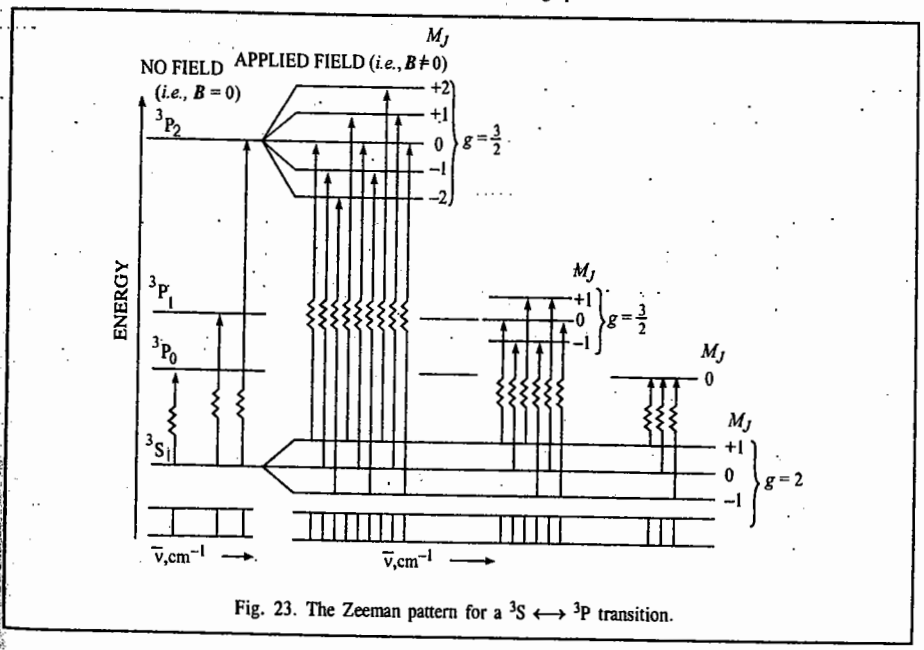

Fig. 23. The Zeeman pattern for a $^3S \longleftrightarrow {}^3P$ transition.

We may conclude this discussion of Zeeman effect by referring to the **Paschen-Back Effect**. This effect arises when the strength of the applied magnetic field becomes greater than the multiplet splittings. In this region the orbital and the spin angular momenta are no longer coupled to each other but are coupled separately to the magnetic field. In this case only the normal Zeeman effect is observed even when doublet or higher spin states are present.

C. Stark Effect

The splitting of spectral lines in the presence of an applied electric field, E is called the Stark effect, first observed by the German physicist J. Stark in 1913. This effect arises as a result of the interaction between E and the induced electric dipole moment, μ, as a result of electron polarization. The energy of interaction is given by

$$E_{int} = -\mu . E \qquad ...(212)$$

Since, however, μ is proportional to E, the splitting of the energy levels is proportional to E^2. The differences between the Zeeman and the Stark effects are that in the latter case the splitting pattern is not symmetric about the original line, and the energy values depend on $M_J^2 E^2$.

D. Hyperfine structure

The hyperfine interaction arises as a result of the interaction of the electron spin with the nuclear spin. Recall that fine structure arises from the interaction of the electron spin with the electron orbital motion. The nuclear spin, I, may be zero, integral or half-integral, depending on the nature of the nucleus. The nuclear spin angular momentum is given by

$$I = \sqrt{I(I+1)}\,\hbar \qquad ...(213)$$

The total angular angular momentum (electronic + nuclear) of an atom is defined by

$$F = \sqrt{F(F+1)}\,\hbar \qquad ...(214)$$

where F is the total momentum quantum number. If J is the total electronic angular momentum quantum number ($J = L + S$) then,

$$F = J + I, J + I - 1, \ldots . \mid J - I \mid \qquad ...(215)$$

thus giving $2J + 1$ or $2I + 1$ different energy states whichever is less. The hyperfine structure splitting is always far less than fine structure splitting.

Example 23. Show that the hyperfine structure (HFS) is smaller than the fine structure (FS) by approximately the ratio $m_e/(m_p Z)$.

Solution : Rigorously speaking, FS is the result of the interaction between the magnetic moment, μ_e of the electron and the Coulumb field, E, of the nucleus. Thus, the fine structure energy is given by

$$E_{FS} = \mu_e . S = g_e \mu_B E \qquad ...(i)$$

(where g_e is the electron g-factor and μ_B is the Bohr magneton). HFS, on the other hand, is due to the interaction between the magnetic moment, μ_n, of the nucleus and the magnetic field B, produced at the nucleus by the orbital motion of the electron. The hyperfine interaction energy is

$$E_{HFS} = \mu_n . B = g_N \mu_N B \qquad ...(ii)$$

(where g_N is the nuclear g-factor and μ_N is the nuclear magneton). We see from Eqs. *(i)* and *(ii)* that

$$E_{FS} \propto 1/m_e \text{ ; and } E_{HFS} \propto 1/m_p$$

However, E_{FS} also increases with increasing nuclear charge, Z, so that $E_{FS} \propto Z$. Hence, $E_{FS} \propto Z/m_e$.

We thus see that

$$E_{HFS}/E_{FS} = m_e/m_p Z \qquad ...(iii)$$

THOMAS-FERMI MODEL OF THE ATOM

Thomas–Fermi model of the atom is a statistical one in which the electrons are treated as a gas obeying Fermi-Dirac statistics. In this model, the central potential $V(r)$ is assumed to be slowly varying, slow enough to have number of electrons in an electron wavelength. In other words, many electrons are localized within a volume over which the potential is almost a constant. As the electrons are treated as a gas of fermions, one can apply the concept of cells in phase space to the states of individual electrons.

The volume of phase space occupied by electrons which have momenta less than p and are in the volume dV is $(4/3)\pi p^3\, dV$. The number of cells (states) corresponding to this volume is $2(4/3)\pi p^3\, dV$, the factor of 2 being included to account for the two possible spin states. Assuming that all these states are occupied, the number of electrons per unit volume $n(r)$ whose kinetic energy does not exceed $p^2/2m$ is given by

$$n(r) = \frac{8\pi p^3}{3h^3} = \frac{p^3}{3\pi^2 \hbar^3} \qquad ...(216)$$

For the electrons not to escape from the nucleus, the maximum allowed kinetic energy at any distance r from the nucleus is $-V(r)$. That is,

$$p^2/2m = -V(r) \qquad ...(217)$$

From Eqs. 216 and 217,

$$n(r) = \frac{[-2m\,V(r)]^{3/2}}{3\pi^2 \hbar^3} \qquad ...(218)$$

The electrostatic potential $-V(r)/e$ and the charge density $-en(r)$ obey the Poisson equation

$$-\frac{1}{e}\nabla^2 V(r) = -4\pi e n(r) \qquad ...(219)$$

The potential is spherically symmetric since the nucleus is at the origin and, therefore,

$$\nabla^2 V(r) = \frac{1}{r^2}\frac{d}{dr}\left(r^2 \frac{dV}{dr}\right) \qquad ...(220)$$

With this value of $\nabla^2 V(r)$, Eq. (219) becomes

$$\frac{1}{r^2}\frac{d}{dr}\left(r^2 \frac{dV}{dr}\right) = -4\pi e^2 n(r) \qquad ...(221)$$

Substituting the value of $n(r)$ from Eq. 218 in Eq. 221, we have

$$\frac{1}{r^2}\frac{d}{dr}\left(r^2 \frac{dV}{dr}\right) = -\frac{4e^2}{3\pi \hbar^3}[-2m\,V(r)]^{3/2} \qquad ...(222)$$

When $r \to 0$, the leading term in the potential is due to the nucleus so that $V(r) \to -Ze^2/r$. Hence, it

is convenient to introduce the function $\chi(r)$ defined by

$$V(r) = -\frac{Ze^2\,\chi(r)}{r} \qquad ...(223)$$

Substituting this value of $V(r)$ in Eq. 222, we have

$$\frac{d^2\chi}{dr^2} = \frac{4e^3(2m)^{3/2}Z^{1/2}}{3\pi\hbar^3}\frac{\chi^{3/2}}{r^{1/2}} \qquad ...(224)$$

Eq. 224 can be written in a dimensionless form by writing

$$r = bx \qquad ...(225)$$

The parameter b will be defined shortly. In terms of the new variable, Eq. 224 reduces to

$$\frac{d^2\chi}{dx^2} = b^{3/2}\frac{4e^3(2m)^{3/2}Z^{1/2}}{3\pi\hbar^3}\frac{\chi^{3/2}}{x^{1/2}} \qquad ...(226)$$

We select the value of the parameter b in such a way that the coefficient of $\chi^{3/2}/x^{1/2}$ is unity. This gives

$$b = \frac{1}{2}\left(\frac{3\pi}{4}\right)^{2/3}\frac{\hbar^2}{me^2}\frac{1}{Z^{1/3}} = \frac{0.8853a_0}{Z^{1/3}} \qquad ...(227)$$

where a_0 is the Bohr radius. With this substitution, Eq. 227 becomes

$$\frac{d^2\chi}{dx^2} = \frac{\chi^{3/2}}{x^{1/2}} \qquad ...(228)$$

Eq. 228 is called the **dimensionless Thomas-Fermi equation**. As $V(r) \to -Ze^2/r$ when $r \to 0$, by virtue of Eq. 223, $\chi(0) = 1$. As $r \to \infty$, there will not be any net charge inside the sphere of radius r so that $V(r)$ falls off more rapidly than $1/r$ and $rV(r) \to 0$. Hence, $\chi(\infty) = 0$.

Solution of Eq. 228 subject to these boundary conditions was first carried out by Bush and Caldwell in 1931. A knowledge of $\chi(x)$ allows the determination of charge distribution in the atom and the r-dependence of the potential $V(r)$ in Eq. 223. The Thomas-Fermi model being a statistical model, we can expect better results as atomic number Z increases.

Enrico Fermi (1901-1954), the great Italian physicist, was probably the only 20th century physicist who was equally at home in theory and experiment. He never considered himself a theorist, though theoretical physics has been enriched by several terms associated with his name—Fermi-Dirac statistics, Thomas-Fermi atom, Fermi energy, Fermi level, Fermi sea, Fermi surface, Fermi sphere, Fermi temperature, Fermions, Fermi's theory of beta-secay, Fermi liquid, Fermi's golden rule, Fermi resonance, Fermi contact interaction and last but not least, Fermi-type calculation. He was awarded the 1938 Physics Nobel Prize for his contributions to the existence of new radioactive elements produced by neutron-irradiation, and related nuclear reactions. A staunch opponent of Fascism, Nazism and totalitarianism, he escaped to the U.S.A. in the 1930s with the help of his American admirers, thereby evading the Italian dictator Mussolini who had intended to have him assassinated. He was an outstanding teacher, among his students were the great Chinese-American theorists C.N. Yang and T.D. Lee, the winners of the 1957 Physics Nobel Prize. He along with Edward Teller was associated with the Manhattan Project (under the supervision of physicist J.R. Oppenheimer) which built the first atomic bomb that brought about the horrible devastation of Hiroshima and Nagasaki in August, 1945, thereby ending the Second World War. At the University of Chicago his distinguished colleague was the famous Indian astrophysicist, S. Chandrasekhar, with whom he coauthored a research paper in astronomy. The Enrico Fermi Institute in the University of Chicago has been established in his memory.

ANGULAR MOMENTUM REVISITED

1. Angular Momentum Matrices

The states $|jm>$ form a complete orthonormal set and they can be used as a basis for the matrix representation of angular momentum. In this representation a function F of the angular momentum components can be represented by a matrix with matrix elements $\langle j'm'|\ F\ |jm\rangle$. The rows of the matrix will be labelled by j' and m' values and the columns by the j, m values.

a. Matrices for J^2 and J_z. Since J^2 commutes with J_z the matrices for J^2 and J_z will be diagonal. In that representation J_x and J_y will not be diagonal since J_z does not commute with J_x and J_y. We have already obtained the following eigenvalue equations for J^2 and J_z :

$$J^2\ |\ jm\ \rangle = j\,(j+1)\,\hbar^2\ |\ jm\ \rangle \qquad ...(229)$$

and

$$J_z\ |\ jm\ \rangle = m\hbar\ |\ jm\ \rangle \qquad ...(230)$$

Multiplication of Eqs. 1 and 2 from left by $\langle\ j'\ m'\ |$ gives

$$\langle\ j'\ m'\ |\ J^2\ |\ jm\ \rangle = j\,(j+1)\ \hbar^2\ \delta_{jj'}\ \delta_{mm'} \qquad ...(231)$$

and

$$\langle j'm'\ |\ J_z\ |\ jm\ \rangle = m\hbar\ \delta_{jj'}\ \delta_{mm'} \qquad ...(232)$$

The presence of the Kronecker deltas $\delta_{jj'}$ and $\delta_{mm'}$ indicates that the matrices are diagonal, as expected. The explicit form of J^2 and J_z matrices are given in Tables 1 and 2; they are of infinite dimensions.

b. Matrices for J_+, J_-, J_x and J_y : We have already shown that

$$J_z J_+ \mid jm \rangle = (m+1)\hbar\ J_+ \mid jm \rangle \qquad \ldots(233)$$

This implies that $J_+ \mid jm \rangle$ is an eigenket (eigenfunction) of J_z with eigenvalue $(m+1)\hbar$. The eigenvalue equation for J_z with eigenvalue $(m+1)\hbar$ can also be written as

$$J_z \mid j, m+1 \rangle = (m+1)\ \hbar \mid j, m+1 \rangle \qquad \ldots(234)$$

Since the eigen values of J_z (Eqs. 233 and 234) are equal, the eigenvectors can differ at most by a multiplicative constant, say a_m.

$$J_+ \mid jm \rangle = a_m \mid j, m+1 \rangle \qquad \ldots(235)$$

Similarly, we get

$$J_- \mid jm \rangle = b_m \mid j, m-1 \rangle \qquad \ldots(236)$$

where $$a_m = \langle j, m+1 \mid J_+ \mid jm \rangle \quad \text{or} \quad a_m^* = \langle jm \mid J_- \mid j, m+1 \rangle \qquad \ldots(237)$$

$$b_m = \langle j, m-1 \mid J_- \mid jm \rangle \quad \text{or} \quad b_{m+1} = \langle jm \mid J_- \mid j, m+1 \rangle \qquad \ldots(238)$$

Comparison of Eqs. 237 and 238 gives

$$a_m^* = b_{m+1} \qquad \ldots(239)$$

Operating on Eq. 235 from the left by J_- gives

$$J_- J_+ \mid jm \rangle = a_m J_- \mid j, m+1 \rangle \qquad \ldots(240)$$

It can be shown that

$$J_- J_+ = J^2 - J_z^2 - \hbar J_z \qquad \ldots(241)$$

Using this result and Eq. 236 we obtain

$$(J^2 - J_z^2 - \hbar J_z) \mid jm \rangle = a_m\, b_{m+1} \mid jm \rangle \qquad \ldots(242)$$

or $$[j(j+1) - m^2 - m]\ \hbar^2 \mid jm \rangle = \mid a_m \mid^2 \mid jm \rangle \qquad \ldots(243)$$

or $$a_m = [j(j+1) - m(m+1)]^{1/2}\hbar \qquad \ldots(244)$$

With this value of a_m

$$J_+ \mid jm \rangle = [j(j+1) - m(m+1)]^{1/2}\ \hbar \mid jm \rangle \qquad \ldots(245)$$

or $$\langle j' m' \mid J_+ \mid jm \rangle = [j(j+1) - m(m+1)^{1/2}\ \hbar\ \delta_{jj'}\ \delta_{m', m+1} \qquad \ldots(246)$$

Similarly,

$$\langle j' m' \mid J_- \mid jm \rangle = [j(j+1) - m(m-1)^{1/2}\ \hbar\ \delta_{jj'}\ \delta_{m', m-1} \qquad \ldots(247)$$

Eqs. 246 and 247 give the matrix elements for J_+ and J_-. They are infinite-dimensional matrices like J^2 and J_z matrices. The nature of the Kronecker deltas in Eqs. 246 and 247 indicates that all non-vanishing elements occur in blocks along the diagonal corresponding to $j' = j$. The block matrices corresponding to $j = 0$, 1/2 and 1 are given below. The rows are labelled by the value of m' and the columns by the value of m. The non-vanishing matrices for J_x and J_y are evaluated using the relation

$$J_x = \frac{1}{2}(J_+ + J_-) \qquad \text{and} \qquad J_y = \frac{1}{2i}(J_+ - J_-) \qquad \ldots(248)$$

For $j = 0$, $J_+ = 0$, $J_- = 0$, $J_x = 0$, $J_y = 0$ $\qquad \ldots(249)$

For $j = 1/2$,

$$J_+ = \hbar\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \qquad J_- = \hbar\begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}$$

$$J_x = \frac{1}{2}\hbar\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad J_y = \frac{1}{2}\hbar\begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} \qquad \ldots(250)$$

For $j = 1$,

$$J_+ = \hbar\begin{pmatrix} 0 & \sqrt{2} & 0 \\ 0 & 0 & \sqrt{2} \\ 0 & 0 & 0 \end{pmatrix}, \quad J_- = \hbar\begin{pmatrix} 0 & 0 & 0 \\ \sqrt{2} & 0 & 0 \\ 0 & \sqrt{2} & 0 \end{pmatrix}$$

$$J_x = \frac{1}{\sqrt{2}}\hbar\begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}, \quad J_y = \frac{1}{\sqrt{2}}\hbar\begin{pmatrix} 0 & -i & 0 \\ i & 0 & -i \\ 0 & i & 0 \end{pmatrix} \qquad \ldots(251)$$

Our discussion would be incomplete without a word about the eigen function (eigenvector). The eigen vector with respect to the $\mid jm \rangle$ basis would be a column vector of infinite extent. The appropriate part of this infinite column vector would be used for the particular cases : j=0, j=1/2, j=1, ...

2. Spin Angular Momentum and Pauli Spin Matrices

It may be recalled that space quantization of spin angular momentum had been demonstrated by the great Stern-Gerlach experiment in 1921. Also, to account for the multiplicity of atomic states Uhlenbeck and Goudsmit had proposed in 1925 that an electron in an atom possesses an *intrinsic* (or *internal*) angular momentum, called the spin angular momentum, in addition to orbital angular momentum. This spin angular momentum S, as we have said above, has $S_z = m_s\hbar$, where $m_s = \pm\ 1/2$, on the z-axis.

Associated with S is an intrinsic (spin) magnetic moment, μ_S, given by

$$\mu_S = -(e/m_e)\, S \qquad ...(252)$$

Assuming that all stable and unstable particles have spin angular momentum S, we expect its components S_x, S_y and S_z to obey the general commutation relations

$$[\hat{S}_x, \hat{S}_y] = i\hbar S_z, \quad [\hat{S}_y, \hat{S}_z] = i\hbar \hat{S}_x, \quad [\hat{S}_z, \hat{S}_x] = i\hbar \hat{S}_y \qquad ...(253)$$

and $\hat{S}^2$ and $\hat{S}_z$ to have eigenvalues $s(s+1)\hbar^2$ and $m_s\hbar$, where $m_s = -s, -s+1, \ldots\ldots\ldots, s$, respectively.

For most of the spin-1/2 systems (such as stable elementary particles like electrons, protons, neutrons, etc.) the matrices representing S_x, S_y and S_z are obtained directly from the J_x, J_y and J_z matrices by taking the part corresponding to $j = 1/2$. Hence,

$$S_x = \frac{1}{2}\hbar\begin{pmatrix}0 & 1\\ 1 & 0\end{pmatrix}; \quad S_y = \frac{1}{2}\hbar\begin{pmatrix}0 & -i\\ i & 0\end{pmatrix}; \quad S_z = \frac{1}{2}\hbar\begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix} \qquad ...(254)$$

Often it is convenient to work with a matrix σ defined by

$$S = \frac{1}{2}\hbar\sigma \qquad ...(255)$$

where

$$\sigma_x = \begin{pmatrix}0 & 1\\ 1 & 0\end{pmatrix}; \quad \sigma_y = \begin{pmatrix}0 & -i\\ i & 0\end{pmatrix}; \quad \sigma_z = \begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix} \qquad ...(256)$$

The σ_x, σ_y and σ_z matrices are called the **Pauli spin matrices**. From the definition, it is obvious that their eigenvalues are ± 1. These matrices satisfy the relations

$$\sigma_x^2 = \sigma_y^2 = \sigma_z^2 = 1 \qquad ...(257)$$

$$\sigma_x\sigma_y = i\sigma_z, \quad \sigma_y\sigma_z = i\sigma_x, \quad \sigma_z\sigma_x = i\sigma_y \qquad ...(258)$$

$$\sigma_x\sigma_y + \sigma_y\sigma_x = \sigma_y\sigma_z + \sigma_z\sigma_y = \sigma_z\sigma_x + \sigma_x\sigma_z = 0 \qquad ...(259)$$

Pauli was the first to recognize the necessity of two-component state vectors to explain certain observed features of atomic spectra.

3. Spin Vectors for Spin-1/2 System

If we include the spin, then the spin-1/2 system such as an electron has four degrees of freedom, *viz.*, the three position coordinates (x, y, z) and another observable pertaining to spin. Taking the z-component S_z as the fourth variable, the electron wave function can be written as $\psi(r, S_z)$ or $\psi(r, m_s)$; the coordinate m_s takes the values $+1/2$ or $-1/2$. When the interaction between the spin and space parts is negligible, the wave function can be written as the product function :

$$\psi(r, m_s) = \phi(r)\,\chi(m_s) \qquad ...(260)$$

where $\phi(r)$ represents the part that depends on the space coordinates and $\chi(m_s)$, the part that depends on the spin coordinates. The eigenvectors of the spin matrices S_x, S_y and S_z can easily be obtained by writing the eigenvalue equation. Since the matrices are 2×2, the eigenvectors must be column vectors with two components. The eigenvalue equation for S_z with eigenvalue $\hbar/2$ is

$$\frac{1}{2}\hbar\begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix}\begin{pmatrix}a_1\\ a_2\end{pmatrix} = \frac{1}{2}\hbar\begin{pmatrix}a_1\\ a_2\end{pmatrix} \quad \text{or} \quad \begin{pmatrix}a_1\\ -a_2\end{pmatrix} = \begin{pmatrix}a_1\\ a_2\end{pmatrix}$$

It is evident that $a_2 = 0$. The normalization condition gives

$$|a_1|^2 = 1 \text{ or } a_1 = 1$$

The eigenvector of the matrix S_z corresponding to the eigenvalue $\hbar/2$ is then $\begin{pmatrix}1\\ 0\end{pmatrix}$.

Proceeding on similar lines, the eigenvector for the eigenvalue $-\hbar/2$ is $\begin{pmatrix}0\\ 1\end{pmatrix}$.

These eigenvectors are denoted by α and β and are usually called the *spin-up* and *spin-down* states respectively :

$$\alpha = \begin{pmatrix}1\\ 0\end{pmatrix}, \qquad \beta = \begin{pmatrix}0\\ 1\end{pmatrix} \qquad ...(261)$$

The two-component eigenvectors of spin-(1/2) particles are sometimes called **spinors.** Eigenvectors of S_x and S_y can also be found in the same way. The spin matrices of a spin-(1/2) system along with their eigenvalues and eigenvectors are tabulated in Table 3.

TABLE 3

Spin Matrices S_x, S_y and S_z of a Spin-(1/2) System with Their Eigenvalues and Eigenvectors

Spin component	Spin matrix	Eigenvalue	Eigenvectors
S_x	$\frac{\hbar}{2}\begin{pmatrix}0 & 1\\ 1 & 0\end{pmatrix}$	$\frac{\hbar}{2}$ $-\frac{\hbar}{2}$	$\frac{1}{\sqrt{2}}\begin{pmatrix}1\\ 1\end{pmatrix}$ $\frac{1}{\sqrt{2}}\begin{pmatrix}1\\ -1\end{pmatrix}$
S_y	$\frac{\hbar}{2}\begin{pmatrix}0 & -i\\ i & 0\end{pmatrix}$	$\frac{\hbar}{2}$ $-\frac{\hbar}{2}$	$\frac{1}{\sqrt{2}}\begin{pmatrix}1\\ i\end{pmatrix}$ $\frac{1}{\sqrt{2}}\begin{pmatrix}1\\ -i\end{pmatrix}$
S_z	$\frac{\hbar}{2}\begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix}$	$\frac{\hbar}{2}$ $-\frac{\hbar}{2}$	$\begin{pmatrix}1\\ 0\end{pmatrix}$ $\begin{pmatrix}0\\ 1\end{pmatrix}$

4. Addition of Angular Momenta

Addition of angular momenta is very important in the study of atomic spectra and nuclear structure. We shall consider here the general problem of the addition of two angular momenta. We consider two non-interacting systems having angular momenta J_1 and J_2 and eigenkets $|j_1m_1\rangle$ and $|j_2m_2\rangle$, respectively. Thus,

$$J_1^2 |j_1m_1\rangle = j_1(j_1+1)\hbar^2 |j_1m_1\rangle \qquad ...(262)$$

$$J_{1z} |j_1m_1\rangle = m_1\hbar |j_1m_1\rangle \qquad ...(263)$$

and

$$J_2^2 |j_2m_2\rangle = j_2(j_2+1)\hbar^2 |j_2m_2\rangle \qquad ...(264)$$

$$J_{2z} |j_2m_2\rangle = m_2\hbar |j_2m_2\rangle \qquad ...(265)$$

where $m_1 = j_1, j_1 - 1, \ldots\ldots, -j_1$; $m_2 = j_2, j_2 - 1, \ldots\ldots, -j_2$

(Clebsch-Gordon series)

Since the two systems are non-interacting

$$[J_1, J_2] = 0 \quad \text{and} \quad [J_1^2, J_2^2] = 0 \qquad \ldots(266)$$

and therefore the operators $J_1^2, J_{1z}, J_2^2, J_{2z}$ form a complete set with simultaneous eigenkets $|\, j_1 m_1, j_2 m_2\rangle$, which is a product of $|\, j_1 m_1\rangle$ and $|\, j_2 m_2\rangle$. For given values of j_1 and j_2

$$|\, j_1 m_1, j_2 m_2\rangle = |\, j_1 m_1\rangle\, |\, j_2 m_2\rangle = |\, m_1 m_2\rangle \qquad \ldots(267)$$

Since m_1 and m_2 can respectively have $(2j_1 + 1)$ and $(2j_2 + 1)$ orientations, the subspace with definite values of j_1 and j_2 will have $(2j_1 + 1)\,(2j_2 + 1)$ dimensions.

Clebsch-Gordon Coefficients. For the total angular momentum vector

$$J = J_1 + J_2$$

$$J \times J = i\,\hbar\, J \qquad \ldots(268)$$

Also, it follows that

$$[J^2, J_z] = 0, \quad [J^2, J_1^2] = [J^2, J_2^2] = 0 \qquad \ldots(269)$$

The orthonormal eigenkets of J^2 and J_z will be $|\, jm\rangle$. Since J^2 commutes with J_z, J_1^2 and J_2^2, they form another complete set and their simultaneous eigenkets will be $|\, j_1 j_2 jm\rangle$. For given values of j_1 and j_2, $|j_1 j_2\, jm\rangle = |jm\rangle$. The completeness of the known kets $|\, m_1 m_2\rangle$ allows us to express the unknown kets $|jm\rangle$ as a linear combination of $|m_1 m_2\rangle$:

$$|jm\rangle = \sum_{m_1, m_2} C_{jmm_1m_2}\, |m_1 m_2\rangle \qquad \ldots(270)$$

The coefficients of this linear combination are called **Clebsch-Gordon coefficients** or **Wigner coefficients** or **vector coupling coefficients**. Multiplying Eq. 270 with the bra $\langle m_1 m_2|$, we get

$$\langle m_1 m_2 \mid jm\rangle = C_{jmm_1m_2} \qquad \ldots(271)$$

Substituting this value of the coefficient in Eq. 270, we have

$$|\, jm\rangle = \sum_{m_1, m_2} |\, m_1 m_2\rangle \langle m_1 m_2 \mid jm\rangle \qquad \ldots(272)$$

As the coefficients $\langle m_1 m_2 |\, jm\rangle$ relate two orthonormal bases, $|j, m\rangle$ and $|m_1, m_2\rangle$ they form a unitary matrix. In the matrix formed by these elements, m_1, m_2 label the rows and j, m label the columns. The parameters j_1 and j_2 are not appearing explicitly in the coefficients as we are working for definite values of j_1 and j_2. In the strict sense the coefficients would be $\langle j_1 m_1, j_2 m_2 \mid j_1 j_2\, jm\rangle$. The inverse of Eq. 272 is given by

$$|\, m_1 m_2\rangle = \sum_{j, m} \langle jm \mid m_1 m_2\rangle \mid jm\rangle \qquad \ldots(273)$$

where the summation over m is from $-j$ to j and j is from $|\, j_1 - j_2 \,|$ to $j_1 + j_2$. The unitary character of Clebsh-Gordon coefficients is expressed by the equations.

$$\sum_{j, m} \langle m_1 m_2 \mid jm\rangle \langle jm \mid m_1' m_2'\rangle = \langle m_1 m_2 \mid m_1' m_2'\rangle = \delta m_1 m_1' \delta m_2 m_2' \qquad \ldots(274a)$$

and $$\sum_{j, m} \langle jm \mid m_1 m_2\rangle \langle m_1 m_2 \mid j'm'\rangle = \langle jm \mid j'm'\rangle = \delta jj'\, \delta mm' \qquad \ldots(274b)$$

where $$\langle jm \mid m_1 m_2\rangle = \langle\, m_1 m_2 \mid jm\,\rangle^* \qquad \ldots(274c)$$

Omitting details which are found in advanced books, we can obtain the recursion relations connecting the Clebsch-Gordon coefficients which enable us in determining the Clebsch-Gordon coefficients. The results are shown in Tables.4 and 5.

TABLE 4.

Clebsch-Gordon Coefficients for $|\, m_1 m_2\,\rangle = |\, j_1, j_2 - 1\rangle$ and $|\, j_1 - 1, j_2\,\rangle$

m_1	m_2	$\mid jm\,\rangle$	
		$\mid j_1 + j_2, j_1 + j_2 - 1\rangle$	$\mid j_1 + j_2 - 1, j_1 + j_2 - 1\rangle$
j_1	$j_2 - 1$	$\left(\frac{j_2}{j_1 + j_2}\right)^{1/2}$	$\left(\frac{j_1}{j_1 + j_2}\right)^{1/2}$
$j_1 - 1$	j_2	$\left(\frac{j_1}{j_1 + j_2}\right)^{1/2}$	$-\left(\frac{j_2}{j_1 + j_2}\right)^{1/2}$

TABLE 5.

Clebsch-Gordon Coefficients for $|\, m_1 m_2\rangle = |\, j_1, j_2 - 2\rangle$, $|\, j_1 - 1, j_2 - 1\rangle$ and $|\, j_1 - 2, j_2\rangle$

m_1	m_2	$\mid jm\,\rangle$		
		$\mid j_1 + j_2, j_1 + j_2 - 2\rangle$	$\mid j_1 + j_2 - 1, j_1 + j_2 - 2\rangle$	$\mid j_1 + j_2 - 2, j_1 + j_2 - 2\rangle$
j_1	$j_2 - 2$	$\left[\frac{j_2(2j_2 - 1)}{(j_1 + j_2)A}\right]^{1/2}$	$\left[\frac{j_1(2j_2 - 1)}{(j_1 + j_2)B}\right]^{1/2}$	$\left[\frac{j_1(2j_1 - 1)}{AB}\right]^{1/2}$
$j_1 - 1$	$j_2 - 1$	$\left[\frac{4j_1 j_2}{(j_1 + j_2)A}\right]^{1/2}$	$\frac{j_1 - j_2}{[(j_1 + j_2)B]^{1/2}}$	$-\left[\frac{(2j_1 - 1)(2j_2 - 1)}{AB}\right]^{1/2}$
$j_1 - 2$	j_2	$\left[\frac{j_2(2j_1 - 1)}{(j_1 + j_2)A}\right]^{1/2}$	$-\left[\frac{j_2(2j_1 - 1)}{(j_1 + j_2)B}\right]^{1/2}$	$\left[\frac{j_2(2j_2 - 1)}{AB}\right]^{1/2}$

where $A = 2j_1 + 2j_2 - 1$ and $B = j_1 + j_2 - 1$.

Note : The standard treatise on this subject is E.U. Condon and G.H. Shortley, *The Theory of Atomic Spectra*, Cambridge, 1935. Angular momentum has fascinated the finest theorists of 20th century physics, among them G. Racah, J.C. Slater, J.S. Schwinger, and, of course, E.P. Wigner. Their papers have been reprinted in L.C. Biedenharn and H. van Dam (eds.), *Quantum Theory of Angular Momentum*, Academic Press, 1965. The reader is encouraged to study this monumental volume. This is the stuff dream research is made of. Here imagination and creativity have gone hand-in-hand. The depth of mathematical treatment is astounding. It is pertinent to mention here that Charlotte E. Moore (1898-1990), the great American spectroscopist, produced and critically analyzed a very complete compilation of spectral data and atomic energy levels. The result of her effort, *Atomic Energy Levels*, is a classic work that provides data for 485 atomic species in a uniform clear format with standardized notation.

I. Review Questions

1. Using the first-order time-independent perturbation theory solve the Schrödinger wave equation for the ground state energy of helium atom.
2. Using the variation method solve the Schrödinger wave equation for the ground state energy of helium atom.
3. State and prove variation theorem.
4. Outline the salient features of the Hartree-Fock self-consistent field (SCF) theory for solving the Schrödinger wave equation for a many-electron atom.
5. Construct the angular momentum matrices for J^2 and J_z.
6. Write a short note on spin angular momentum and Pauli spin matrices.

II. Problems

1. Use the variational principle to istimate the ground state energy of a linear harmonic oscillator using the trial function $\psi(x) = 1/(1 + \beta x^2)$, where β, is variational parameter. [Ans. $E_{min} = 0.707\,\hbar\,(k/\mu)^{1/2}$]
2. Use the trial function of the form $\exp(-\alpha r)$ to calculate the ground state energy of hydrogen atom. [Ans. $E_{min} = -1/2$ (a.u)]
3. Use the first-order perturbation theory to calculate the energy of a particle in a one-dimensional box from $x = 0$ to $x = a$ with a slanted bottom, such that $V(x) = V_0 x/a$, $0 \le x \le a$ [V_0 is a constant]

$$\left[\text{Ans. } E = \frac{n^2\hbar^2}{8ma^2} + \frac{V_0}{2} + O\left(V_0^2\right),\ n = 1,2,3\ldots\right]$$

4. Using the Gaussian trial wavefunction $e^{-\alpha r^2}$ for the ground state of hydrogen atom show that the ground-state energy is given by $E(\alpha) = \frac{3\hbar^2\alpha}{2m_e} = \frac{e^2\alpha^{1/2}}{2^{1/2}\varepsilon_0\pi^{3/2}}$ and that $E_{min} = -\frac{4}{3\pi}\frac{m_e e^4}{16\pi^2\varepsilon_0^2\hbar^2}$. Use the Hamiltonian

$$\hat{H} = -\frac{\hbar^2}{2m_e r^2}\frac{d}{dr}\left(r^2\frac{d}{dr}\right) - \frac{e^2}{4\pi\varepsilon_0 r}$$

5. Tabulate the number of angular, radial and total nodes for the following hydrogenic wavefunctions :
(*a*) 1s, (*b*) 2s, (*c*) 2p, (*d*) 3p, and (*e*) 3d.
[Ans. The number of angular nodes is l ; the number of radial nodes is $n - l - 1$; the total number of nodes is $n - 1$]

	1s	2s	2p	3p	3d
n	1	2	2	3	3
l	0	0	1	1	2
Angular	0	0	1	1	2
Radial	0	1	0	1	0
Total	0	1	1	2	2

CHAPTER 3

CHEMICAL BONDING : MOLECULAR QUANTUM MECHANICS

After the discovery of wave (quantum) mechanics by E. Schrödinger in 1926, matrix mechanics by W. Heisenberg in 1925 (which was later modified by M. Born, P. Jordan and Heisenberg) and the relativistic quantum mechanics by P. Dirac in 1927, the new mechanics was applied to determine atomic and molecular structure. The idea of chemical bonding between two atoms based on sharing of electrons was given by G.N. Lewis in 1916. The Lewis picture of bonding is still relevant today but the quantum mechanical formulation, incorporating de Broglie's wave particle duality, Pauli's exclusion principle and Heisenberg's uncertainty principle, gave a deeper insight into the nature of the chemical bond.

The attack on the chemical bonding proceeded along two lines : **The valence bond theory (VBT)** and the conceptually simpler and popular **molecular orbital theory (MOT).** VBT was pioneered by W. Heitler and F. London (in 1928) and later by J.C. Slater and L. Pauling. During the same period (1927–1932), molecular orbital theory was developed by F. Hund, R.S. Mulliken and J.E. Lennard-Jones, though it is Mulliken who is credited with the real formulation of MOT. During this period, E. Hückel formulated the molecular orbital theory of conjugated systems. It was modified as EHT (**extended Hückel theory**) in 1963 by R. Hoffmann. Quantum theory of organic reactivity was proposed during 1951–1965 by K. Fukui, R. Woodward and R. Hoffmann in the form of **conservation of orbital symmetry.** R. Marcus applied quantum theory and activated complex theory to the understanding of electron transfer reactions. The formidable difficulties encountered in solving the Schrödinger wave equation for large molecules were partially surmounted by J. Pople. Again, in 1964, W. Kohn formulated **density functional theory (DFT)** which bypasses Schrödinger's wave equation and is an alternative approach to comprehend the subtleties of chemical bonding. The major theme that runs through chemistry and chemical physics is summed up in the Japanese word **BONSAI** meaning '*Bonding Structure and Interactions*'. The following scientists have been awarded Nobel Prizes in chemistry for applying quantum mechanics to various aspects of chemical bonding : Pauling (1954) for VBT, Mulliken (1966) for MOT, Fukui and Hoffmann (1981) for conservation of orbital symmetry in pericyclic reactions ; Marcus (1992) for electron-transfer reactions, and Pople who shared the 1998 Nobel Prize with Kohn.

Broadly speaking, there are two types of bonds between atoms :

1. **Ionic bond** in which electrons are transferred between atoms and the bond arises from the coulombic interactions between the resulting ions.
2. **Covalent bond** in which electron pairs are shared more or less equally between neighbouring atoms. The idea of a **dative bond** or **covalent-coordinate bond,** in which one partner donates both the electrons of the shared pair, symbolized by $B \rightarrow A$, is now obsolete and the term 'covalent bond' signifies that a bond has been formed by electron-sharing irrespective of the donor of the electron pair.

A covalent bond may be further classified as polar or non-polar. A **polar covalent bond** is a covalent bond in which the electron pair is shared unequally between the two atoms, with the result that the two atoms carry partial electric charges. A **non-polar covalent bond** is a covalent bond in which the electron pair is shared equally between the two atoms. Covalent bonds are also classified as single, double or triple. A single bond consists of one shared pair of electrons; a double bond consists of two shared pairs of electrons and a triple bond consists of three shared pairs of electrons. Quadruple bonds containing four shared pairs of electrons are rarely encountered though they occur quite frequently in the transition metal clusters. Modern theories of chemical bonding have largely dispensed with the distinction between the various types of bonds. They consider bonding as a consequence of the lowering of energy that occurs when electrons occupy molecular orbitals that spread over all the atoms in the molecule. The bonding influence of an electron pair, according to MOT, may be distributed over many atoms. In fact, an electron-pair is not essential to bond formation but merely represents the maximum number of electrons that can occupy a given orbital thereby contributing to bonding.

MOLECULAR ORBITAL THEORY (MOT)

Just as the atomic orbitals are the solutions of the time-independent Schrodinger wave equation for atoms, molecular orbitals are the corresponding solutions for molecules. Molecular orbital theory is very simple to treat mathematically and is a landmark in molecular quantum mechanics. The electrons in atoms occupy atomic orbitals (AOs) that are represented as the regions around the nuclei where there is a high probability of finding the electrons. In the so-called **LCAO (linear combination of atomic orbitals)** approach, as pioneered by Hund and Mulliken, when AOs come close together, they *overlap* forming MOs (molecular orbitals). Two AOs can overlap to form two MOs, one of which lies at a lower energy level than the overlapping AOs and is called a **bonding molecular orbital (BMO)** and the other lies at a higher energy level and is called an **antibonding molecular orbital (ABMO)**. Each MO can hold one or two electrons in accordance with Pauli's exclusion principle. MOT can explain the paramagnetism of molecules such as O_2 and NO and other spectral features. The ordering of the molecular energy levels can be verified experimentally by photoelectron spectroscopy (PES). The Hartree–Fock Self-Consistent-Field (SCF) theory can be extended to molecules in which case it is called Hartree–Fock–Roothaan theory. Its relativistic version is called Dirac–Hartree–Fock–Roothaan (DHFR) theory.

Of great importance to molecular quantum mechanics is the **Born–Oppenheimer approximation,** according to which it is supposed that the nuclei, being so much heavier than the electron, move relatively slowly. Thus, nuclei can be treated as stationary so that the electrons move relative to them. Treating the nuclei as being fixed at an arbitrary distance, the Schrödinger wave equation can be solved for the electronic wave functions. This approximation holds good for the ground state of molecules and may break down for the excited states.

The mathematical treatment of the Born-Oppenheimer Approximation is discussed later in this chapter.

We shall deal with the molecular orbital theory of a homonuclear diatomic, H_2, molecule. In the LCAO–MO method, the MO ψ can be written as

$$\psi = c_1\phi_1 + c_2\phi_2 \qquad \ldots(1)$$

where the ϕs are the AOs (in this case, the two 1*s* orbitals) centered on hydrogen atoms, 1 and 2 and c_1, c_2 are the coefficients of these AOs. (The atomic orbitals such as *s, p, d,* etc., are called the *basis sets*). The energy E of the MO can be obtained by solving the Schrödinger wave equation

$$\hat{H}\psi = E\psi \qquad \ldots(2)$$

where $\hat{H}$ is the Hamiltonian operator.

Since the MOs are unnormalized, the energy E is given by

$$E = \int \psi^* \hat{H} \psi d\tau \Big/ \int \psi^* \psi d\tau \qquad \ldots(3)$$

If ψs are real, then $\psi^* = \psi$.

Substituting Eq. 1 into Eq. 3, we have

$$E = \frac{\int (c_1\phi_1 + c_2\phi_2)\hat{H}(c_1\phi_1 + c_2\phi_2)d\tau}{\int (c_1\phi_1 + c_2\phi_2)^2 d\tau}$$

$$= \frac{\int (c_1\phi_1\hat{H}c_1\phi_1 + c_1\phi_1\hat{H}c_2\phi_2 + c_2\phi_2\hat{H}c_1\phi_1 + c_2\phi_2\hat{H}c_2\phi_2)d\tau}{\int (c_1^2\phi_1^2 + 2c_1c_2\phi_1\phi_2 + c_2^2\phi_2^2)d\tau} \qquad \ldots(4)$$

Let $\quad H_{11} = \int \phi_1 \hat{H} \phi_1 d\tau$

$$H_{12} = H_{21} = \int \phi_1 \hat{H} \phi_2 d\tau = \int \phi_2 \hat{H} \phi_1 d\tau ; H_{22} = \int \phi_2 \hat{H} \phi_2 d\tau$$

$$S_{11} = \int \phi_1^2 d\tau ; S_{22} = \int \phi_2^2 d\tau ; S_{12} = S_{21} = \int \phi_1\phi_2 d\tau$$

In the above notation, H_{11}, H_{12}, H_{22}, etc., are called **matrix elements**. Using this notation, Eq. 4 can be written in a simplified form as

$$E = \frac{c_1^2H_{11} + 2c_1c_2H_{12} + c_2^2H_{22}}{c_1^2S_{11} + 2c_1c_2S_{12} + c_2^2S_{22}} \qquad \ldots(5)$$

The energy obtained above gives always the **upper bound**. The ground state energy is obtained by using the *variation theorem;* this is done by carrying out the differentiation $(\partial E/\partial c_i)$, *i.e.,* by differentiating with respect to each coefficient (i = 1, 2) independently and setting the derivative equal to zero; $\partial E/\partial c_i = 0$. Thus, we have

$$\frac{\partial E}{\partial c_1} = \frac{(c_1^2S_{11} + 2c_1c_2S_{12} + c_2^2S_{22})(2c_1H_{11} + 2c_2H_{12})}{(c_1^2S_{11} + 2c_1c_2S_{12} + c_2^2S_{22})^2}$$

$$- \frac{(c_1^2H_{11} + 2c_1c_2H_{12} + c_2^2H_{22})(2c_1S_{11} + 2c_2S_{12})}{(c_1^2S_{11} + 2c_1c_2S_{12} + c_2^2S_{22})^2} = 0 \qquad \ldots(6)$$

Hence, $\quad c_1H_{11} + c_2H_{12} = \dfrac{(c_1^2H_{11} + 2c_1c_2H_{12} + c_2^2H_{22})(c_1S_{11} + c_2S_{12})}{c_1^2S_{11} + 2c_1c_2S_{12} + c_2^2S_{22}} \qquad \ldots(7)$

From Eqs. 5 and 7, we obtain

$$c_1H_{11} + c_2H_{12} = E(c_1S_{11} + c_2S_{12})$$

or $\quad c_1(H_{11} - ES_{11}) + c_2(H_{12} - ES_{12}) = 0 \qquad \ldots(8)$

Similarly, minimizing E with respect to c_2, by requiring that $\partial E/\partial c_2 = 0$, we have

$$c_1(H_{21} - ES_{21}) + c_2(H_{22} - ES_{22}) = 0 \qquad \ldots(9)$$

Eqs. 8 and 9 form a system of two simultaneous linear equations in the two unknowns c_1 and c_2. According to the principle of linear algebra, the essential condition for these equations to have a **non-trivial solution** is that the determinant of the coefficients of c_1 and c_2 should vanish, *i.e.*,

$$\begin{vmatrix} H_{11} - ES_{11} & H_{12} - ES_{12} \\ H_{21} - ES_{21} & H_{22} - ES_{22} \end{vmatrix} = 0 \qquad ...(10)$$

Eq. 10 is called the 2×2 **secular equation** and the left-hand side of this equation is called the **secular determinant.**

Generalizing this result to a MO of the form

$$\psi_i = \sum_{j=1}^{n} c_{ij}\phi_j \qquad (i = 1, 2, 3, \ldots\ldots, n) \qquad ...(11)$$

where ϕs are the AOs, we obtain an $n \times n$ secular determinantal equation :

$$\begin{vmatrix} H_{11} - S_{11}E & H_{12} - S_{12}E & H_{13} - S_{13}E & \ldots & \ldots & H_{1n} - S_{1n}E \\ H_{21} - S_{21}E & H_{22} - S_{22}E & H_{23} - S_{23}E & \ldots & \ldots & H_{2n} - S_{2n}E \\ H_{31} - S_{31}E & H_{32} - S_{32}E & H_{33} - S_{33}E & \ldots & \ldots & H_{3n} - S_{3n}E \\ \ldots\ldots & \ldots\ldots & \ldots\ldots & \ldots & \ldots & \ldots\ldots \\ \ldots\ldots & \ldots\ldots & \ldots\ldots & \ldots & \ldots & \ldots\ldots \\ \ldots\ldots & \ldots\ldots & \ldots\ldots & \ldots & \ldots & \ldots\ldots \\ H_{n1} - S_{n1}E & H_{n2} - S_{n2}E & H_{n3} - S_{n3}E & \ldots & \ldots & H_{nn} - S_{nn}E \end{vmatrix} = 0 \qquad ...(12)$$

The secular equation (12) is a very important feature of both MOT and VBT. It consists of three kinds of integrals, *viz.*, Coulomb integral, the exchange integral and the overlap integral.

(i) Coulomb integral $H_{ii} = \int \phi_i H \phi_i \, d\tau$. It represents the energy of the electron in the AO centred on atom i

(ii) Exchange integral $H_{ij} = \int \phi_i H \phi_j \, d\tau$. It represents the energy of interaction of electrons in the atoms i and j.

(iii) Overlap integral $S_{ij} = \int \phi_i \phi_j \, d\tau$. It represents the overlap of the orbitals centered on atoms i and j. If $i=j$, then $S_{ii} = \int \phi_i \phi_i \, d\tau = 1$ (for normalized AOs).

The solution of Eq. 12 on the computer gives the values of energy levels of the MOs of an n-electron molecule. For diatomic molecules, the secular Eq. 10 is solved to obtain the energies of the MOs.

The theoretical treatment outlined in Eqs. 1 through 10 applies both to H_2^+ and H_2. To determine the coefficients c_1 and c_2, we proceed as follows : Consider H_2^+. If we label the two nuclei as a and b rather than 1 and 2 (for the sake of notational convenience), then (Fig. 1) the electronic Hamiltonian in the Born-Oppenheimer approximation is written as

$$\hat{H} = -\frac{\hbar^2}{2m_e}\nabla^2 - \frac{e^2}{4\pi\varepsilon_0}\left(\frac{1}{r_a} + \frac{1}{r_b} - \frac{1}{R}\right) \qquad ...(13)$$

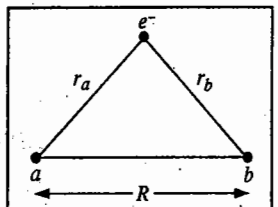

Fig. 1. The coordinates of H_2^+.

where m_e is the mass of the electron, r_a, r_b and R are the distances between the electron and the nucleus a,

between the electron and the nucleus b and the internuclear distance, respectively. It is customary to use atomic units in quantum chemistry : $e = m_e = \hbar = 1/4\pi\varepsilon_0 = 1$ (Note that these quantities are not really equal but they are arbitrarily set equal to unity). Then,

$$\hat{H} = -\frac{1}{2}\nabla^2 - \frac{1}{r_a} - \frac{1}{r_b} + \frac{1}{R} \qquad ...(14)$$

The secular equation (10) is rewritten as

$$\begin{vmatrix} H_{aa} - E & H_{ab} - SE \\ H_{ab} - SE & H_{bb} - E \end{vmatrix} = 0 \qquad ...(15)$$

Expansion of Eq. 15 gives a quadratic equation which has two solutions E_g and E_u :

$$E_g = (H_{aa} + H_{ab})/(1 + S) \qquad ...(16)$$

$$E_u = (H_{aa} - H_{ab})/(1 - S) \qquad ...(17)$$

Substitution of Eq. 16 or 17 into Eq. 8, which is rewritten as

$$c_1(H_{aa} - E) + c_2(H_{ab} - SE) = 0 \qquad ...(18)$$

yields

$$c_1 = c_2 \quad \text{or} \quad c_1 = -c_2 \qquad ...(19)$$

Substitution of Eq. 19 into Eq. 1 gives, after normalization,

$$\psi_g = \frac{1}{[2(1+S)]^{1/2}}(\phi_a + \phi_b) \qquad ...(20)$$

$$\psi_u = \frac{1}{[2(1-S)]^{1/2}}(\phi_a - \phi_b) \qquad ...(21)$$

where $\phi_a \equiv 1s_a$, $\phi_b \equiv 1s_b$, ψ_g is BMO and ψ_u is ABMO.

When a molecule (such as H_2^+ or H_2) has a centre of symmetry, the wave function may or may not change sign when it is inverted through the centre of symmetry. If, for instance, $\psi(x,y,z) = \psi(-x, -y, -z)$, the wave function is said to have *even parity* and is designated by the subscript g for *gerade* (German for even). If $\psi(x, y, z) = -\psi(-x, -y, -z)$, the wave function is said to have *odd parity* and is designated with a subscript u for *ungerade* (German for odd). ψ_g is called BMO because the electron density ψ_g^2 is increased midway between the nuclei and ψ_u is called ABMO because ψ_u^2 is zero midway between the nuclei (Fig. 2). Another way of expressing it is that the BMO arises from the constructive interference of the neighbouring AOs and the ABMO arises from their destructive interference. The BMO has no node and the ABMO has a node between the atoms.

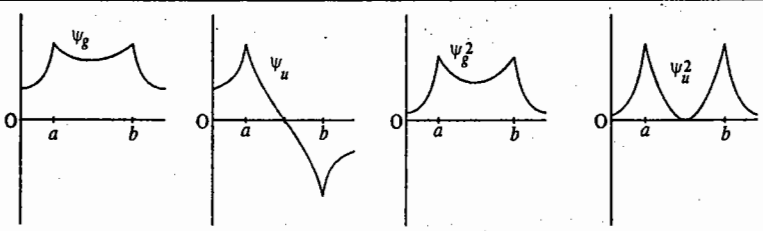

Fig. 2. MOs ψ_g and ψ_u for H_2^+ ion and the corresponding electron densities ψ_g^2 and ψ_u^2 along the internuclear axis.

Example 1. Write the Hamiltonian opertar for He_2^+ molecule-ion.

Solution : The complte Hamiltonian operator is given by

$$\hat{H} = \frac{-\hbar^2}{2}\sum_{\alpha}^{\text{all nuclei}}\frac{1}{m_\alpha}\nabla^2 + \frac{-\hbar^2}{2m_e}\sum_{i}^{\text{all electrons}}\nabla_i^2 + \sum_{\beta}\sum_{\alpha<\beta}\frac{Z_\alpha Z_\beta e^2}{4\pi\varepsilon_0 r_{\alpha\beta}} - \sum_{i}\sum_{\alpha}\frac{Z_\alpha e^2}{4\pi\varepsilon_0 r_{i\alpha}} + \sum_{j}\sum_{i<j}\frac{e^2}{4\pi\varepsilon_0 r_{ij}} \quad \ldots (i)$$

The *Born-Oppenheimer approximation* allows neglecting the ∇_α^2 terms and treating the $r_{\alpha\beta}^{-1}$ terms as constants at a given time. For the three electrons in He_2^+, (Eqn. (*i*) gives

$$\hat{H} = \frac{\hbar^2}{2m_e}(\nabla_1^2 + \nabla_2^2 + \nabla_3^2) + \frac{e^2}{4\pi\varepsilon_0}\left(\frac{4}{r_{ab}} - \frac{2}{r_{1a}} - \frac{2}{r_{2a}} - \frac{2}{r_{3a}} - \frac{2}{r_{1b}} - \frac{2}{r_{2b}} - \frac{2}{r_{3b}} + \frac{1}{r_{12}} + \frac{1}{r_{13}} + \frac{1}{r_{23}}\right) \quad \ldots (ii)$$

where $Z_a = Z_b = 2$.

Example 2. Write the Hamiltonian operator for the K_2 molecule.

Solution : The electrons in this molecule can be classified into two types : the core electrons around each atom that do not contribute to the bonding and the two valence electrons that provide the bonding. Using the *valence-electron approximation* Eq. (*i*) in example 1, gives

$$1\hat{H} = \frac{-\hbar^2}{2m_e}(\nabla_1^2 + \nabla_2^2) + \frac{e^2}{4\pi\varepsilon_0}\left(\frac{1}{r_{ab}} - \frac{1}{r_{1a}} - \frac{1}{r_{2a}} - \frac{1}{r_{1b}} - \frac{1}{r_{2b}} + \frac{1}{r_{12}}\right)$$

where the effective nuclear charge of 1 was used.

Example 3. Write the expression for a trial wave function for the He_2^+ system.

Solution : The wave function ϕ can be written as the product of wavefunctions for the individual electrons.

$$\phi = \phi_1\phi_2\phi_3 \ldots \quad \ldots (i)$$

where the $\phi_{(i)}$ are produced by taking linear combinations of hydrogenic atomic orbitals (LCAO) :

$$\phi_i = c_{ia}\psi_a(i) + c_{ib}\psi_b(i) + \ldots \quad \ldots (ii)$$

The $a_{i\alpha}$ terms are constants, and ψ_α (*i*) denotes a hydrogenic atomic wavefunction describing electrion *i* in terms of position with respect to nucleus α. In this case, using Eqs (*i*) and (*ii*) gives

$$\phi = \phi_1\phi_2\phi_3$$
$$\phi_1 = c_1\psi_a(1) + c_2\psi_b(1)$$
$$\phi_2 = c_3\psi_a(2) + c_4\psi_b(2)$$
$$\phi_3 = c_5\psi_a(3) + c_6\psi_b(3)$$

where ψ_a and ψ_b would be the 1s wavefunction for H.

Example 4. Write the expression for a trial wave function for the K_2 molecules.

Solution : Assuming the valence-electron approximation, using (*i*) and (*ii*) gives

$$\phi = \phi_1\phi_2$$
$$\phi_1 = c_1\psi_a(1) + c_2\psi_b(1)$$
$$\phi_2 = c_3\psi_a(2) + c_4\psi_b(1)$$

where ψ_a and ψ_b would be the 4s wavefunction for H.

Example 5. Write the expression for a trial wave function describing the HF molecule.

Solution : Assuming the valence-electron approximation, using Eqs., (*i*) and (*ii*) in examples 3 gives

$$\phi = \phi_1\phi_2$$

$$\phi_1 = c_1\psi_a(1) + c_2\psi_b(1)$$
$$\phi_2 = c_3\psi_a(2) + c_4\psi_b(1)$$

where ψ_a would be the 1*s* wavefunction for H and ψ_b would be the 2*p* wavefunction for F.

Example 6. Identify the ionic and covalent terms in the expression for ϕ determined in examples 5.

Solution : The complete trial wavefunction for HF is

$$\phi = \phi_1\phi_2 = [c_1\psi_a(1) + c_2\psi_n(1)]\,[c_3\psi_a(2) + c_4\psi_b(2)]$$
$$= c_1c_2\psi_a(1)\,\psi_a(2) + c_2c_3\psi_b(1)\,\psi_a(2) + c_1c_2\psi_a(1)\,\psi_a(2) + c_2c_4\psi_b(1)\,\psi_b(2)$$

The first and fourth terms in this expression for ϕ each indicate that both electrons are araound the same nucleus and are the ionic terms. The second and third terms each indicate that the electrons are around different nuclei and are the covalent terms.

Example 7. Because He_2^+ is a homonuclear diatomic system, assume that the $c_{i\alpha}$ are all equal to *c* and that identical normalized hydrogenlike wave functions are chosen. Determine the value of *c* in terms of *S* where $S_{aa} = S_{bb} = 1$ and $S_{ab} = S_{ba} = S$ is the overlap integral.

Solution : The overlap integral is

$$\int \phi^*\phi d\tau = \int (\phi_1\phi_2\phi_3)^*(\phi_1\phi_2\phi_3)\,d\tau_1\,d\tau_2 d\tau_3 = \int \phi_1^*\phi_2^*\phi_1\phi_2 d\tau_1 d\tau_2 \int \phi_3^*\phi_3 d\tau_3$$

$$= \int \phi_1^*\phi_1 d\tau_1 \int \phi_2^*\phi_2 d\tau_2 \int \phi_3^*\phi_3 d\tau_3 = \left(\int \phi_1^*\phi_1 d\tau_1\right)^3$$

Substituting $\psi_1 = a\psi_a(1) + a\psi_b)(1)$ gives

$$\int \phi_1^*\phi_1 d\tau_1 = \int [c\psi_a(1) + c\psi_b(1)]^*\,[c\psi_a(1) + c\psi_b(1)]\,d\tau_1$$

$$= c^2\left(\int [\psi_a^*(1)\,\psi_a(1) + \psi_a^*(1)\,\psi_b(1) + \psi_b^*(1)\psi_a(1) + \psi_b^*(1)\,\psi_a(1)]\,d\tau\right)$$

$$= c^2(S_{aa} + S_{ab} + S_{ba} + S_{bb}) = c^2(1 + S + S + 1) = c^2(2 + 2S)$$

The overlap integral becomes

$$\int \phi^*\phi d\tau = [c^2(2 + 2S)]^3 = 1$$

Solving $c = (2 + 2S)^{-1/2}$.

Example 8. Determine the energy of the He_2^+ molecule-ion in terms of H_{aa}, H_{ab} and *S* using the variation method.

Solution : The secular determinant for the system is given by

$$\begin{vmatrix} H_{aa} - ES_{aa} & H_{ab} - ES_{ab} \\ H_{ba} - ES_{ba} & H_{bb} - ES_{bb} \end{vmatrix} = 0$$

in this case $H_{aa} = H_{bb}$, $S_{ab} = S_{ba} = S$, and $S_{aa} = S_{bb} = 1$, giving

$$\begin{vmatrix} H_{aa} - E & H_{ab} - ES \\ H_{ab} - ES & H_{aa} - E \end{vmatrix} = 0$$

Expanding gives

$$(H_{aa} - E)^2 - (H_{ab} - ES)^2 = 0$$
$$[(H_{aa} - E) + (H_{ab} - ES)]\,[(H_{aa} - E) - (H_{ab} - ES)] = 0$$

The two roots are $$E_1 = \frac{H_{aa} + H_{ab}}{1 + S} \quad \ldots (i)$$

and $$E_2 = \frac{H_{aa} - H_{ab}}{1 - S} \quad \ldots (ii)$$

Example 9. For the He_2^+ molecular ion described by the wave function

$$\phi = \phi_1 = a_1\psi_a(1) + a_2\psi_b(1) \quad \ldots (iii)$$

it can be shown that $$H_{aa} = E(\mathrm{H}) + J \quad \ldots (iv)$$

$$H_{ab} = E(\mathrm{H})S + J \quad \ldots (v)$$

where $E(\mathrm{H})$ is the ground-state energy of the hydrogen atom ($-13{\cdot}60eV = 2{\cdot}179 \times 10^{-18}J$), the *Coulomb integral* is given by

$$J = \frac{-e^2}{4\pi\varepsilon_0} \int \psi_a^*(1) \frac{1}{r_{ib}} \psi_a(1)\, d\tau$$

the *exchange* (or *resonance*) *integral* is given by

$$K = \frac{-e^2}{4\pi\varepsilon_0} \int \psi_b^*(1) \frac{1}{r_{ib}} \psi_a(1)\, d\tau$$

and the *overlap integral* is given by

$$S = \int \psi_a^*(1)\, \psi_a(1)\, d\tau$$

Rewrite the expressions for energy given by Eqs. (*i*) and (*ii*) in example 8 in terms of these integrals.

Solution : Substituting Eqs. (*iv*) and (*v*) into Eqs. (*i*) and (*ii*) gives

$$E_1 = \frac{[E(\mathrm{H}) + J] + [E(\mathrm{H})S + K]}{1 + S} = E(\mathrm{H}) + \frac{J + K}{1 + S}$$

$$E_2 = \frac{[E(\mathrm{H}) + J] + [E(\mathrm{H})S + K]}{1 - S} = E(\mathrm{H}) + \frac{J - K}{1 - S}$$

Example 10. The observed internuclear distance in H_2^+ is 0·1057 nm. Calculate the total energy of the system at this value of r_{ab} assuming that ψ_α (*i*) is given by 1s hydrogenlike orbitals.

Solution : If the $\psi_\alpha(i)$ are hydrogenlike 1*s* atomic orbitals, the various integrals are given by

$$S = e^{-\rho}\left(1 + \rho + \frac{\rho^2}{3}\right) \quad \ldots (i)$$

$$J = \frac{e^2}{4\pi\varepsilon_0 a_0}\left[\frac{-1}{\rho} + e^{-2\rho}\left(1 + \frac{1}{\rho}\right)\right] \quad \ldots (ii)$$

$$K = \frac{-e^2}{4\pi\varepsilon_0 a_0} e^{-\rho}(1 + \rho) \quad \ldots (iii)$$

where $$\rho = r_{ab}/a_0 \quad \ldots (iv)$$

and $a_0 = 0{\cdot}0529$ nm. Substituting $r_{ab} = 0{\cdot}1057$ nm into Eq. (*iv*) gives

$$\rho = \frac{0{\cdot}1057 \text{ nm}}{0{\cdot}0529 \text{ nm}} = 1{\cdot}997$$

Substitution of this value of ρ into Es. (*i*), (*ii*) and (*iii*) gives

$$S = e^{-1{\cdot}997}\left(1 + 1{\cdot}997 + \frac{(1{\cdot}997)^2}{3}\right) = 0{\cdot}5873$$

$$J = \left[\frac{(1{\cdot}602 \times 10^{-19}\mathrm{C})^2\,[1 \text{ kg m s}^{-2})/(1\mathrm{N})\,[(1\mathrm{J})/(1 \text{ kg m}^2\,\mathrm{s}^{-2})]}{(1{\cdot}112 \times 10^{-10}\,\mathrm{C}^2\,\mathrm{N}^{-1}\,\mathrm{m}^{-2})\,(5{\cdot}292 \times 10^{-11}\,\mathrm{m})}\right]\left[\frac{-1}{1{\cdot}997} + e^{-2\,(1{\cdot}997)}\left(1 + \frac{1}{1{\cdot}997}\right)\right]$$

$$= (4{\cdot}360 \times 10^{-18}\,\mathrm{J})\,(-0{\cdot}4731) = -2{\cdot}063 \times 10^{-18}\,\mathrm{J}$$

$$= (-4{\cdot}360 \times 10^{-18}\,\mathrm{J})\,e^{-1{\cdot}997}(1 + 1{\cdot}997) = -1{\cdot}774 \times 10^{-18}\,\mathrm{J}$$

Substitution of these values of S, J and K into the expressions for E_1 and E_2 in example 9 gives

$$E_1 = -2{\cdot}179 \times 10^{-18}\mathrm{J} + \frac{-2{\cdot}063 \times 10^{-18}\,\mathrm{J} + (-1{\cdot}774 \times 10^{-18}\mathrm{J})}{1 + 0{\cdot}5873} = -4{\cdot}596 \times 10^{-18}\,\mathrm{J}$$

$$E_2 = -2{\cdot}179 \times 10^{-18}\mathrm{J} + \frac{-2{\cdot}063 \times 10^{-18}\,\mathrm{J} - (-1{\cdot}774 \times 10^{-18}\mathrm{J})}{1 - 0{\cdot}5873} = -2{\cdot}879 \times 10^{-18}\,\mathrm{J}$$

The total energy (E') is found by adding the nuclear repulsion term that was treated as a constant in Eq. (*i*) in example 1 by the Born-Oppenheimer approximation :

$$E_1' = E_1 + \frac{e^2}{4\pi\varepsilon_0 r_{ab}} = -4{\cdot}596 \times 10^{-18}\,\mathrm{J} + \frac{(1{\cdot}602 \times 10^{-19})^2}{(1{\cdot}112 \times 10^{-10})\,(1{\cdot}057 \times 10^{-10})}$$

$$= -2{\cdot}413 \times 10^{-18}\,\mathrm{J}$$

$$E_2' = -2{\cdot}879 \times 10^{-18} + 2{\cdot}183 \times 10^{-18} = -0{\cdot}696 \times 10^{-18}\,\mathrm{J}$$

The results of similar calculations are plotted in Fig. 3.

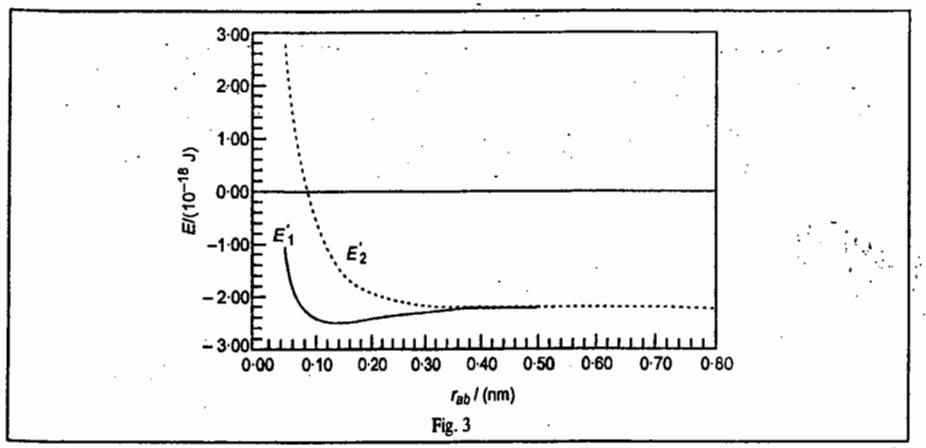

Fig. 3

Example 11. What is the limit of the total energy for H_2^+ as $r_{ab} \to \infty$?

Solution : Taking the limits of Eqs. (*i*), (*ii*) and (*iii*) in example 10, and the nuclear repulsion term as r_{ab} or $\rho \to \infty$ gives

$$\lim_{\rho\to\infty}(S) = \lim_{\rho\to\infty}\left(\frac{1+\frac{2}{3}\rho}{-e^{-\rho}}\right) = \lim_{\rho\to\infty}\left(\frac{\frac{2}{3}}{e^{-\rho}}\right) = 0\ ; \quad \lim_{\rho\to\infty}(J) = 0$$

$$\lim_{\rho\to\infty}(K) = \frac{-e^2}{4\pi\varepsilon_0 a_0}\lim_{\rho\to\infty}\left(\frac{1}{-e^{-\rho}}\right) = 0;\ \lim_{\rho\to\infty}\left(\frac{e^2}{4\pi\varepsilon_0 r_{ab}}\right) = 0$$

The limiting values of total energy are

$$E_1' = E(\mathrm{H}) + \frac{0+0}{1+0} + 0 = E(\mathrm{H}) = -2{\cdot}179 \times 10^{-18}\ J$$

$$E_2' = E(\mathrm{H}) + \frac{0-0}{1-0} + 0 = E(\mathrm{H})$$

Example 12. Using Fig. 3, predict the equilibrium value of r_{ab} and the dissociation energy for the H_2^+ molecule-ion.

Solution : The minimum value of E_1' in Fig. 3 appears at $r_{ab} = 0{\cdot}132$ nm and $-2{\cdot}46 \times 10^{-18}$ J. The predicted equilibrium value of r_{ab} is 0·132 nm, which is 1·24 times greater than the observed value of 0·1057 nm. In example 11, the limiting value of E_1' was determined to be $-2{\cdot}179 \times 10^{-18}$ J as $r_{ab} \to \infty$. The difference gives the predicted value of the dissociation energy(D_e) as

$$D_e = (-2{\cdot}179 \times 10^{-18}\mathrm{J}) - (-2{\cdot}46 \times 10^{-18}\mathrm{J}) = 0{\cdot}28 \times 10^{-18}\mathrm{J}$$

which is considerably less than the observed value of $0{\cdot}4472 \times 10^{-18}$ J.

Example 13. Assuming the H_2^+ molecule-ion to be described by the wavefunction $\phi = \phi_1 = c_1\psi_a(1) + c_2\psi_b(1)$, determine the relation between c_1 and c_2.

Soluton : For this system the secular equation (Eq. 15) simplifies to

$$c_1(H_{aa} - E) + c_2(H_{ab} - ES) = 0$$

Substituting the expression for E_1 in Example 8 gives

$$c_1\left(H_{aa} - \frac{H_{aa}+H_{ab}}{1+S}\right) + c_2\left(H_{ab} - \frac{H_{aa}+H_{ab}}{1+S}\right) = 0$$

$$c_1[(1+S)H_{aa} - H_{aa} - H_{ab}] + c_2[(1+S)H_{ab} - SH_{aa} - SH_{ab}] = 0$$

$$c_1(SH_{aa} - H_{ab}) + c_2(H_{ab} - SH_{aa}) = 0$$

$$c_1 = c_2$$

for E_1. Likewise, substituting the expresion for E_2 in example 8, gives $c_1 = -c_2$ for E_2.

Example 14. Evaluate c_1 and c_2 in the wave function given in Example 13.

Solution : For E_1, it was shown in Example 13 that $c_1 = c_2$. The wavefunction becomes

$$\phi = c_1\psi_a(1) + c_1\psi_b(1) = c_1[\psi_a(1) + \psi_b(1)]$$

Using the normalization requirement, we have

$$\int \phi^*\phi\, d\tau = \int c_1[\psi_a(1) + \psi_b(1)]^*\, c_1[\psi_a(1) + \psi_b(1)]\, d\tau$$

$$= c_1^2\left(\int \psi_a^*(1)\,\psi_a(1)\,d\tau + \int \psi_a^*(1)\,\psi_b(1)\,d\tau\right) + \int \psi_a^*(1)\,\psi_a(1)\,d\tau + \int \psi_b^*(1)\,\psi_b(1)\,d\tau\Big)$$

$$= c_1^2(S_{aa} + S_{ab} + S_{ba} + S_{bb}) = c_1^2(1+S+S+1) = c_1^2(2+2S) = 1 \qquad \ldots (i)$$

$$c_1 = (2+2S)^{-1/2}$$

where $S_{aa} = S_{bb} = 1$ and $S_{ab} = S_{ba} = S$. The wave function corresponding to E_1 is given by

$$\phi_1 = (2+2s)^{-1/2}[\psi_a(1) + \psi_b(1)] \qquad \ldots(ii)$$

Likewise for E_2, $c_1 = (2-2S)^{-1/2}$, giving

$$\phi_2 = (2-2S)^{-1/2}[\psi_a(1) - \psi_b(1)] \qquad \ldots (iii)$$

Example 15. Prepare a plot of $\phi^*\phi$ for the wavefunctions give in Example 14, along the internuclear axis using $r_{ab} = 0{\cdot}1057$ nm.

Solution : The hydrogenic 1s wavefunction is

$$\psi_{1s} = \left(\frac{Z}{a_0}\right)^{3/2}\frac{1}{\pi^{1/2}}e^{-Zr/a_0} = \frac{e^{-r/a_0}}{a_0^{3/2}\pi^{1/2}}$$

At $r_{ab} = 0{\cdot}1057$ nm, $S = 0{\cdot}5873$ (see Example 10). Substituting (eq. (*ii*)) gives

$$\phi_1 = \frac{e^{-r_a/a_0} + e^{-r_b/a_0}}{[2+2(0{\cdot}5873)]^{1/2}\,a_0^{3/2}\pi^{1/2}} = \frac{e^{-r_a/a_0} + e^{-r_b/a_0}}{1{\cdot}216\times10^{-15}\mathrm{m}^{3/2}} \qquad \ldots (iv)$$

Likewise,

$$\phi_2 = \frac{e^{-r_a/a_0} + e^{-r_b/a_0}}{[2-2(0{\cdot}5873)]^{1/2}a_0^{3/2}\pi^{1/2}} = \frac{e^{-r_a/a_0} + e^{-r_b/a_0}}{6{\cdot}199\times10^{-16}\mathrm{m}^{3/2}} \qquad \ldots (v)$$

Because these wave functions consist of only real terms, $\phi^*\phi = \phi_i^2$. As a sample calculation, consider a point along the bonding axis that is 0·0500 nm from nucleus *a*. If nucleus *a* is placed at $r_{ab} = 0$ and nucleus *b* is placed at $r_{ab} = 0{\cdot}1057$ nm, the values of r_a and r_b used in Eqs. (*iv*) and (*v*) will be

$$r_a = |\,r\,| = 0{\cdot}0500 \text{ nm}$$

$$r_b = |\,r - 0{\cdot}1057 \text{ nm}\,| = |0.0500\text{nm} - 0{\cdot}1057 \text{ nm}\,| = 0{\cdot}0557 \text{ nm}$$

giving

$$\phi_1^*\phi_1 = \left[\frac{e^{-(0{\cdot}0500\text{ nm})(0.0529\text{nm})} + e^{-(0{\cdot}0557\text{ nm})/(0{\cdot}0529\text{ nm})}}{1{\cdot}216\times10^{-15}\mathrm{m}^{3/2}}\right]^2 = 3{\cdot}68\times10^{29}\ \mathrm{m}^{-3}$$

$$\phi_2^*\phi_2 = \left[\frac{e^{-(0{\cdot}0500)/(0{\cdot}0529)} - e^{-(0{\cdot}0557)/(0{\cdot}0529)}}{6{\cdot}199\times10^{-16}\mathrm{m}^{3/2}}\right]^2 = 4{\cdot}24\times10^{27}\ \mathrm{m}^{-3}$$

This plot is shown in Fig. 4.

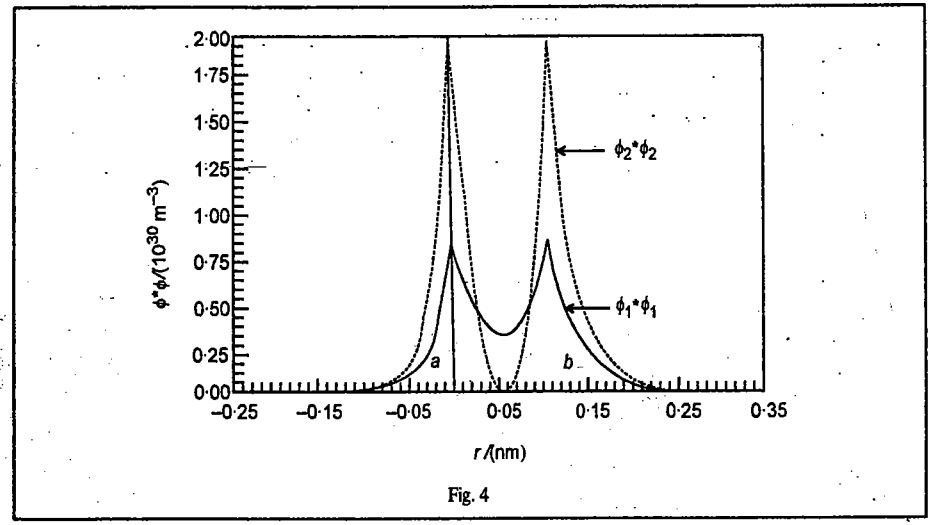

Fig. 4

Example 16. Calculate the probability of finding the electron in a small volume element of 1 pm^3 located along the bonding axis in H_2^+ at r = 0·0500 nm. Assume that the nuclei are separated at a distance of 0·1057 nm.

Solution : The probability is given by $P = \phi^*\phi\, d\tau$, where the values of $\phi^*\phi$ were determined in Example 15 for this system. The respective probabilities are

$$P_1 = (3{\cdot}68 \times 10^{29}\text{m}^{-3})\ (1 \times 10^{-12}\ \text{m})^3 = 3{\cdot}68 \times 10^{-7}$$

$$P_2 = (4{\cdot}24 \times 10^{27})\ (1 \times 10^{-12})^3 = 4{\cdot}24 \times 10^{-9}$$

Example 17. Repeat the calculations of example 16 for the volume element located at r = 0·0500 nm from nucleus a and at a distance of 0·0200 nm off the bonding axis.

Solution : The values of r_a and r_b to be used in Es. (*iv*) and (*v*) in eqample 15 can be determined using the

$$r_a = [(0{\cdot}0500\ \text{nm}) + (0{\cdot}0200\ \text{nm})^2]^{1/2} = 0{\cdot}0539\ \text{nm}$$

$$r_b = [(0{\cdot}1057\ \text{nm} - 0{\cdot}0500\ \text{nm})^2 + (0{\cdot}0200\ \text{nm})^2]^{1/2} = 0{\cdot}0592\ \text{nm}$$

Substituting into Eq. (*iv*) in example 15 gives

$$\phi_1 = \frac{e^{-(0{\cdot}0539\ \text{nm})/(0{\cdot}0529\ \text{nm})} + e^{-(0{\cdot}0532\ \text{nm})/(0{\cdot}0592\ \text{nm})}}{1{\cdot}216 \times 10^{-15}\text{m}^{3/2}} = 5{\cdot}65 \times 10^{14}\ \text{m}^{-3/2}$$

Likewise, $\phi_2 = 5{\cdot}55 \times 10^{13}\ \text{m}^{-3/2}$. The respective probabilities are

$$P_1 = (5{\cdot}65 \times 10^{-14}\ \text{m}^{-3/2})^2 \cdot (1 \times 10^{-12}\ \text{m})^3 = 3{\cdot}19 \times 10^{-7}$$

$$P_2 = (5{\cdot}55 \times 10^{-13})^2\ (1 \times 10^{-12})^3 = 3{\cdot}08 \times 10^{-9}$$

Term Symbols for a Diatomic Molecule

The hydrogen molecule (and other diatomic molecules) have a large number of excited electronic states which are designated by ***molecular term symbols.*** As in an atom, in diatomic molecules the orbital angular momenta of electrons couple to give a resultant orbital angular momentum L and the electron spin momenta couple to give a resultant spin angular momentum S. The component of the orbital angular momentum along the axis of the molecule is given by

$$M_L = m_1 + m_2 + \cdots\cdots\cdots$$

where $m_i = 0$ for a σ orbital and $m_i = \pm 1$ for a π orbital, and so on. The quantum number Λ is defined as the absolute value of M_L and is represented by the code letters

Λ =	0	1	2	3
Symbol =	Σ	Π	Δ	Φ

in analogy to atomic term symbols. The multiplicity of an electronic state of a diatomic molecule is given by $2S+1$ where S is the sum of the spins of the electrons in the molecule. The term symbol of a molecule is represented by $^{2S+1}\Lambda$.

For Σ terms, a superscript of plus or minus is added according to the behaviour of the wave function upon reflection in the plane containing the internuclear axis. A plus sign indicates that the wave function is invariant under this operation and a negative sign indicates that the wave function changes sign on reflection in this plane. If a diatomic molecule, such as a homonuclear diatomic, has a centre of symmetry, a right subscript of g or u is attached to the term symbol to denote the *parity* of the orbital. The parity of an orbital is determined by observing the *inversion* symmetry. When a point on an orbital is inverted an equal distance through the centre of the molecule, the orbital is said to be *gerade* (g) if it has the same sign at the two points; otherwise it is said to be *ungerade* (u); The reader can convince himself of the fact that in an atom an s orbital is g, a p orbital is u, a d orbital is g, and an f orbital is u. The parity of a multielectron molecule is obtained by noting g or u for every orbital and forming products, using the relations :

$$g \times g = g,\ g \times u = u,\ u \times u = g$$

Example 18. Show that the ground state term symbol of H_2 is $^1\Sigma_g^+$.

Solution : The H_2 molecule has the electronic configuration $(\sigma_g, 1s)^2$, *i.e.*, both the electrons are in the σ_g

orbital. For the σ electrons, $m_1 = 0$, $m_2 = 0$ so that $M_L = 0$. Since $s = |M_L|$, hence, Λ = 0. This means that the term symbol is Σ. Since $S_1 = 1/2$ and $S_2 = -1/2$, hence, $S = S_1 + S_2 = 0$ so that multiplicity $2S + 1 = 1$ which corresponds to a singlet state. Since the σ orbital is invariant under reflection in the plane containing the internuclear axis, we use the superscript of plus (+). Again, since the orbital is gerade (g), we use the subscript g. Thus, the complete term symbol for H_2 is $^1\Sigma_g^+$.

Symmetry of Molecular Orbitals. Some of the possible combinations of atomic orbitals in the LCAO–MO scheme are shown in Fig. 5. Those orbitals which are cylindrically symmetrical about the

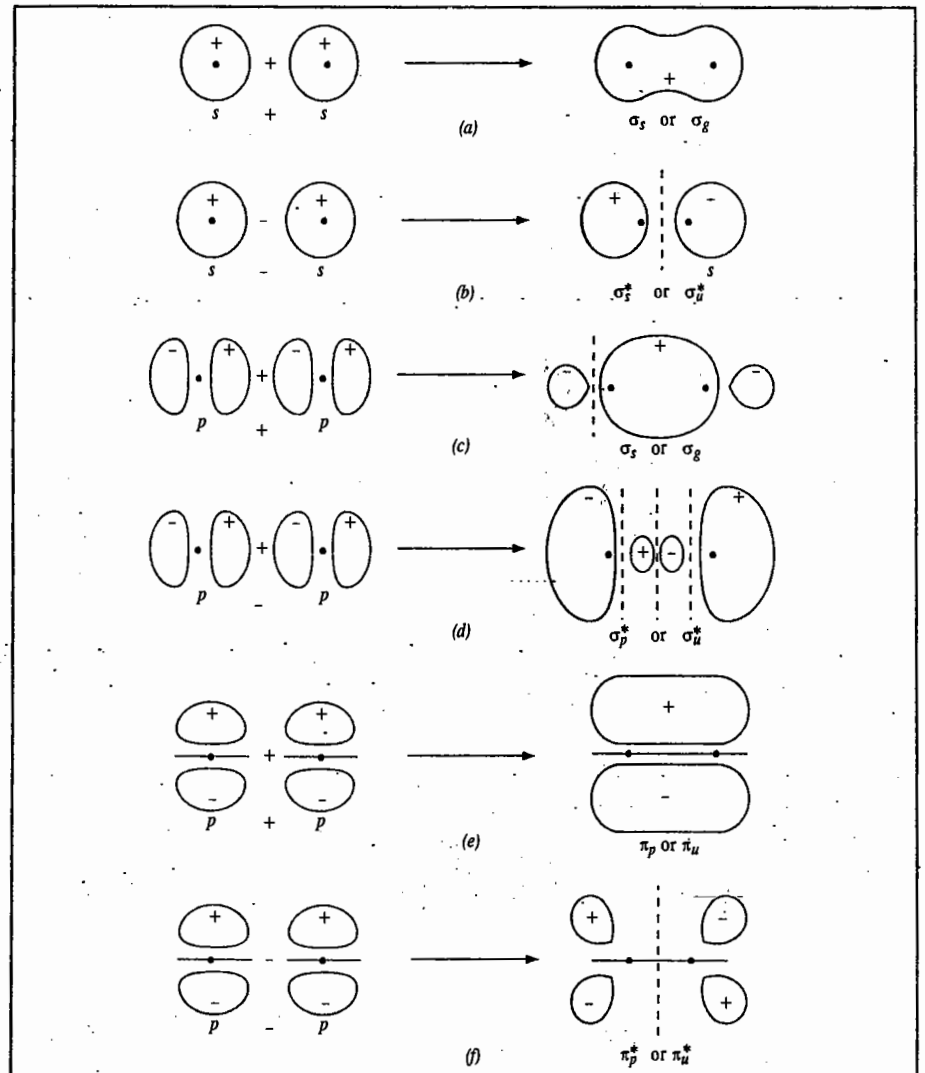

Fig. 5. Combinations of s, s and p, p atomic orbitals to form molecular orbitals of different symmetries. The figure displays the contours of the atomic and molecular orbitals. The traditional shapes of s and p orbitals arise from the projection of the contours on the respective axes.

internuclear axis are called σ orbitals, analogous to an *s* orbital of the highest symmetry. If the internuclear axis lies in the nodal plane, a π bond is formed. In δ bonds (encountered in the metal-metal quadruple bond in transition-metal chemistry), the internuclear axis lies in two mutually perpendicular nodal planes. All antibonding orbitals, identified with an *, possess an additional nodal plane perpendicular to the internuclear axis and lying between the nuclei. Also the MOs may or may not have a centre of symmetry. Thus, π_{p-p} orbitals are ungerade and π^*_{p-p} orbitals are gerade.

MOs for Homonuclear Diatomic Molecules

The simplest molecules are those containing two atoms of the same element ; these are called homonuclear diatomics. We shall now consider the LCAO-MO approximation for such molecules using the basis functions of the two atoms, such as the AOs 1*s*, 2*s*, 2*p*, 3*s*, etc. The two criteria that must be satisfied for the formation of BMOs are *(i)* the overlap between the AOs must be positive, the energies of the AOs must be approximately the same in order that there is effective interaction between the AOs of different atoms.

The molecules are built up by adding electrons to MOs in the same way as the atoms are built up by adding electrons to AOs. The principles involved in both cases are the same. The basic principles can be summed up as follows :

1. The MO with the lowest energy is filled first.
2. The maximum number of electrons in a MO cannot exceed two and the two electrons must be of opposite sign.
3. If there are two degenerate MOs, pairing of electrons will occur only after each degenerate MO has one electron.

It is useful to define the term **bond order** that is roughly proportional to the strength of bonding. This is equal to one-half the difference between the number of bonding electrons and the number of antibonding electrons. Thus,

$$\text{Bond order} = \tfrac{1}{2}(N_b - N_a) \qquad \ldots(22)$$

Bond orders of 1, 2 and 3 signify single, double and triple bonds. Bond order of zero means that no bond is formed. The bond order of a molecule is directly proportional to its bond dissociation energy. This means that the higher the bond order, the larger the bond dissociation energy and the smaller the bond length.

We shall now consider the homonuclear diatomic molecules of the first and second row elements of the Periodic table.

1. $H_2 : \sigma(1s)^2$; bond order $= \frac{1}{2}(2 - 0) = 1$. The molecule has a single bond.

The bond dissociation energy of H_2 molecule has been found to be 458 kJ mol^{-1} and bond length equal to 0·74 Å.

2. Hydrogen molecule ion, H_2^+. This molecule has been detected spectroscopically when electric discharge is passed through hydrogen gas under reduced pressure. The molecule has only one electron and its electronic configuration is

$$H_2^+ : (\sigma(1s)^1 \quad \text{and its bond order} = \tfrac{1}{2}(1 - 0) = \tfrac{1}{2}$$

The positive value of bond order indicates that the bond is formed and the molecule is stable. However, the bond in H_2^+ ion is weaker than that in H_2 molecule. The bond dissociation energy of H_2^+ ion (269 kJ mol^{-1}) is less than that of H_2 molecule (458 kJ mol^{-1}). The bond length in H_2^+ ion (1·04 Å) is larger than that in H_2 molecule (0·74 Å). These observations support the fact that the bond in H_2^+ ion is weaker than the bond in H_2 molecule.

3. He_2. The electronic configuration of hypothetical He_2 molecule is

$$He_2 : \sigma(1s)^2\, \sigma^*(1s^2) \quad \text{and its bond order} = \tfrac{1}{2}(2 - 2) = 0.$$

The zero bond order indicates that the molecule does not exist. Calculations have shown that the antibonding effect of an antibonding MO is stronger than the bonding effect of a bonding MO. Consequently, there is no possibility whatsoever for the existence of He_2 molecule.

Diatomic Molecules of the Second Row Elements. In these elements, the 1*s* orbitals are completely filled. In the formation of molecular orbitals, the electrons in the inner shells (*i.e.*, 1*s* electrons) of each atom remain essentially unperturbed in their respective atomic orbitals and may be kept out of consideration. In the formulation of electronic configurations of these molecules, the letters *KK* are generally used for denoting the fully filled inner shells (*K* shells) in the two atoms.

4. Li_2. The electronic configuration of lithium atom ($Z = 3$) is $1s^2\, 2s^1$. There are six electrons to be accommodated in lithium molecule. The four electrons are present in *K* sheils and there are only two electrons to be accommodated in molecular orbitals. These two electrons go into σ(2*s*) BMO which has lower energy and σ*(2*s*) ABMO remains empty. The electronic configuration of Li_2 molecule is thus represented as

$$Li_2 : KK\, \sigma(2s)^2 \quad \text{and its bond order} = \tfrac{1}{2}(2 - 0) = 1$$

Thus, there is one Li - Li sigma bond. The bond dissociation energy of the molecule is quite low, being about 105 kJ mol^{-1}. The bond length is 2·67 Å.

5. Be_2. The elecronic configuration of Be_2 molecule is

$Be_2 : KK\sigma(2s)^2\, \sigma^*(2s)^2$ and its bond order $= \frac{1}{2}(2 - 2) = 0$

The zero bond order suggests that the existence of stable Be_2 molecule is not possible.

6. B_2. The electronic configuration of B_2 molecule is

$B_2 : KK\, \sigma(2s)^2\, \sigma^*(2s^2)\, \pi(2p_x)^1\, \pi(2p_y)^1$ and its bond order $= \frac{1}{2}(4 - 2) = 1$

The molecule has only one B—B sigma bond. The bond dissociation energy is 289 kJ mol^{-1} and bond length is equal to 1·59 Å.

7. C_2. The electronic configuration of C_2 molecule is

$C_2 : KK\, \sigma(2s)^2\, \sigma^*(2s^2)\, \pi(2p_x)^2\, \pi(2p_y)^2$ and its bond order $= \frac{1}{2}(6 - 2) = 2$

Since C_2 molecule does not have any unpaired electron, it is diamagnetic, as observed experimentally. The bond dissociation energy of C_2 molecule is 627·9 kJ mol^{-1} and bond length equal to 1·31 Å.

8. N_2. The electronic configuration of nitrogen molecule is

$N_2 : KK\, \sigma(2s)^2\, \sigma^*(2s)^2\, \pi(2p_x)^2\, \pi(2p_y)^2\, \sigma(2p_z)^2$ and its bond order $= \frac{1}{2}(8 - 2) = 3$.

Thus, nitrogen molecule contains a triple bond.

It is evident that in the formation of N_2 molecule, only one ABMO is involved, the remaining four being all BMOs. Hence, the nitrogen molecule is highly stable. This is confirmed by its high bond dissociation energy, *viz.*, 945·6 kJ mol^{-1} and small bond length equal to 1·10 Å. Also since there are no unpaired electrons in any orbital, N_2 molecule is diamagnetic.

9. O_2. The electronic configuration of O_2 molecule is

$$O_2 : KK\, \sigma(2s)^2\, \sigma^*(2s)^2\, \sigma(2p_z)^2\, \pi(2p_x)^2\, \pi(2p_y)^2\, \pi^*(2p_x)^1\, \pi^*(2p_y)^1$$

Since it contains two unpaired electrons, the oxygen molecule is paramagnetic.

Bond order $= \frac{1}{2}(8 - 4) = 2$. O_2 moelcule, thus, contains a double bond.

Because of the presence of 4 electrons in ABMOs, O_2 molecule is less stable than N_2 molecule. Its bond dissociation energy is much less, being 494·6 kJ mol^{-1} and bond length is larger, being 1·21 Å.

10. F_2. The electronic configuration of fluorine molecule is

$$F_2 : KK\, \sigma(2s)^2\, \sigma^*(2s)^2\, \sigma(2p_z)^2\, \pi(2p_x)^2\, \pi(2p_y)^2\, \pi^*(2p_x)^2\, \pi^*(2p_y)^2$$

Bond order is $\frac{1}{2}(8 - 6) = 1$. The F_2 molecule, thus, contains a single bond. Because of the presence of as many as 6 electrons in the ABMOs, the bonding in F_2 is weaker than that in O_2. Therefore, bond dissociation energy of F_2 is very low, being 155 kJ mol^{-1} and bond length is 1·42 Å.

Since there are no unpaired electrons, the molecule is diamagnetic.

11. Ne_2. The electronic configuration of the hypothetical neon molecule is

$$Ne_2 : KK\ \sigma(2s)^2\ \sigma^*(2s)^2\ \sigma(2p_z)^2\ \pi(2p_x)^2\ \pi(2p_y)^2\ \pi^*(2p_x)^2\ \pi^*(2p_y)^2\sigma^*(2p_z)^2$$

Bond order is equal to $\frac{1}{2}(8 - 8) = 0$. Since ABMOs slightly dominate over BMOs, Ne_2 molecule would be incapable of existence.

Molecular Orbital Energy Level Diagrams of Heteronuclear Diatomic Molecules

The cases of heteronuclear diatomic molecules, in which the two atoms constituting a molecule are different, may now be considered. The principles involved in the distribution of electrons are the same as discussed before. However, the molecular orbital diagrams will not be symmetrical.

Let us discuss the electronic configurations and molecular orbital diagrams for some common heteronuclear diatomic molecules.

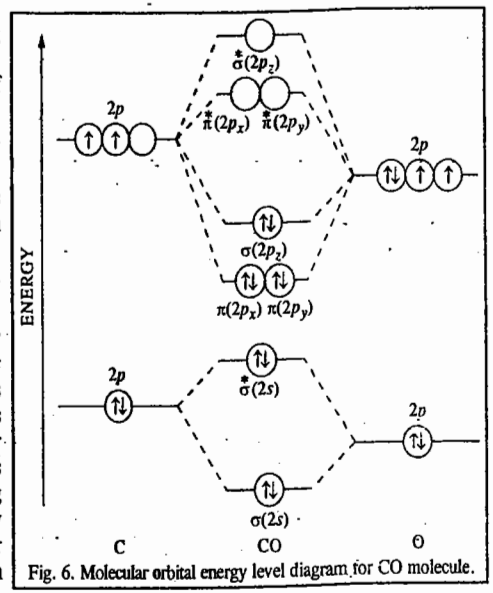

Fig. 6. Molecular orbital energy level diagram for CO molecule.

1. CO. The electronic configurations of C and O atoms are $1s^2 2s^2 p^2$ and $1s^2 2s^2 p^4$, respectively. There are 4 electrons in the outer shell of carbon and 6 electrons in the outer shell of oxygen. Thus, a total of 10 outer electrons are to be accommodated in the molecular orbitals of CO molecule. Because of higher electronegativity of oxygen, its atomic orbitals would be of lower energy than the corresponding atomic orbitals of carbon. Due to this energy difference, the bonding and antibonding molecular orbitals will receive different contributions from atomic orbitals of carbon and oxygen. The bonding molecular orbitals will receive more contribution from atomic orbitals of lower energy, *i.e.*, the atomic orbitals of oxygen and would be closer to it in energy than the antibonding molecular orbitals which would be closer to carbon in energy, as shown in Fig. 6. The bonding molecular orbitals would have more characteristics of atomic orbitals of oxygen and antibonding molecular orbitals would have more characteristics of carbon.

The electronic configuration of CO molecule is

$$CO : KK\ \sigma(2s)^2\ \sigma^*(2s)^2\ \pi(2p_x)^2\ \pi(2p_y)^2\ \sigma(2p_z)^2$$

Bond order is $\frac{1}{2}(8 - 2) = 3$. Thus, CO contains a triple bond. Its bond dissociation energy is 1067 kJ mol^{-1} and bond length is equal to 1·14 Å.

2. NO. The electronic configurations of N and O atoms are $1s^2 2s^2 p^3$ and $1s^2 2s^2 p^4$, respectively. There are 5 electrons in the outer shell of nitrogen and 6 electrons in the outer shell of oxygen. Thus, a total of 11 outer electrons are to be accommodated in the molecular orbitals of NO molecule.

The electronic configuration of NO molecule is, thus,

$$NO : KK\ \sigma(2s)^2\ \sigma^*(2s)^2\ \sigma(2p_z)^2\ \pi(2p_x)^2\ \pi(2p_y)^2\ \pi^*(2p_x)^1$$

The bond order is $\frac{1}{2}(8 - 3) = 2\frac{1}{2}$. This represents one σ bond and two π bonds less the anti-bonding

effect of one unpaired electron in the $\pi^*(2p_x)$ molecular orbital. The presence of this anti-bonding electron makes the NO molecule less stable than the N_2 molecule. This is confirmed by the fact that the bond dissociation energy of nitric oxide, *viz.*, 667·8 kJ mol^{-1}, is less than that of nitrogen which is 945·6 kJ mol^{-1}. Since NO contains an unpaired electron, it is paramagnetic.

As in the case of CO molecule, the bonding molecular orbitals would have greater characteristics of atomic orbitals of oxygen and the antibonding molecular orbitals would have greater characteristics of atomic orbitals of nitrogen.

3. HF. The electronic configurations of hydrogen and fluorine are $1s^1$ and $1s^2 2s^2 p^5$, respectively. In the formation of HF molecule, only the 2*p* electrons of fluorine atom would combine effectively with the solitary electron of hydrogen atom. As has been already explained, only a p_z orbital is able to combine with an *s* orbital. The combination of a p_x or p_y orbital with an *s* orbital is ruled out on symmetry considerations. The $2p_z$ orbital of fluorine gives a highly effective overlap with the *s* orbital of hydrogen to form $\sigma(sp)$ BMO and $\sigma^*(sp)$ ABMO.

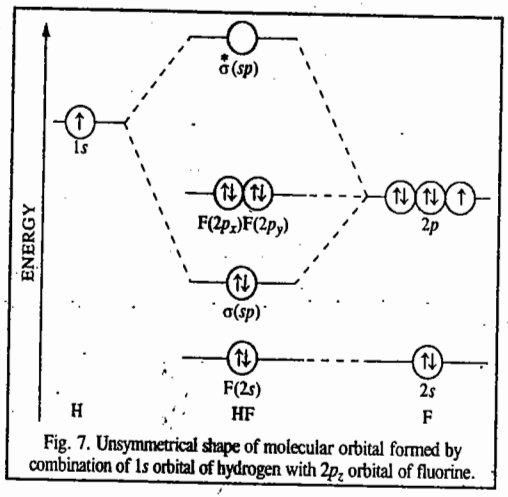

Fig. 7. Unsymmetrical shape of molecular orbital formed by combination of 1*s* orbital of hydrogen with $2p_z$ orbital of fluorine.

The bonding molecular orbital is fully filled with 2 electrons. The rest of the electrons remain in their atomic orbitals. The MO formed in the case of HF molecule will not be symmetrical. The asymmetry occurs because the energies of H(1*s*) and F($2p_z$) atomic orbitals are not the same. The MO diagram for HF molecule is shown in Fig. 7.

As can be seen, the bonding MO has an energy which lies closer to that of $2p_z$ orbital of fluorine than to that of higher energy 1*s* orbital of hydrogen.

4. HCl. The electronic configurations of H and Cl atoms are $1s^1$ and $1s^2 2s^2 p^6 3s^2 p^5$, respectively. In this case also, there is only one bonding MO and one anti-bonding MO formed by the combination of 1*s* orbital of hydrogen with $3p_z$ orbital of chlorine. The rest of the electrons of the chlorine atom remain in their respective AOs.

The electronic configuration of HCl may thus be represented as

$$HCl : KL\ (3s)^2\ \sigma(sp)^2\ (3p_x)^2\ (3p_y)^2$$

Here, too, the MO formed will not be symmetrical. The MO energy level diagram of HCl molecule will be exactly similar to the one shown in Fig. 7 for HF molecule.

Example 19. Write the electronic configurations of H_2, H_2^+ and the hypothetical species H_2^- in terms of molecular orbital theory.

Solution : H_2, H_2^- and H_2^+ have 2, 1 and 3 electrons, respectively. Hence, their electronic configurations are :

$$H_2 : \sigma(1s)^2$$

$$H_2^+ : \sigma(1s)^1$$

$$H_2^- : \sigma(1s)^2\ \sigma^*(1s)^1$$

Example 20. Why does He_2^+ exist whereas He_2 does not ?

Solution : Electronic configuration of He_2 is : $\sigma(1s)^2\sigma^*(1s)^2$

$$\therefore \quad \text{Bond order} = \frac{1}{2}(2 - 2) = 0$$

Electronic configuration of He_2^+ is = $\sigma(1s)^2\sigma^*(1s)^1$

$$\therefore \quad \text{Bond order} = \tfrac{1}{2}(2-1) = \tfrac{1}{2}$$

Thus, while the bond order of He_2 is zero, that of He_2^+ is 1/2. Hence, He_2^+ exists while He_2 does not.

Example 21. Of the species O_2, O_2^+, O_2^- and O_2^{2-}, which would have the maximum bond strength ?

Solution : Higher bond orders are associated with shorter bond lengths and higher bond strengths. We will first calculate the bond orders for the various species from their electronic configurations :

O_2 : $KK\ \sigma(2s)^2\ \sigma^*(2s^2)\ \sigma(2p_z)^2\ \pi(2p_x)^2\pi(2p_y)^2\pi^*(2p_x)^1\pi^*(2p_y)^1$

$$\text{Bond order} = \tfrac{1}{2}(8-4) = 2$$

O_2^+ : One electron is removed from the antibondng $\pi^*(2p_y)$ MO.

$$\text{Bond order} = \tfrac{1}{2}(8-3) = 2\tfrac{1}{2}$$

O_2^- : One electron is added to the antibonding $\pi^*(2p_x)$ MO.

$$\text{Bond order} = \tfrac{1}{2}(8-5) = 1\tfrac{1}{2}$$

O_2^{2-} : Two electrons are added to the outermost antibonding MOs.

$$\text{Bond order} = \tfrac{1}{2}(8-6) = 1$$

Since O_2^+ has the highest bond order, it has the shortest bond length and hence the **maximum bond strength.**

Example 22. Of the following species, which has the shortest bond length : NO, NO^+, NO^{2+}, NO^- ?

Solution : We shall first calculate the bond orders for the given species from their electronic configurations.

NO : $KK\ \sigma(2s)^2\ \sigma^*(2s)^2\sigma(2p_z)^2\ \pi(2p_x)^2\pi(2p_y)^2\pi^*(2p_x)^1$

$$\text{Bond order} = \tfrac{1}{2}(8-3) = 2\tfrac{1}{2}$$

NO^+ : One electron is removed from the antibonding $\pi^*(2p_x)$ MO.

$$\text{Bond order} = \tfrac{1}{2}(8-2) = 3$$

NO^{2+} : One electron is removed from the antibonding $\pi^*(2p_x)$ MO and the other electron is removed from the bonding $\pi(2p_y)$ MO.

$$\text{Bond order} = \tfrac{1}{2}(7-2) = 2\tfrac{1}{2}$$

NO^- : One electron is added to the antibonding $\pi^*(2p_x)$ MO.

$$\text{Bond order} = \tfrac{1}{2}(8-4) = 2$$

Evidently, the species NO^+ has the highest bond order and thus has the **shortest bond length.**

Example 23. Compare the bond energy, bond length and magnetic character of CN and CN^- species with the help of molecular orbital theory.

Solution : We shall first calculate bond orders for these species from their electronic configurations.

CN has 13 electrons and its electronic configuration is

$$CN : KK\ \sigma(2s)^2\ \sigma^*(2s)^2\ \pi(2p_x)^2\ \pi(2p_y)^2\ \sigma(2p_z)^1$$

$$\text{Bond order} = \tfrac{1}{2}(7-2) = 2\tfrac{1}{2}$$

CN^- : In this case, one electron is added to $\sigma(2p_z)$ MO so that its electronic configuration is

$$CN^- : KK\ \sigma(2s)^2\ \sigma^*(2s)^2\ \pi(2p_x)^2\ \pi(2p_y)^2\ \sigma(2p_z)^2$$

$$\text{Bond order} = \tfrac{1}{2}(8-2) = 3$$

Since CN^- has a higher bond order, it has larger bond energy and smaller bond length than CN. Further, since there is one unpaired electron in $\sigma(2p_z)$ MO of CN, it is paramagnetic. CN^- is evidently diamagnetic.

Example 24. Construct a molecular orbital wave function for the bond between H and Cl in HCl assuming that the bond is formed from the 1s electron of H atom and a 3p electron of Cl atom.

Solution : Let H atom be designated by A and Cl atom by B. Let the 1s electron of H atom be labelled as electron 1 and 3p electron of Cl atom be labelled as electron 2.

For notational convenience, we shall use the symbol ψ for MO and the symbol ϕ for AO.

$$\psi_{MO} = \psi_1\psi_2 \cdot \text{ where}$$

$$\psi_1 = c_1\phi_A(1) + c_2\phi_B(1)$$

and $$\psi_2 = c_1\phi_A(2) + c_2\phi_B(2)$$

$$\therefore \quad \psi_{MO} = \psi_1\psi_2 = [c_1\phi_A(1) + c_2\phi_B(1)]\,[c_1\phi_A(2) + c_2\phi_B(2)]$$

$$= c_1^2[\phi_A(1)\phi_A(2)] + c_1c_2[\phi_A(1)\,\phi_B(2) + \phi_A(2)\phi_B(1)] + c_2^2[\phi_B(1)\phi_B(2)]$$

As can be seen, the first and the last terms are *ionic* whereas the middle terms are *covalent.* Also the covalent terms have *equal weight* but the ionic terms have *different weights* from the covalent terms and also from each other.

Example 25. Write down the molecular orbital wave function for H_2^- molecule anion.

Solution : H_2^- molecule anion contains three electrons which may be labelled as 1, 2 and 3. It contains two nuclei which may be designated as A and B.

$$\psi_{MO} = \psi_1\psi_2\psi_3$$

where

$$\psi_1 = c_1\phi_A(1) + c_2\phi_B(1)$$

$$\psi_2 = c_3\phi_A(2) + c_4\phi_B(2)$$

$$\psi_3 = c_5\phi_A(3) + c_6\phi_B(3)$$

Example 26. Using the LCAO for the wave function for H_2^+, obtain the normalised wave function for the BMO and the ABMO.

Solution : Using the LCAO-MO approximation, the wave function for H_2^+ is written as

$$\psi = N(c_1\phi_A + c_2\phi_B) \qquad \ldots(i)$$

where N is the normalisation constant.

According to the normalization condition, for real ψ (using Dirac's 'bra' and 'ket' notation),

$$\psi^2 d\tau \equiv <\psi|\psi> = 1 \qquad \ldots(ii)$$

Incorporating the value of ψ from Eq. *(i)* in Eq. *(ii)*, we have

$$N^2 <(c_1\phi_A + c_2\phi_B)\,|\,(c_1\phi_A + c_2\phi_B)> = 1$$

or $$c_1^2[<\phi_A|\phi_A>] + c_2^2.[<\phi_B|\phi_B>] + 2c_1c_2\,[<\phi_A|\phi_B>] = 1/N^2 \qquad \ldots(iii)$$

Assuming that ψ_A and ψ_B are normalised, *i.e.*,

$$<\phi_A|\psi_A> \equiv \int\phi_A^2 d\tau = 1 \text{ and } <\phi_B|\phi_B> \equiv \int\phi_B^2 d\tau = 1,$$

we have $c_1^2 + c_2^2 + 2c_1c_2S = 1/N^2$ where S is the overlap integral defined as $\qquad \ldots(iv)$

$$S = <\phi_A|\phi_B> \equiv \int\phi_A\phi_B d\tau \qquad \ldots(v)$$

so that $$N = (c_1^2 + c_2^2 + 2c_1c_2S)^{-1/2} \qquad \ldots(vi)$$

Hence, from Eq. *(i)*, $$\psi = (c_1^2 + c_2^2 + 2c_1c_2S)^{-1/2}(c_1\phi_A + c_2\phi_B) \qquad \ldots(vii)$$

We know that for BMO, $c_1 = c_2$ and for ABMO, $c_1 = -c_2$

Hence, from Eq. *(vii)*, $$\psi_{BMO} = \frac{1}{\sqrt{2(1+S)}}(\phi_A + \phi_B)$$

and $$\psi_{ABMO} = \frac{1}{\sqrt{2(1-S)}}(\phi_A - \phi_B)$$

Example 27. Write down the wavefunction for the BMO for a heteronuclear diatomic molecule AB assuming that the electron on an average spends 90% of its time on nucleus *A* and 10% of its time on nucleus B.

Solution : In the LCAO-MO scheme, $\psi_{MO} = c_A\phi_A + c_B\phi_B$

where the coefficients c_A and c_B are such that $[c_A]^2$ and $[c_B]^2$ determine the probability of finding the electron in the AOs ϕ_A and ϕ_B, respectively. Then, clearly,

$$[c_A]^2 = 90\% = 0{\cdot}9 \text{ and}$$

$$[c_B]^2 = 10\% = 0{\cdot}1$$

Hence, $c_A = \pm\sqrt{0.9} = \pm 0.95$ and

$c_B = \pm\sqrt{0.1} = \pm 0.32$

Thus, $\psi_{MO} = 0.95\phi_A + 0.32\phi_B$

Table 1 gives the ground state electronic configurations of homonuclear diatomics (along with other relevant data) in a slightly different notation.

TABLE 1

Ground State Electronic Configurations of Homonuclear Diatomics

VALENCE BOND THEORY (VBT)

This theory was the first quantum mechanical theory of the chemical bond proposed by Heitler and London in 1927 and subsequently developed by Slater and Pauling in the 1930s. It is collectively referred to as the Heitler–London–Slater–Pauling (HLSP) theory and was fully formulated by Pauling during 1940–1960.

VBT draws heavily on the Lewis concept of a covalent bond as a shared pair of electrons. The theory makes the **perfect pairing approximation** in which it is assumed that structures with electrons paired in all possible ways dominate the wave function of the molecule. The overall wave function is a superposition of all possible perfectly paired canonical structures, with those of the lowest energy making the main contribution.

Let us determine the normalized valence bond eigenfunction of H_2 molecule which has only one perfectly paired canonical structure, the one corresponding to the Lewis structure H—H. Let the two electrons of H_2 be designated 1 and 2 and the two nuclei a and b (Fig. 8). The valence bond wave function can be written as

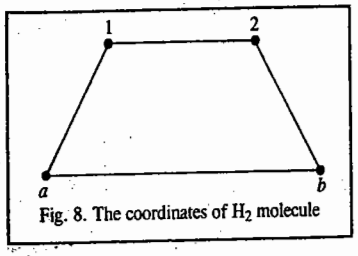

Fig. 8. The coordinates of H_2 molecule

$$\psi_{AB} = c_1\psi_1 + c_2\psi_2 \qquad ...(23)$$

where c_1 and c_2 are the coefficients and ψ_1 and ψ_2 can be written as

$$\psi_1 = \phi_a(1)\,\phi_b(2) \qquad ...(24a)$$

$$\psi_2 = \phi_b(1)\,\phi_a(2) \qquad ...(24b)$$

where the ϕs are the 1s atomic orbitals (AOs) of the two hydrogen atoms. (Here we have neglected the spins of the two electrons for the sake of simplicity). ψ_1 is the wave function corresponding to the situation where electron 1 is on the AO ϕ_a, centred on the nucleus a and electron 2 is on the AO ϕ_b, centred on the nucleus b. Since H_2 is a homonuclear diatomic molecule, it is evident that $c_1 = \pm c_2$. Substituting Eqs. 24 a and b in Eq. 23 we obtain the following Heitler–London wave functions for H_2 :

$$\psi_+ = N_+[\phi_a(1)\,\phi_b(2) + \phi_b(1)\,\phi_a(2)] \qquad ...(25a)$$

$$\psi_- = N_-[\phi_a(1)\,\phi_b(2) - \phi_b(1)\,\phi_a(2)] \qquad ...(25b)$$

where N_+ and N_- are the corresponding normalization constants. According to the normalization condition (embodied in the Born interpretation of the wave function)

$$\int_{-\infty}^{\infty} \psi_\pm^* \psi_\pm \, d\tau \equiv \langle \psi_\pm | \psi_\pm \rangle = 1$$

Let us normalize ψ_+. Assuming that the wave functions are real,

$$\int \psi_+^2 \, d\tau \equiv \langle \psi_+ \mid \psi_+ \rangle = N_+^2\left[\int \phi_a^2(1)\phi_b^2(2)\,d\tau + 2\int \phi_a(1)\phi_b(1)\phi_a(2)\phi_b(2)\,d\tau + \int \phi_b^2(1)\phi_a^2(2)\,d\tau\right] = 1$$

or $N_+^2\left[\int \phi_a^2(1)\,d\tau_1 \int \phi_b^2(2)\,d\tau_2 + 2\int \phi_a(1)\phi_b(1)\,d\tau_1 \times \int \phi_a(2)\phi_b(2)\,d\tau_2 + \int \phi_b^2(1)\,d\tau_1 \times \int \phi_a^2(2)\,d\tau_2\right] = 1$ ($\because d\tau = d\tau_1\, d\tau_2$)

Since the ϕs are normalized,

$$\int \phi_a^2(1)\,d\tau_1 = \int \phi_b^2(2)\,d\tau_2 = \int \phi_b^2(1)\,d\tau_1 = \int \phi_a^2(2)\,d\tau_2 = 1$$

and $$= \int \phi_a(1)\phi_b(1)\,d\tau_1 = \int \phi_a(2)\phi_b(2)\,d\tau_2 = S$$

where S is the overlap integral. Hence,

$$N_+^2[(1)(1) + 2(S)(S) + (1)(1)] = 1$$

or $$N_+^2[2(1 + S^2)] = 1 \text{ whence } N_+ = 2/(1 + S^2)^{\frac{1}{2}}$$

Substituting in Eq. 25a, the normalized VB wave function is

$$\psi_+ = \frac{1}{\sqrt{2(1 + S^2)}}\,[\phi_a(1)\,\phi_b(2) + \phi_b(1)\,\phi_a(2)] \qquad ...(26a)$$

Similarly, we can show that

$$\psi_- = \frac{1}{\sqrt{2(1 - S^2)}}\,[\phi_a(1)\,\phi_b(2) - \phi_b(1)\,\phi_a(2)] \qquad ...(26b)$$

Since $0 < S < 1$ and, in general, $S << 1$. We can write

$$\psi_+ = \frac{1}{\sqrt{2}}[\phi_a(1)\phi_b(2) + \phi_b(1)\phi_a(2)] \qquad ...(27a)$$

$$\psi_- = \frac{1}{\sqrt{2}}[\phi_a(1)\phi_b(2) - \phi_b(1)\phi_a(2)] \qquad ...(27b)$$

Let us now consider the role of the ionic structures in VBT. For H_2 molecule the ionic structures are those in which the electrons 1 and 2 are located on nucleus a or on b giving rise to structures $H_a^+H_b^-$ and $H_a^-H_b^+$. A little reflection shows that these structures are unlikely since there is no electronegativity

difference between the two hydrogen atoms. However, such structures become important in heteronuclear diatomics. Thus, the valence bond wave function can be written as composed of a covalent part and an ionic part.

$$\psi_{VB} = \psi_{covalent} + \lambda\psi_{ionic} \quad ...(28)$$

or, equivalently, as $$\psi_{VB} = (1 - \lambda)\,\psi_{covalent} + \lambda\psi_{ionic} \quad ...(29)$$

The second form is generally preferred. Here λ is a parameter whose value determines the polar character **(ionicity)** of the bond.

Example 28. Write down the valence bond wave function for the HF molecule (assuming that it is formed from 1*s* orbital of H and $2p_z$ orbital of F) in the following three cases : *(a)* HF is purely covalent *(b)* HF is purely ionic and *(c)* HF is 80% covalent and 20% ionic.

Solution : Let the H atom be represented by A and F atom by B. Let the electron numbered 1 be the 1*s* electron of H atom and the electron numbered 2 be the p_z electron of F atom.

(a) For purely covalent structure of HF, the wave function is written as

$$\psi_{covalent} = \phi_A(1)\phi_B(2) + \phi_A(2)\phi_B(1)$$

(b) For purely ionic structure H^+F^-, both the electrons are on the F atom so that

$$\psi_{ionic} = \phi_B(1)\phi_B(2)$$

(c) HF is a resonance hybrid shown as

$$H{-}F \longleftrightarrow H^+F^-$$

$$\therefore \quad \psi = c_1\psi_{covalent} + c_2\psi_{ionic} \quad \text{with} \quad c_1^2 + c_2^2 = 1$$

Since $c_1^2 = 0{\cdot}80$ and $c_2^2 = 0{\cdot}20$ (given), hence,

$$c_1 = \sqrt{0{\cdot}80} = 0{\cdot}89$$

and $$c_2 = \sqrt{0{\cdot}20} = 0{\cdot}45$$

$$\therefore \quad \psi = 0{\cdot}89\,[\phi_A(1)\phi_B(2) + \phi_A(2)\phi_B(1)] + 0{\cdot}45\,[\phi_B(1)\,\phi_B(2)].$$

Example 29. Assuming that the ionic character in H—Br bond is 11%, calculate the fraction of the contribution of ionic character to the valence bond wave function.

Solution : According to Eq. 28, $\psi_{AB} = \psi_{covalent} + \lambda\psi_{ionic}$

The % ionic character is given by $\dfrac{\lambda^2}{1+\lambda^2} \times 100$

$$\therefore \quad 11 = 100\lambda^2/(1 + \lambda^2)$$

or $$\lambda^2 = 11/89$$

Hence, $$\lambda = \sqrt{11/89} = 0 \cdot 35$$

Thus, the fraction of contribution of ionic character to ψ_{AB} is **0·35.**

Example 30. Write down the normalised VB wave function and MO wave function for H_2 molecule and comment on the expressions obtained.

Solution : H_2 molecule contains two electrons labelled 1 and 2 and two hydrogen nuclei labelled A and B. The pairing of electrons leads to the formation of a covalent bond. In the VB approach, if electron 1 is on nucleus A, then electron 2 would be on nucleus B and vice-versa. Since, however, the two electrons are indistinguishable, therefore, the VB wave function for H_2 molecule can be written as

$$\psi_{AB} = (1/\sqrt{2})\,[\phi_A(1)\,\phi_B(2) + \phi_A(2)\,\phi_B(1)] \quad ...(i)$$

where $1/\sqrt{2}$ is the normalization constant obtained by normalizing ψ_{VB}.

In the MO theory, the MO wave function for H_2 molecule is given by

$$\psi_{MO} = \psi_1\psi_2 \quad ...(ii)$$

where ψ_1 and ψ_2 are the normalised wave functions for MOs of H_2 given by

$$\psi_1 = (1/\sqrt{2})[\phi_A(1) + \phi_B(1)] \quad ...(iii)$$

$$\psi_2 = (1/\sqrt{2})[\phi_A(2) + \phi_B(2)] \quad ...(iv)$$

Multiplying ψ_1 and ψ_2, we get the ψ_{MO} as

$$\psi_{MO} = \phi_1\phi_2\,[\phi_A\,(1) + \phi_B\,(1)]\,[\phi_A\,(2) + \phi_B\,(2)] \quad ...(v)$$

$$= \tfrac{1}{2}\,[\phi_A(1)\,\phi_A(2) + \phi_B(1)\,\phi_B(2)] + 1/2\,[\phi_A(1)\,\phi_B(2) + \phi_B(1)\,\phi_A(2)] \quad ...(vi)$$

In Eq. *(vi)*, the first two terms represent the probability of finding both the electrons on the same atom at the same time. In other words, these terms represent the ionic structures of H_2 molecule which may be written as

$$\overset{+}{H}_A\overset{-}{H}_B \quad \text{and} \quad \overset{-}{H}_A\overset{+}{H}_B.$$

The last two terms in Eq. *(vi)* represent the covalent structure of the H_2 molecule.

Comparing ψ_{VB} and ψ_{MO}, we observe that while the wave function in VBT does not give any weightage to ionic structures, the MOT gives equal weightage to covalent and ionic structures.

Example 31. Determine the energy of H_2 molecule at infinite internuclear separation using the Heitler-London (valence bond) normalized wave functions

$$\phi = \frac{1}{2^{1/2}}\,[\psi_a(1)\,\psi_b(2) \pm \psi_a(2)\,\psi_b(1)] \quad ...(i)$$

where ψ_α is the hydrogenic 1s wavefunction.

Solution : The Hamiltonian operator for this system is given by

$$\hat{H} = \frac{-\hbar^2}{2m_e}(\nabla_1^2 + \nabla_2^2) + \frac{e^2}{4\pi\varepsilon_0}\left(\frac{1}{r_{ab}} - \frac{1}{r_{1a}} - \frac{1}{r_{2a}} - \frac{1}{r_{1b}} - \frac{1}{r_{2b}} + \frac{1}{r_{12}}\right)$$

At infinite separation of the nuclei, the Hamiltonian reduces to

$$\hat{H} = \frac{-\hbar^2}{2m_e}(\nabla_1^2 + \nabla_2^2) + \frac{e^2}{4\pi\varepsilon_0}\left(-\frac{1}{r_{1a}} - \frac{1}{r_{2b}}\right) \quad ...(ii)$$

Hence, the expectation value of energy is

$$< E > = \int \phi^* \left[\frac{-\hbar^2}{2m_e}\left(\nabla_1^2 + \nabla_2^2\right) - \frac{e^2}{4\pi\varepsilon_0}\left(\frac{1}{r_{1a}} + \frac{1}{r_{2b}}\right)\right]\phi\, d\tau$$

$$= \int \phi^* \left[\frac{-\hbar^2}{2m_e}\nabla_1^2 - \frac{e^2}{4\pi\varepsilon_0}\left(\frac{1}{r_{1a}}\right)\right]\phi\, d\tau$$

$$+ \int \phi^* \left[\frac{-\hbar^2}{2m_e}\nabla_2^2 - \frac{e^2}{4\pi\varepsilon_0}\left(\frac{1}{r_{2b}}\right)\right]\phi\, d\tau = 2\int \phi^* \hat{H}(\mathrm{H})\,\phi\, d\tau$$

where $\hat{H}$ (H) is the Hamiltonian operator for a hydrogen atom. Substituting Eq. *(i)* gives

$$< E > = 2\int \frac{1}{2^{1/2}}\,\psi_a(1)\,\psi_b(2) \pm \psi_a(2)\,\psi_b(1)]^*\,\hat{H}(\mathrm{H})\,\frac{1}{2^{1/2}}[\psi_a(1)\,\psi_b(2) \pm \psi_a\,(2)\,\psi_b(1)]\,d\tau$$

$$= \int \psi_a^*(1)\, \psi_b^*(2)\, \hat{H}(H)\, \psi_b(2)\, d\tau \pm \int \psi_a^*(2)\, \psi_b^*(1)\, \hat{H}(H)\, \psi_a(1)\, \psi_b(2)\, d\tau$$

$$\pm \int \psi_a^*(1)\, \psi_b^*(2)\, \hat{H}(H)\, \psi_a(2)\, \psi_b(1)\, d\tau + \int \psi_a^*(2)\, \psi_b^*(1)\, \hat{H}(H)\, \psi_a(2)\, \psi_b(1)\, d\tau$$

At infinite separation of the nuclei, the second and third integrals are equal to zero, giving

$$< E > = \int \psi_a^*(1)\, \hat{H}(H) \psi_a(1)\, d\tau \int \psi_b^*(2)\, \psi_b(2)\, d\tau$$

$$\pm 0 \pm 0 + \int \psi_b^*(1)\, \hat{H}(H)\, \psi_b(1)\, d\tau \int \psi_a^*(2)\, \psi_a(2)\, d\tau$$

$$= E(H)\, S_{bb} + E(H)\, S_{aa} = 2E(H)$$

where $S_{aa} = S_{bb} = 1$ and $E(H)$ is the energy of the hydrogen atom.

Example 32. Write the complete normalized wave functions in VBT for H_2 molecule, including the spin wave functions.

Solution : The wave function with the positive sign is symmetric with respect to the exchange of electrons :

$$\hat{P}(1, 2)\, \phi_+ = \hat{P}(1, 2) \frac{1}{2^{1/2}} [\psi_a(1)\, \psi_b(2) + \psi_a(2)\, \psi_b(1)]$$

$$= \frac{1}{2^{1/2}} [\psi_a(2)\, \psi_b(1) + \psi_a(1)\, \psi_b(2)] = \phi_+$$

According to the Pauli exclusion principle, an antisymmetric spin wave function must be used. Thus, using antisymmetric spin wave function, we obtain

$$\phi_1 = \frac{1}{2^{1/2}} [\psi_a(1)\, \psi_b(2) + \psi_a(2)\, \psi_b(1)] \frac{2^{1/2}}{2} [\alpha(1)\, \beta(2) - \beta(1)\, \alpha(2)]$$

$$= \frac{1}{2} [\psi_a(1)\, \psi_b(2) + \psi_a(2)\, \psi_b(1)][\alpha(1)\, \beta(2) - \beta(1)\, \alpha(2)]$$

Likewise, the wave function with the negative sign can be shown to be antisymmetric, and the symmetric spin wave functions are used, giving

$$\phi_2 = \frac{1}{2^{1/2}} [\psi_a(1)\, \psi_b(2) - \psi_a(2)\, \psi_b(1)]\alpha(1)\, \beta(2)]$$

$$\phi_3 = \frac{1}{2^{1/2}} [\psi_a(1)\, \psi_b(2) - \psi_a(2)\, \psi_b(1)]\beta(1)\, \beta(2)$$

$$\phi_4 = \frac{1}{2} [\psi_a(1)\, \psi_b(2) - \psi_a(2)\, \psi_b(1)][\alpha(1)\, \beta(2) + \beta(1)\, \alpha(2)]$$

When VBT is applied to polyatomics, each canonical structure is formed by pairing all the available electrons. Thus, each canonical structure corresponds to a possible Lewis structure of the molecule, and each has its characteristic energy. Consider, for instance, CO_2 molecule which is a resonance hybrid of three canonical structures :

$$\underset{\text{I}}{O{=}C{=}O} \quad \longleftrightarrow \quad \underset{\text{II}}{\overset{+}{O} \equiv C - \overset{-}{O}} \quad \longleftrightarrow \quad \underset{\text{III}}{\overset{-}{O} - C \equiv \overset{+}{O}}$$

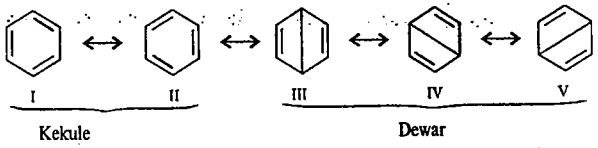
The wave function of CO_2 can be written as a linear combination of the wave functions corresponding to the three structures :

$$\psi = c_I \psi_I + c_{II} \psi_{II} + c_{III} \psi_{III} \qquad ...(30)$$

Since ionic structures II and III are equivalent, $c_{II} = c_{III}$, so that

$$\psi = c_I \psi_I + c_{II}(\psi_{II} + \psi_{III}) \qquad ...(31)$$

Again, consider C_6H_6 which is a resonance hybrid of two Kekule structures (I and II) and three 'long bond' structures, the so-called Dewar structures (III, IV and V) :



The corresponding valence bond wave function is

$$\psi = c_I \psi_I + c_{II} \psi_{II} + c_{III} \psi_{III} + c_{IV} \psi_{IV} + c_V \psi_V \qquad ...(32)$$

Since the two Kekule structures and the three Dewar structures are equivalent, their coefficients must be the same, *i.e.*,

$$c_I = c_{II} = c_1 \text{ (say)}$$

$$c_{III} = c_{IV} = c_V = c_2 \text{ (say)}$$

Hence, $$\psi = c(\psi_I + \psi_{II}) + c_2(\psi_{III} + \psi_{IV} + \psi_V) \qquad ...(33)$$

The number of canonical structures to be included in the wave function increases dramatically with increase in the number of atoms in the molecule. Thus, for naphthalene and anthracene the number of canonical structures are 42 and 429, respectively and for coronene the number is more than 10^5. Naturally the theorist feels rather uneasy with VBT for the solution of the Schrödinger wave equation for even a moderately large molecule.

American chemical physicists Linus Pauling (1901–1994) and Robert S.Mulliken (1896–1986) are the pioneers of VBT and MOT, respectively. Pauling's work cuts across the frontiers of chemistry, physics and molecular biology. He is the only scientist who has won two Nobel prizes : for chemistry (1954) and for peace (1963); both prizes were *unshared.* He is generally considered to be the greatest 20th century chemist. However, Mulliken's MOT is, as said above, conceptually simpler than Pauling's VBT; but *we need both the theories.* In the words of the eminent inorganic chemist J.E. Huheey, "the chemist who does not become thoroughly familiar with both the theories is like the carpenter who refuses to carry a saw because he already has a hammer ! Both are severely limiting their skills by limiting their tools."

HYBRIDIZATION

Beryllium, boron and carbon (Atomic Nos. 4, 5 and 6) furnish interesting cases of compound formation. According to the ground state electronic configurations of the atoms of these elements, Be ($1s^2 2s^2$), with *no* half-filled orbital, should be *zero-valent* ; B($1s^2 2s^2 2p_z^1$), with *one* half-filled orbital, should be *monovalent* and C ($1s^2 2s^2 p_z^1 p_x^1$), with *two* half-filled orbitals should be *bivalent*. But actually, Be is bivalent, B is trivalent and C is tetravalent. In order to explain these anomalies, Pauling introduced the concept called **hybridization.** This concept is extremely helpful. We shall elucidate this concept by referring to the formation of beryllium fluoride.

For Be atom the promotion of a $2s$ electron to a $2p$ orbital results in an excited state configuration of Be, *viz.*, $1s^2 2s^1 p^1$ which has two half-filled orbitals. Thus, Be atom in its excited state is capable of showing a covalency of 2. The energy required for the promotion of $2s$ electrons is the energy that is released when Be atom and, say, F atoms combine to form BeF_2 molecule. If the energy supplied to Be atom for the promotion of the electron from $2s$ to $2p$ orbital is less than the energy released due to the formation of the two covalent bonds in BeF_2, the formation of BeF_2 would be energetically feasible.

This offers a plausible explanation for the existence of stable compounds of beryllium such as BeF_2, BeH_2, etc.

Since 2*s* and 2*p* orbitals have different energies, hence the two bonds in BeF_2 should have different strengths. This is because one Be—F bond will be formed by the overlapping of 2*s* orbital of beryllium and 2*p* orbital of fluorine while the second Be—F bond will be formed by the overlapping of 2*p* orbital of beryllium and 2*p* orbital of fluorine. But, actually both the bonds are of equal strength. This is explained by postulating that the *s* and *p* orbitals of beryllium mix, *i.e.*, hybridise to give two identical orbitals, *i.e.*, orbitals of equivalent energy. The redistribution of energy by mixing different orbitals of an atom to give new orbitals of equivalent energy is called hybridization. The new orbitals thus formed are called hybrid orbitals. The bonds formed by such orbitals are called hybrid bonds. Since in the formation of bivalent compounds of beryllium, one *s* and one *p* orbital is involved in hybridisation, it is called *sp hybridization* and the two identical orbitals which result from this process are known as *sp* hybrid orbitals.

The amount of energy released $(B.E.)_1$ due to the formation of sigma bonds between Be and X atoms involving hybrid orbitals is greater than the energy released $(B.E.)_2$ in case the sigma bonds had involved the pure *s* and *p* orbitals. This is illustrated in Fig. 9. It is evident from Fig. 9 that some additional energy is released due to the involvement of the *sp* hybrid orbitals in bond formation. Because of this additional decrease of energy, the sigma bonds formed by hybrid orbitals of Be are stronger than the bonds formed by pure *s* and *p* orbitals.

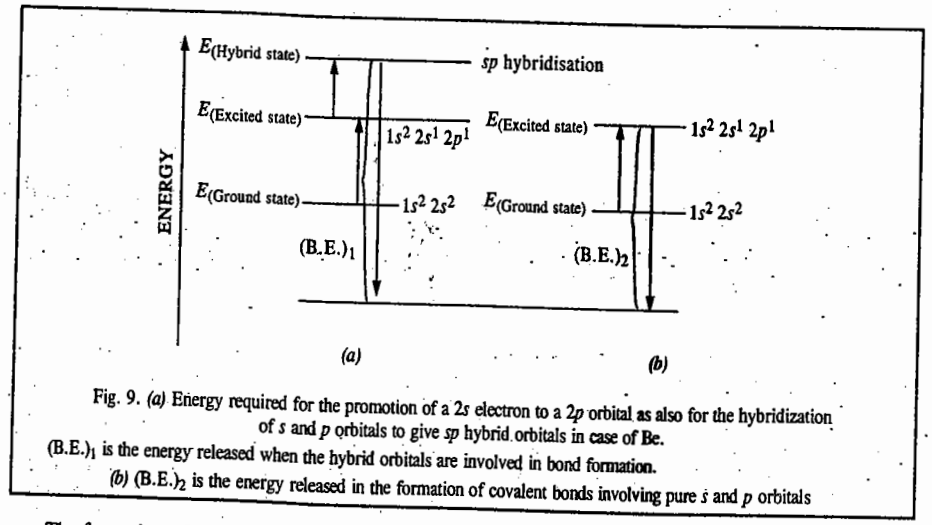


Fig. 9. *(a)* Energy required for the promotion of a 2*s* electron to a 2*p* orbital as also for the hybridization of *s* and *p* orbitals to give *sp* hybrid orbitals in case of Be.
$(B.E.)_1$ is the energy released when the hybrid orbitals are involved in bond formation.
(b) $(B.E.)_2$ is the energy released in the formation of covalent bonds involving pure *s* and *p* orbitals

The formation of *sp* hybrid orbitals is shown pictorially in Fig. 10.

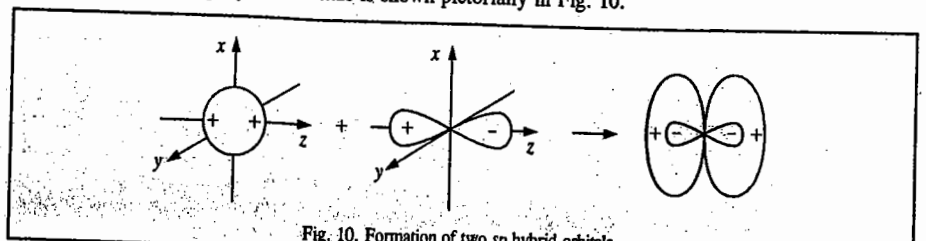

Fig. 10. Formation of two *sp* hybrid orbitals.

In the formation of BeF_2, the half-filled *p* orbital of each fluorine atom overlaps with each of the two half-filled *sp* hybrid orbitals of Be atom. We next consider the sp^2 hybridization.

In the case of boron (ground state configuration $1s^2 2s^2 p^1$), for instance, the promotion of one of the 2*s* electrons into one of the vacant 2*p* orbitals gives rise to an excited state configuration, *viz.*, $1s^2 2s^1 p_z^1 p_x^1$. There are, thus, three half-filled orbitals which account for tri-covalency of boron. The three orbitals, *viz.*, one 2*s* and two 2*p*, hybridise to give three sp^2 hybrid orbitals of equivalent energy. The formation of three sp^2 hybrid orbitals is shown in Fig. 11.

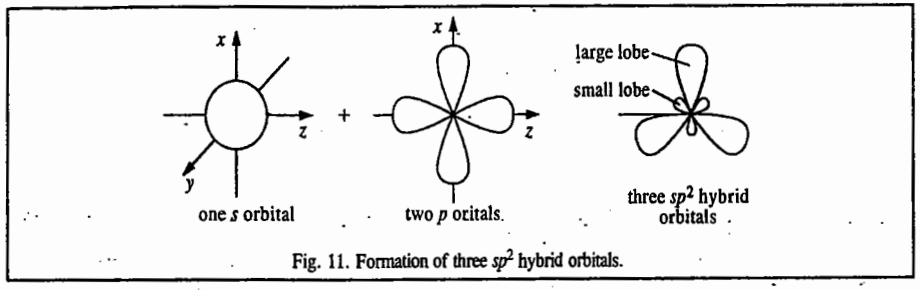

Fig. 11. Formation of three sp^2 hybrid orbitals.

In the formation of boron trifluoride, BF_3, molecule, the half-filled *p* orbital of each fluorine atom overlaps with each of the three half-filled sp^2 hybrid orbitals of the boron atom.

In the case of carbon (ground state configuration $1s^2 2s^2 p_z^1 p_x^1$), the promotion of one of the 2*s* electrons into the vacant $2p_y$ orbital yields an excited state configuration, *viz.*, $1s^2\ 2s^1 p_z^1 p_x^1 p_y^1$. There are now four half-filled orbitals which account for the tetracovalency of carbon. These four orbitals, *i.e.*, one *s* and three *p* orbitals hybridise to give four sp^3 hybrid orbitals of equivalent energy. The formation of four sp^3 hybrid orbitals is shown in Fig. 12.

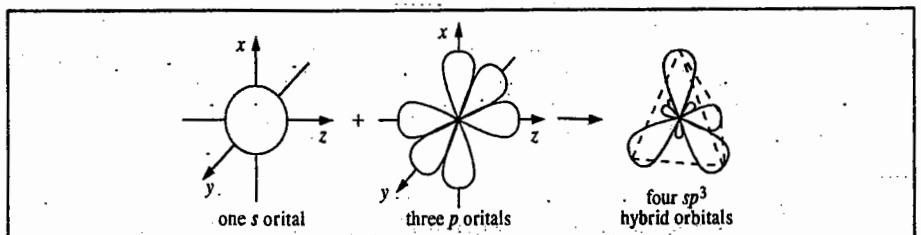

Fig. 12. Formation of four sp^3 hybrid orbitals by overlapping of one *s* and three *p* orbitals.

In the formation of methane, CH_4, molecule, the half-filled 1*s* orbital of each hydrogen atom overlaps with each of the four half-filled sp^3 hybrid orbitals of the carbon atom. Similarly, we can explain the sp^3d hybridisation in PCl_5 and sp^3d^2 hybridization in SF_6.

The salient features of hybridization may be summed up as follows :

1. One of the electrons from an orbital in the ground state configuration of the atom gets promoted to the next available orbital of higher energy (as, for example, from 2*s* to 2*p* orbital in case of second row elements and from n(*s*) to (n–1)*d* orbital in case of transition elements), resulting in an excited state configuration with appropriate number of half-filled orbitals. This process would require sufficient amount of energy. The orbitals in the excited state undergo hybridization giving hybrid orbitals of equivalent energy. The process of hybridization, *i.e.*, mixing of orbitals, requires some additional amount of energy. The entire input of energy is, however, more than recovered when the hybrid orbitals undergo covalent bond formation with other atoms accompanied by the release of energy.

2. The number of hybrid orbitals formed is equal to the number of pure atomic orbitals which undergo hybridisation.

3. The energy released during sigma bond formation involving hybrid orbitals is much more than the energy released if sigma bond formation involves pure atomic orbitals. Therefore, the sigma bonds formed with hybrid orbitals are more stable than those formed with pure orbitals.

4. Hybridization invariably involves atomic orbitals of the same atom.

5. Effective hybridization occurs only when the orbitals undergoing hybridisation are of similar energy.

6. The electronic charge in hybrid orbitals is concentrated more in one direction. This leads to a better overlap with orbitals of the other atoms.

7. Hybrid orbitals generally form either sigma bonds or contain lone pairs of electrons. They do not form pi bonds.

8. The hybrid orbitals are associated with higher energy than the parent pure orbitals. The stability of bonds formed by the hybrid orbitals is due to excessive overlapping of orbitals provided by them.

Calculation of the Coefficients of AOs used in Hybridization

The wavefunctions for the hybrid orbitals are obtained by taking linear combination of the angular wave functions of the appropriate AOs. Many organic molecules involve hybrid orbitals which are formed from the linear combination of s and p AOs. The wave function for the ith hybrid orbital formed from the s and p AOs is given by

$$\phi_i = a_i s + b_i p_x + c_i p_y + d_i p_z \qquad \ldots(34)$$

The coefficients a_i, b_i, c_i, d_i can be determined from the following rules :

1. Each wavefunction is normalized, *i.e.*,

$$a_i^2 + b_i^2 + c_i^2 + d_i^2 = 1 \qquad \ldots(35)$$

2. Each hybrid orbital in the set of hybrid orbitals must be orthogonal to the other hybrids, *i.e.*,

$$a_i a_j + b_i b_j + c_i c_j + d_i d_j = 0 \qquad \ldots(36)$$

3. The squares of the coefficients of any component atomic function summed over all the hybrids in which it participates must be equal to unity, *i.e.*,

$$\sum_i a_i^2 = 1 \qquad \ldots(37)$$

With the help of the above rules the following procedure is employed to generate the equivalent hybrid orbitals:

1. Choose a cartesian coordinate system and place one of the ith hybrid orbitals along one of the coordinate axes and as many of the other orbitals as possible in the plane containing this axis and other coordinate axes.

2. Since the s orbital has a spherical symmetry, each equivalent hybrid orbital of a set contains $1/n$ of the total of the unit s orbital distributed in n hybrid orbitals. Hence, the coefficient in each hybrid orbital is $1/\sqrt{n}$.

Example 33. Construct the wavefunctions for the sp hybrid orbitals.

Solution : We shall take the example of BeH_2. The two sp hybrid orbitals are :

$$\psi_{sp(1)} = a_1 2s + b_1 2p_x \qquad \ldots(i)$$

$$\psi_{sp(2)} = a_2 2s + b_2 2p_x \qquad \ldots(ii)$$

Since the s orbital is equally distributed between the two hybrid orbitals, hence,

$$a_1^2 = a_2^2 = 1/2$$

$$\therefore \quad a_1 = a_2 = 1/\sqrt{2}$$

Since $\psi_{sp(1)}$ is normalized, hence

$$\int \psi_{sp(1)}^2 d\tau = \int (a_1 2s + b_1 2p_x)^2 d\tau$$

$$= a_1^2 \int (2s)^2 d\tau + b_1^2 \int (2p_x)^2 d\tau + 2a_1 b_1 \int (2s)(2p_x) d\tau = 1$$

Since the AOs are individually normalized and orthogonal, hence

$$\int \psi_{sp(1)}^2 d\tau = a_1^2(1) + b_1^2(1) + 2a_1 b_1(0) = a_1^2 + b_1^2 = 1$$

Since $a_1 = 1/\sqrt{2}$, hence $b_1 = 1/\sqrt{2}$

Again, since $\psi_{sp(1)}$ and $\psi_{sp(2)}$ are orthogonal, we have

$$a_1 a_2 + b_1 b_2 = 0$$

Substituting for a_1, a_2 and b_1, we have

$(1/\sqrt{2})(1/\sqrt{2}) + (1/\sqrt{2}) b_2 = 0$, whence

$$b_2 = -1/\sqrt{2}$$

Hence, the two hybrid orbital wavefunctions are

$$\psi_{sp(1)} = 1/\sqrt{2}\,(2s + 2p_x) \qquad \ldots(iii)$$

$$\psi_{sp(2)} = 1/\sqrt{2}\,(2s - 2p_x) \qquad \ldots(iv)$$

Example 34. Construct the wavefunctions for the sp^2 hybrid orbitals.

Solution : We shall take the example of BH_3. The wavefunctions for the three sp^2 hybrid orbitals are :

$$\psi_{sp^2(1)} = a_1 2s + b_1 2p_x + c_1 2p_y \qquad \ldots(i)$$

$$\psi_{sp^2(2)} = a_2 2s + b_2 2p_x + c_2 2p_y \qquad \ldots(ii)$$

$$\psi_{sp^2(3)} = a_3 2s + b_3 2p_x + c_3 2p_y \qquad \ldots(iii)$$

Since the s orbital is equally distributed among the three hybrid orbitals, we have

$a_1^2 = a_2^2 = a_3^2 = 1$ so that

$$a_1 = a_2 = a_3 = 1/\sqrt{3}$$

Assume that $\psi_{sp^2(1)}$ points towards the x-axis. Hence, this hybrid orbital will have contribution from $2s$ and $2p_x$ orbitals only. The contribution of the $2p_y$ orbital will be zero so that $c_1 = 0$.

Since $\psi_{sp^2(1)}$ is normalized,

$$a_1^2 + b_1^2 + c_1^2 = 1 \quad \text{or} \quad a_1^2 + b_1^2 = 1$$

Since $a_1 = 1/\sqrt{3}$, hence $b_1 = \sqrt{(2/3)}$

Since $\psi_{sp^2(1)}$ and $\psi_{sp^2(2)}$ are orthogonal (as also are $\psi_{sp^2(1)}$ and $\psi_{sp^2(3)}$), hence

$$a_1 a_2 + b_1 b_2 = 0$$

$$a_1 a_3 + b_1 b_3 = 0$$

Hence

$$b_2 = -\frac{a_1 a_2}{b_1} = -\frac{\left(\frac{1}{\sqrt{3}} \cdot \frac{1}{\sqrt{3}}\right)}{\sqrt{\frac{2}{3}}} = -\frac{1}{\sqrt{6}}$$

$$b_3 = -\frac{a_1 a_3}{b_1} = -\frac{\left(\frac{1}{\sqrt{3}} \cdot \frac{1}{\sqrt{3}}\right)}{\sqrt{\frac{2}{3}}} = -\frac{1}{\sqrt{6}}$$

Again, since $\psi_{sp^2}(2)$ is normalized,

$$a_2^2 + b_2^2 + c_2^2 = 1$$

Hence, $$c_2^2 = 1 - (a_2^2 + b_2^2) = 1 - (1/3 + 1/6) = 1/2$$

Thus, $$c_2 = \pm 1/\sqrt{2}$$

Further, since $\psi_{sp^2(3)}$ is normalized,

$$a_3^2 + b_3^2 + c_3^2 = 1$$

Hence, $$c_3^2 = 1 - (a_3^2 + b_3^2) = 1 - (1/3 + 1/6) = 1/2$$

Thus, $$c_3 = \pm 1/\sqrt{2}$$

Let c_2 have a positive value ; then, the value for c_3 will have to be negative, so that $\psi_{sp^2(2)}$ and $\psi_{sp^2(3)}$ fulfil the requirement of orthogonality, *i.e.*, $a_2a_3 + b_2b_3 + c_2c_3 = 0$. Thus,

if $$c_2 = +1/\sqrt{2} \text{ and } c_3 = -1/\sqrt{2}$$

Hence, the three sp^2 hybrid orbital wavefunctions are :

$$\psi_{sp^2(1)} = \left(1/\sqrt{3}\right) 2s + \left(\sqrt{2/3}\right) 2p_x \quad \ldots(iv)$$

$$\psi_{sp^2(2)} = \left(1/\sqrt{3}\right) 2s - \left(1/\sqrt{6}\right) 2p_x + \left(1/\sqrt{2}\right) 2p_y \quad \ldots(v)$$

$$\psi_{sp^3(3)} = \left(1/\sqrt{3}\right) 2s - \left(1/\sqrt{6}\right) 2p_x - \left(1/\sqrt{2}\right) 2p_y \quad \ldots(vi)$$

Example 35. Construct the wavefunctions for the sp^3 hybrid orbitals.

Solution : We shall consider the case of the hybrid orbitals of CH_4. The wave functions for the four sp^3 hybrid orbitals are :

$$\psi_{sp^3(1)} = a_1 2s + b_1 2p_x + c_1 2p_y + d_1 2p_z \quad \ldots(i)$$

$$\psi_{sp^3(2)} = a_2 2s + b_2 2p_x + c_2 2p_y + d_2 2p_z \quad \ldots(ii)$$

$$\psi_{sp^3(3)} = a_3 2s + b_3 2p_x + c_3 2p_y + d_3 2p_z \quad \ldots(iii)$$

$$\psi_{sp^3(4)} = a_4 2s + b_4 2p_x + c_4 2p_y + d_4 2p_z \quad \ldots(iv)$$

Since the s orbital is equally distributed among the four hybrid orbitals, we have

$$a_1^2 = a_2^2 = a_3^2 = a_4^2 = 1/4$$

Hence, $$a_1 = a_2 = a_3 = a_4 = 1/\sqrt{4} = 1/2$$

Assuming that $\psi_{sp^3(1)}$ is developed along the x-axis, this hybrid will have contributions from $2s$ and $2p_x$ orbitals only so that the contributions of $2p_y$ and $2p_z$ orbitals will vanish, with the result that

$$c_1 = d_1 = 0$$

Since $\psi_{sp^3(1)}$ is normalized, hence,

$$a_1^2 + b_1^2 + c_1^2 + d_1^2 = 1$$

or $$a_1^2 + b_1^2 = 1 \qquad (\because c_1 = d_1 = 0)$$

Hence, $$b = \sqrt{1 - a_1^2} = \sqrt{1 - 1/4} = \sqrt{3}/2$$

The orthogonality conditions for $\psi_{sp^3(1)}$ and $\psi_{sp^3(2)}$, $\psi_{sp^3(1)}$ and $\psi_{sp^3(3)}$ and $\psi_{sp^3(1)}$ and $\psi_{sp^3(4)}$ are

$$a_1a_2 + b_1b_2 = 0$$

$$a_1a_3 + b_1b_3 = 0$$

$$a_1a_4 + b_1b_4 = 0$$

Hence, $$b_2 = b_3 = b_4 = -a_1a_2/b_1 = -a_1a_3/b_1 = -a_1a_4/b_1$$

$$= -\frac{(1/2)(1/2)}{\sqrt{3}/2} = -\frac{1}{2\sqrt{3}}$$

Assuming that $\psi_{sp^3(2)}$ lies in the xz-plane, the hybrid orbital will have contributions from $2s$, $2p_x$ and $2p_z$ orbitals and the contribution of $2p_y$ to $\psi_{sp^3(2)}$ will vanish, so that

$$c_2 = 0$$

The normalization condition for $\psi_{sp^3(2)}$ gives

$$a_2^2 + b_2^2 + c_2^2 + d_2^2 = 1$$

or, $$a_2^2 + b_2^2 + d_2^2 = 1 \quad (\because c_2 = 0)$$

Hence, $$d_2^2 = 1 - (a_2^2 + b_2^2) = 1 - (1/4 + 1/12) = 2/3$$

Thus, $$d_2 = \sqrt{2/3}$$

The requirement of orthogonality conditions for $\psi_{sp^3(2)}$ and $\psi_{sp^3(3)}$, and for $\psi_{sp^3(2)}$ and $\psi_{sp^3(4)}$ gives

$$a_2a_3 + b_2b_3 + d_2d_3 = 0$$

$$a_2a_4 + b_2b_4 + d_2d_4 = 0$$

Hence, $$d_3 = d_4 = -(a_2a_3 + b_2b_3)/d_2$$

or, $$-\frac{a_2a_4 + b_2b_4}{d_2} = -\frac{(1/4 + 1/12)}{\sqrt{2/3}} = -\frac{1}{\sqrt{6}}$$

The normalization requirement for $\psi_{sp^3(3)}$ gives

$$a_3^2 + b_3^2 + c_3^2 + d_3^2 = 1$$

$$c_3^2 = 1 - (a_3^2 + b_3^2 + d_3^2)$$

$$= 1 - \left(\frac{1}{4} + \frac{1}{12} + \frac{1}{6}\right) = \frac{1}{2}$$

$$\therefore \quad c_3 = 1/\sqrt{2}$$

Proceeding in this way, the normalization requirement for $\psi_{sp^3(4)}$ and the orthogonality condition between $\psi_{sp^3(3)}$ and $\psi_{sp^3(4)}$ gives

$$c_4 = -1/\sqrt{2}$$

Hence, the four sp^3 hybrid wave functions are

$$\psi_{sp^3(1)} = (1/2)2s + \left(\sqrt{3}/2\right)2p \quad \ldots(v)$$

$$\psi_{sp^3(2)} = (1/2)2s - (1/2)2p_x + \left(\sqrt{2/3}\right)2p_z \quad \ldots(vi)$$

$$\psi_{sp^3(3)} = (1/2)2s - \left(1/2\sqrt{3}\right)2p_x + \left(1/\sqrt{2}\right)2p_y - \left(1/\sqrt{6}\right)2p_z \quad \ldots(vii)$$

$$\psi_{sp^3(4)} = (1/2)2s - \left(1/2\sqrt{3}\right)2p_x + \left(1/\sqrt{2}\right)2p_y - \left(1/\sqrt{6}\right)2p_z \quad \ldots(viii)$$

Conjugated Molecules

The linear conjugated dienes and polyenes can be treated quantum mechanically by the so-called **free-electron molecular orbital (FEMO) theory.** It is assumed that the p electrons which form pi bonds in compounds such as 1,3-butadiene and 1,3, hexatriene

$CH_2=CH-CH=CH_2$ (1,3-butadiene) $\qquad$ $CH_2=CH-CH=CH-CH=CH_2$ (1,3-hexatriene)

move freely in a constant potential along the molecular skeleton. This treatment is, then, analogous to the motion of a particle in a one-dimensional box of infinite height for which the energy levels are given by

$$E_n = n^2h^2/8m_ea^2\ ;\ n = 1, 2, 3,..... \qquad ...(38)$$

In Eq. 38, a is the length of the linear conjugated chain, m_e is the mass of the electron. The electrons in the pi MOs are filled in accordance with the Pauli exclusion principle and Hund's rules. If N is the number of π orbitals (formed from the overlap of Np atomic orbitals) then only $N/2\pi$ orbitals are filled in the ground state since each orbital can accommodate two electrons with spins paired. The longest wave length transition involves the HOMO → LUMO transition, *i.e.*, excitation of the electron from the $N/2$ highest occupied molecular orbital (HOMO) to the $(N/2)+1$ (lowest unoccupied molecular orbital LUMO). Thus, for the HOMO → LUMO transition,

$$\Delta E = E_2 - E_1 \equiv E_{(N/2)+1} - E_{N/2} = h\nu \qquad ...(39)$$

so that the excitation frequency is given by

$$\nu = \Delta E/h$$

$$= \frac{h}{8m_ea^2}\left[(N/2+1)^2 - (N/2)^2\right] = \frac{(N+1)h}{8m_ea^2} \qquad ...(40)$$

Since $\nu = c/\lambda = \bar{\nu}$ (where $\bar{\nu} = 1/\lambda$), hence,

$$\bar{\nu} = \frac{(N+1)h}{8m_ea^2c} \qquad ...(41)$$

Before we can use Eq. 41, we must estimate a, the length of the conjugated chain. This quantity is generally considered as equal to the number of actual bonds between N carbon atoms $+2$. If l is the length of the C—C bond in a delocalized conjugated system, then

$$a = (N-1+2)\,l = (N+1)\,l \qquad ...(42)$$

where l=139 pm. In arriving at Eq. 42, we assume that the π MO can extend one bond length beyond the end carbon atom. Substituting for a in Eq. 41, we have

$$\bar{\nu} = \frac{(N+1)h}{8m_ec(N+1)^2l^2} = \frac{h}{8m_ec(N+1)l^2} \qquad ...(43)$$

Using the values of h, m_e, c and l, we obtain for the HOMO ⟶ LUMO transition,

$$\bar{\nu} = 148{,}137\cdot6/(N+1)\ \text{cm}^{-1} \qquad ...(44)$$

Better agreement with experiment is obtained if the π electrons are assumed to move along the skeletal frame work in a sinusoidal potential with a minimum at the centre of each double bond. In that case, Eq. 44 is modified to

$$\bar{\nu} = \frac{153{,}000\,\text{cm}^{-1}}{N+1} + (16{,}000\,\text{cm}^{-1})\left(1-\frac{1}{N}\right) \qquad ...(45)$$

Example 36. Using the FEMO theory, calculate the frequency (in cm^{-1}) of the HOMO ⟶ LUMO transition in 1, 3, 5-hexatriene molecule. The observed frequency is 37,313·4 cm^{-1}.

Solution : In 1,3,5-hexatriene, $CH_2=CH-CH=CH-CH=CH_2$, $N = 6$ so that, using Eq. 40,

$$\bar{\nu} = \frac{148{,}137\cdot6}{N+1}\ \text{cm}^{-1} = 21{,}162\cdot5\ \text{cm}^{-1}.$$

The agreement with the observed frequency is very poor. However, if we use the modified Eq. 41, then,

$$\bar{\nu} = \frac{153{,}000\ \text{cm}^{-1}}{7} + (16{,}000\ \text{cm}^{-1})(1-1/6) = \mathbf{34{,}495\cdot3\ cm^{-1}}$$

We see that the agreement with the observed value is now satisfactory.

Hückel Molecular Orbital (HMO) Theory of Conjugated Systems

The conjugated linear polyenes such as 1,3-butadiene and 1,3,5-hexatriene and cyclic polyenes such as benzene, naphthalene, etc., were investigated by E. Hückel in 1931. His treatment was extended by C. Coulson, H.C. Longuet-Higgins and R. Hoffmann. In a conjugated unsaturated hydrocarbon with alternate single and double bonds, the molecule is generally planar. In an n-carbon system, each carbon atom is sp^2 hybridized and has a $2p_z$ orbital centred on it. The electrons in the sp^2 hybrid orbitals, called the σ electrons, are contained in the molecular plane. Each $2p_z$ orbital which is perpendicular to the molecular plane contains one π electron. According to the LCAO-MO approximation, the molecular orbital is written as

$$\psi_i = \sum_{j=1}^{n} c_{ij}\,\phi_j \quad (i = 1, 2, 3,.....n) \qquad ...(46)$$

where ϕ_j is the $2p_z$ orbital centered on carbon atom j. The ϕs are called the *basis set*. The n π MOs are formed by the overlap of n $2p_z$ AOs. The HMO theory is similar to the MOT of homonuclear diatomics. In the HMO theory the basis functions are $2p_z$ AOs whereas in the case of H_2 the basis functions are the $1s$ AOs. Proceeding as before, we obtain the secular equation (12). Hückel made the following asumptions about the three kinds of integrals, Coulomb integral, exchange (resonance) integral and overlap integral, to simplify this secular equation :

1. All overlap integrals are zero, *i.e.*, $S_{ij} = 0$.
2. Coulomb integral H_{ii}, which refers to the energy of an electron in the $2p_z$ orbital on the ith carbon atom, is denoted by the symbol α.
3. The exchange integrals $H_{ij}=H_{ji}=0$ unless the ith and jth orbitals are on adjacent carbon atoms in which case they are designated as β.

The neglect of the overlap integrals on adjacent carbon atoms in a conjugated molecule is the severest assumption of the HMO theory and is not really justified. However, despite this assumption this theory gives a good description of bonding and qualitative agreement between theory and experiment.

The Hückel secular equation can now be written as

$$\begin{vmatrix} \alpha-E & \beta & 0 & 0 & .... & 0 & .... \\ \beta & \alpha-E & \beta & 0 & .... & 0 & .... \\ 0 & \beta & \alpha-E & \beta & .... & 0 & .... \\ 0 & 0 & \beta & \alpha-E & & \beta & .... \\ .... & .... & .... & .... & .... & .... & .... \\ .... & .... & .... & .... & .... & .... & .... \\ .... & .... & .... & .... & .... & .... & .... \end{vmatrix} = 0 \qquad ...(47)$$

Defining a dimensionless parameter x as $x = (\alpha - E)/\beta$, Eq. 47 becomes :

$$\begin{vmatrix} x & 1 & 0 & 0 & .... & 0 & .... \\ 1 & x & 1 & 0 & .... & 0 & .... \\ 0 & 1 & x & 1 & .... & 0 & .... \\ 0 & 0 & 1 & x & & 1 & .... \\ .... & .... & .... & .... & .... & .... & .... \\ .... & .... & .... & .... & .... & .... & .... \\ .... & .... & .... & .... & .... & .... & .... \end{vmatrix} = 0 \qquad ...(48)$$

Expansion of this $n \times n$ determinant yields a polynomial equation which has n real roots ; thus, the conjugated polymer has n energy levels and n MOs. The energy of the kth MO is given by

$$E_k = \alpha + x_k \beta \qquad ...(49)$$

where x_k is the kth root of the polynomial. Since the Coulomb integral α and the resonance integral β are both negative, a positive value of x_k represents an energy level which is more negative and, hence, more stable than the energy of an electron in a carbon $2p_z$ orbital. This energy level is called a BMO. Similarly, a negative value of x_k corresponds to an ABMO.

We shall now briefly consider the application of HMO theory to ethylene, 1,3–butadiene and benzene. The application to ethylene, though a good starting point, is not of much interest since it is not a conjugated system.

Ethylene. (Fig. 13). The Hückel secular equation is

$$\begin{vmatrix} x & 1 \\ 1 & x \end{vmatrix} = 0; \quad (\text{where } x = (\alpha - E)/\beta) \qquad ...(50)$$

which, upon expansion, gives

$$x^2 - 1 = 0, \quad \text{or} \quad x = \pm 1$$

For $x = -1$, $E_1 = \alpha + \beta$ (BMO) ...(51)

For $x = +1$, $E_2 = \alpha - \beta$ (ABMO) ...(52)

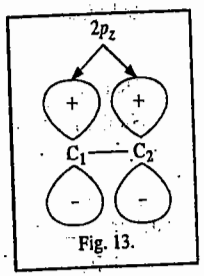

Fig. 13.

The two π electrons of ethylene occupy the BMO (Fig. 14) in the ground state in accordance with the Pauli exclusion principle.

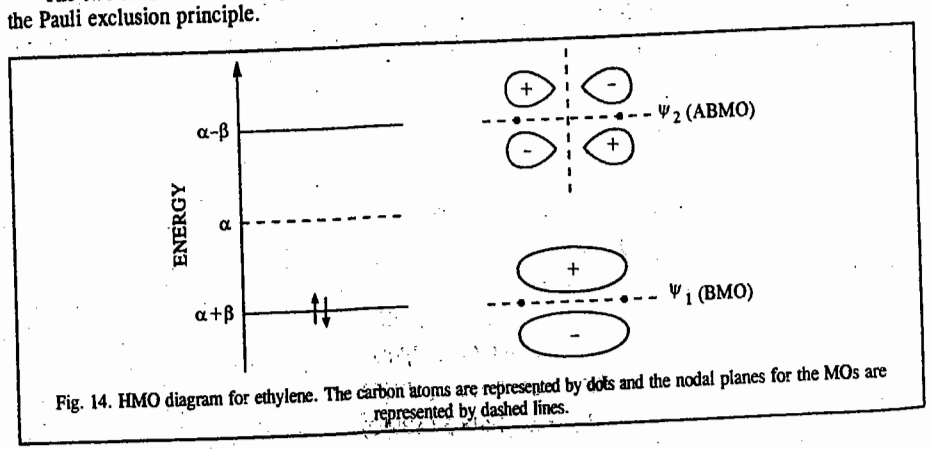

Fig. 14. HMO diagram for ethylene. The carbon atoms are represented by dots and the nodal planes for the MOs are represented by dashed lines.

The total π–electron energy, E_π, is equal to $2(\alpha + \beta)$. Since the energy of the two electrons in the isolated carbon $2p_z$ orbital is equal to 2α, the π–bond energy in ethylene is equal to $[2(\alpha + \beta) - 2\alpha]$, *i.e.*, 2β.

To determine the BMO ψ_1 and the ABMO ψ_2, we proceed as follows : The secular equation corresponds to the two simulataneous linear equations

$$c_1 x + c_2 = 0 \text{ and } c_1 + c_2 x = 0 \qquad ...(53)$$

For the BMO ψ_1, $x = -1$ so that substitution gives

$$-c_1 + c_2 = 0 \text{ and } c_1 - c_2 = 0, \textit{ i.e.}, c_1 = c_2 \text{ (in each case).}$$

Since ψ_1 must be normalized, *i.e.*, $\int \psi_1 \psi_1 \, d\tau = 1$, we have

$$\int (c_1\phi_1 + c_2\phi_2)(c_1\phi_1 + c_2\phi_2) d\tau = 1 \qquad ...(54)$$

or $c_1^2 \int \phi_1\phi_1 \, d\tau + c_2^2 \int \phi_2\phi_2 \, d\tau + 2c_1c_2 \int \phi_1\phi_2 \, d\tau = 1 \qquad ...(55)$

Again, ϕs form an orthonormal set, *i.e.*,

$$\int \phi_i \phi_j \, d\tau = \delta_{ij} = \begin{cases} 1, & i = j \\ 0, & i \neq 1 \end{cases} \qquad ...(56)$$

where δ_{ij} is called the Kronecker delta.

In the present case, it implies that

$$\int \phi_1\phi_1 \, d\tau = \int \phi_2\phi_2 \, d\tau = 1 \quad \text{and} \quad \int \phi_1\phi_2 \, d\tau = 0 \qquad ...(57)$$

Substitution in Eq. 55 gives

$$c_1^2 + c_2^2 = 1 \text{ or } c_1 = 1/\sqrt{2} \; (\because c_1 = c_2) \qquad ...(58)$$

Hence, $\psi_1 = (\phi_1 + \phi_2)/\sqrt{2}$ ...(59)

Similarly, for $x = 1$, proceeding as above, we can show that

$$\psi_2 = (\phi_1 - \phi_2)/\sqrt{2} \qquad ...(60)$$

Note that nodes (and the nodal planes) are the regions in which the probability of finding the π electrons is zero.

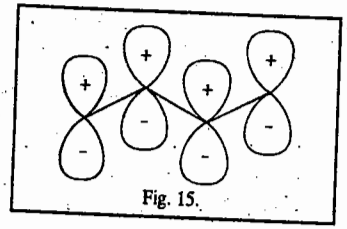

Fig. 15.

1, 3–Butadiene. This system consists of four carbon $2p_z$ orbitals and four π electrons. (Fig. 15) The Hückel secular equation is

$$\begin{vmatrix} x & 1 & 0 & 0 \\ 1 & x & 1 & 0 \\ 0 & 1 & x & 1 \\ 0 & 0 & 1 & x \end{vmatrix} = 0 \text{ (where } x = (\alpha - E)/\beta) \qquad ...(61)$$

which, upon expansion, gives the polynomial equation

$$x^4 - 3x^2 + 1 = 0$$

which has the roots $x = \pm 1{\cdot}618, \pm 0{\cdot}618$ ...(62)

We obtain the following four energy levels : ...(63)

$E_1 = \alpha + 1{\cdot}618\,\beta$ (BMO) ...(64)

$E_2 = \alpha + 0{\cdot}618\,\beta$ (BMO) ...(65)

$E_3 = \alpha - 0{\cdot}618\,\beta$ (ABMO) ...(66)

$E_4 = \alpha - 1{\cdot}618\,\beta$ (ABMO) ...(67)

The four π electrons of 1,3-butadiene occupy the two BMOs ψ_1 and ψ_2 (Fig. 16) in the ground state of the molecule in accodance with Pauli exclusion principle.

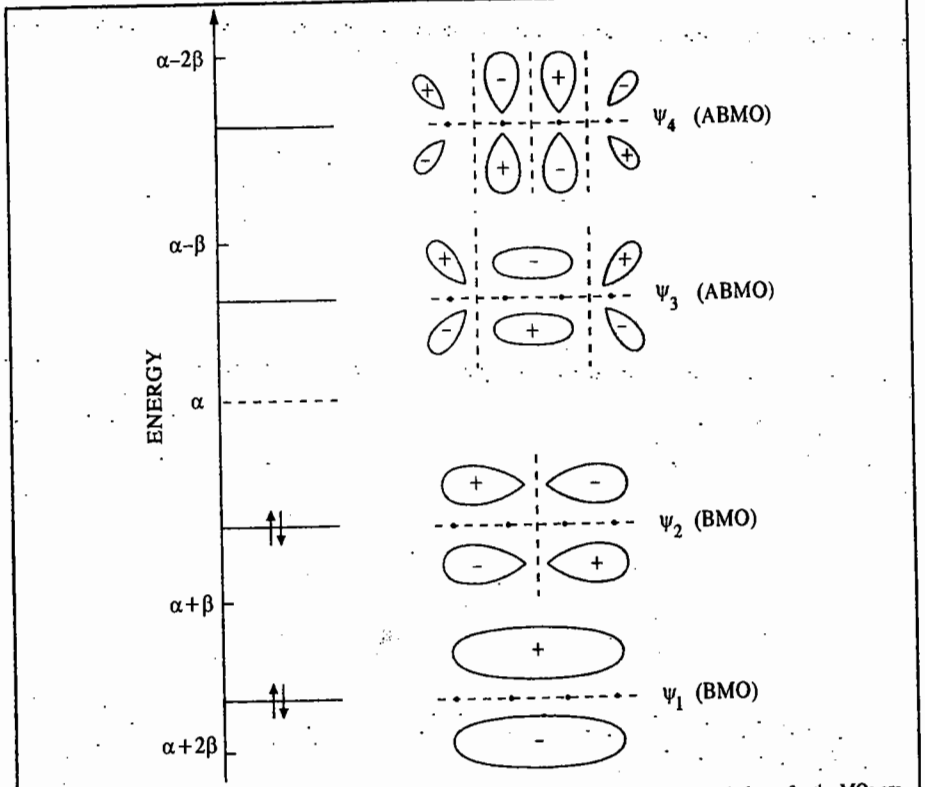

Fig. 16. HMO diagram for 1,3-butadiene. The carbon atoms are represented by dots and the nodal planes for the MOs are represented by dashed lines.

The four MOs (two BMOs and two ABMOs) can be obtained using a procedure employed in the case of ethylene molecule. It is found that

$$\psi_1 = 0{\cdot}3755\,(\phi_1 + \phi_4) + 0{\cdot}6070\,(\phi_2 + \phi_3) \quad ...(68)$$

$$\psi_2 = 0{\cdot}6070\,(\phi_1 - \phi_4) + 0{\cdot}3755\,(\phi_2 - \phi_3) \quad ...(69)$$

$$\psi_3 = 0{\cdot}6070\,(\phi_1 + \phi_4) - 0{\cdot}3755\,(\phi_2 + \phi_3) \quad ...(70)$$

$$\psi_4 = 0{\cdot}3755\,(\phi_1 - \phi_4) - 0{\cdot}6070\,(\phi_2 - \phi_3) \quad ...(71)$$

These HMOs are sketched in Fig. 16.

As remarked earlier, nodes (and nodal planes) are regions where the probability of finding the electrons is zero. Ground state has no node. The number of nodes in an MO increases with increase in energy. Thus, ψ_2 has one node, ψ_3 has two nodes and ψ_4 has three nodes.

The total π electron energy, E_π, is equal to $[2(\alpha+1{\cdot}618\,\beta) + 2\,(\alpha + 0{\cdot}618\,\beta)]$, *i.e.*, $4\alpha + 4{\cdot}472\,\beta$. As proved earlier, the energy of two π electrons in ethylene is $2(\alpha+\beta)$. The delocalization energy (*DE*), also called the resonance energy (RE), is defined as the difference in energy of π electrons in a molecule and sum of the energies of *isolated* double bonds present in the classical structure of the same

molecule. Thus, for 1,3-butadiene, DE (or RE) = $4\alpha+4{\cdot}472\,\beta - 2(2\alpha+2\beta) = 0{\cdot}472\,\beta$. Since DE is a measure of the stability of the molecule, hence 1,3-butadiene is more stable than two ethylene molecules by an energy of $0{\cdot}472\,\beta$.

Example 37. Set up the Hückel secular equation for cyclobutadiene, calculate the energies of the π orbitals and determine the DE (delocalization energy).

Solution : See Fig. 17.

The Hückel secular equation is

$$\begin{vmatrix} x & 1 & 0 & 1 \\ 1 & x & 1 & 0 \\ 0 & 1 & x & 1 \\ 1 & 0 & 1 & x \end{vmatrix} = 0, \text{ (where } x = (\alpha - E)/\beta) \quad ...(72)$$

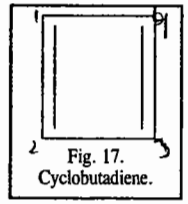

Fig. 17. Cyclobutadiene.

which upon expansion gives the polynomial equation

$$x^4 - 4x^2 = 0 \quad \text{or} \quad x = 0 \text{ (twice)} ; \pm 2 \quad ...(73)$$

Hence, the energy levels are

$$x = -2 \; : \; E = \alpha + 2\beta \text{ (BMO)} \quad ...(74)$$

$$x = 0 \; : \; E_2 = E_3 = \alpha \text{ (degenerate pair); (NBMO)} \quad ...(75a)$$

$$x = 2 \; : \; E_4 = \alpha - 2\beta \text{ (ABMO)} \quad ...(75b)$$

The molecular diagram for cyclobutadiene is shown in Fig. 18.

The four π electrons occupying the MOs, in accordance with the Pauli exclusion principle and Hund's rule, are shown in Fig. 18. Two π electrons occupy the lowest orbital (of energy $\alpha+2\beta$) and two occupy the doubly degenerate orbitals (of energy α); Thus, E_π is equal to $[2(\alpha+2\beta)+2\alpha)]$, *i.e.*, $4\alpha + 4\beta$. Hence, DE = $4\alpha+2\beta - 4(\alpha+\beta) = 0$. We see that HMO theory predicts that cyclobutadiene is unstable because its DE=0. Bayer's theory had earlier ascribed the instability of the four-membered cyclic ring to the tremendous ring strain. The Hückel theory gives a better explanation for this instability.

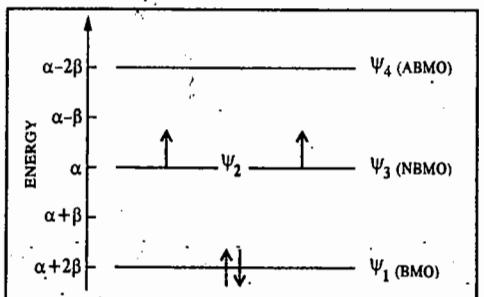

Fig. 18. HMO diagram for cyclobutadiene.

Benzene. (Fig. 19) The Hückel secular equation is

$$\begin{vmatrix} x & 1 & 0 & 0 & 0 & 1 \\ 1 & x & 1 & 0 & 0 & 0 \\ 0 & 1 & x & 1 & 0 & 0 \\ 0 & 0 & 1 & x & 1 & 0 \\ 0 & 0 & 0 & 1 & x & 1 \\ 1 & 0 & 0 & 0 & 1 & x \end{vmatrix} = 0 \text{ (where } x = (\alpha - E)/\beta) \quad ...(76)$$

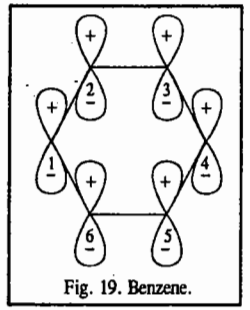

Fig. 19. Benzene.

which on expansion gives the polynomial equation

$$x^6 - 6x^4 + 9x^2 - 4 = 0 \quad ...(77)$$

with roots $x = -2 ; -1$ (twice) ; $+1$ (twice); 2 ...(78)

(These roots can be found by the inspection of the polynomial).

Hence, the energy levels are

$$x = -2 \;:\; E_1 = \alpha + 2\beta \qquad \text{(BMO)} \qquad ...(79)$$

$$x = -1 \;:\; E_2 = E_3 = \alpha + \beta \qquad \text{(degenerate pair, BMO)} \qquad ...(80)$$

$$x = +1 \;:\; E_4 = E_5 = \alpha - \beta \qquad \text{(degenerate pair, ABMO)} \qquad ...(81)$$

$$x = +2 \;:\; E_6 = \alpha - 2\beta \qquad \text{(ABMO)} \qquad ...(82)$$

The molecular diagram for benzene is shown in Fig. 20.

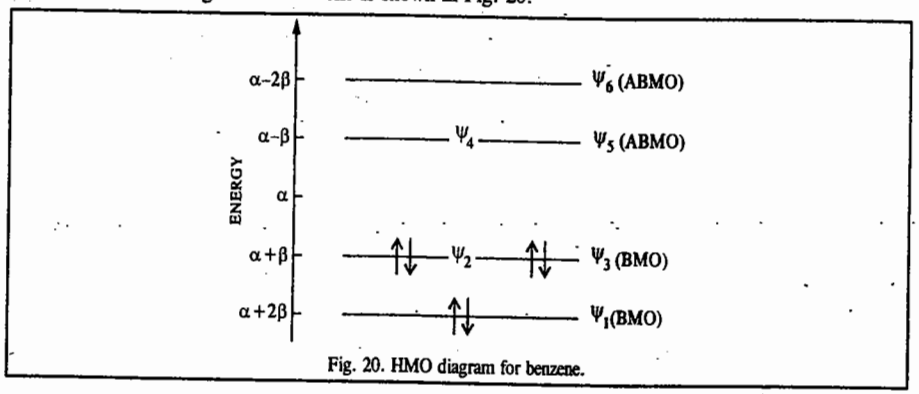

Fig. 20. HMO diagram for benzene.

The occupancy of the six π electrons in the three BMOs is shown in Fig. 20.

$$E_\pi = 2(\alpha + 2\beta) + 4(\alpha + \beta) = 6\alpha + 8\beta \qquad ...(83)$$

$$\text{DE} = 6\alpha + 8\beta - 6(\alpha + \beta) = -2\beta \qquad ...(84)$$

The six normalized HMOs are found to be

$$\psi_1 = \frac{1}{\sqrt{6}}(\phi_1 + \phi_2 + \phi_3 + \phi_4 + \phi_5 + \phi_6) \qquad ...(85)$$

$$\psi_2 = \frac{1}{2}(\phi_1 + \phi_2 - \phi_4 - \phi_5) \qquad ...(86)$$

$$\psi_3 = \frac{1}{\sqrt{12}}(\phi_1 - \phi_2 - 2\phi_3 - \phi_4 + \phi_5 + 2\phi_6) \qquad ...(87)$$

$$\psi_4 = \frac{1}{2}(\phi_1 - \phi_2 + \phi_4 - \phi_5) \qquad ...(88)$$

$$\psi_5 = \frac{1}{\sqrt{12}}(\phi_1 + \phi_2 - 2\phi_3 + \phi_4 + \phi_5 - 2\phi_6) \qquad ...(89)$$

$$\psi_6 = \frac{1}{\sqrt{6}}(\phi_1 - \phi_2 + \phi_3 - \phi_4 + \phi_5 - \phi_6) \qquad ...(90)$$

It may be noted that benzene is a classic example of delocalization conferring extra stability. This molecule is often represented in the languages of both VBT and MOT, VBT being used for its σ-framework (where each carbon atom is sp^2 hybridized) and MOT being used to describe the π electrons. Since the resonance integral $\beta \approx 75$ kJ mol^{-1}, hence DE for benzene $\approx -2\beta \approx -150$ kJ mol^{-1}. The strong aromatic stability of benzene arises from two contributions. First, the shape of the regular hexagon is ideal for forming a strong and relaxed σ bond frame work. Second, the three HMOs which accommodate the six π electrons are all BMOs.

Hückel's $4n+2$ Rule of Aromaticity (Aromatic Character)

An important result of HMO theory is the celebrated *Hückel rule*, according to which an aromatic molecule must contain cyclic clouds of delocalized π electrons above and below the plane of the

molecule; furthermore, the π electron clouds must contain $(4n+2)$ π electrons, *i.e.*,

$$N_\pi = (4n + 2) \text{ where } n = 0, 1, 2, 3, 4, ... \qquad ...(91)$$

Thus, for systems containing π electrons, $N_\pi = 2, 6, 10, 14, 18...$ are aromatic.

Example 38. Using the Hückel rule, determine which of the following molecules are aromatic or non-aromatic :

(a) benzene (b) cyclopentadienyl cation (c) cycloheptadienly radical (d) cyclopentadienyl anion (e) cycloheptatrienyl cation (tropylium cation) (f) cycloheptatrienyl radical (g) cycloheptatrienyl anion (h) cyclooctatetraene (i) cyclooctatetraenyl dianion (j) cyclopropenyl cation (k) cyclopropenyl radical (l) cyclopropenyl anion (m) cyclooctadecanonaene.

Solution : $N_\pi = 4n+2$, $n = 0, 1, 2, 3, ...$ (Hückel Rule),

(a)  $N_\pi = 6$ (aromatic)

(b)  $N_\pi = 4$ (non-aromatic)

(c)  $N_\pi = 5$ (non-aromatic)

(d)  $N_\pi = 6$ (aromatic)

(e)  $N_\pi = 6$ (aromatic)

(f)  $N_\pi = 7$ (non-aromatic)

(g)  $N_\pi = 8$ (non-aromatic)

(h) Cyclooctatetraene $N_\pi = 8$ (non-aromatic)

(i) cyclooctatetraenyl dianion $N_\pi = 10$ (aromatic)

(j) cyclopropenyl cation $N_\pi = 2$ (aromatic)

(k) cyclopropenyl radical $N_\pi = 3$ (non-aromatic)

(l) cyclopropenyl anion $N_\pi = 4$ (aromatic)

(m) cyclooctadecanonaene $N_\pi = 18$ (aromatic)

Example 39. Using HMO theory set up and solve the Hückel secular determinantal equation for the allyl system which consists of the allyl radical and the related cation and the anion. Calculate the resonance energy, also known as the delocalization energy (DE) for the three species and construct molecular diagrams for each species.

Solution : Labelling the carbon atoms of the skeletal framework as 1, 2, 3 as shown below Fig. 21, the wavefunction (MO) for the π-electron in the LCAO-MO approximation is

$$\psi_j = \sum_{i=1}^{3} c_{ij}\,\phi_i \;;\; (j = 1, 2, 3) \qquad ...(92a)$$

Using only one subscript for the coefficients,

$$\psi = \sum_{i=1}^{3} c_i\,\phi_i = c_1\phi_1 + c_2\phi_2 + c_3\phi_3 \qquad ...(92b)$$

where the c_i's are the coefficients to be determined and ϕ_i's are the $2p_z$ AOs of the basis set, centred on the three carbon atoms.

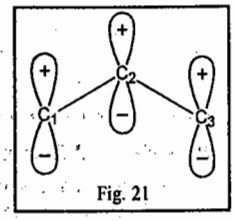

Fig. 21

Using the rules for setting up the Hückel secular determinant, we get

$$\begin{vmatrix} & \phi_1 & \phi_2 & \phi_3 \\ \phi_1 & x & 1 & 0 \\ \phi_2 & 1 & x & 1 \\ \phi_3 & 0 & 1 & x \end{vmatrix} = 0 \qquad ...(93)$$

where $x = (\alpha - E)/\beta$.

This determinant, upon expansion, gives the cubic equation

$$x^3 - 2x = 0$$
$$x(x^2 - 2) = 0$$
$$x(x + \sqrt{2})(x - \sqrt{2}) = 0$$

Thus, the roots are $x = 0, \pm\sqrt{2}$

Hence, the energy levels are :

$$\left.\begin{aligned} x = -\sqrt{2}:\ E_1 &= \alpha + \sqrt{2}\beta \quad \text{(BMO)} \\ x = 0:\ E_2 &= \alpha \quad \text{(NBMO)} \\ x = +\sqrt{2}:\ E_3 &= \alpha - \sqrt{2}\beta \quad \text{(ABMO)} \end{aligned}\right\} \qquad ...(94)$$

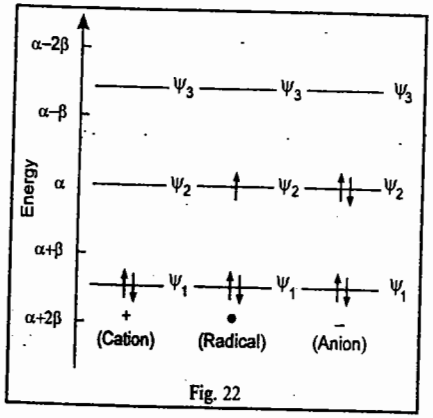

Fig. 22

Now, in the allyl system the cation has two electrons, the radical three electrons and the anion four electrons. Recalling that the resonance integral β is a negative quantity we can construct the energy level diagram for the allyl system as shown in Fig. 22.

In accordance with the Pauli exclusion principle the filling up of the orbitals in the three subsystems is shown in Fig. 22. The two π-electrons in the allyl carbonium ion, $C_3H_5^+$, are placed in the bonding molecular orbital (BMO), ψ_1, having total π-electron energy

$$E_\pi^{\oplus} = 2(\alpha + \sqrt{2}\ \beta) = 2\alpha + 2\sqrt{2}\ \beta \qquad ...(95)$$

Of the three π-electrons in the allyl radical, $C_3H_5^{\bullet}$, the first two go in ψ_1 and the third in the non-bonding molecular orbital (NBMO), ψ_2 having total π-electron energy

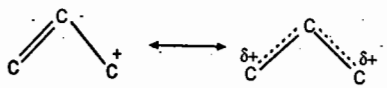
$$E_\pi^{\odot} = 2(\alpha + \sqrt{2}\ \beta) + \alpha = 3\alpha + 2\sqrt{2}\ \beta \qquad ...(96)$$

The four π-electrons of the allyl anion, $C_3H_5^-$ are accommodated in ψ_1 BMO and the ψ_2 NBMO. Thus,

$$E_\pi^{\ominus} = 2(\alpha + \sqrt{2}\ \beta) + 2\alpha = 4\alpha + 2\sqrt{2}\ \beta \qquad ...(97)$$

Calculation of the Delocalization Energy (*DE*)

(1) $C_3H_5^+$. The cation resonates between the following structures :

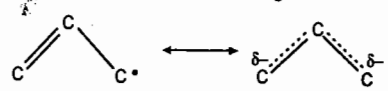


(*i*) (*ii*)

In structure (*i*), the π-electrons are localized in the double bond and the molecule has no resonance stabilization. In structure (*ii*), the electrons are delocalized over the entire molecular framework. The resonance energy, also called the delocalization energy DE, is defined as the energy difference between the energy of the localized structure, $(E_\pi)_{loc}$ and the energy of the actual molecule, E_π. The localized structure (*i*) has two π-electrons in the ethylenic linkage with energy $2(\alpha + \beta)$, *viz.*, the same energy as that of an isolated ethylene molecule, whereas the actual energy of the carbonium ion, from Eq. 95 is $2(\alpha + \sqrt{2}\ \beta)$. Hence, the π-electron delocalization energy of the cation is

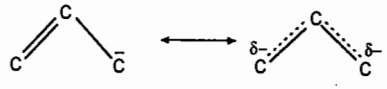
$$DE \equiv (E_\pi^+)_{deloc} = 2(\alpha + \beta) - 2(\alpha + \sqrt{2}\ \beta) = -0{\cdot}828\ \beta \qquad ...(98)$$

(2) $C_3H_5^{\bullet}$. The free radical resonates between the following structures :



$$(E_\pi^{\bullet})_{deloc} = 2(\alpha + \beta) - (3\alpha + 2\sqrt{2}\ \beta) = -0{\cdot}828\beta \qquad ...(99)$$

(3) $C_3H_5^-$. Similarly, for the anion resonating between the following structures,



$$E_\pi^- = [2\ (\alpha + \beta) + 2\alpha] - [2(2\alpha + \sqrt{2}\ \beta)] = -0{\cdot}828\ \beta \qquad ...(100)$$

From Eqs. 98, 99 and 100 we see that the allyl cation, radical and anion have the same DE. This is understandable since while in the localized structures (going in the sequence cation ⟶ radical ⟶ anion), we put electrons in the $2p_z$ orbitals of the isolated atom having energy α, in the actual molecule, electrons are fed into the NBMO having the same energy α. Thus, DE remains the same.

Determination of the MOs

The requirement of normalization stipulates that for each MO

$$\sum_{i=1}^{3} c_i^2 = 1 \qquad ...(101)$$

If we reincorporate coefficients c_1, c_2, c_3 into the secular determinantal equation, (93), we obtain

$$\begin{vmatrix} c_1x & c_2 & 0 \\ c_1 & c_2x & c_3 \\ 0 & c_2 & c_3x \end{vmatrix} = 0 \qquad ...(102)$$

which corresponds to a system of the following three simultaneous linear homogenous equations in three unknown coefficients c_1, c_2, c_3 :

$$\left.\begin{aligned} c_1x + c_2 &= 0 \\ c_1 + c_2x + c_3 &= 0 \\ c_2 + c_3x &= 0 \end{aligned}\right\} \qquad ...(103)$$

For the BMO ψ_1, $x = -\sqrt{2}$

Substituting this value of x in Eq. 103, we get

$$\left.\begin{aligned} -\sqrt{2}c_1 + c_2 &= 0 \\ c_1 - \sqrt{2}c_2 + c_3 &= 0 \\ c_2 - \sqrt{2}c_3 &= 0 \end{aligned}\right\} \qquad ...(104)$$

From the first of Eqs. 104, $c_2 = \sqrt{2}\ c_1$

From the third of Eqs. 104, $c_2 = \sqrt{2}\ c_3$

Hence, $c_1 = c_3$

Since $c_1^2 + c_2^2 + c_3^2 = 1$ (from Eq. 101)

$c_1^2 + 2c_1^2 + c_1^2 = 1$ or $c_1 = c_3 = \frac{1}{2}$ and $c_2 = \frac{1}{\sqrt{2}}$

Hence, $\psi_1 = \frac{1}{2}\phi_1 + \frac{1}{\sqrt{2}}\phi_2 + \frac{1}{2}\phi_3$

$$= \frac{1}{2}(\phi_1 + \sqrt{2}\phi_2 + \phi_3) \qquad ...(105)$$

Again, for the NBMO ψ_2, $x = 0$.

Substituting the value of x in Eq. 103, we get

$$\left.\begin{aligned} c_2 &= 0 \\ c_1 + c_3 &= 0 \\ c_2 &= 0 \end{aligned}\right\} \quad ...(106)$$

Hence, $c_1 = -c_3$; $c_2 = 0$

Since $c_1^2 + c_2^2 + c_3^2 = 1$ (from Eq. 101)

$\therefore$ $c_1^2 + c_1^2 = 1$ or $c_1 = \frac{1}{\sqrt{2}}$ and $c_3 = -\frac{1}{\sqrt{2}}$

Hence, $\psi_2 = \frac{1}{\sqrt{2}}(\phi_1 - \phi_3)$ ...(107)

For the ABMO ψ_3, $x = \sqrt{2}$

Substituting this value of x in Eq. 103, we have

$$\left.\begin{aligned} \sqrt{2}c_1 + c_2 &= 0 \\ c_1 + \sqrt{2}c_2 + c_3 &= 0 \\ c_2 + \sqrt{2}c_3 &= 0 \end{aligned}\right\} \quad ...(108)$$

Hence, $c_2 = -\sqrt{2}c_1 = -\sqrt{2}c_3$ so that $c_1 = c_3$

Since $c_1^2 + c_2^2 + c_3^2 = 1$ (from Eq. 101)

$\therefore$ $c_1^2 + 2c_1^2 + c_1^2 = 1$

Hence, $4c_1^2 = 1$ or $c_1 = \frac{1}{2}$

Thus, $c_3 = \frac{1}{2}$ and $c_2 = \frac{1}{\sqrt{2}}$

$\therefore$ $\psi_3 = \frac{1}{2}(\phi_1 - \sqrt{2}\phi_2 + \phi_3)$ ...(109)

To sum up, from Eqs. 105, 107 and 109, the normalized MOs for the allyl system are

$$\left.\begin{aligned} \psi_1 &= \tfrac{1}{2}(\phi_1 + \sqrt{2}\phi_2 + \phi_3) \quad \text{(BMO)} \\ \psi_2 &= \frac{1}{\sqrt{2}}(\phi_1 - \phi_3) \quad \text{(NBMO)} \\ \psi_3 &= \tfrac{1}{2}(\phi_1 - \sqrt{2}\phi_2 + \phi_3) \quad \text{(ABMO)} \end{aligned}\right\} \quad ...(110)$$

The qualitative shape of the three MOs is shown in Fig. 23.

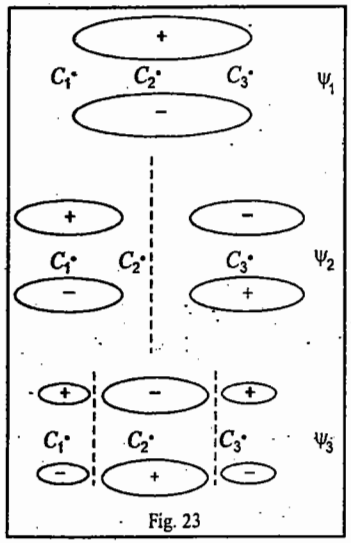


Fig. 23

We see that ψ_1 has no node, ψ_2 has one node passing through c_2 and ψ_3 has two nodes between c_1 and c_2 and between c_2 and c_3. Nodes are the points where the probability of the electron being found is zero.

Example 40. Set up and solve the Hückel secular determinantal equation for the cyclopropenyl system which consists of the cyclopropenyl radical and the related cation and anion. Calculate the delocalization energy (DE) of the system.

Solution : The MO for the cyclopropenyl system (Fig. 24), in the LCAO-MO approximation is

$$\psi_i = \sum_{i=1}^{3} c_{ij}\,\phi_i \; ; \quad (j = 1, 2, 3) \quad ...(111)$$

or $$\psi = \sum_{i=1}^{3} c_i\,\phi_i = c_1\phi_1 + c_2\phi_2 + c_3\phi_3 \quad ...(112)$$

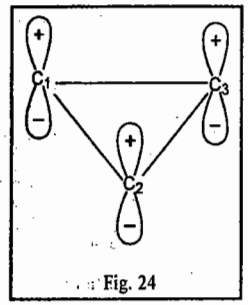

Fig. 24

The secular equation, in terms of the dimensionless variable x, is

$$\begin{vmatrix} & \phi_1 & \phi_2 & \phi_3 \\ \phi_1 & x & 1 & 1 \\ \phi_2 & 1 & x & 1 \\ \phi_3 & 1 & 1 & x \end{vmatrix} = 0 \quad ...(113)$$

where $x = (\alpha - E)/\beta$

This determinant, upon expansion, gives the polynomial equation,

$$x^3 - 3x + 2 = 0 \quad \text{or} \quad (x + 2)(x - 1)^2 = 0$$

whence $x = -2, 1, 1$

Hence, the energy levels β are

$$\left.\begin{aligned} x = -2: \quad & E_1 = \alpha + 2\beta \\ x = +1: \quad & E_2 = E_3 = \alpha - \beta \quad \text{(degenerate pair)} \end{aligned}\right\} \quad ...(114)$$

In the cyclopropenyl system, the radical has three π-electrons, the cation has two π-electrons and the anion has four π-electrons. The resonance integral β being negative, the energy level diagram for the three subsystems and the filling up of the MOs is as shown in Fig. 25.

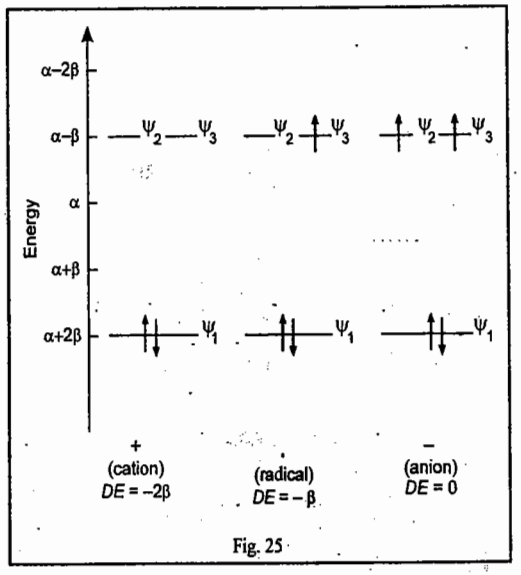

Fig. 25

The total π-electron energy is given by

$E_\pi^+ = 2(\alpha + 2\beta) = 2\alpha + 4\beta$

$E_\pi^\cdot = 2(\alpha + 2\beta) + (\alpha - \beta) = 3\alpha + 3\beta$

$E_\pi^- = 2(\alpha + 2\beta) + 2(\alpha - \beta) = 4\alpha + 2\beta$

The delocalization energy is

$(E_\pi^+)_{deloc} = 2(\alpha + \beta) - (2\alpha + 4\beta) = -2\beta$

$(E_\pi^\cdot)_{deloc} = 2(\alpha + \beta) + \alpha - (3\alpha + 3\beta) = -\beta$

$(E_\pi^-)_{deloc} = 2(\alpha + \beta) + 2\alpha - (4\alpha + 2\beta) = 0$

We see that the cation is more stable, the stability decreasing in the order :

cation > radical > anion

Determination of the MOs

Reincorporating coefficients c_1, c_2, c_3 in the secular equation (109), we get the following simultaneous linear equations :

$$\left.\begin{aligned} c_1x + c_2 + c_3 &= 0 \\ c_1 + c_2x + c_3 &= 0 \\ c_1 + c_2 + c_3x &= 0 \end{aligned}\right\} \quad ...(115)$$

For $x = -2$, we get

$$\left.\begin{aligned} -2c_1 + c_2 + c_3 &= 0 \\ c_1 - 2c_2 + c_3 &= 0 \\ c_1 + c_2 - 2c_3 &= 0 \end{aligned}\right\} \quad ...(116)$$

Subtracting the second equation from the first, $c_1 = c_2$

Subtracting the third equation from the first, $c_1 = c_3$

Since $c_1^2 + c_2^2 + c_3^2 = 1$ (from normalization condition)

$$3c_1^2 = 1$$

Thus, $$c_1 = c_2 = c_3 = \frac{1}{\sqrt{3}}$$

Hence, $$\psi_1 = \frac{1}{\sqrt{3}}(\phi_1 + \phi_2 + \phi_3)$$

It is not possible, using MO theory, to determine the coefficients of the degenerate MOs ψ_2 and ψ_3. However, according to a theorem of quantum mechanics if two eigenfunctions of a Hermitian operator have different eigenvalues, they are orthogonal. Since the Hamiltonian operator is Hermitian and ψ_2 and ψ_3 are its eigenfunctions, hence

$$\langle \psi_2 \mid \psi_3 \rangle = 0 \quad ...(117)$$

Also, $$\langle \psi_1 \mid \psi_2 \rangle = 0 \quad ...(118)$$

For $x = 1$, we obtain from Eq. 115,

$$\left.\begin{aligned} c_1 + c_2 + c_3 &= 0 \\ c_1 + c_2 + c_3 &= 0 \\ c_1 + c_2 + c_3 &= 0 \end{aligned}\right\} \quad ...(119)$$

Now, as long as the coefficients c_1, c_2, c_3 satisfy the normalization requirement,

$$c_1^2 + c_2^2 + c_3^2 = 1$$

we can choose any values for them. Let $c_2 = 0$ so that

$$c_1 = -c_3$$

$$c_1^2 + c_3^2 = 1$$

whence, $$c_1 = \frac{1}{\sqrt{2}}; \qquad c_3 = -\frac{1}{\sqrt{2}}$$

Hence, $$\psi_2 = \frac{1}{\sqrt{2}}(\phi_1 - \phi_3) \quad ...(120)$$

Let us now determine ψ_3.

Since $$\psi_3 = c_1\phi_1 + c_2\phi_2 + c_3\phi_3, \quad ...(121)$$

hence, from Eqs. 117, 120 and 121,

$$\langle \psi_2 \mid \psi_3 \rangle = \int \frac{1}{\sqrt{2}}(\phi_1 - \phi_3)(c_1\phi_1 + c_2\phi_2 + c_3\phi_3)d\tau = 0$$

or $$\frac{c_1}{\sqrt{2}}\langle \phi_1 \mid \phi_1 \rangle + \frac{c_2}{\sqrt{2}}\langle \phi_1 \mid \phi_2 \rangle + \frac{c_3}{\sqrt{2}}\langle \phi_1 \mid \phi_3 \rangle - \frac{c_1}{\sqrt{2}}\langle \phi_1 \mid \phi_3 \rangle - \frac{c_2}{\sqrt{2}}\langle \phi_2 \mid \phi_3 \rangle - \frac{c_3}{\sqrt{2}}\langle \phi_3 \mid \phi_3 \rangle = 0$$

Now, $$\langle \phi_i \mid \phi_j \rangle = \delta_{ij} = \begin{cases} 1, & i = j \\ 0, & i \neq j \end{cases}$$

Hence, all the integrals in the above expression, except the first and the last, vanish, giving

$$\frac{1}{\sqrt{2}}(c_1 - c_3) = 0 \quad \text{or} \quad c_1 = c_3$$

Also, from Eq. 119, $c_1 + c_2 + c_3 = 0$ so that $c_2 = -2c_1$

Again, $c_1^2 + c_2^2 + c_3^2 = 1$ (from normalization condition)

$$(c_1^2) + (-2c_1)^2 + (c_1)^2 = 1$$

$$6c_1^2 = 1$$

Thus, $$c_1 = c_3 = \frac{1}{\sqrt{6}}; \qquad c_2 = \frac{-2}{\sqrt{6}}$$

Hence, $$\psi_3 = \frac{1}{\sqrt{6}}(\phi_1 - 2\phi_2 + \phi_3)$$

To sum up,

$$\left.\begin{aligned} \psi_1 &= \frac{1}{\sqrt{3}}(\phi_1 + \phi_2 + \phi_3) \\ \psi_2 &= \frac{1}{\sqrt{2}}(\phi_1 - \phi_3) \\ \psi_3 &= \frac{1}{\sqrt{6}}(\phi_1 - 2\phi_2 + \phi_3) \end{aligned}\right\} \quad ...(122)$$

Example 41. A mnemonic device, called Frost-Hückel circle mnemonic, has been suggested for obtaining MO energies of cyclic conjugated systems, C_nH_n. Using this mnemonic, show diagrammatically the energy levels of C_nH_n (where n = 3, 4, 5, 6, 7, 8).

Solution : As we have noticed in Hückel calculations on the cyclic polyenes (also called polymethines), done earlier, the ground state energy level is nondegenerate but the higher energy levels are doubly degenerate except the top energy level for n even, where n is the number of conjugated carbon atoms. This result can be shown diagrammatically by means of the Frost-Hückel circle mnemonic. First, we draw a circle of radius $2|\beta|$ (where β is the resonance integral of the HMO theory). Then, we inscribe the appropriate regular polygon in the circle in such a way that one vertex is placed at the bottom of the circle. Each corner of the polygon corresponds to the carbon atom of the skeletal framework. For the cyclopropenyl system, C_3H_3, we inscribe an upside down equilateral triangle ; for cyclobutadiene, C_4H_4, a square with one vertex down; for the cyclopentadienyl system, a pentagon, for benzene, a hexagon ; for cyclohepta-trienyl, a heptagon; and for cyclooctatetraene, an octagon. Corresponding to each intersection of the polygon with the circle there exists an MO whose energy is given by the vertical placement, *i.e.*, its projection on a vertical energy scale. The centre of the circle is taken as the zero, the bottom as $+2\beta$ and the top as -2β. Using simple trigonometry the vertical placements from zero can be obtained. The circle mnemonics for C_nH_n are shown in Fig. 26. So we see that these mnemonics enable us to write the energy levels without actually solving the Hückel secular equation.

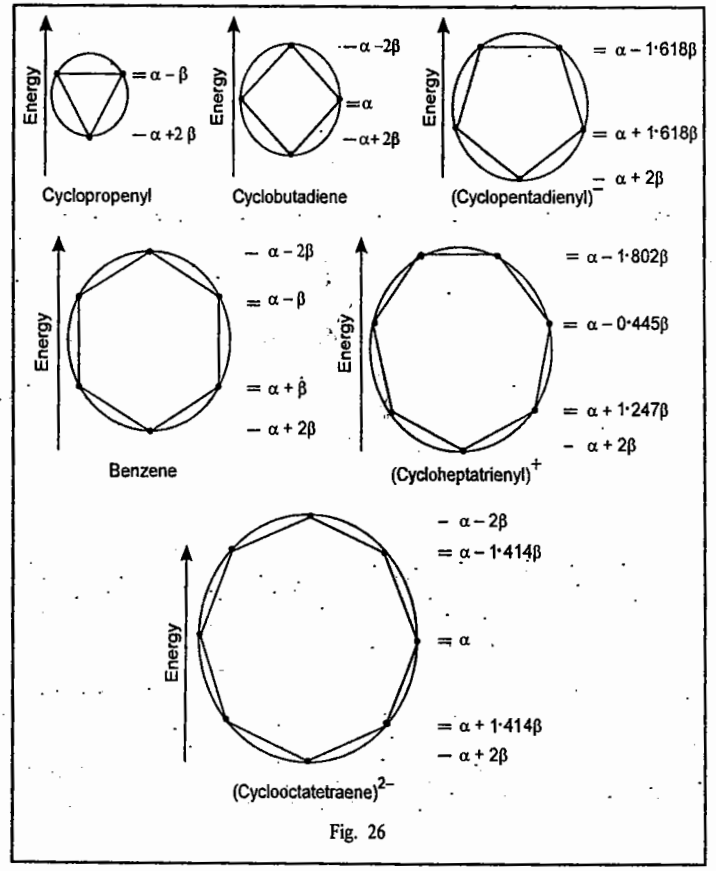

Fig. 26

Example 42. Using HMO theory determine the most stable structure of the H_3 system.

Solution. The H_3 system consists of the cation, H_3^+; the radical, H_3 and the anion H_3^-. The cation

contains two electrons, the free radical three electrons and the anion four electrons. Strictly speaking, we cannot solve this problem with the Hückel approximation since the electrons which hold the three molecular species together are not π-electrons. However, if we assume that the electrons are delocalized over the entire nuclear framework—which is a reasonable assumption—then the H_3 system is amenable to Hückel treatment. The geometrical structure can be (*a*) linear and (*b*) bent, triangular.

Case (*a*). Linear Structure $H_1 - H_2 - H_3$

The secular equation is

$$\begin{vmatrix} x & 1 & 0 \\ 1 & x & 1 \\ 0 & 1 & x \end{vmatrix} = 0 \qquad \ldots(123)$$

The determinant on expansion gives the cubic equation

$$x^3 - 2x = 0$$

$$x(x^2 - 2) = 0$$

$$x(x + \sqrt{2})(x - \sqrt{2}) = 0 \qquad \text{or,} \qquad x = -\sqrt{2}, 0, +\sqrt{2}$$

Hence, the Hückel energy levels are.

$$\left.\begin{aligned} x = -\sqrt{2}: \quad & E_1 \equiv \alpha + \sqrt{2}\beta \quad \text{(BMO)} \\ x = 0: \quad & E_2 = \alpha \quad \text{(NBMO)} \\ x = +\sqrt{2}: \quad & E_3 = \alpha - \sqrt{2}\beta \quad \text{(ABMO)} \end{aligned}\right\} \qquad \ldots(124)$$

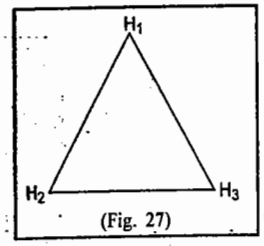
The total Hückel energy is

$$\left.\begin{aligned} H_3^+: \quad & E = 2(\alpha + \sqrt{2}\beta) = 2\alpha + 2\sqrt{2}\beta \\ H_3: \quad & E = 2(\alpha + \sqrt{2}\beta) + \alpha = 3\alpha + 2\sqrt{2}\beta \\ H_3^-: \quad & E = 2(\alpha + \sqrt{2}\beta) + 2\alpha = 4\alpha + 2\sqrt{2}\beta \end{aligned}\right\} \qquad \ldots(125)$$

Case (*b*) : Triangular Configuration (Fig. 27)

The secular equation is

$$\begin{vmatrix} x & 1 & 1 \\ 1 & x & 1 \\ 1 & 1 & x \end{vmatrix} = 0 \qquad \ldots(126)$$



(Fig. 27)

which, on expansion, gives the polynomial

$$x^3 - 3x + 2 = 0$$

$$(x + 2)(x - 1)^2 = 0 \qquad \text{or} \qquad x = -2, 1, 1$$

Hence, the Hückel energy levels are

$$\left.\begin{aligned} x = -2: \quad & E_1 = \alpha + 2\beta \\ x = 1: \quad & E_2 = E_3 = \alpha - \beta \quad \text{(degenerate pair)} \end{aligned}\right\} \qquad \ldots(127)$$

The total Hückel energy is

$$\left.\begin{aligned} H_3^+: \quad & E = 2(\alpha + 2\beta) = 2\alpha + 4\beta \\ H_3: \quad & E = 2(\alpha + 2\beta) + (\alpha - \beta) = 3\alpha + 3\beta \\ H_3^-: \quad & E = 2(\alpha + 2\beta) + 2(\alpha - \beta) = 4\alpha + 2\beta \end{aligned}\right\} \qquad \ldots(128)$$

In may be recalled that the resonance integral β is a negative quantity. The criterion for the stability of a molecule in a given configuration is that it should have lower energy in the ground state. From Eqs. 125 and 128 we conclude that

H_3^+ : Triangular configuration is more stable
H_3 : Both configurations are about equally stable
H_3^- : Linear configuration is more stable.

Example 43. Calculate the Hückel energies of pyridine. Compare the energy level diagram of this molecule with that of benzene.

[Hint : In contrast to pyrrole, the N-atom in pyridine supplies only one *p*-electron to the ring. The secular equation for pyridine is exactly analogous to that for benzene. As in the case of pyrrole, the α and β integrals have to be adjusted. If N atom is numbered as 1, the following substitutions are made :

$$\alpha_1 = \alpha_N = \alpha + k\beta, \quad k = 0.2$$
$$\alpha_2 = \alpha_6 = \alpha + l\beta, \quad l = k/8$$
$$\beta_{12} = \beta_{16} = m\beta, \quad m = l$$

(The values of k, l and m have been recommended from more elaborate calculations). Hence, the secular equation for pyridine is

$$\begin{vmatrix} (\alpha+k\beta)-E & m\beta & 0 & 0 & 0 & m\beta \\ m\beta & (\alpha+l\beta)-E & \beta & 0 & 0 & 0 \\ 0 & \beta & \alpha-E & \beta & 0 & 0 \\ 0 & 0 & \beta & \alpha-E & \beta & 0 \\ 0 & 0 & 0 & \beta & \alpha-E & \beta \\ m\beta & 0 & 0 & 0 & \beta & (\alpha+l\beta)-E \end{vmatrix} = 0 \qquad \ldots(129)$$

The solution of the secular equation gives the energy level diagram shown in Fig. 28, where the energy level diagram for benzene is also shown for comparison.

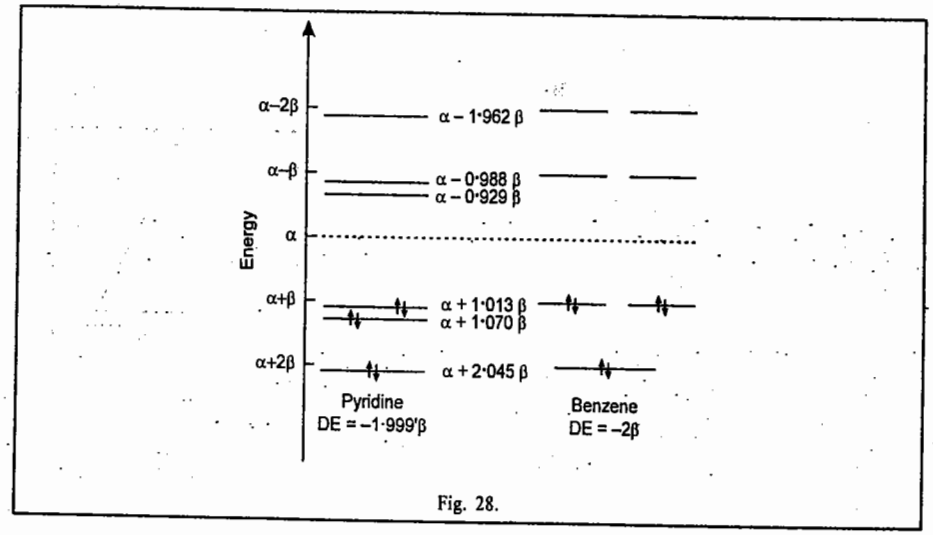


Fig. 28.

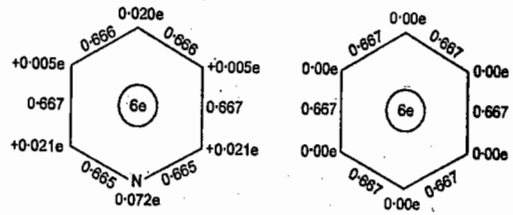
The charge densities ρ_μ and the bond order $p_{\mu\nu}$ are



Example 44. In the various problems dealt with earlier on HMO theory, the delocalization energy (*DE*) has been expressed in terms of the resonance integral, β. The next task, therefore, is to evaluate β. Outline methods which lead to the determination of β.

Solution : Three experimental methods have been used to determine β. They are : (*a*) Measurement of ionization potentials (*b*) Electronic spectral data and (*c*) Measurement of DE.

(*a*) **Measurement of Ionization Potentials.** In a molecule where each MO is doubly occupied in accordance with the requirements of the Pauli principle, the total energy is given by

$$E = 2\sum_m E_m \qquad ...(130)$$

where the summation is over the occupied MO*s*. When the molecule absorbs sufficient energy to remove the electron from the highest occupied molecular orbital (HOMO), the topmost orbital, say, ψ_n, is singly occupied. Hence, the total π-electron energy of the ion is

$$E\ (\text{ion}) = 2\sum_m E_m + E_n (m \neq n) \qquad ...(131)$$

Ionization potential, *I*, is the difference in energy between the molecule and the ion. It is the energy required to ionize the molecule. From Eqs. 129 and 130,

$$I = E\ (\text{ion}) - E = -E_n \qquad ...(132)$$

From Eq. 129 we see that the ionization potential is equal to minus the energy of HOMO. This statement is known as Koopmans' theorem.

Experimental measurement of the ionization potential enables us to determine both the Coulomb integral, α and the resonance integral, β. For graphite the value of I = 4·3 eV. Since for graphite the highest orbital has an energy equal to α, therefore, α = − 4·3 eV. Once α is known from measurements on graphite, β can be determined from the ionization potentials and the orbital energies of a series of related molecules. The data for the polyacene series is tabulated below :

Polyacene	Ionization Potential, eV	E_n
C_6H_6	9·57	α + β
$C_{10}H_8$	8·68	α + 0·618 β
$C_{14}H_{10}$	8·20	α + 0·414 β
$C_{18}H_{12}$	7·71	α + 0·295 β

A plot of I versus $-E_n$ gives β ≈ −2·4 eV = 230 kJ mol^{-1}.

(*b*) **Electronic Spectra :** When an electron in a conjugated system occupying the orbital ψ_m with energy $E_m = \alpha + x_m \beta$, undergoes a transition to the orbital ψ_n with energy $E_n = \alpha + x_n \beta$, the energy of transition, ΔE, which lies in the ultraviolet region, is given by

$$\Delta E = E_n - E_m = (\alpha + x_n\beta) - (\alpha + x_m\beta) = (x_n - x_m)\ \beta$$

The frequency of transition, in cm^{-1}, is

$$\bar{\nu} = \Delta E/hc$$

Thus, if $\bar{\nu}$ is known for a series of conjugated compounds from the u.v. spectra, it can be correlated with the results of HMO theory, leading to the determination of β.

(*c*) **Measurement of the DE :** Taking the example of benzene, the actual heat of formation is determined from thermochemical measurements. The energy of a hypothetical moleeule having a Kekule structure is then estimated by using the energies for the C–C, C=C and C–H bonds found in molecules such as ethane and ethylene. The difference between the two energies gives the resonance energy which is the same as the DE of the HMO theory. Thus,

$$3(D_{C\text{–}C}) + 3(D_{C=C}) + 6(D_{C\text{–}H}) = 4{,}184 \text{ kJ mol}^{-1}$$

The observed heat of formation is 4,347 kJ mol^{-1}. Since

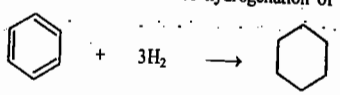
$$DE = -2\beta$$

Therefore,

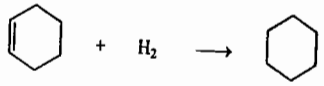
$$|\ \beta\ | = \frac{1}{2}(DE) = \frac{1}{2}(4{,}347 - 4{,}184) = 84 \text{ kJ mol}^{-1}.$$

The β-values for other members of the polyacene series, *viz.*, naphthalene, anthracene, naphthacene, etc., are also found to be in the same range.

Alternatively, β can be evaluated as follows. The heat of hydrogenation of benzene to cyclohexane is found



to be −208.4 kJ mol^{-1}. The heat of hydrogenation of cyclohexene to cyclohexane is found to be −119.6 kJ mol^{-1}.



The DE of benzene is the difference between three times the heat of hydrogenation of cyclohexene and the heat of hydrogenation of benzene :

$$DE = 3(-119{\cdot}6) - (-208{\cdot}4) = -150{\cdot}4 \text{ kJ mol}^{-1}.$$

Thus,

$$|\ \beta\ | = \frac{1}{2}\ DE = 75 \text{ kJ mol}^{-1}.$$

The measurement of DE is the most accurate method of determining β. The ionization potential method, outlined in (a) above, gives very high values of β and is not reliable. The consistency of the β values obtained from various molecules provides a measure of the validity of the HMO theory.

Example 45. Since in a conjugated system the π-electrons are delocalized over the entire molecule and even the single bonds partake of the double bond character, it is natural to speak of "electron density" at a given atom, the "bond-order" between a pair of atoms, and the residual valence at each atom. Such concepts have, indeed, been introduced into HMO theory. Calculate (*i*) the π-electron charge density, (*ii*) the charge density, (*iii*) the π-electron bond order (also called mobile bond order), and (*iv*) free-valence index in the following molecules :

a. **the allyl system** ***b.*** **the butadiene [butadiene]$^+$ and [butadiene]$^-$ systems and** ***c.*** **benzene.**

Solution : The total π-electron charge density q_μ at an atom μ is defined as

$$q_\mu = \sum_{\nu\ \text{occ.}} n_\nu\, c_{\mu\nu}^2 \qquad ...(133)$$

where n_ν is the number of electrons in the νth MO and the summation is over all the occupied MOs. Since according to Pauli's principle n_ν = 2,

hence

$$q_\mu = 2\sum_{\nu\ \text{occ.}} c_{\mu\nu}^2 \qquad ...(134)$$

The quantity $c_{\mu\nu}^2$ is the partial electron density at atom μ due to the electron in the MO ψ_ν.

Originally, there was one π-electron at each carbon atom. Since this electron is delocalized over the entire molecular framework, the charge density at atom μ is defined as

$$\rho_\mu = 1 - q_\mu \qquad ...(135)$$

The partial mobile π-bond order is defined for the μν bond in the λth MO as

$$p_{\mu\nu}^{\lambda} = c_{\mu\lambda}\, c_{\nu\lambda} \qquad ...(136)$$

Hence, the total π-electron bond order $p_{\mu\nu}$ between μ and ν is

$$p_{\mu\nu} = \sum_{\text{all electrons}} p_{\mu\nu}^{\lambda} = \sum_{\lambda\ \text{occ.}} n_\lambda c_{\mu\lambda}\, c_{\nu\mu} = 2\sum_{\lambda\ \text{occ.}} c_{\mu\lambda}\, c_{\nu\lambda} \qquad ...(137)$$

The free valence index F_μ at an atom μ is defined as

$$F_\mu = 4{\cdot}732 - \sum_{\text{bond}} p_{\mu\lambda} \qquad ...(138)$$

where 4·732 is the maximum possible bonding power of the μth atom. The last term in Eq. 138 is the sum of

the bond orders of all bonds to the μth atom, including the σ-bonds of the skeletal framework. In this definition the σ-bonds have the order of 1.

a. **Allyl System**

1. Cation (carbonium ion). The two π-electrons occupy MO ψ_1.

$$\psi_1 = \frac{1}{2}(\phi_1 + \sqrt{2}\,\phi_2 + \phi_3)$$

(*i*) $q_1 = q_3 = 2\left(\frac{1}{2}\right)^2 = 0.5$ (using Eq. 134)

$$q_2 = 2\left(\frac{\sqrt{2}}{2}\right)^2 = 1.00$$

(*ii*) $\rho_1 = \rho_3 = 1 - .5 = 0.5$ (using Eq. 135)

$\rho_2 = 1 - 1.00 = 0.00$

(*iii*) $p_{12} = 2\left(\frac{1}{2}\right)\left(\frac{\sqrt{2}}{2}\right) = 0.707$ (using Eq. 137)

$$p_{23} = 2\left(\frac{\sqrt{2}}{2}\right)\left(\frac{1}{2}\right) = 0.707$$

Thus, $p_{12} = p_{23}$

(*iv*) The σ-bond order = 3

Thus, $F_1 = 4.732 - \Sigma p$ (using Eq. 138)

$= 4.732 - (3.00 + p_{12})$

$= 4.732 - (3.00 + .707) = 1.02$

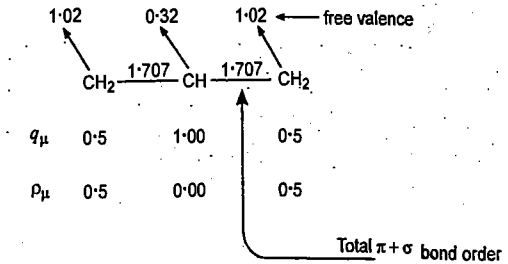
$F_3 = 4.732 - (3.00 + p_{23}) = 1.02 = F_1$

$F_2 = 4.732 - (3.00 + p_{12} + p_{23})$

$= 4.732 - (3.00 + 0.707 + 0.707)$

$= 0.32$

The numerical results can be represented schematically as follows :



2. Radical. The three π-electrons occupy the MOs ψ_1 and ψ_2.

$$\psi_1 = \frac{1}{2}(\phi_1 + \sqrt{2}\phi_2 + \phi_3) \quad \text{and} \quad \psi_2 = \left(\frac{1}{\sqrt{2}}\right)(\phi_1 - \phi_3)$$

(*i*) $q_1 = 2\left(\frac{1}{2}\right)^2 + (1)\left(\frac{1}{\sqrt{2}}\right)^2 = \frac{1}{2} + \frac{1}{2} = 1.00$

$$q_2 = 2\left(\frac{\sqrt{2}}{2}\right)^2 + (0)^2 = 1.00$$

$$q_3 = 2\left(\frac{1}{2}\right)^2 + (1)\left(-\frac{1}{\sqrt{2}}\right)^2 = 1.00$$

(*ii*) $\rho_1 = \rho_2 = \rho_3 = 0.00$

(iii) $p_{12} = 2\left(\frac{1}{2}\right)\left(\frac{\sqrt{2}}{2}\right) + (1)\left(\frac{1}{\sqrt{2}}\right)(0) = \frac{1}{\sqrt{2}} = 0.707$

$$p_{23} = 2\left(\frac{\sqrt{2}}{2}\right)\left(\frac{1}{2}\right) + (1)(0)\left(-\frac{1}{\sqrt{2}}\right) = \left(\frac{1}{\sqrt{2}}\right) = 0.707$$

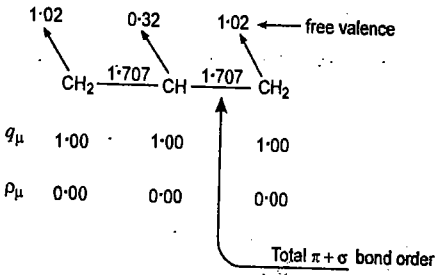
Thus, $p_{12} = p_{23}$

(*iv*) $F_1 = 4.732 - (3.00 + 0.707) = 1.02$

Similarly, $F_3 = F_1 = 1.02$

$F_2 = 4.732 - (3.00 + 0.707 + 0.707) = 0.32$

Schematically,



3. Anion (Carbanion). The four π-electrons occupy the MOs ψ_1 and ψ_2. The reader can verify that

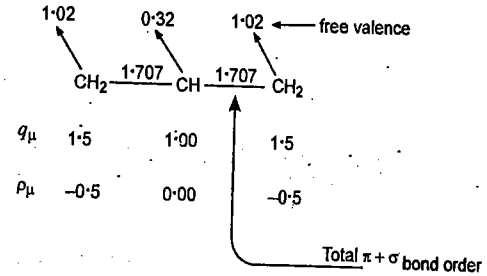
(*i*) $q_1 = q_3 = 1.5$ $q_2 = 1.00$

(*ii*) $\rho_1 = \rho_3 = -0.5$ $\rho_2 = 0.00$

(*iii*) $p_{12} = p_{23} = 0.707$

(*iv*) $F_1 = F_3 = 1.02$ $F_2 = 0.32$

Schematically,



b. **Butadiene.** The four π-electrons occupy MOs ψ_1 and ψ_2 :

$\psi_1 = 0.372\,\phi_1 + 0.602\,\phi_2 + 0.602\,\phi_3 + 0.372\,\phi_4$

$\psi_2 = 0.602\,\phi_1 + 0.372\,\phi_2 - 0.372\,\phi_3 - 0.602\,\phi_4$

(*i*) $q_1 = 2(0.372)^2 + 2\,(0.602)^2 = 1$

$q_2 = 2(0.602)^2 + 2\,(0.372)^2 = 1$

$q_3 = 2(0.602)^2 + 2\,(-0.372)^2 = 1$

$q_4 = 2(0.372)^2 + 2\,(-0.602)^2 = 1$

Thus, $q_1 = q_2 = q_3 = q_4 = 1$

(*ii*) $\rho_1 = \rho_2 = \rho_3 = \rho_4 = 0.00$

(*iii*) $p_{12} = 2(0{\cdot}372)(0{\cdot}602) + 2\,(0{\cdot}602)(0{\cdot}372) = 0{\cdot}896$

$p_{23} = 2(0{\cdot}602)(0{\cdot}602) + 2\,(0{\cdot}372)(-0{\cdot}372) = 0{\cdot}448$

$p_{34} = 2(0{\cdot}602)(0{\cdot}372) + 2(-0{\cdot}372)(-0{\cdot}602) = 0{\cdot}896$

Thus, $p_{12} = p_{34} = 0{\cdot}896$

(*iv*) $F_1 = 4{\cdot}732 - \Sigma p = 4{\cdot}732 - (3{\cdot}00 + p_{12})$

$= 4{\cdot}732 - (3{\cdot}00 + 0{\cdot}896) = 0{\cdot}830$

$F_4 = 4{\cdot}732 - (3{\cdot}00 + p_{34}) = 0{\cdot}830$

Thus, $F_1 = F_4 = 0{\cdot}830$

$F_2 = 4{\cdot}732 - (3{\cdot}00 + p_{12} + p_{23})$

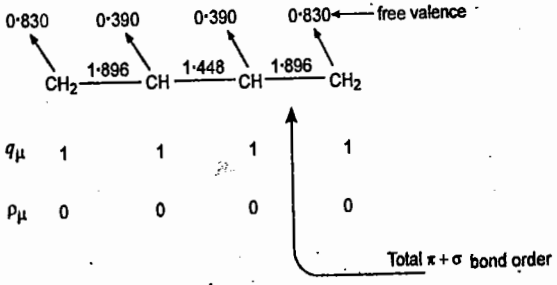
$= 4{\cdot}732 - (3{\cdot}00 + 0{\cdot}896 + 0{\cdot}448) = 0{\cdot}390$

$F_3 = 4{\cdot}732 - (3{\cdot}00 + p_{23} + p_{34})$

$= 4{\cdot}732 - (3{\cdot}00 + 0{\cdot}448 + 0{\cdot}896) = 0{\cdot}390$

Thus, $F_2 = F_3 = 0{\cdot}390$

Schematically,



c. **Benzene.** The six π-electrons occupy the MOs ψ_1, ψ_2 and ψ_3.

$$\psi_1 = \frac{1}{\sqrt{6}}(\phi_1 + \phi_2 + \phi_3 + \phi_4 + \phi_5 + \phi_6)$$

$$\psi_2 = \frac{1}{2}(\phi_1 + \phi_2 - \phi_4 - \phi_5)$$

$$\psi_3 = \frac{1}{\sqrt{12}}(\phi_1 - \phi_2 - 2\phi_3 - \phi_4 + \phi_5 + 2\phi_6)$$

(*i*) $q_1 = 2\left(\frac{1}{\sqrt{6}}\right)^2 + 2\left(\frac{1}{2}\right)^2 + 2\left(\frac{1}{\sqrt{12}}\right)^2 = 1{\cdot}00$

$q_2 = 2\left(\frac{1}{\sqrt{6}}\right)^2 + 2\left(\frac{1}{2}\right)^2 + 2\left(-\frac{1}{\sqrt{12}}\right)^2 = 1{\cdot}00$

$q_3 = 2\left(\frac{1}{\sqrt{6}}\right)^2 + 2\,(0)^2 + 2\left(\frac{-2}{\sqrt{12}}\right)^2 = 1{\cdot}00$

$q_4 = 2\left(\frac{1}{\sqrt{6}}\right)^2 + 2\left(-\frac{1}{2}\right)^2 + 2\left(-\frac{1}{\sqrt{12}}\right)^2 = 1{\cdot}00$

$q_5 = 2\left(\frac{1}{\sqrt{6}}\right)^2 + 2\left(-\frac{1}{2}\right)^2 + 2\left(\frac{1}{\sqrt{12}}\right)^2 = 1{\cdot}00$

$$q_6 = 2\left(\frac{1}{\sqrt{6}}\right)^2 + 2\,(0)^2 + 2\left(\frac{-2}{\sqrt{12}}\right)^2 = 1{\cdot}00$$

Thus, $q_1 = q_2 = q_3 = q_4 = q_5 = q_6 = 1{\cdot}00$

(*ii*) $\rho_1 = \rho_2 = \rho_3 = \rho_4 = \rho_5 = \rho_6 = 0{\cdot}00$

(*iii*) $p_{12} = 2\left(\frac{1}{\sqrt{6}}\right)\left(\frac{1}{\sqrt{6}}\right) + 2\left(\frac{1}{2}\right)\left(\frac{1}{2}\right) + 2\left(\frac{1}{\sqrt{12}}\right)\left(-\frac{1}{\sqrt{12}}\right) = \frac{2}{3} = 0{\cdot}667$

$p_{23} = 2\left(\frac{1}{\sqrt{6}}\right)\left(-\frac{1}{\sqrt{6}}\right) + 2\left(\frac{1}{2}\right)(0) + 2\left(-\frac{1}{\sqrt{12}}\right)\left(-\frac{2}{\sqrt{12}}\right) = \frac{2}{3} = 0{\cdot}667$

Similarly, we can compute other bond-orders. The result is

$p_{12} = p_{23} = p_{34} = p_{45} = p_{56} = p_{61} = 0{\cdot}667$

(*iv*) $F_1 = 4{\cdot}732 - \Sigma p = 4{\cdot}732 - (3{\cdot}00 + p_{12} + p_{61})$

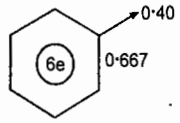
$= 4{\cdot}732 - (3{\cdot}00 + 0{\cdot}667 + 0{\cdot}667) = 0{\cdot}40$

$F_2 = 4{\cdot}732 - (3{\cdot}00 + p_{12} + p_{23}) = 0{\cdot}40$

It can be easily verified that

$F_1 = F_2 = F_3 = F_4 = F_5 = F_6 = 0{\cdot}40$

Schematically, we have



$q_\mu = 1{\cdot}00$, $\rho_\mu = 0{\cdot}00$

Walsh Diagrams. The Walsh diagram, introduced by A.D. Walsh in 1953, also known as the Mulliken-Walsh diagram, is a **correlation diagram** that portrays the variation in the orbital energies of a molecule as its shape is changed (for instance, as a bond angle is changed). By selecting the bond angle that results in the lowest total energy (which may be approximated by the sum of the orbital energies) we can predict the probable shape of the molecule from the occupation of its orbitals. Also, from a knowledge of the changes in the populations of the orbitals one can predict how the shape will change when the molecule is electronically excited.

Consider the general case of the H_2A molecule (H_2O is a particular example of this kind of molecule). The atomic orbital basis set consists of the 1*s* orbitals of the two H atoms and the four valence A *s* and A *p* orbitals of the central A atom. Their relative energies are estimated by considering how their overlap with each other varies as the bond angle is varied. Six MOs can be built from these six AOs using the LCAO-MO approximation. The plot of the energies of the MOs as the bond angle changes from 180° in the linear molecule to 90° in the angular molecule gives the Walsh diagram (Fig. 28).

The lowest orbital in 90° H_2A molecule is the one labelled 1*a*, which is constructed from the overlap of the A *s* and A p_z orbitals with one *symmetry adapted combination* of the H 1*s* orbitals. As the bond angle is changed to 180°, the two H 1*s* orbitals overlap less and hence are raised in energy. In the linear molecule, however, only the A *s* orbital contributes to the bond and the elimination of the higher-energy A *p* component of the orbital *lowers* the overall energy of the MO. When the mixing of the A orbitals is significant, the energy of the orbital falls as the molecule becomes linear.

The energy of the orbital 1 b_2 is lowered because the H 1*s* orbitals move into a better position for overlap with A p_y orbital. The biggest change occurs for the 2 a_1 orbital. In the first place, it contains

considerable A s character in the 90° molecule but is pure A p in the 180° molecule. Secondly, though it is largely AH nonbonding and slightly HH bonding in the 90° molecule, it is purely nonbonding in the 180° molecule.

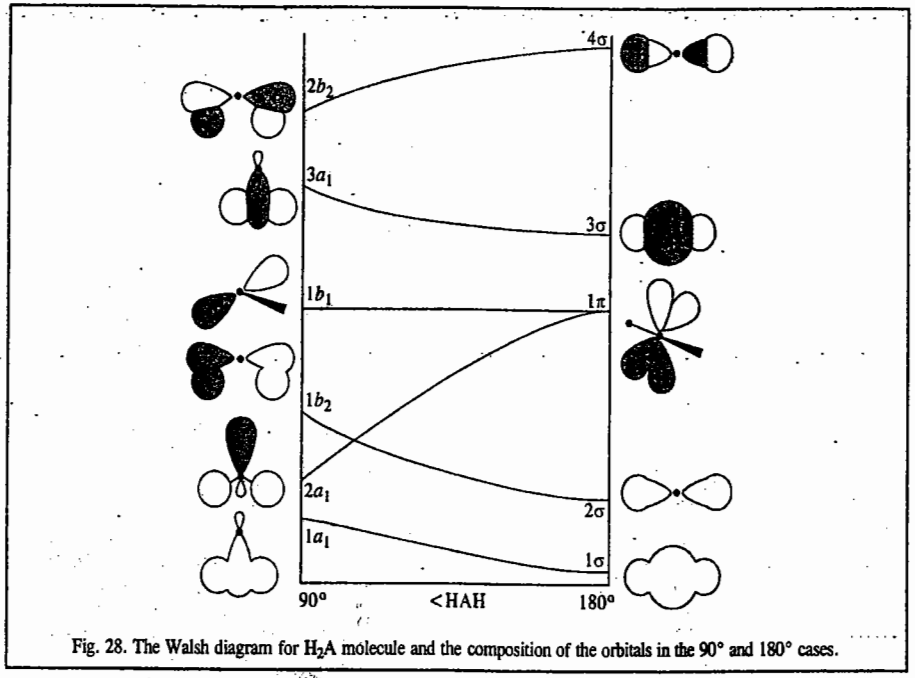


Fig. 28. The Walsh diagram for H_2A molecule and the composition of the orbitals in the 90° and 180° cases.

The $1b_1$ orbital is a nonbonding A p_x orbital perpendicular to the molecular plane in the 90° molecule and it remains nonbonding in the linear molecule. Therefore, its energy hardly changes with angle. The $3a_1$ orbital is antibonding in the 90° molecule and has both A s and A p character ; in the linear molecule it is pure A s on the central atom and possibly less antibonding. Hence, its energy decreases as the molecule becomes linear. The uppermost orbital, $2b_2$, is the antibonding partner of the $1b_2$ orbital and increases in energy as the H $1s$ orbitals achieve better overlap in the linear molecule.

The main feature which determines whether or not the H_2A molecule is bent is whether the $2a_1$ orbital is occupied. The $2a_1$ orbital has a much lower energy in the angular molecule than in the linear molecule. Hence, a lower total energy is achieved if, when it is occupied, the molecule is angular. The shape adopted by an H_2A molecule, therefore, depends on the number of electrons occupying the orbital. In H_2O, which has eight valence electrons to accommodate, the $2a_1$ orbital must be occupied ; so we predict that the molecule will be bent. On the other hand, the transient BeH_2 molecule, which has four valence electrons, is predicted to be linear since the $2a_1$ orbital is not occupied and the occupied orbitals have only a weak effect on the molecular geometry.

Molecular geometry is predicted using the two theories, *viz.*, the VSEPR (valence shell electron pair repulsion) theory and the Walsh diagrams. The former was proposed by N.V. Sidgwick and H.M. Powell in the 1930s but given a modern formulation by R. Nyholm and R.J. Gillespie. It is discussed in detail in Inorganic Chemistry books. Suffice it to state here that the generally accepted view (accepted because it works, not because it is fully understood) is that in a molecule lone pairs repel more strongly than bonding pairs; so the order of repulsions is

$$(LP, LP) > (LP, BP) > (BP, BP)$$

where LP stands for a nonbonding lone pair and BP stands for a bonding pair (or super pair). The molecule adjusts its shape so that the repulsions are minimized in the light of this ordering.

The Walsh diagram approach has an advantage over the VSEPR theory in that it is formulated in terms of the occupation of the delocalized MOs and the energies of these orbitals incorporate electron–electron and nucleus–nucleus repulsions, electron–nucleus attractions, and the kinetic energies of the electrons. Thus, the Walsh diagram approach is, in principle, richer than the VSEPR theory, for the latter is expressed entirely in terms of repulsions between localized pairs of electrons. However, in the words of P.W. Atkins, "to some extent the advantage is illusory because the VSEPR theory can be expressed in more sophisticated terms and there is some uncertainty about the precise significance of the 'orbital energy' that is plotted in a Walsh diagram". The two approaches attempt qualitatively to identify dominant bonding influences. The Walsh approach is useful for discussing the excited states of molecules, an area where the VSEPR approach is almost completely silent. It must be emphasized again that *in the Walsh model the shape of a molecule is predicted on the basis of the occupation of MOs that, in a correlation diagram, show a strong dependence on bond angle.* In general, any H_2A molecule with from five to eight valence electrons is predicted to be angular. The observed bond angles are :

BeH_2	BH_2	CH_2	NH_2	OH_2
180	131	136	103	105

These experimental observations are qualitatively in line with Walsh's approach but for detailed quantitative predictions one has to rely on detailed MO calculations.

Problem 46. Using the Walsh diagram predict the geometry of *(i)* BeH_2 *(ii)* CH_2 *(iii)* H_2O molecules.

Solution. *(i)* **BeH_2** has four valence electrons. These four electrons occupy the lowest two MOs. If the lowest energy is achieved with the molecule being angular, then that will be its shape. We can decide whether the molecule is angular by accommodating the electrons in the lowest two MOs corresponding to an arbitrary bond angle in the Walsh diagram (Fig. 28). We then note that the HOMO (highest occupied molecular orbital) decreases in energy on going to the right of the diagram and that the lowest total energy is obtained when the molecule is linear. Hence, BeH_2 is predicted to be **linear** and has the configuration $1\sigma^2 2\sigma^2$.

(ii) **CH_2** molecule has two more electrons than BeH_2; hence, three of the MOs must be occupied. Here, the lowest energy is achieved if the molecule is **angular** and has the configuration $1a_1^2 2a_1^2 1b_2^2$.

(iii) **H_2O.** Here, too, as in cases *(i)* and *(ii)*, we choose an intermediate bond angle along the horizontal axis of the Walsh diagram and accommodate the eight valence electrons. The resulting configuration is $1a_1^2 2a_1^2 1b_2^2 1b_1^2$. The $2a_1$ orbital is occupied; so we expect the molecule to be **nonlinear** since in this configuration it has lower energy than the linear molecule.

We have given a brief survey of the most important applications of quantum mechanics to atomic structure (Chapters 1 and 2) and chemical bonding (this Chapter). Physicists have used it to explain the interaction of electrons and photons, the nature of the solid state, the band theory of metals, the phenomena of superconductivity and superfluidity and theories of cosmology and gravity. Quantum mechanics ranks with the Relativity as the two most important theories in Physics in the twentieth century. Quantum Electrodynamics (QED), pioneered in the 1940s by the 1965 Physics Nobel Laureates R.P. Feynman, J.S. Schwinger and S. Tomonaga, has been called the "Jewel of Physics". Quantum mechanics is, indeed, a fascinating theory ; it has challenged the best minds. In the words of the 1963 Physics Nobel Laureate, E.P. Wigner (1902 - 1995), "The discovery of quantum mechanics was nearly a total surprise. It described the physical world in a way that was fundamentally new. It seemed to many of us a miracle". The significance of quantum mechanics was described by Dirac (the cowinner, with Schrödinger, of the 1933 Physics Nobel Prize) very boldly in the following words :

"The underlying physical laws necessary for the mathematical theory of a large part of physics and the whole of chemistry are thus completely known and the difficulty is only that the exact application of these laws leads to equations which are too complicated to be soluble."

If Dirac were alive he would be happy to know that computational quantum chemistry has, thanks to the high-speed computers, made tremendous strides in surmounting the difficulties he had anticipated, and that quantum chemistry has, indeed, a bright future ahead.

Born-Oppenheimer Approximation

For a molecule consisting of N nuclei ($\mu,\nu\ldots$) and n electrons ($i, j,\ldots$), the complete Hamiltonian operator, neglecting the spin-orbit interaction and other magnetic interactions, is given by

$$\hat{H} = -\frac{\hbar^2}{2}\sum_{\mu}^{N}\frac{1}{m_\mu}\nabla_\mu^2 - \frac{\hbar^2}{2m_e}\sum_{i}^{n}\nabla_i^2 + \sum_{\mu,\nu}\frac{Z_\mu Z_\nu e^2}{(4\pi\varepsilon_0)r_{\mu\nu}} - \sum_{i,\mu}\frac{Z_\mu e^2}{(4\pi\varepsilon_0)r_{i\mu}} + \sum_{i,j}\frac{e^2}{(4\pi\varepsilon_0)r_{ij}} \quad \ldots(139)$$

In Eq. 139, the first term represents nuclear kinetic energy; the second, electronic kinetic energy; the third, nuclear potential energy; the fourth, nuclear–electron attraction potential energy and the fifth, electronic repulsion potential energy.

The Schrödinger equation for the molecule can be written as

$$\hat{H}\psi = E\psi \quad \ldots(140)$$

where E is the total energy and ψ the total wave function. The proton being about 1840 times as heavy as the electron, the electronic motion is extremely fast compared with the nuclear motion. If we assume that the two motions are independent of each other, the total wave function can be written as a product of the electronic wave function ψ_e and the nuclear wave function, ψ_n :

$$\psi = \psi_e\psi_n \quad \ldots(141)$$

In the Born-Oppenheimer approximation, the nuclear kinetic energy is neglected while writing the Schrödinger equation for electronic motion. Thus, we have, from Eqs. 139 and 140,

$$\left[-\frac{\hbar^2}{2m_e}\sum_{i}^{n}\nabla_i^2 + \sum_{\mu,\nu}\frac{Z_\mu Z_\nu e^2}{(4\pi\varepsilon_0)r_{\mu\nu}} - \sum_{i,\mu}\frac{Z_\mu e^2}{(4\pi\varepsilon_0)r_{i\mu}} + \sum_{i,j}\frac{e^2}{(4\pi\varepsilon_0)r_{ij}}\right]\psi_e = E\psi_e \quad \ldots(142)$$

We see that for a particular fixed nuclear framework, the electronic wave function, ψ_e depends only on the coordinates of the electrons. Of course, the nuclear coordinates *do* affect ψ_e and E_e. But, if we have a fixed nuclear configuration, then the nuclear repulsion potential energy, given by the second term in Eq. 142, can be considered a constant. The electronic energy E_e is then given by

$$E_e = E - \sum_{\mu\nu}\frac{Z_\mu Z_\nu e^2}{(4\pi\varepsilon_0)r_{\mu\nu}} \quad \ldots(143)$$

Hence. Eq. 142 becomes

$$\left[\sum_i\left(-\frac{\hbar^2}{2m_e}\nabla_i^2 - \sum_{i,\mu}\frac{Z_\mu e^2}{(4\pi\varepsilon_0)r_{i\mu}}\right) + \sum_{i,j}\frac{e^2}{(4\pi\varepsilon_0)r_{ij}}\right]\psi_e = E_e\psi_e \quad \ldots(144)$$

The Schrödinger equation for nuclear motion is written as

$$\left[-\frac{\hbar^2}{2}\sum_{\mu}^{N}\frac{1}{m_\mu}\nabla_\mu^2 + E_e(r_{\mu\nu})\right]\psi_n = E_n\psi_n \quad \ldots(145)$$

The nuclear wave function ψ_n describes the rotational and vibrational motions in a potential field supplied by the *electrons*. Thus, we see from Eq. 145 that we can describe the nuclear motion by using an effective Hamiltonian in which the potential energy is the one that is provided by the electrons in the

fixed nuclei approximation. Eqs. 144 and 145 show that, as a result of the Born-Oppenheimer approximation, the electronic and nuclear motions have been separated. Eq. 144 is solved for a fixed value of internuclear separation, $r_{\mu\nu}$ (usually designated as R), thereby obtaining E_e as a function of R : $E_e = E_e(R)$. For a diatomic molecule, a plot of $E_e(R)$ versus R gives the potential energy curve shown in Fig. 29. The most stable nuclear configuration for a given electronic state corresponds to the value of R leading to a minimum in the energy. The value of E_e obtained from Eq. 144 is used as potential energy in Eq. 145. The total energy, E, of the molecule is the sum of the contributions from the electronic and the nuclear motions :

$$E = E_e + E_n$$

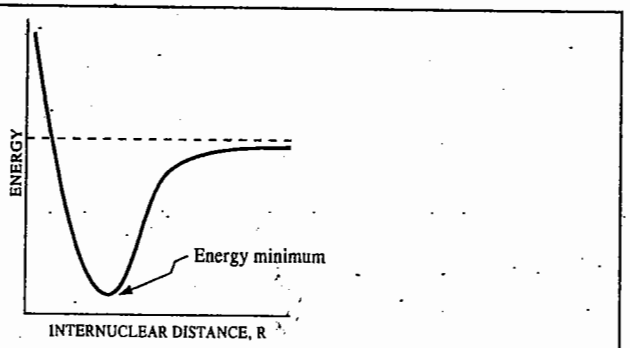

Fig. 29. Potential energy curve obtained by plotting energy *versus* internuclear distance.

Hellmann-Feynman Theorem

The concept of energy, as embodied in the Schrödinger wave equation, pervades chemical thinking of chemists, physicists and bioscientists. However, the **force concept** introduced by the German physicist H.Hellmann and, independently, by the American physicist Richard Feynman in the late 1930s, is a novel and penetrating way of gaining deeper insight into the nature of chemical bonding. The **Hellmann-Feynman electrostatic theorem** states that the effective force acting on a nucleus in a molecule can be calculated by simple electrostatics as the sum of the Coulombic forces exerted by the other nuclei and by a hypothetical electron cloud whose charge density, *viz.*, $-e\rho(x,y,z)$, is found by solving the electronic Schrödinger wave equation.

We consider a system with a time-independent Hamiltonian $\hat{H}$ that involves parameters. An obvious example is the molecular electronic Hamiltonian which depends parameterically on the nuclear coordinates. The stationary state wave functions also depend on the parameters in $\hat{H}$. We now investigate how E_n varies with each of the parameters. More specifically, let λ be one of the parameters. We are interested in evaluating $\partial E_n/\partial\lambda$, where the partial derivative is taken with all other parameters held constant. The Schrödinger wave equation is

$$\hat{H}\psi_n = E_n\psi_n \quad \ldots(146)$$

where ψ_n are the normalized stationary state eigenfunctions. Because of normalization, we have

$$E_n = \int \psi_n^*\,\hat{H}\,\psi_n\,d\tau \quad \ldots(147)$$

and

$$\frac{\partial E_n}{\partial\lambda} = \frac{\partial}{\partial\lambda}\int \psi_n^*\,\hat{H}\,\psi_n\,d\tau \quad \ldots(148)$$

The integral in Eq. 147 is a definite integral over all space and its value depends parameterically on λ since $\hat{H}$ and ψ_n depend on λ. Provided the integrand is well behaved, we can find the integral's derivative *w.r.t.* a parameter by differentiating the integral *w.r.t.* the parameter and then integrating. Thus,

$$\frac{\partial E_n}{\partial \lambda} = \int \frac{\partial}{\partial \lambda}(\psi_n^* \hat{H} \psi_n) d\tau = \int \frac{\partial \psi_n^*}{\partial \lambda} \hat{H} \psi_n \, d\tau + \int \psi_n^* \frac{\partial}{\partial \lambda}(\hat{H} \psi_n) d\tau \quad ...(149)$$

Also, we have

$$\frac{\partial}{\partial \lambda}(\hat{H} \psi_n) = \frac{\partial}{\partial \lambda}(\hat{T} \psi_n) + \frac{\partial}{\partial \lambda}(\hat{V} \psi_n) \quad ...(150)$$

The potential energy operator is simple multiplication by V so that

$$\frac{\partial}{\partial \lambda}(\hat{V} \psi_n) = \frac{\partial V}{\partial \lambda} \psi_n + V \frac{\partial \psi_n}{\partial \lambda} \quad ...(151)$$

Similarly, $$\frac{\partial}{\partial \lambda}(\hat{T} \psi_n) = \left(\frac{\partial \hat{T}}{\partial \lambda}\right) \psi_n + \hat{T}\left(\frac{\partial \psi_n}{\partial \lambda}\right) \quad ...(152)$$

where $\partial \hat{T} / \partial \lambda$ is found by differentiating $\hat{T}$ *w.r.t.* λ just as if it were a function instead of an operator. From Eqs. 151 and 152,

$$\frac{\partial}{\partial \lambda}(\hat{H} \psi_n) = \left(\frac{\partial \hat{H}}{\partial \lambda}\right) \psi_n + \hat{H}\left(\frac{\partial \psi_n}{\partial \lambda}\right) \quad ...(153)$$

Thus, Eq. 149 becomes

$$\frac{\partial E_n}{\partial \lambda} = \int \frac{\partial \psi_n^*}{\partial \lambda} \hat{H} \psi_n \, d\tau + \int \psi_n^* \frac{\partial \hat{H}}{\partial \lambda} \psi_n \, d\tau + \int \psi_n^* \hat{H} \frac{\partial \psi_n}{\partial \lambda} d\tau \quad ...(154)$$

For the first integral in Eq. 154, we have

$$\int \frac{\partial \psi_n^*}{\partial \lambda} \hat{H} \psi_n \, d\tau = E_n \int \frac{\partial \psi_n^*}{\partial \lambda} \psi_n \, d\tau \quad ...(155)$$

The Hermitian property of $\hat{H}$ and Eq. 146 give, for the last integral in Eq. 154,

$$\int \psi_n^* \hat{H} \frac{\partial \psi_n}{\partial \lambda} d\tau = \int \frac{\partial \psi_n^*}{\partial \lambda} (\hat{H} \psi_n)^* d\tau = E_n \int \psi_n^* \frac{\partial \psi_n}{\partial \lambda} d\tau \quad ...(156)$$

Hence, $$\frac{\partial E_n}{\partial \lambda} = \int \psi_n^* \frac{\partial \hat{H}}{\partial \lambda} \psi_n \, d\tau + E_n \int \frac{\partial \psi_n^*}{\partial \lambda} \psi_n \, d\tau + E_n \int \psi_n^* \frac{\partial \psi_n}{\partial \lambda} d\tau \quad ...(157)$$

Since the wavefunctions are normalized,

$$\int \psi_n^* \psi_n \, d\tau = 1 \quad \text{and} \quad \frac{\partial}{\partial \lambda} \int \psi_n^* \psi_n \, d\tau = 0$$

or $$\int \frac{\partial \psi_n^*}{\partial \lambda} \psi_n \, d\tau + \int \psi_n^* \frac{\partial \psi_n}{\partial \lambda} d\tau = 0 \quad ...(158)$$

Hence, from Eqs. 157 and 158, we obtain

$$\frac{\partial E_n}{\partial \lambda} = \int \psi_n^* \frac{\partial \hat{H}}{\partial \lambda} \psi_n \, d\tau \quad ...(159)$$

Eq. 159 is called the **generalized Hellmann-Feynman theorem.** The Hellmann-Feynman theorem, with E_n being the Hartree-Fock energy, is obtained by Hartree-Fock (as well as exact) wave functions.

It is reasonable to suppose that the Hellmann-Feynman theorem follows from the Born-Oppenheimer approximation since the rapid motion of the electrons allows the electronic wave function and probability density to adjust immediately to changes in nuclear configuration. The rapid motion of the electrons causes the sluggish nuclei to 'see' the electrons as a charge cloud rather than as discrete particles. The fact that the effective forces on the nuclei are electrostatic affirms that there are no 'mysterious quantum-mechanical forces' acting in molecules.

Application of Hellmann-Feynman Theorem to Chemical Bonding. Let us consider a diatomic molecule. We take the internuclear axis as the z-axis (Fig. 30).

By symmetry, the x and y components of the effective forces on the two nuclei are zero. For the z-component of force on nucleus a, we have (in a.u.) :

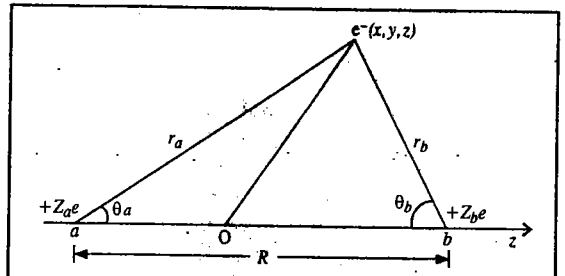

Fig.30. The coordinate system for a diatomic molecule; the origin is at O.

$$F_{z,a} = -Z_a \iiint \rho \frac{z_a - z}{r_a^3} dx\, dy\, dz - \frac{Z_a Z_b}{R^2} \quad ...(160)$$

where R is the internuclear distance, given by

$$R = [(x_a - x_b)^2 + (y_a - y_b)^2 + (z_a - z_b)^2]^{1/2}$$

From Fig. 30, we see that

$r_a \cos \theta_a = -z_a + z$ (z_a is negative). Hence,

$$F_{z,a} = Z_a \iiint \rho \frac{\cos \theta_a}{r_a^2} dx\, dy\, dz - \frac{Z_a Z_b}{R^2} \quad ...(161)$$

Similarly, we find that

$$F_{z,b} = -Z_b \iiint \rho \frac{\cos \theta_b}{r_b^2} dx\, dy\, dz + \frac{Z_a Z_b}{R^2} \quad ...(162)$$

Also, $$F_{z,a} = -\frac{dE(R)}{dz_a} = -\frac{\partial E(R)}{\partial R} \frac{\partial R}{\partial z_a} = -\frac{dE}{dR} \frac{z_a - z_b}{R}$$

$$= \frac{dE}{dR} \frac{\partial R}{\partial z_b} = -F_{z,b} \quad ...(163)$$

The effective forces on nuclei a and b are equal in magnitude and opposite in direction. From Eq. 161, the z-component of the effective force on nucleus a due to the element of electronic charge in the region about (x, y, z) is $Z_a \rho (\cos \theta_a / r_a^2) dx dy dz$. Similarly, the z-component of force on nucleus b due to this charge is $-Z_b \rho (\cos \theta_b / r_b^2)\, dx dy dz$. In these expressions the value corresponds to a force in the $+z$ direction, that is, to the right of Fig. 30. When the force on nucleus a is algebraically greater than the force on nucleus b, then the element of electronic charge tends to draw a towards b. Hence the electronic charge that is binding is located in the region where

$$Z_a \rho \frac{\cos \theta_a}{r_a^2} dx\, dy\, dz > -Z_b \rho \frac{\cos \theta_b}{r_b^2} dx\, dy\, dz \quad ...(164)$$

Since the probability density ρ is non-negative, division by ρ preserves the direction of inequality sign and the binding region of space is where

$$Z_a \frac{\cos\theta_a}{r_a^2} + Z_b \frac{\cos\theta_b}{r_b^2} > 0 \qquad \ldots(165)$$

When the force on b is algebraically greater than that on a, the electronic charge element tends to draw b away from a. The antibinding region of space is thus characterized by a negative value for the left side of Eq. 165. The surfaces for which the left side of Eq. 165 equals zero divide the space into the **binding** and **antibinding regions.** This concept of binding and antibinding regions was proposed by T. Berlin in 1951. Berlin's ideas have been extended to polyatomic molecules. Figs. 31 and 32 show the binding and antibinding regions for a homonuclear and a heteronuclear diatomic molecule.

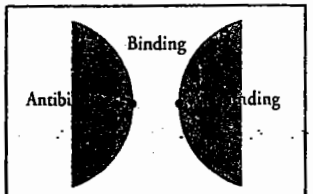

Fig. 31. Cross section of binding and antibinding regions in a homonuclear diatomic molecule. To obtain the three-dimensional regions, we rotate about the internuclear axis.

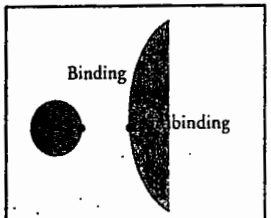

Fig. 32. Binding and antibinding regions for a heteronuclear diatomic molecule with $Z_b > Z_a$.

As might be expected, the binding region for a homonuclear diatomic molecule lies between the nuclei. Charge in this region tends to draw the nuclei together. From the basic principles of bonding we know that bonding leads to a transfer of charge probability density into the region between the nuclei because of the overlap of the bonding AOs. Fundamental work on Hellmann-Feynman theorem has been done by R.F.W. Bader and his coworkers (Henneker, P. Cade, A.K. Chandra) and B.M. Deb. For further applications of the Hellmann-Feynman theorem, one can refer to the following book :

B.M. Deb (ed.), *The Force Concept in Chemistry*, Van Nostrand Reinhold, 1981.

COMPUTATIONAL QUANTUM CHEMISTRY

Thanks to the pioneering contributions of J.A. Pople and his colleagues in the U.S.A., computational quantum chemistry has revolutionized research in theoretical chemistry since the 1960s. Much of the modern computational quantum chemistry uses Gaussian orbitals as a basis set. Pople has developed algorithms for the **ab initio calculation** of molecular properties based on Gaussian orbitals. The computer programs developed by Pople and his many collaborators have been packaged as a commonally available program called GAUSSIAN 94. This program, released in 1994, was developed at Carnegie-Mellon university in the U.S.A. In the **ab initio calculations** (which use the exact Hamiltonian), the task is greatly simplified by expressing the AOs used in the LCAO as linear combinations of Gaussian orbitals. A **Gaussian type orbital (GTO)** is a function of the form $e^{-\alpha r^2}$. However, in the **semi-empiricial calculations**, the AOs have been used as Slater-type orbitals as basis sets. A **Slater-type orbital** (STO) is a function of the form $e^{-\alpha r}$. (Hydrogenic orbitals as basis sets are not at all satisfactory.) We may recall that the set of AOs used to construct LCAO-MOs is called the **basis set.** In the case of diatomic molecules, the hydrogenic orbitals form the basis set. For example, the 1s orbitals of the two atoms constitute the basis set for the MO $\sigma_g(1s)$. For polyatomic molecules, the first basis set used in large scale computational studies consisted of STOs :

$$S_{nlm}(r, \theta, \phi) = N_n r^{n-1} e^{-\xi r} Y_{l,m}(\theta, \phi) \qquad \ldots(166)$$

where N_n is the normalization constant defined as

$$N_n = \frac{(2\xi)^{n+1/2}}{[(2n)!]^{1/2}}$$

where ξ (zeta) is the **orbital exponent,** n and l are the principal and orbital momentum (azimuthal) quantum numbers and $Y_{l,m}(\theta, \phi)$ are the angularly dependent spherical harmonics. The STOs differ from

the hydrogenic orbitals in that the STOs have no nodes and the orbital exponent is not necessarily equal to Z/n. In principle, the orbital exponents should be chosen to minimize the energy but this selection is still a formidable task even with modern computers. Slater has given a set of empirical rules for determining ξ for orbitals in free atoms. ξ increases with increasing atomic number, reflecting the contraction of the orbitals as the nuclear charge increases.

The STOs are not used directly in modern theoretical research because the integrals in the resulting secular determinants are difficult to evaluate. In particular, integrals involving more than one nuclear centre, called **multicentre integrals,** are awkward to evaluate using STOs. If we use GTOs instead of STOs, however, all the multicentre integrals are very easy to evaluate. As a matter of fact, the four-centre integrals can become two-centre integrals which can be easily computed. The use of GTOs was suggested in 1950 by S.F. Boys. The advantage of GTOs is that the product of two Gaussian functions is itself a Gaussian function that lies between the centres of the two contributing functions. The GTOs may be represented by

$$G_{nlm}(r, \theta, \phi) = N_n r^{n-1} e^{-\alpha r^2} Y_{l,m}(\theta, \phi) \qquad \ldots(167)$$

for the basis set in MO calculations.

The GTO does a reasonably good job of describing the STO for values of r greater than a_0 (the Bohr radius) but it underestimates its magnitude for values of r less than a_0. These discrepancies turn out to be very significant in molecular calculations. To overcome this difficulty quantum theorists prefer the use of curve-fit STOs to sums of Gaussian functions, the curve-fit improving with N, the number of Gaussian functions used. If, for instance, $N=3$, *i.e.*, we use a sum of three Gaussian functions to represent one STO ; such a basis set is called the **STO-3G basis set.** In the STO-3G basis set, all AOs are described by a sum of three Gaussian functions. Although this procedure leads to a proliferation of integrals to evaluate, each one is relatively easy. Thus, the overall procedure is quite efficient. However, there are some disadvantages, too, in using GTOs since many GTOs are needed to obtain for atoms the same degree of accuracy as the STOs.

It will be pertinent to define here the so-called **valence state ionization potentials.** Consider the electronic configuration of carbon atom, *viz.*, $1s^2\,\chi_1^1\,\chi_2^1\,\chi_3^1\,2p_z^1$ where χ_i (i=1, 2, 3) are the three triply hybridized orbitals in the sp^2 hybridised state, the hybrids being formed from 2s, 2p_x and 2p_y AOs. Here the carbon atom is said to be promoted to a **valence state** obtained through electronic rearrangement prior to the bond formation. This electronic configuration may be considered to be equivalent to the configuration $1s^2 2s^1 2p_x^1 2p_y^1 2p_z^1$. The valence state ionization potential of the $2p_z$ orbital in the carbon atom is given by the difference in energy between neutral carbon atom in the configuration $1s^2\,2s^1\,2p_x^1\,2p_y^1\,2p_z^1$ and the C^+ ion in the configuration $1s^2\,2s^1\,2p_x^1\,2p_y^1$. Similarly, the valence state ionization potential of the 2s orbital in carbon atom is given by the energy difference between the neutral atom configuration $1s^2\,2s^1\,2p_x^1\,2p_y^1\,2p_z^1$ and the C^+ ion in the configuration $1s^2 2p_x^1 2p_y^1 2p_z^1$. Typical values of the valence state ionization potentials are –13·60 eV (for hydrogen 1s), –21·4 eV (for carbon 2s), –11·4 eV (for carbon 2p) and – 26·0 eV (for nitrogen 2s).

A few remarks are in order for three important terms, *viz.*, correlation energy, electron correlation and configuration interaction, which are often involved in both the Hartree-Fock SCF theory of multielectron atoms and Hartree-Fock-Roothaan SCF theory of polyatomic molecules. It may be recalled that for helium atom, the use of a hydrogenic 1s orbital with variable orbital exponent gives a ground state energy of –77·5 eV, compared with the true value of –79·0 eV. The Hartree-Fock wave function for the helium ground state gives an energy of –77·9 eV which is still in error by 1·1 eV. The energy error of the Hartree-Fock wave function is called the **correlation energy** since it results from the fact that the Hartree Fock wave function neglects the instantaneous correlations in the motions of the electrons. Electrons repel one another and correlate their motions to avoid being close together; this phenomenon is called **electron correlation.**

Let us now consider **configuration interaction.** A method used to improve the Hartree-Fock wave function is configuration interaction. When a Hartree-Fock ground state wave function of an atom or a molecule is calculated, one also obtains expressions for unoccupied excited state orbitals. It is possible to show that the set of functions obtained by making all possible assignments of electrons to the available orbitals is a complete set. Hence, the true wave function of the ground state can be expressed as

$$\psi = \sum_j c_j \psi_{\text{orb}.j} \qquad \ldots(168)$$

where the $\psi_{\text{orb}.j}$s are approximate orbital functions that differ in the assignment of electrons to orbitals. Each $\psi_{\text{orb}.j}$ is a Slater determinant of spin orbitals. The functions $\psi_{\text{orb}.j}$ are called **configuration functions** (or **configurations**). One uses a variation procedure to find the values of the coefficients c_j that minimize the variational integral. This type of calculation is called **configuration interaction.**

A. Hartree-Fock-Roothaan Self-Consistent Field (SCF) Method for Polyatomic Molecules

The Hartree-Fock SCF method for atoms was extended by Roothaan in 1951 to polyatomic molecules. This SCF formulation of the MO theory is based on the many-electron Hamiltonian. (It may be recalled that the HMO theory uses an effective one-electron Hamiltonian which fails to consider electron repulsion energy term such as e^2/r_{ij} adequately). For a π-electron system, the Hamiltonian operator (in a.u.) is given by

$$\hat{H} = \sum_i^{\text{all electrons}} \hat{H}_i(\text{core}) + \frac{1}{2}\sum_{i\neq j}\frac{1}{r_{ij}} \qquad \ldots(169)$$

The first term in Eq. 169 is the attraction energy of the core for the π-electron. This is a one-electron operator since it depends on the coordinates of one electron only and is given by

$$\hat{H}_i(\text{core}) = -\frac{1}{2}\nabla_i^2 - \sum_a^{\text{all nuclei}} Z_a/r_{ia} \qquad \ldots(170)$$

where Z_a is the nuclear charge on nucleus a and r_{ia} is the distance of the ith electron from nucleus a. Each $1/r_{ij}$ term in Eq. 169 involves the coordinates of both electrons simultaneously and cannot be evaluated exactly. We can, however, approximate this term by considering, say, electron 1, subjected to the average potential field of electron 2 occupying the MO, say ψ_i. The average field is given by

$$\int \psi_i^2(2)(1/r_{12})\,d\tau_2$$

Since electrons can be exchanged among MOs, this can be taken care of by including the term

$$\int \psi_i(2)\psi_j(2)(1/r_{12})d\tau_2$$

These two terms are then summed over all the occupied MOs. Thus, the eigenvalue equation to be solved for electron 1 in MO, say, $\psi_j(1)$, is

$$\left[\sum_i^{\text{all electrons}} \hat{H}_i(\text{core}) + \sum^{\text{occupied MOs}} (2\hat{J}_i - \hat{K}_i)\right]\psi_j(1) = \varepsilon_j \psi_j(1) \qquad \ldots(171)$$

where

$$\hat{J}_i\,\psi_j(1) = \left\{\int \psi_i^2(2)(1/r_{12})\,d\tau_2\right\}\psi_j(1)$$

$$\hat{K}_i\,\psi_j(1) = \left\{\int \psi_i(2)\psi_j(2)(1/r_{12})\,d\tau_2\right\}\psi_i(1)$$

$\hat{J}$ and $\hat{K}$ are called the **Coulomb** and **exchange operators.** The Coulomb term is double since each MO is occupied by two electrons. The exchange term, on the other hand, is a single term; it vanishes unless

the MOs ψ_i and ψ_j refer to the same spin. The operator on the L.H.S. of Eq. 171 is called **effective Fock operator,** $\hat{F}$, which thus obeys the eigenvalue equation

$$\hat{F}\,\psi_i = \varepsilon_i\,\psi_i \qquad \ldots(172)$$

In the LCAO–MO approximation, the MOs are given by

$$\psi_i = \sum_j^{\text{All AOs}} c_{ij}\,\phi_j \qquad \ldots(173)$$

where ϕ_js are the AOs. Applying the variation method and minimizing the energy, we obtain the secular determinantal equation :

$$\begin{vmatrix} \alpha_{11}-\varepsilon & \beta_{12}-S_{12}\varepsilon & \beta_{13}-S_{13}\varepsilon & \ldots \\ \beta_{12}-S_{12}\varepsilon & \alpha_{22}-\varepsilon & \beta_{23}-S_{23}\varepsilon & \ldots \\ \ldots & \ldots & \ldots & \ldots \\ \ldots & \ldots & \ldots & \ldots \end{vmatrix} = 0 \qquad \ldots(174)$$

where

$$\left.\begin{aligned} \alpha_i &= F_{ii} \equiv \langle \phi_i \mid \hat{F} \mid \phi_i \rangle \\ \beta_{ij} &= F_{ij} \equiv \langle \phi_i \mid \hat{F} \mid \phi_j \rangle \\ S_{ij} &= \langle \phi_i \mid \phi_j \rangle \end{aligned}\right\} \qquad \ldots(175)$$

Evaluation of the diagonal terms, α_i and the off-diagonal terms, β_{ij}, omitting details, gives

$$\alpha_i = \alpha_i(\text{core}) + \tfrac{1}{2}q_i \langle \phi\phi_i \mid \phi\phi_i \rangle + \sum_{j\neq i} \langle \phi_i\phi_i \mid \phi_j\phi_j \rangle \qquad \ldots(176)$$

$$\beta_{ij} = \beta_{ij}(\text{core}) - \tfrac{1}{2}p_{ij} \langle \phi_i\phi_i \mid \phi_j\phi_j \rangle \qquad \ldots(177)$$

where q_i is the total π-electron density on atom i, p_{ij} is the mobile bond order if i and j are neighbouring atoms linked directly; α_i *(core)* and β_{ij} *(core)* are defined as

$$\alpha_i(\text{core}) = \langle \phi_j \left| \sum_i^{\text{all electrons}} \hat{H}_i(\text{core}) \right| \phi_j \rangle ;\ i = j \qquad \ldots(178)$$

$$\beta_{ij}(\text{core}) = \langle \phi_j \left| \sum_i^{\text{all electrons}} \hat{H}_i(\text{core}) \right| \phi_j \rangle ;\ i \neq j \qquad \ldots(179)$$

$$= 0, \text{ otherwise.} \qquad \ldots(180)$$

We shall now comment on the matrix elements (integrals) in Eqs. 176 and 177. The integral $\langle \phi_i\,\phi_i \mid \phi_i\,\phi_i \rangle$ in Eq. 176 represents electron repulsion between two electrons in the field of the same core; the integral $\langle \phi_i\,\phi_i \mid \phi_j\,\phi_j \rangle$ in Eq. 177 describes electron repulsion between electrons on the neighbouring cores.

Pariser-Parr-Pople Approximation (PPP Approximation). This appoximation, proposed independently, in 1953, by Pariser and Parr (in a joint publication) and by Pople, attempts to evaluate the matrix elements α_i (core), β_{ij} (core) and the one-centre and two-centre electron repulsion integrals of Eqs. 176 and 177. They suggested that

$$\alpha_i(\text{core}) = -I_c \qquad \ldots(181)$$

where I_c is the valence state ionization potential of carbon and that

$$< \phi_c\phi_c \mid \phi_c\phi_c > = I_c - A_c \qquad ...(182)$$

where A_c is the corresponding valence state electron affinity of carbon atom. The resonance integral β_{ij} (core) was assumed to be zero for all orbitals except those on the nearest neighbouring atoms. For the C—C bond in benzene it was estimated to be −2·39 eV. The two-centre integrals, *viz.*, $< \phi_i \phi_i \mid \phi_j \phi_j >$, which depend on the internuclear separation R_{ij}, must follow the following boundary conditions :

$$\left.\begin{aligned} \gamma_{ij} &= \gamma_{ii}, \quad R_{ij} \to 0 \text{ (one - centre integral)} \\ \gamma_{ij} &= e^2/R_{ij}, \quad R_{ij} \to \infty \end{aligned}\right\} \qquad ...(183)$$

where $\gamma_{ij} = < \phi_i \phi_i \mid \phi_j \phi_j >$

Configuration Interaction

In order to calculate molecular properties to a high degree of accuracy, one must usually go beyond the Hartree-Fock-Roothaan SCF method and include electron correlation. This can be done using the configuration interaction (CI). The steps in a CI calculation are : (1) One chooses a set of basis functions $g_1, g_2 \ldots, g_i, \ldots$ (2) Each MO ϕ_j is written as a linear combination of basis functions : $\phi_j = \sum c_i g_i$ where the expansion coefficients c_i are to be determined. This expression for the MOs is substituted into the Hartree-Fock equations $\hat{F}\phi_j = \varepsilon_j \phi_j$ and the SCF interation procedure in carried out to solve for the coefficient c_i which determine the MOs, ϕ_j. The SCF procedure gives expressions for many MOs, some occupied and some unoccupied. The unoccupied MOs are called **virtual orbitals.** The ground state SCF wave function is a Slater determinant with the lowest MO occupied. (3) The molecular wave function ψ is then expressed as a linear combination of the SCF wave functions found in step 2 and functions with one or more electrons placed in virtual orbitals : $\psi = \Sigma_j a_j \psi_{orb.j}$ and the variation method is used to find the coefficients a_j that minimize the variational integral.

If the sum $\Sigma_j\, a_j\, \psi_{orb.j}$ includes functions with all possible assignments of electrons to virtual orbitals (this is called *full* CI) and if the basis set used to expand the MOs is a complete set, then one can prove that the exact wave function will be obtained. In practice, the basis set must be limited in size (and is, therefore, incomplete), and full CI takes far too much computer time to be feasible (except for small molecules and small basis sets).

In practice, it has been formed that the Hartree-Fock-Roothaan SCF-CI calculations with small basis sets do not give highly accurate results for molecular properties and basis sets at least as large as 6-31 G* should be used in CI calculations. (The basis sets (listed in the order of increasing size) include the STO-3G, 3-21G, 3-21G*, 6-31G* and 6-31G** sets where the numbers and symbols are related to the number of basis functions on each atom. STO-3G is a minimal basis set and often gives unreliable results, so this set is essentially obsolete. The 6–31 G* basis set is not a particularly large set and many larger sets have been formed by adding functions to 6–31 G**.)

B. Semi-Empirical and Ab Initio Methods

We have already dealt briefly with the semi-empirical PPP approximation used to evaluate the multicentre integrals occurring in the Hartree-Fock-Roothaan SCF theory. Thus, in **semi-empirical methods** many of the integrals are estimated by appealing to spectroscopic data or physical properties such as ionization energies and using several rules to set certain integrals to zero. In the **ab initio methods,** an attempt is made to calculate all integrals that appear in the secular determinant explicitly and, after using the SCF procedure, to derive the MOs. It is evident that for a given size of computation, semi-empirical methods are applicable to a fairly large molecule whereas the ab initio methods apply to a small-sized molecule.

Extended Hückel Theory (EHT). We recall that in the Hückel molecular orbital (HMO) theory of 1931, the π orbitals in a conjugated π-electron system are treated separately from the σ orbitals and the latter form a rigid framework that determines the shape of the molecule. This assumption is called the

σ – π separability. The EHT, formulated by Hoffmann in 1963, includes both σ and π orbitals and so it is not confined to planar conjugated hydrocarbons. Also, EHT does not ignore overlap but calculates all the overlap integrals explicitly. It employs a one-electron Hamiltonian. In the LCAO-MO approximation, each MO is written as

$$\psi_i = \sum_\nu c_{i,\nu} \phi_\nu \qquad ...(184)$$

where the ϕ_νs are the nonmalized STOs (for the valence electrons) on the ν-th atom in the molecule; the subscript i refers to the MOs and ν to the AOs. On each centre, except hydrogen atom, there is more than one AO. Thus, STOs are the basis set in EHT. Application of the variation method leads to the secular determinant :

$$\begin{vmatrix} H_{11} - \varepsilon & H_{12} - S_{12}\varepsilon & H_{13} - S_{13}\varepsilon & \ldots \\ H_{12} - S_{12}\varepsilon & H_{22} - \varepsilon & H_{23} - S_{23}\varepsilon & \ldots \\ \ldots & \ldots & \ldots & \ldots \end{vmatrix} = 0 \qquad ...(185)$$

The matrix elements $H_{\mu\nu}$ are defined as

$$H_{\mu\nu} = < \phi_\mu | \hat{H} | \phi_\nu > \qquad ...(186)$$

The diagonal matrix elements $H_{\mu\mu}$ (or α_μ) are set equal to the negative of the valence state ionization potential of the appropriate AO. The off-diagonal elements $H_{\mu\nu}$ (corresponding to β and 0 in the HMO theory) are assumed to be proportional to the overlap integral, $S_{\mu\nu}$. A typical expression, proposed by Ballhausen and Gray in 1962, is

$$H_{\mu\nu} = 0{\cdot}5\, [H_{\mu\mu} + H_{\nu\nu}]\, S_{\mu\nu} K \text{ with } K = 1{\cdot}75 \qquad ...(187)$$

The integrals $S_{\mu\nu}$ are calculated using the STOs and the secular determinant (Eq. 20) is then solved for the orbital energies and the coefficients. The total energy is calculated by summing the energies of the occupied MOs by taking into consideration their occupancy numbers. For a closed shell, for instance, the total electronic energy is given by

$$E_{EHT} = 2\sum_i^{occ.} \varepsilon_i \qquad ...(188)$$

The EHT method was also independently proposed by Wolfsberg and Helmholz. The Hückel and extended Hückel methods are quite crude in that they use a very simplified Hamiltonian that contains no inter-electron repulsion terms. Several improved semi-empirical theories have been developed that include some of the electron repulsion terms in the Hamiltonian operator and that apply to both conjugated and non-conjugated molecules. The most widely used are the methods AM1 and PM3.

The AM1 (**Austin Model 1**) method (named after the University of Texas at Austin where the method was developed) was devised by M.J.S. Dewar and coworkers in 1985. AM1 treats only the valence electrons. It solves equations resembling the Hartree-Fock equations $\hat{F}\phi_i = \varepsilon_i \phi_i$ (where $\hat{F}$ is the Fock operator) to find the SCF MOs but since an approximate Hamiltonian is used and rather drastic approximations are made for many of the integrals that occur, the MOs found are only rough approximations to the Hartree-Fock-Roothaan MOs. By choosing reasonable values of the parameters, the AM1 method gives reasonable values of the heats of atomization of many compounds. PM3 (parametric method 3) is similar to AM1 except that it uses different sets of parameters. The molecular geometries and molecular dissociation energies calculated using these methods are not very accurate though they do give satisfactory bond lengths and bond angles.

Current versions of EHT are easy to implement with a computer and give useful qualitative pictures of MOs in molecules with known structures. Unfortunately, it cannot predict the correct three-dimensional structures of even simple molecules. Thus, for instance, EHT predicts that linear H_2O molecule has lower energy than angular H_2O molecule.

We shall conclude the discussion on EHT by briefly commenting on the so-called **population analysis.** For a two-atom MO of the form $\psi = c_1\phi_1 + c_2\phi_2$ (where ϕ_1 and ϕ_2 are the AOs centered on atoms 1 and 2), the probability density for an electron that occupies this orbital is given by $\psi^2 = c_1^2\phi_1^2 + c_2^2\phi_2^2 + 2c_1c_2\phi_1\phi_2$. The integral of this probability density over all space gives the total probability of finding the electron in the molecule :

$$1 = c_1^2 + c_2^2 + 2c_1c_2S_{12} \qquad ...(189)$$

This expression suggests that the total probability of finding the electron in the molecule is the sum of the probability of finding it on orbital 1 (the term c_1^2), the probability of finding it on orbital 2 (the term c_2^2) and the probability that it is in the overlap region between the two atoms (the term $2c_1c_2S_{12}$). The last term is called the **overlap population.** This kind of apportioning of the population is called the **Mulliken Population Analysis (MPA),** after R. S. Mulliken who suggested it in 1955. In general, for an MO expressed as a linear combination of AOs with coefficients c_i, the **atomic populations,** ρ_i, are given by

$$\rho_i = c_i^2 \qquad ...(190)$$

and the overlap populations are given by

$$\rho_{ij} = 2\, c_i c_j\, S_{ij} \qquad ...(191)$$

If two electrons occupy an orbital, then these contributions should be doubled. The overall populations are the sums of these quantities for all the occupied MOs in the molecule multiplied by the number of electrons in each MO. If we apportion one-half of each overlap population to the neighbouring atoms, we obtain the **gross orbital population.**

Semi-Empirical Self-Consistent-Field (SCF) Theory. The semi-empirical SCF theory makes use of the Roothaan method to obtain the SCF MOs for all valence electrons. In 1965, Pople, Santry and Segal introduced the **zero differential overlap (ZDO)** approximation, according to which if ϕ_μ and ϕ_ν are two AOs centered either on the two nuclei or on the same nucleus, then $\phi_\mu\phi_\nu = 0$ wherever they occur. Other elements of the Fock operator were determined by appeal to experimental data. The ZDO approximation is more drastic than the neglect of the overlap integral ($S_{\mu\nu}=0$). This seminal 1965 paper of Pople, inspired other semi-empirical theories such as **complete neglect of differential overlap (CNDO), intermediate neglect of differential overlap (INDO)** and **modified intermediate neglect of differential overlap (MINDO)** (as proposed by M.J.S. Dewar and coworkers). Let us illustrate CNDO by reference to the Fock matrix which has **multicentre integrals** of the form,

$$\langle \phi_a\, \phi_b \mid \phi_c\, \phi_d \rangle = \int \phi_a(1)\phi_b(1)(1/r_{12})\phi_c(2)\phi_d(2)\, d\tau_1\, d\tau_2 \qquad ...(192)$$

where ϕ_a, ϕ_b, ϕ_c and ϕ_d are AOs which, in general, are centered on different nuclei. We can appreciate that, if there are several dozen AOs used to construct the MOs, then there will be tens of thousands of integrals to evaluate. In the CNDO approximation all integrals are set equal to zero unless ϕ_a and ϕ_b are the same AOs centred on the same nucleus, and likewise for ϕ_c and ϕ_d. The surviving integrals are then adjusted until the energy levels are in good agreement with experiment. The CNDO procedure and its descendants (INDO, MINDO, etc.) are now readily available in commercial software packages and can be used with very little detailed knowledge of their mode of calculation. The packages also have sophisticated graphical output procedures which enable one to analyse the shapes of orbitals and the electric charge distribution in molecules. Commercial software packages are also available for *ab initio* calculations to evaluate as efficiently as possible thousands of integrals. Use of GTOs in *ab initio* methods plays a very important role, as already stated. We must emphasize that an *ab initio* calculations uses the true molecular Hamiltonian and does not use empirical data in the calculations. A semi-empirical method uses a simpler Hamiltonian than the true one; it also uses empirical data to assign values to some of the integrals that occur in the calculations and neglects some of the integrals.

Further Remarks on Computer Programs. As already stated, Gaussian is the most widely used program for *ab initio* and density functional theory (DFT) calculations. The first version of Gaussian,

developed by Pople and coworkers, was released in 1970. Its updated versions Gaussian 94 and Gaussian 98 were released in 1994 and 1998, respectively. Some other quantum-chemistry programs are the free program GAMESS, Q-Chem, Jaguar, SPARTAN, HyperChem, MOPAC 2000 and AMPAC. These are available on World Wide Web (www). Gaussian exists in versions for UNIX workstations and Windows personal computers. The free Windows program Arguslab does Hartree-Fock, AM1 and PM3 calculations. Computer programs such as MATHEMATICA and MAPLE are used for less demanding mathematical calculations. Most computer programs in use today can be obtained from the Quantum Chemistry Program Exchange (QCPE), Chemistry department, Indiana University, Bloomington, U.S.A. We may also mention here that though the two-electron integrals can be evaluated by a variety of procedures, one can save a great deal of labour using general formulas found in several different compilations frequently used by quantum chemists. A few of these compilations are :

Miller, J., J.M. Gerhausen and F.A. Matsen, *Quantum Chemistry Integrals and Tables*, University of Texas Press, Austin (U.S.A.), 1959.

Kotani, M., *et al*, *Tables of Molecular Integrals*, Maruzen, Tokyo (Japan), 1963.

Preuss, H., *Integraltafeln zur Quantenchemie*, 4 vols; Springer-Verlag, Berlin, 1956.

Abramowitz, M., and I.A. Stegun (ed)., *Handbook of Mathematical Functions*, Dover Publications, New York, 1963. (P.W. Atkins has remarked that this amazing book is "an ideal desert-island book for shipwrecked quantum chemists.")

C. Density-Functional Theory (DFT). In the last decade of the twentieth century, **DFT** attained great prominence in quantum chemistry research. The enthusiasts of DFT—and there are a host of them—claim that this theory will be *the* theory of chemical bonding in the twenty-first century. What is DFT ? What is so exciting about it ? Or rather, what is *not* so very exciting about it ? We shall deal briefly with this topic here.

In DFT we do not calculate the molecular wave function. Instead, we work with electron probability density $\rho(x, y, z)$. DFT is based on the **Hohenberg-Kohn theorem,** proposed in 1964 by P. Hohenberg and W. Kohn. This theorem states that *the energy and all other properties of a ground state molecule are uniquely determined by the ground state electron probability density.* This is expressed by saying that the ground state electronic energy E_{gs} is a *functional* of ρ. This is written as $E_{gs}=E_{gs}[\rho(x, y, z)]$ or simply as

$$E_{gs} = E_{gs}[\rho] \qquad ...(193)$$

where the square brackets denote a functional relation. (In mathematics a function of a function is called a **functional**.)

Kohn-Sham Method. Unfortunately, the functional $E_{gs}[\rho]$ in Eq. 28 is unknown, so the Hohenberg-Kohn theorem does not tell us *how* to calculate E_{gs} from ρ or how to find ρ without first finding the ground state molecular electronic function. In 1965, W. Kohn and L.J. Sham devised a practical method to calculate E_{gs} from ρ. Of course, the Kohn-Sham equations do contain an unknown functional, but using a combination of physical insight and guesswork, theorists have developed approximations to this functional that allow accurate calculations of molecular properties thereby turning DFT into a landmark in quantum theory.

Kohn-Sham method uses a **fictitious reference system** (usually denoted by the subscript s) that contains the same number of electrons (n) as the molecule under study, but differs from the molecule in that (a) the electrons in the reference system do not exert forces on one another, (b) each electron i ($i=1, 2, \ldots, n$) in the reference system experiences a potential energy $V_s(x_i, y_i, z_i)$, where V_s is the same function for each electron and is such as to make the electron probability density ρ_s in the reference system exactly equal to the ground state electron probability density ρ in the real molecule : $\rho=\rho_s$. The actual form of V_s is not known. (In the real molecule, the electrons experience attractions to the nuclei but these are not present in the reference system.)

Because the electrons in the reference system do not interact with one another, the Hamiltonian $\hat{H}_s$ of the reference system is the sum of the Hamiltonians of the individual electrons :

$$\hat{H}_s = -\frac{\hbar^2}{2m_e}\sum_{i=1}^{n}\nabla_i^2 + \sum_{i=1}^{n}V_s(x_i,y_i,z_i) \equiv \sum_{i=1}^{n}\hat{h}_i^{KS}$$

where $$\hat{h}_i^{KS} = -\frac{\hbar^2}{2m_e}\nabla_i^2 + V_s(x_i,y_i,z_i) \quad ...(194)$$

In Eq. 194, $\hat{h}_i^{KS}$ is the one-electron Kohn-Sham Hamiltonian. Since the reference system *s* consists of non-interacting particles, its ground state wave function, including both the spatial and spin wave functions, is a Slater determinant of spin-orbitals, one for each electron. Each spin orbital is the product of a spatial orbital θ_i^{KS} and a spin function (either α or β). The Kohn-Sham orbitals θ_i^{KS} are eigenfunctions of θ_i^{KS} :

$$\hat{h}_i^{KS}\theta_i^{KS} = \varepsilon_i^{KS}\theta_i^{KS} \quad ...(195)$$

where ε_i^{KS} is the Kohn-Sham orbital energy of θ_i^{KS}. Each Kohn-Sham orbital holds two electrons of opposite sign. By definition,

$$\rho = \rho_s = \sum_{i=1}^{n}|\theta_i^{KS}|^2 \quad ...(196)$$

Kohn-Sham Energy Expression. Next we need the energy expression for the molecule's ground state electronic energy E_e. (The reference system and the molecule have the same probability density function but they do not have the same ground-state energy.) Kohn and Sham derived the following exact equation for E_e :

$$E_e = < K_{e,s} > + < V_{Ne} > + J + V_{NN} + E_{xc}[\rho] \quad ...(197)$$

In Eq. 197, $< K_{e,s} >$ is the average electronic kinetic energy in the reference system; $< V_{Ne} >$ is the average potential energy of attractions between the electrons and nuclei in the molecule ; J is the classical energy of electrical repulsion that arises between the infinitesimal charge elements of a hypothetical smeared-out electron charge cloud whose probability density is $\rho(x, y, z)$. It can be calculated from $\rho(x, y, z)$. $< K_{es} >$ and $< V_{Ne} >$ can be calculated from the Kohn-Sham orbitals of the reference system. (We are not interested here in the explicit formulas for the calculation of these two quantities.) The internuclear repulsion potential energy, V_{NN}, is a constant that depends on the nuclear charges and the internuclear distances and is calculated from the molecular geometery at which the calculation is being made. $E_{xc}[\rho]$, called the **exchange-correlation energy functional**, is a functional of ρ that is defined as

$$E_{xc}[\rho] \equiv < K_e > - < K_{es} > + < V_{ee} > - J \quad ...(198)$$

$E_{xc}[\rho]$ is the sum of two differences : (*a*) the difference $< K_e > - < K_{es} >$ between the average electronic kinetic energy in the molecule and in the reference system and (*b*) the difference $< V_{ee} > - J$ between the average potential energy of interelectronic repulsion $< V_{ee} >$ in the molecule and the classical charge-cloud self-repulsion energy J. The values of $< K_e >$ and $< K_{es} >$ are expected to be similar to each other; also the values of $< V_{ee} >$ and J are similar. Hence, the two differences in Eq. 198 are relatively small quantities. These two differences are not zero because the Pauli exclusion principle requirement that the wave function be antisymmetric with respect to exchange, produces exchange effects on the energy and because the instantaneous correlation between the motions of the electrons produces *correlation* effects on the energy.

Eq. 197 is an exact expression for the molecular electronic energy. However, the true mathematical expression for the functional E_{xc} is not known. The terms $E_{xc}[\rho]$ can be found if we know ρ and if we know what the functional E_{xc} is. If Eq. 198 is substituted into Eq. 197, we obtain

$$E_e = < K_e > + < V_{Ne} > + < V_{ee} > + V_{NN} \quad ...(199)$$

an equation that follows from the Born-Oppenheimer approximation, *viz.*, $\hat{H}_e = \hat{K}_e + \hat{V}_{Ne} + \hat{V}_{ee} + \hat{V}_{NN}$ by taking average values of each side of this approximation.

Kohn-Sham Orbitals. As we have noted in the discussion following Eq. 197, the quantities $< K_{es} >$, $< V_{Ne} >$, J and E_{xc} can all be calculated if we know the Kohn-Sham orbitals θ_i^{KS}. V_{NN} is easily calculated from the location of the nuclei. Thus, if the Kohn-Sham orbitals are known, E_e can be calculated. Hohenberg and Kohn proved that the true ground state electron probability ρ minimizes the functional $E_e[\rho]$ for the energy. Since ρ is determined by the KS orbitals θ_i^{KS} (Eq. 196), one can vary the orbitals θ_i^{KS} so as to minimize E_e in Eq. 197.

Parr and Yang have shown that the orthonormal (*i.e.*, orthogonal and normalized) KS orbitals that minimize E_e satisfy the eigenvalue equation Eq. 195 where the one-electron KS Hamiltonian $\hat{h}_i^{KS}$ is given by the sum of the following four one-electron terms : (*a*) The one-electron energy operator $-\left(\frac{\hbar^2}{2m_e}\right)\nabla_i^{KS}$; (*b*) The potential energy $-\sum\alpha Z\alpha e^2/4\pi\varepsilon_0 r_{1\alpha}$ of attraction between electron 1 and the nuclei ; (*c*) the potential energy of repulsion between electron 1 and a hypothetical charge cloud of electron density ρ due to smeared-out electrons; (*d*) an exchange-correlation potential $V_{xc}(x_1, y_1, z_1)$ whose form is discussed below. (The sum of terms *b*, *c* and *d* equals what is called V_s in Eq. 194).

It is pertinent to mention here that the first three terms in $\hat{h}_i^{KS}$ are, in fact, identical to the first three terms in the Fock operator $\hat{F}$ of the Hartree-Fock equations $\hat{F}\phi_i = \varepsilon_i\phi_i$. The only difference between the Hartree-Fock equations for the Hartree-Fock orbitals and the Kohn-Sham equations [Eq. 195] is that the exchange operator (term *d*) of the Hartree-Fock equations is replaced by the **exchange-correlation potential,** V_{xc}. The expression for V_{xc} is found to be

$$V_{xc}(x, y, z) = \frac{\delta E_{xc}[\rho]}{\delta\rho} \quad ...(200)$$

where the notation $\delta E_{xc}/\delta\rho$ indicates the **functional derivative** of the functional E_{xc} that occurs in the energy equation 197. The fourth term (*d*) in the Fock operator $\hat{F}$ of the Hartree-Fock equations allows for the effects of electron exchange (the Pauli principle) but does not allow for electron correlation. The fourth term V_{xc} in the KS operator $\hat{h}_i^{KS}$ allows for both exchange and correlation.

DFT Calculational Procedure. If we assume that a reasonable approximation for the exchange-correlation energy functional $E_{xc}[\rho]$ exists, then we proceed as follows : We start with an initial guess for the molecule's electron density $\rho(x, y, z)$ found by superimposing calculated electron densities of the individual atoms at the nuclear geometry chosen for the calculation. From the initial ρ, we find $E_{xc}[\rho]$ and then find its functional derivative to obtain an initial estimate of V_{xc} (Eq. 200) . This V_{xc} is used in the Kohn-Sham equations (Eq. 195) to solve for initial estimates of the orbitals θ_i^{KS}. (As is done in solving the Hartree-Fock equations, we usually expand the unknown orbitals using a basis set. Many of the same basis sets used for the Hartree-Fock calculations are also used in the Kohn-Sham calculations.) The initial orbitals θ_i^{KS} are used to calculate an improved probability density ρ from Eq. 196. This improved ρ is used to find an improved $E_{xc}[\rho]$ from which an improved V_{xc} is found. The improved V_{xc}

is used in the KS equations (Eq. 195) to find improved *KS* orbitals. The iterations are continued until no further significant change is found from one cycle to the next. The molecular energy is then found from Eq. 197 using the final orbitals and ρ.

Exchange-Correlation Energy Functional $E_{xc}[\rho]$. Kohn and Sham proposed a certain form for $E_{xc}[\rho]$, called the **local (spin) density approximation (LDA or LSDA)** that theory shows to be accurate when the electron density ρ varies slowly with position. In a molecule, ρ does not vary very slowly with position. It is found that LSDA KS DFT calculations give satisfactory results for molecular geometries, dipole moments and vibrational frequencies but poor results for atomization energies.

It is convenient to split E_{xc} into an exchange part and a correlation part :

$$E_{xc}[\rho] = E_x[\rho] + E_c[\rho] \qquad ...(201)$$

This is a good approximation for $E_{xc}[\rho]$ suggested by Kohn and Sham. A better approximation used in the late 1980s was the so-called **generalized-gradient approximation (GGA)**, in which E_{xc} is expressed as an integral of a certain function of ρ and the derivatives $\partial\rho/\partial x$, $\partial\rho/\partial y$, $\partial\rho/\partial z$. (These derivatives are called the *gradient* of ρ). Another functional called a **hybrid functional** has also been used ; it is of the form $E_{xc}^{GGA} + aE_x^{HF}$ where E_x^{HF} has the form of the expression used for the exchange energy in Hartree-Fock calculations but is evaluated using the KS rather than Hartree-Fock orbitals, and a is an empirical parameter whose value was chosen to optimize the performance of E_{xc} in calculations on a series of molecules. The most widely used functional in DFT calculations done in the period 1995-2000 was the hybrid functional called B3LYP where B indicates that it includes a term for E_x^{GGA} devised by Becke, LYP indicates a term for E_c^{GGA} devised by Lee, Yang and Parr, and 3 indicates that it contains three empirical parameters whose values were chosen to optimize the performance.

The time needed to do a DFT calculation is roughly the same as the time needed to do a Hartree-Fock calculation on the same molecule with the same basis set. In practice, since the true functional $E_{xc}[\rho]$ is unknown, DFT calculations yield approximate results. The quality of the result depends on how good the E_{xc} used in the calculation is. With present-day E_{xc} functionals, DFT calculations yield substantially more accurate results than Hartree-Fock calculations. DFT calculations should not be done with basis sets smaller than 6–31*G**. Although the KS orbitals are calculated for the fictitious reference system (and not for the real molecule), one finds that these orbitals closely resemble the Hartree-Fock SCF MOs calculated for the real molecule.

Despite its many successes, DFT does have some drawbacks. DFT is basically a ground state theory. Researchers are currently working to extend it to excited states. In DFT, the performance of a given functional cannot be predicted and one must try it out on a variety of molecules and properties to assess its performance. There is no systematic way in DFT to devise better functionals. The currently available functionals do not give good accuracy when dealing with van der Waals intermolecular interactions, nor can they match the performance of very high-level *ab initio* methods. For more details on DFT and on quantum chemistry, the following books should be referred :

TIME-DEPENDENT PERTURBATION THEORY (TDPT)

Time-dependent perturbation theory (TDPT) is of great importance in quantum mechanics. It is concerned with the solution of the time-dependent Schrödinger equation (TDSE) even as the time-independent perturbation theory (TIPT) is concerned with the approximate solution of the time-independent

Schrödinger equation (TISE). The transition probabilities between the stationary state energy levels, and thus the selection rules for spectral transitions, are derived from TDPT. When a system is isolated and the Hamiltonian is independent of time, the energy eigenstates are true stationary states. If the system initially is in a particular state ψ_n, which is an eigenstate (eigenfunction) of the unperturbed time-independent Hamiltonian $H^{(0)}$, it will stay there for all time. The time-dependence of ψ_n is of the form

$$\psi_n(t) = \psi_n(0) \exp(-iE_nt/\hbar) \qquad ...(202)$$

where E_n is the energy of the state n. If however, the Hamiltonian is time-dependent, the energy is no longer a constant of motion. In that case, the knowledge of the behaviour of the system is obtained by solving the TDSE

$$i\hbar\frac{\partial}{\partial t}\psi = \hat{H}\psi \qquad ...(203)$$

We assume that the Hamiltonian of the system can be divided into two parts :

$$\hat{H} = \hat{H}^{(0)}(r) + \hat{V}(r,t) \qquad ...(204)$$

where $\hat{H}^{(0)}$ is the unperturbed time-independent Hamiltonian whose wave functions describe the stationary states of the unperturbed system ; $\hat{V}(r,t)$ is a very small perturbation that depends on both space and time variables such that

$$|H^{(0)}(r)| >> |\hat{V}(r,t)| \qquad ...(205)$$

Since the total Hamiltonian $\hat{H}(r,t)$ is time-dependent, the energy cannot be conserved, so that there are no stationary states. Let ψ_n denote the set of eigenfunctions (eigenkets) of $\hat{H}^{(0)}$:

$$\hat{H}^{(0)}\psi_n = E_n\psi_n = \hbar\omega\psi_n \qquad ...(206)$$

where E_n ($= \hbar\omega_n$) represents the corresponding energy eigenvalues. The wave function corresponding to the actual state $\Psi(t)$ can be expanded in terms of ψ_n :

$$\Psi(t) = \sum_n b_n(t)\psi_n(r) \qquad ...(207)$$

where $|b_n(t)|^2$ can be interpreted as the probability of finding the system in the state n at time t. For the sake of convenience, we write

$$b_n(t) = a_n(t)e^{-i\omega_n t}$$

so that

$$\Psi(t) = \sum_n a_n(t)\,e^{-i\omega_n t}\psi_n(r) \qquad ...(208)$$

Obviously, $|a_n(t)|^2$ will also represent the probability of finding the system in the state n at time t. Our objective is to develop a perturbation theory for the calculation of $a_n(t)$ for a given $V(t)$. (We shall write $V(r, t)$ as $V(t)$ and $H^{(0)}(r)$ as $\hat{H}^{(0)}$ for the sake of convenience).

From Eqs. 203, 204 and 208, we have

$$i\hbar\frac{\partial}{\partial t}\Psi(t) = (\hat{H}^{(0)} + \hat{V}(t))\Psi(t)$$

$$= (\hat{H}^{(0)} + \hat{V}(t))\sum_n a_n(t)e^{-i\omega_n t}\psi_n(r) = \sum_n (E_n + V)a_n(t)\psi_n(r)e^{-i\omega_n t} \qquad ...(209)$$

where in the last step we have used Eq. 208. Using Eq. 209, the left-hand side of Eq. 209 becomes

$$i\hbar\frac{\partial}{\partial t}\Psi(t) = i\hbar\frac{\partial}{\partial t}\sum_n a_n(t)\,e^{-i\omega_n t}\psi_n = i\hbar\sum_n[\dot{a}_n - i\omega_n a_n]e^{-i\omega_n t}\psi_n \quad ...(210)$$

where the dot over a refers to differentiation with respect to time, t.

Thus, we have

$$i\hbar\sum_n[\dot{a}_n - i\omega_n a_n]e^{-i\omega_n t}\psi_n = \sum_n(E_n + V)a_n(t)\,e^{-i\omega_n t}\psi_n \quad ...(211)$$

where the second term on the left hand side cancels the first term on the right hand side. Multiplying the left hand side by ψ_m^* and remembering the orthonormality relation

$$\int\psi_m^*\psi_n d\tau = <m|n> = \delta_{mn} \quad ...(212)$$

where δ_{mn} is the Kronecker delta, we get

$$i\hbar\frac{da_m}{dt} = \sum_n a_n(t)V_{mn}(t)\exp(i\omega_{mn}t) \quad ...(213)$$

where

$$\omega_{mn} = \omega_m - \omega_n = (E_m - E_n)/\hbar \quad ...(214)$$

$$V_{mn}(t) = \int\psi_m^* V(t)\psi_n d\tau = <m|V|n> \quad ...(215)$$

Assume that at time t, the amplitudes have not changed very much from their values at $t = 0$, *i.e.*, we replace $a_n(t)$ by $a_n(0)$ on the right hand side of Eq. 213. We can then integrate Eq. 213 to give

$$i\hbar\,[a_m(t) - a_m(0) = \sum_n a_n(0)\int_0^t V_{mn}\exp(i\omega_{mn}t)dt \quad ...(216)$$

We can apply this to the case where we know that the system is in a particular state i at $t = 0$. Thus,

$$a_m(0) = 1 \text{ for } m = i \quad ...(217)$$
$$= 0 \qquad \text{for } m \neq i$$

so that

$$a_f(t) = \frac{1}{i\hbar}\int_i^t V_{fi}(t)\exp(i\omega_{fi}t)dt \quad (f \neq i) \quad ...(218)$$

Eq. 218 gives the probability amplitudes at later times of states other than the initial one.

Let us now suppose that at $t = 0$, the perturbation is switched on and for $t > 0$, is independent of time; then,

$$a_f(t) = \frac{1}{i\hbar}V_{fi}\int_0^t\exp(i\omega_{fi}t)dt = -V_{fi}\frac{\exp(i\omega_{fi}t)-1}{\hbar\omega_{fi}} \quad ...(219)$$

Thus, the probability for reaching the state f (at time t) is given by

$$P_f(t) = |a_f(t)|^2 = |V_{fi}|^2\frac{1}{\hbar^2}\frac{\sin^2(\omega_{fi}t/2)}{(\omega_{fi}/2)^2} \quad ...(220)$$

We rewrite Eq. 220 in terms of E_f and E_i :

$$P_f(t) = |V_{fi}|^2\left[\frac{\sin(E_f - E_i)t/2\hbar}{(E_f - E_i)/2}\right]^2 \quad ...(221)$$

Fig. 33 shows the behaviour of $P_f(t)$ as a function of E_f.

We note the following :

(i) The perturbation theory result, *viz.* Eq. 221, is valid only when $P_f(t) << 1$.

(ii) As long as t is small enough such that

$$(E_f - E_i)(t/2\hbar) << 1 \quad ...(222)$$

the quantity $P_f(t)$ is proportional to t^2 for all values of E_f. In fact

$$P_f(t) \approx |V_{fi}|^2(t^2/\hbar^2) \quad ...(223)$$

(iii) $\lim_{E_f \to E_i} P_f(t) = |V_{fi}|^2(t^2/\hbar^2)$ ...(224)

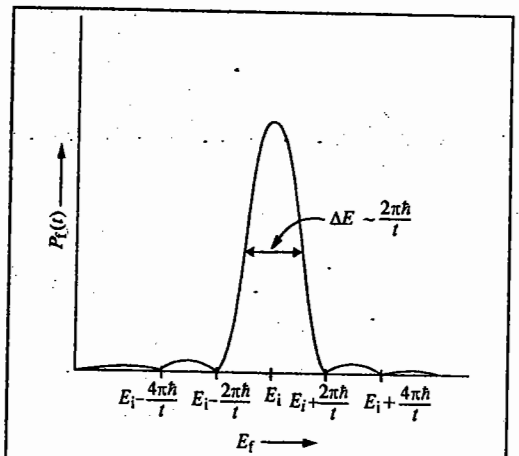

Fig. 33. The variation of $P_f(t)$ [$= |V_{fi}|^2 \sin(E_f - E_i)t/2\hbar \div \{(E_f - E_i)/2\}^2$] as a function of E_f.
Notice that the function is peaked at $E_f = E_i$ with a width $\Delta E \sim \hbar/t$.

Eq. 221 represents the probability of transition to one particular state ψ_f. We are, in fact, interested in transitions to a group of closely spaced states. Thus, the probability of transition to any one of the states is given by

$$w = \int P_f(t)\rho_f(E_f)dE_f, \quad ...(225)$$

where $\rho_f(E_f)\,dE_f$ represents the number of final states in the energy interval dE_f. The **density of states (DOS)** is usually a very smoothly varying function and since $P_f(t)$ is very sharply peaked around $E_f \approx E_i$, we may write

$$w \approx \rho_f(E_i)\int_{\Delta E}P_f(t)dE_f \quad ...(226)$$

where ΔE represents the central peak. We may now replace the limits of integration by $-\infty$ and $+\infty$ to obtain

$$w \approx \rho_f(E_i)|V|^2\int_{-\infty}^{+\infty}\left[\frac{\sin(E_f - E_i)t/2\hbar}{(E_f - E_i)/2}\right]^2 dE_f \approx \rho_f(E_i)\frac{2t}{\hbar}|V|^2\int_{-\infty}^{+\infty}\frac{\sin^2\xi}{\xi^2}d\xi$$

or

$$w \approx \frac{2\pi}{\hbar}|V_{fi}|^2\rho_f(E_i)t \quad ...(227)$$

The transition probability per unit time is given by

$$\Gamma = \frac{dw}{dt} = \frac{2\pi}{\hbar}|V_{fi}|^2\rho_f(E_i) \quad ...(228)$$

which is usually referred to as **Fermi's golden rule.** We may mention here that in carrying out the integration of Eq. 227, we have assumed that t is large enough so that the function $P_f(t)$ is very sharply peaked about $E_f = E_i$ (so that ρ_f can be taken outside the integral). We shall not discuss here the applications of TDPT; these are available in standard texts on quantum mechanics.

In his marvellous book, *Quanta : A Handbook of Concepts*, 2nd edn; P.W. Atkins writes (p.2), "Scientific disciplines collect acronyms like combs collect hairs, and quantum chemistry is no exception". For an uptodate account of these acronyms and software packages for electronic structure calculations the reader is referred to P. Atkins and R. Friedman, *Molecular Quantum Machanics*, 4th edition, and to I.N. Levine, *Quantum Chemistry*, 6th edition. Here the researcher will learn why theoreticians are obsessed with molecules. Incidentally, quantum chemists affectionately refer to Mulliken, the pioneer of MOT, as "Mr. Molecule".

I. Review Questions

1. What is molecular orbital theory ? Discuss it mathematically, leading to the derivation of the secular equation.
2. Outline the solution of the Schrödinger equation for H_2^+ ion. Sketch the BMO and ABMO and the corresponding electron density on the bond axis.
3. Explain valence bond theory. How would you determine the normalized valence bond eigenfunctions of H_2 molecule?
4. What is hybridisation ? Explain showing sp, sp^2, sp^3, dsp^2 and d^2sp^3 hybridization.
5. Define the terms resonance, resonance hybrid and resonance energy.
6. What is Walsh diagram ? Illustrate giving an example.
7. Set up and solve the Hückel secular equation for the cyclopropenyl system and show the results on an M.O. diagram. Also, calculate the resonance energy.
8. Repeat the above problem for 1, 3-butadiene.
9. Repeat the above problem for benzene.
10. Outline the Hartee-Fock-Roothaan SCF theory of polyatomic molecules.
11. What is the PPP approximation in MOT ?
12. Outline the salient features of the extended Hückel theory.
13. Discuss the Kohn-Sham treatment of density functional theory (DFT). What are its limitations ?
14. Discuss the application of the Hellmann-Feynman theorem to chemical bonding.
15. Discuss the basic features of TDPT.

CHAPTER 4

GROUP THEORY–I. BASIC CONCEPTS

Symmetry is a very fascinating phenomenon in nature. It is found in geometrical figures such as a cube, a sphere, an equilateral triangle, a rectangle, a square, a regular pentagon, a regular hexagon, etc. Its importance was recognized by eminent Greek philosophers Pythagoras and Plato. However, in this chapter we shall be concerned with the symmetry found in molecules and solids. Mathematical study of symmetry is called **Group theory**. Its foundations were laid in the 19th century by the French mathematician E. Galois and the European mathematicians Jordan, Frobenius, Sylvester, Sylow, Cayley, Lie and Abel. In the 20th century, applications of group theory to physics and chemistry were pioneered by H. Weyl and E.P. Wigner, the Hungarian-American mathematical physicist. Murray Gell-Mann, the American theoretical physicist, was awarded the 1969 Physics Nobel Prize for applying symmetry to the classification of elementary particles and the postulation of quarks which are the constituents of hadrons. In the words of P.W. Atkins, "symmetry is the quantification of beauty."

Symmetry Elements and Symmetry Operations

Symmetry Element. A symmetry element is a geometrical entity such as a point, a line or a plane about which a symmetry operation is performed.

Symmetry Operation. A symmetry operation is the movement of a molecule about the symmetry element in such a manner that the resulting configuration of the molecule is indistinguishable from the original. The molecule may assume an *equivalent configuration* or an *identical configuration*.

There are five types of symmetry elements : E, C_n, σ, S_n and i. E is called the identity; C_n is the n-fold proper axis of rotation; σ is the plane of symmetry; S_n is the n-fold improper axis of rotation and i is the centre of symmetry (or the inversion centre). These symmetry elements and the corresponding symmetry operations are listed in Table 1.

TABLE 1

Symmetry Elements and Symmetry Operations

Symmetry Element	Symmetry Operation
1. Identity (E)	The operation leaves the molecule unchanged.
2. Proper axis of rotation (C_n)	Rotation by an angle $\theta = 2\pi/n$ about the axis.
3. Plane of symmetry (σ)	Reflection in the plane.
4. Improper axis of rotation or rotation-reflection axis, S_n	Rotation about the axis followed by reflection in a plane perpendicular to the axis.
5. Inversion centre or centre of symmetry (i)	Inversion of all atoms in the molecule through the inversion centre.

1. Proper Axis of Rotation (C_n). A molecule is said to possess a proper axis of rotation of order n, C_n, if rotation about the axis by an angle $\theta = 2\pi/n$ leaves the molecule in a configuration which is indistinguishable from the original one. Consider, for instance, BF_3 molecule in which there is a C_3 axis, *i.e.*, an axis of order 3, which is perpendicular to the plane containing all the atoms and passing through the boron atom (Fig. 1).

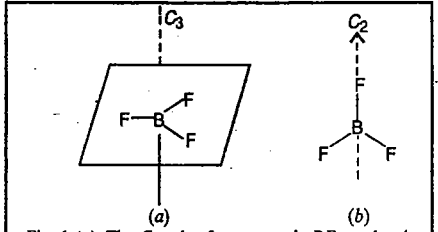

Fig. 1 (*a*) The C_3 axis of symmetry in BF_3 molecule. (*b*) The C_2 axis of symmetry is BF_3 molecule.

The BF_3 molecule also possesses three C_2 axes of symmetry in addition to the C_3 axis. One such axis is shown in Fig. 1(*b*). The C_3 axis is called the *principal axis*. In general, if a molecule possesses C_n axes of different orders, the axis of the highest order is known as the *principal axis*. An H_2O molecule has one two-fold axis C_2 whereas an NH_3 molecule has one three-fold axis C_3 (*i.e.*, rotation axis of order 3), as shown in Figs. 2 (*a*) and (*b*).

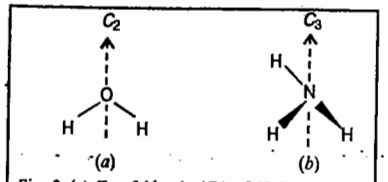

Fig. 2 (*a*) Two-fold axis (C_2) of H_2O molecule. (*b*) Three-fold axis (C_3) of NH_3 molecule

Note that there is only one two-fold rotation associated with a C_2 axis because clockwise and anticlockwise rotations are identical. However, with a three-fold axis C_3, two symmetry operations are associated, one being 120° rotation in a clockwise direction and the other 120° rotation in a counterclockwise sense.

The principal axis of benzene molecule is the six-fold axis, C_6, perpendicular to the regular hexagonal ring (Fig. 3).

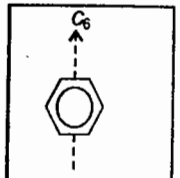

Fig. 3. The 6-fold axis C_6 in benzene.

A sphere possesses an infinite number of symmetry axes (along any diameter) of all possible integral values of *n*.

2. Plane of Symmetry (σ). A molecule possesses a plane of symmetry if reflection through the plane leaves the molecule unchanged. For instance, BF_3 molecule possesses two planes of symmetry, the *vertical plane* (σ_v) and the *horizontal plane* (σ_h). The σ_v plane contains the highest-order rotation axis, *i.e.*, the C_3 axis; σ_h is perpendicular to the C_3 axis (Fig. 4).

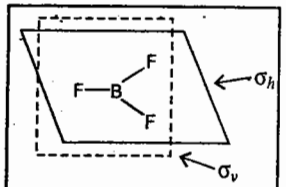

Fig. 4. The vertical and horizontal planes in BF_3 molecule.

Then there is the *dihedral plane* σ_d, which is a vertical plane that bisects the angle between the two C_2 axes.

3. Improper Axis of Rotation (S_n). A molecule is said to possess an improper axis of rotation of order *n* if rotation about the axis by $2\pi/n$ followed by reflection in a plane perpendicular to the axis leaves the molecule in an indistinguishable position. Examples are : allene which possesses an S_2 axis and the staggered form of ethane which possesses an S_6 axis (Figs. 5(*a*) and (*b*)).

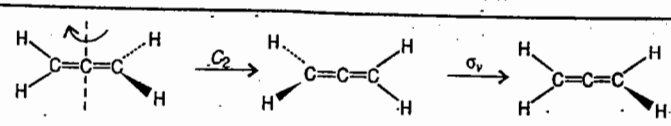

Fig. 5(*a*). Allene : S_2 axis.

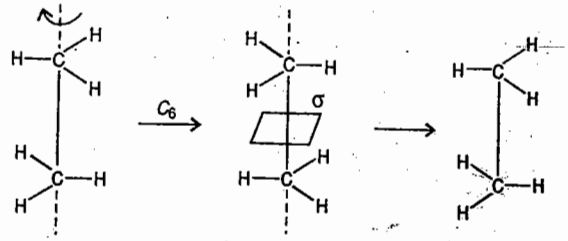

Fig. 5(*b*). Ethane (staggered form) : S_6 axis.

4. Centre of Symmetry (*i*). If in a molecule the coordinates (x, y, z) of every atom are changed into $(-x,-y,-z)$ and the molecule is left in an indistinguishable position, then the point of origin, *i.e.*, $(0, 0, 0)$, is called the centre of symmetry of the molecule. Examples are all homonuclear diatomic molecules and trans-1,2-dichloroethylene (Fig. 6).

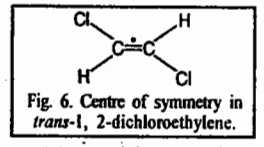

Fig. 6. Centre of symmetry in *trans*-1, 2-dichloroethylene.

5. The Identity Element (*E*). All molecules possess an identity element which does not do anything to the molecule.

Group Postulates. The complete set of operations forms a mathematical group. In order that the symmetry elements *A*,*B*,*C*,... form a mathematical group *G*, the following conditions must be satisfied :

1. Two elements *A* and *B* of a group combine to give the third element *C*, which is also an element of the group :

$$AB = C$$

It means that the application of *B* followed by *A* is equivalent to the application of *C*. If $AB = BA$, the elements *A* and *B* are said to *commute*.

2. An element combines with itself to form another element of the group.

3. The group must contain the identity element *E* which commutes with all the elements and leaves them unchanged :

$$EA = AE = A$$

$$EB = BE = B, \text{ etc.}$$

4. Every element of the group obeys the *associative law of combination* :

$$A(BC) = (AB)C$$

5. Every element *A* of a group has an inverse A^{-1} which is also an element of the group :

$$AA^{-1} = A^{-1}A = E$$

Example 1. Show that the set of rational numbers from zero to infinity forms a mathematical group.

Solution.: Let 5 and 7 be any two rational numbers. Then $5\times7 = 7\times5 = 35$. The numbers 5 and 7 are in the same group and 35 is also in the same group. Also, $1\times4 = 4\times1 = 4$. The number 4 is in the same group and the identity element *E* is 1. Again, $3\times\frac{1}{3}=\frac{1}{3}\times3=1$. $\frac{1}{3}$ is the inverse of 3. Further, $4\times(5\times6) = (4\times5)\times6$. Hence, the set of rational numbers between 0 and ∞ forms a group.

Types of Groups

1. Abelian and non-Abelian Groups. A group is said to be Abelian if all the elements commute and non-Abelian if all the symmetry elements do not commute with one another. We shall later show that H_2O molecule belongs to an Abelian group and NH_3 molucule to a non-Abelian group.

2. Cyclic Groups. A group is said to be cyclic if all its elements can be generated from one symmetry element. Thus, A, A^2, A^3,.....A^n form the elements of a cyclic group ; here $A^n = E$, the identity element. In general, the roots of the equation $x^n-1=0$ form a cyclic group. Note that *all cyclic groups are Abelian.*

Other Definitions

1. Order of a Group. The total number of elements of a group is called the order (h) of the group.

2. Subgroup. This is a group within a group. If any selection or subset of the elements of a group satisfies the definition of a group, then this subset of elements is called a subgroup. A subgroup must necessarily include the identity element E.

3. Multiplication Table. Consider a water molecule. It has four symmetry elements, *viz.*, E, $C_2(z)$, $\sigma_v(xz)$ and $\sigma_v'(yz)$ (Fig. 7).

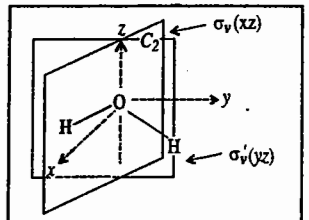

Fig. 7. The four symmetry elements of H_2O molecule.

We can easily show that the product of any two symmetry elements is one of the four elements of the group. Thus, for instance, $C_2(z)\sigma_v(xz) = \sigma_v'(yz)$. Proceeding this way the symmetry operations of H_2O molecule can be listed in a Group Multiplication Table (GMT) (Table 2).

TABLE 2

Group Multiplication Table of the Symmetry Operations of H_2O Molecule

	E	$C_2(z)$	$\sigma_v(xz)$	$\sigma_v'(yz)$
E	E	$C_2(z)$	$\sigma_v(xz)$	$\sigma_v'(yz)$
$C_2(z)$	$C_2(z)$	E	$\sigma_v'(yz)$	$\sigma_v(xz)$
$\sigma_v(xz)$	$\sigma_v(xz)$	$\sigma_v'(yz)$	E	$C_2(z)$
$\sigma_v'(yz)$	$\sigma_v'(yz)$	$\sigma_v(xz)$	$C_2(z)$	E

4. Similarity Transformation and Conjugate Elements. If A and X are two elements of a group obeying the relation

$$X^{-1}AX = B \qquad \ldots (1)$$

where B is also in the same group, then B is called the similarity transformation of A by X and A and B are said to be conjugate to each other.

5. Class. A set of elements in a group which are conjugate to one another is said to form a *class*.

Let us perform the similarity transformation of the C_2 operation of H_2O molecule with all the other operations :

$$E^{-1}\,C_2\,E = C_2 \;; \quad \sigma_v^{-1}\,C_2\,\sigma_v = C_2$$

$$(\sigma_v')^{-1}\,C_2\,\sigma_v' = C_2 \;; \quad (C_2)^{-1}\,C_2\,C_2 = C_2$$

We see that C_2 belongs to a *separate class* since the similarity transformation of C_2 with all the operations generates C_2. A symmetry operation which commutes with all the symmetry operations is in a separate class. Thus, E, σ_h and i belong to separate classes. In an Abelian group, every symmetry operation belongs to a separate class.

Point Groups. All the symmetry operations in a molecule can be combined to form a molecular group. This group is called **point group** since all the symmetry elements of the molecule intersect at a common point which remains fixed under all the symmetry operations. Crystals have very high symmetry. In fact, they have *translational symmetry* which is not found in gaseous molecules. The molecular point

groups are represented by the **Schoenflies symbols** whereas the point groups for crystals are denoted by **Hermann-Mauguin symbols**. Table 3 lists some molecular point groups which are of interest to chemists.

TABLE 3

Some Molecular Point Groups

Point Group	Symmetry Elements	Examples
C_1	E	CHFClBr
C_2	E, C_2	H_2O_2
C_3	E, C_3	C_2H_6
C_s	E, σ_v	NOCl
C_{2v}	E, C_2, $2\sigma_v$	H_2O, $CH_2{=}O$, pyridine
C_{3v}	E, C_3, $3\sigma_v$	NH_3, $CHCl_3$, PH_3
$C_{\infty v}$	E, C_∞, $\infty\sigma_v$	HCl, NO, CO
C_{2h}	E, C_2, σ_h, i	trans CHCl=CHCl
D_{2h}	E, $3C_2$, 3σ, i	$CH_2{=}CH_2$, naphthalene
D_{3h}	E, $2C_3$, $3C_2$ ($\perp$ to C_3), $3\sigma_v$, σ_h, $2S_3$	BF_3(trigonal planar)
D_{4h}	E, C_4, $4C_2$ ($\perp$ to C_4), $2\sigma_v$, $2\sigma_d$, σ_h, C_2, S_4 (coincident with C_4), i	$[PtCl_4]^{2-}$ (square planar)
D_{6h}	E, $2C_6$, $6C_2$ ($\perp$ to C_6), $3\sigma_v$, $3\sigma_d$, σ_h, C_2, $2C_3$, $2S_6$, $2S_3$, i	C_6H_6
T_d	E, $4C_3$, $3C_2$, $3S_4$ (coincident with C_2), $6\sigma_d$	CH_4
O_h	E, $3C_4$, $4C_3$, $3S_4$ and $3C_2$ (both coincident with the C_4 axes), $6C_2$, $4S_6$, $3\sigma_h$, $6\sigma_d$	SF_6

Example 2. The similarity transformation diagonalises a square matrix. Let us consider a 2×2 matrix A and the transformation matrix X, defined by

$$A = \begin{bmatrix} -7 & 6 \\ -18 & 14 \end{bmatrix}; \quad X = \begin{bmatrix} 2 & 1 \\ 3 & 2 \end{bmatrix}$$

Using the similarity transformation, diagonalise A.

Solution : In this example we assume that the reader is familiar with matrix algebra and knows how to determine the inverse of a matrix. The similarity transformation is defined as

$$X^{-1}A\,X = B$$

The inverse X^{-1} of matrix X is given by

$$X^{-1} = \text{adj}\,X/|X|$$

where adj X is the adjoint of X and $|X|$ is the determinant of X ($|X| \neq 0$).

Consider, $X = \begin{bmatrix} 2 & 1 \\ 3 & 2 \end{bmatrix}$. It can be easily shown that $X^{-1} = \begin{bmatrix} 2 & -1 \\ -3 & 2 \end{bmatrix}$.

Hence, $X^{-1}AX = \begin{bmatrix} 2 & -1 \\ -3 & 2 \end{bmatrix}\begin{bmatrix} -7 & 6 \\ -18 & 14 \end{bmatrix}\begin{bmatrix} 2 & 1 \\ 3 & 2 \end{bmatrix} = \begin{bmatrix} 2 & 0 \\ 0 & 5 \end{bmatrix}$

We see that B is a diagonal matrix. Thus, matrix A has been diagonalized.

Representations of Molecular Point Groups. The five kinds of symmetry operations, *viz.*, E, C_n, σ, S_n, i can be represented by matrices. It can be shown (we omit the derivation) that if these operations operate on a two-dimensional position vector

$$\vec{r} = x\hat{i} + y\hat{j} \qquad \ldots (2)$$

where $\hat{i}$, $\hat{j}$ are the unit vectors along the x and y axes, respectively, they generate five 2×2 matrices :

$$\begin{bmatrix} x' \\ y' \end{bmatrix} = \underbrace{\begin{bmatrix} \quad & \quad \\ \quad & \quad \end{bmatrix}}_{2\times2 \text{ matrix}} \begin{bmatrix} x \\ y \end{bmatrix} \qquad \ldots (3)$$

Here we have written the position vector as a column vector and the transformed vector as a primed column vector. The matrices are :

$$E = \begin{bmatrix} 1 & 0 \\ 1 & 0 \end{bmatrix};\ C_2 = \begin{bmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{bmatrix};\ \sigma_{yz} = \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix};\ \text{etc.} \qquad \ldots(4)$$

On the other hand, if the same operations operate on a three-dimensional position vector

$$\vec{r} = x\hat{i} + y\hat{j} + z\hat{k}, \qquad \ldots(5)$$

they generate five 3×3 matrices :

$$E = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix};\ C_n(z) = \begin{bmatrix} \cos\theta & \sin\theta & 0 \\ -\sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{bmatrix};\ \sigma_{yz} = \begin{bmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}; \qquad \ldots(6a)$$

$$S_n = \sigma_{xy}C_n(z) = \begin{bmatrix} \cos\theta & \sin\theta & 0 \\ -\sin\theta & \cos\theta & 0 \\ 0 & 0 & -1 \end{bmatrix};\ i = \begin{bmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & -1 \end{bmatrix};\ \sigma_{xy} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{bmatrix};\ \text{etc.} \qquad \ldots(6b)$$

The sum of the diagonal elements of a matrix is called the **trace or character** χ of the matrix. The characters of the various matrices corresponding to the symmetry operations described above are given in Table 4.

TABLE 4
Characters of the Symmetry Operations

Symmetry operation (R)	Character of R, $\chi(R)$
E	$\chi(E) = 3$
C_n	$\chi(C_n) = 2\cos\theta + 1$
σ	$\chi(\sigma) = 1$
S_n	$\chi(S_n) = 2\cos\theta - 1$
i	$\chi(i) = -3$

We can verify the remarkable fact that these matrices combine like the symmetry operations themselves. Thus, for instance,

$$\sigma_{xz}\sigma_{yz} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 1 \end{bmatrix}\begin{bmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 1 \end{bmatrix} = C_2(z) \qquad \ldots(7)$$

The set of matrices corresponding to the symmetry operations (or the symmetry elements) of a group is called its **representation.** It must be borne in mind that this set of matrices is not a unique set. For a point group of a molecule there can be many other sets of matrices (and hence many representations) which combine in the same way as the symmetry operations themselves. We are, however, interested in the most fundamental representation from which other representations can be derived.

Representations can be classified into (*a*) **Reducible representations (reps)** and (*b*) **Irreducible representations (irreps)**, also called **symmetry species.**

Reps. Let A, B, C,.... be the matrices which form the representation of a group and let X be the similarity transformation matrix of this group such that

$$X^{-1}AX = A' \qquad \ldots(8)$$

$$X^{-1}BX = B' \qquad \ldots(9)$$

$$X^{-1}CX = C' \qquad \ldots(10)$$

Then, if X is the proper transformation matrix, we have

$$X^{-1}AX = A' = \begin{bmatrix} a_1' & & & 0 \\ & a_2' & & \\ & & a_3' & \\ 0 & & & a_4' \end{bmatrix} \qquad \ldots(11)$$

The new matrix A' is now *blocked out* along the diagonal into smaller matrices a_1', a_2', a_3', a_4', etc., with the off-diagonal elements equal to zero. Similarly, we have

$$X^{-1}BX = B' = \begin{bmatrix} b_1' & & & 0 \\ & b_2' & & \\ & & b_3' & \\ 0 & & & b_4' \end{bmatrix};\ \text{etc.} \qquad \ldots(12)$$

This is expressed by saying that the given sets of matrices form a **reducible representation (rep).**

Irreps. If it is not possible to find a similarity transformation which will reduce the matrices A, B, C,.... to block-diagonalized form, the representation is called an **irreducible representation (irrep).**

Grand/Great Orthogonality Theorem (G.O.T.)

This is the most important theorem of group theory. It concerns the matrix elements (*i.e.*, elements of the matrices) which constitute the irreps of a point group. Mathematically, it is stated as follows :

$$\sum_R \Gamma_i(R)_{mn}\Gamma_j(R)^*_{m'n'} = \frac{h}{\sqrt{l_i l_j}}\delta_{ij}\delta_{mm'}\delta_{nn'} \qquad \ldots(13)$$

Here Γ_i and Γ_j are the ith and jth irreps of a point group of order h with dimensions l_i and l_j, respectively ; $\Gamma_i(R)_{mn}$ is the mnth matrix element corresponding to the symmetry operation R belonging to the ith irrep and $\Gamma_j(R)^*_{m'n'}$ is the complex conjugate of the $m'n'$th matrix element corresponding to the symmetry operation R belonging to the jth irrep. The δs are the well known 'Kronecker deltas' which have the following property :

$$\delta_{ij} = \begin{cases} 1, & i = j \\ 0, & i \neq j \end{cases};\quad \delta_{mm'} = \begin{cases} 1, & m = m' \\ 0, & m \neq m' \end{cases};\quad \delta_{nn'} = \begin{cases} 1, & n = n' \\ 0, & n \neq n' \end{cases} \qquad \ldots(14)$$

The summation is performed over all the symmetry operations R of the molecule. If the matrix elements are *real*, then

$$\Gamma_j(R)^*_{m'n'} = \Gamma_j(R)_{m'n'} \qquad \ldots(15)$$

The following three cases arise for the G.O.T. assuming that the matrix elements are real :

1 For two different irreps, $i \neq j$, $m = m'$ and $n = n'$,

$$\sum_R \Gamma_i(R)_{mn}\Gamma_j(R)_{mn} = 0 \qquad \ldots(16)$$

2 For the same irrep $i = j$, $m \neq m'$ and $n \neq n'$,

$$\sum_R \Gamma_i(R)_{mn}\Gamma_i(R)_{m'n'} = 0 \qquad \ldots(17)$$

3 For an irrep i and for $m = m'$, $n = n'$,

$$\sum_R [\Gamma_i(R)_{mn}]^2 = h/l_i \qquad \ldots(18)$$

In practice, we do not use the G.O.T. in the form given above but in a slightly different form involving the *characters* of the irreps, as shown in the next section.

Important Properties of Irreducible Representations (Irreps)

The properties of the *irreps* can be derived from the G.O.T. Consider a point group of order h. Recall that h is the number of symmetry operations of a point group. Let the h symmetry operations be divided

into k classes. We shall denote the irreps by $\Gamma_1, \Gamma_2, \Gamma_3, \ldots \Gamma_k$ and their dimensions by $l_1, l_2, l_3, \ldots l_k$. Using the G.O.T., the following properties of the irreps can be obtained :

1. The number of irreps in a point group is equal to the number of its symmetry classes.

2. The sum of the squares of the dimensions of the irreps of a group is equal to h, the order of the group. Thus,

$$\sum_{i=1}^{k} l_i^2 = h \qquad \ldots (19)$$

3. The sum of the squares of the characters of the identity operation in the irreps is equal to h, the order of the group :

$$\sum_{i=1}^{k} \left(\chi_i(E)\right)^2 = h \qquad \ldots (20)$$

4. The characters of the symmetry operations in two different irreps satisfy the relation

$$\sum_{p=1}^{k} g_p \chi_i(R_p)\chi_j(R_p) = h\delta_{ij} \qquad \ldots (21)$$

where δ_{ij} is the Kronecker delta :

$$\delta_{ij} = \begin{cases} 1, & i = j \\ 0, & i \neq j \end{cases} \qquad \ldots (22)$$

For $i \neq j$, this relation reduces to

$$\sum_{p=1}^{k} g_p \chi_i(R_p)\chi_j(R_p) = 0 \qquad \ldots (23)$$

and for $i = j$, it becomes

$$\sum_{p=1}^{k} g_p \left(\chi_i(R_p)\right)^2 = h \qquad \ldots (24)$$

In these equations, g_p refers to the number of symmetry operations in the *pth* class ; R_p is the symmetry operation of the *pth* class and $\chi_i(R_p)$ and $\chi_j(R_p)$ are the characters of the matrix for the symmetry operation R_p in the i and j irreps, respectively.

5. The characters of all matrices belonging to the symmetry operations in the same class are identical.

Use of G.O.T. to Construct Character Tables for the Molecular Point Groups. Let us use the G.O.T. to construct the character table for the C_{3v} point group to which NH_3 belongs. This point group has three symmetry elements E, C_3 and $3\sigma_v$; the corresponding *six* symmetry operations can be divided into the following *three* classes : E, (C_3^1, C_3^2), $3\sigma_v$.

According to rule 1, the three symmetry classes give rise to three irreps. From rule 2,

$$\sum_{i=1}^{3} l_i^2 = l_1^2 + l_2^2 + l_3^2 = 6 \qquad \ldots (25)$$

where the order of the group is 6.

The only positive integral values of l_i that satisfy Eq. 25 are 1, 1 and 2. Here we state a very important property that every point group possesses a totally symmetric irrep in which all the symmetry operations have character equal to 1. From rule 3,

$$\sum_i [\chi_i(E)]^2 = [\chi_1(E)]^2 + [\chi_2(E)]^2 + [\chi_3(E)]^2 = 6 \qquad \ldots (26)$$

which is satisfied only if

$$\chi_1(E) = 1, \ \chi_2(E) = 1 \text{ and } \chi_3(E) = 2 \qquad \ldots (27)$$

We can now draw up the following table for the characters of different representations :

TABLE 5

Characters of Different Representations

Irrep	$\chi(E)$	$\chi(C_3)$	$\chi(\sigma_v)$
Γ_1	1	1	1
Γ_2	1	p	q
Γ_3	2	r	s

We have to determine the values of the unknown characters p, q, r and s in the irreps Γ_2 and Γ_3. Applying rule 4 to irreps Γ_1 and Γ_2, we have

$$\sum_{p=1}^{k} g_p \chi_i(R_p)\chi_j(R_p) = 0 \qquad \ldots (28)$$

$$\sum_{p=1}^{3} g_p \chi_1(R_p)\chi_2(R_p) = g_1\chi_1(E)\chi_2(E) + g_2\chi_1(C_3)\chi_2(C_3) + g_3\chi_1(\sigma_v)\chi_2(\sigma_v) = 0 \qquad \ldots (29)$$

From Table 5, remembering that $g_1=1$, $g_2=2$ and $g_3=3$, we obtain

$$1 + 2p + 3q = 0 \qquad \ldots (30)$$

Applying Eq. 24 to the irrep Γ_2, we obtain

$$1 + 2p^2 + 3q^2 = 6 \qquad \ldots (31)$$

Solving Eqs. 30 and 31, we obtain

$$p = 1 \text{ and } q = -1$$

Proceeding similarly, we obtain from the irreps Γ_1 and Γ_3, the following equations :

$$2 + 2r + 3s = 0 \qquad \ldots (32)$$

and

$$4 + 2r^2 + 3s^2 = 6 \qquad \ldots (33)$$

Solving Eqs. 32 and 33, we obtain

$$r = -1 \quad \text{and} \quad s = 0$$

Using the values of p, q, r and s in Table 5, we obtain the desired character table (Table 6) for C_{3v} point group.

TABLE 6

Character Table for C_{3v} Point Group

C_{3v}	E	$2C_3$	$3\sigma_v$
$\Gamma_1 \equiv A_1$	1	1	1
$\Gamma_2 \equiv A_2$	1	1	−1
$\Gamma_3 \equiv E$	2	−1	0

The symbols Γ_1, Γ_2 and Γ_3 are the **Bethe notation** for the irreps and A_1, A_2 and E are the **Mulliken notation** for the irreps.

Character Tables for Point Groups

For practical purposes, it is sufficient to know only the characters of each symmetry class of a point group to which a molecule belongs. A character table lists the characters of all the symmetry classes for all the irreps of a group. Character tables for the C_{2v} and C_{3v} point groups are given in Tables 7 and 8.

TABLE 7

Character Table for C_{2v} Point Group

C_{2v} I	E	$C_2(z)$	$\sigma_v(xz)$ II	$\sigma_v(yz)$	III	IV
A_1	1	1	1	1	z	x^2, y^2, z^2
A_2	1	1	−1	−1	R_z	xy
B_1	1	−1	1	−1	x, R_y	xz
B_2	1	−1	−1	1	y, R_x	yz

TABLE 8

Character Table for C_{3v} Point Group

C_{3v} I	E	$2C_3$ II	$3\sigma_v$	III	IV
A_1	1	1	1	z	$x^2 + y^2, z^2$
A_2	1	1	−1	R_z	
E	2	−1	0	(x,y) (R_x,R_y)	(x^2-y^2, xy) (xz,yz)

The character tables can be obtained from the properties of the irreps given above. We can explain the character table by dividing it into four sections I, II, III and IV :

Section I. In the top row, the Schoenflies symbol for the point group is given. This section also lists the Mulliken symbols for the different irreps. Symbols A and B are used to label one-dimensional irreps and E and T to label two-dimensional and three-dimensional irreps, respectively. The nomenclature E should *not* be confused with the identity operation. A is used when the character for the rotation about the *principal axis* is +1 and B when it is −1. In other words, A stands for symmetric and B for antisymmetric to such rotation. For a molecule having a centre of symmetry, the subscripts g and u are used to label the irreps that are respectively symmetric and antisymmetric to inversion through the centre of symmetry. Subscripts 1 and 2 are used to label the irreps that are respectively symmetric and antisymmetric to reflection in a vertical plane σ_v. The superscripts ′ and ″ are used it denote the irreps that are respectively symmetric and antisymmetric to reflection in a horizontal plane σ_h.

Section II. This section gives the characters for all the symmetry operations of different irreps. The characters of the identity operation for the one-dimensional, two-dimensional and three-dimensional irreps are, respectively, 1, 2 and 3.

Section III. It gives the transformation properties of the Cartesian coordinates x, y, z and rotations R_x, R_y, R_z about these axes.

Section IV. It gives the transformation properties of the binary products of Cartesian coordinates xy, yz, zx, etc. and the squares of the coordinates x^2, y^2, z^2, x^2+y^2, $x^2+y^2+z^2$, etc. The Cartesian coordinates, their squares and binary products, etc., listed in sections III and IV are referred to as the **basis functions** on which the symmetry operations operate.

Example 3. Verify that the characters given in the C_{2v} point group obey the properties of the irreps.

Solution : Refer to the Character Table 7 for the C_{2v} point group. We find that

(*i*) the number of irreps is equal to the number of classes (in this case 4) of the group.

(*ii*) All the four irreps are one-dimensional so that

$$\sum_{i=1}^{4} l_i^2 = l_1^2 + l_2^2 + l_3^2 + l_4^2 = (1)^2 + (1)^2 + (1)^2 + (1)^2 = 4$$

which is the order of the group.

(*iii*) $$\sum_{i=1}^{4}\left(\chi_i(E)\right)^2 = \left(\chi_{A_1}(E)\right)^2 + \left(\chi_{A_2}(E)\right)^2 + \left(\chi_{B_1}(E)\right)^2 + \left(\chi_{B_2}(E)\right)^2 = (1)^2 + (1)^2 + (1)^2 + (1)^2 = 4$$

(*iv*) $$\sum_{p=1}^{4} g_p \chi_i(R_p)\chi_j(R_p) = h\,\delta_{ij}$$

For the A_1 and A_2 irreps, we obtain (1)(1)(1) + (1)(1)(1) + (1)(1)(−1) + (1)(1)(−1) = 0 and for the B_1 irrep, we obtain (1)(1)^2 + (1)(−1)^2 + 1(1)^2 + 1(−1)^2 = 4 and so on. **Hence the result.**

Example 4. Verify that the characters given in the C_{3v} point group obey the properties of the irreps.

Solution : Refer to the Character Table 8 for the C_{3v} point group. We find that

(*i*) the number of irreps is equal to the number of classes (in this case 3) of the group.

(*ii*) Two irreps A_1 and A_2 are one-dimensional, *i.e.*, $l_1 = l_2 = 1$ and the third is two-dimensional, *i.e.*, $l_3 = 2$. Thus,

$$\sum_{i=1}^{3} l_i^2 = l_1^2 + l_2^2 + l_3^2 = (1)^2 + (1)^2 + (2)^2 = 6$$

which is the order of the group.

(*iii*) $$\sum_{i=1}^{3}\left(\chi_i(E)\right)^2 = \left(\chi_{A_1}(E)\right)^2 + \left(\chi_{A_2}(E)\right)^2 + \left(\chi_E(E)\right)^2 = (1)^2 + (1)^2 + (2)^2 = 6$$

(*iv*) $$\sum_{p=1}^{3} g_p \chi_1(R_p)\chi_j(R_p) = h\delta_{ij}$$

For the irreps A_2 and E (say), this relation gives (1)(1)(2) + (2)(1)(−1) + 3(−1)(0) = 0

For the irreps A_1 and A_2 (say), it gives (1)(1)(1) + (2)(1)(1) + (3) (1)(−1) = 0 and for the irrep E, it gives (1)(2)^2 + 2(−1)^2 + 3(0)^2 = 6 and so on. **Hence the result.**

It is important to recognize the point groups of some common molecules. Homonuclear diatomic molecules (H_2, N_2, O_2, Cl_2, etc.) and linear molecules with a centre of symmetry (CO_2, HC≡CH) belong to the point group $D_{\infty h}$. On the other hand, heteronuclear diatomic molecules and other linear molecules that do not have a centre of symmetry (HCl, CO, NO, OCS, NNO) belong to the point group $C_{\infty v}$. Tetrahedral (T_d) and octahedral (O_h) molecules have more than one non-collinear principal axes of symmetry. A tetrahedral molecule such as CH_4 has four non-collinear C_3 axes, one along each C–H bond. A closely related group, the icosahedral group I_h which characterises the icosahedron has non-collinear five-fold axes. The icosahedral group I_h occurs prominently in boron compounds and in fullerene (C_{60}) molecule. A regular tetrahedron has four equilateral triangles for its faces, an octahedron has eight, a dodecahedron twelve and an icosahedron has twenty faces. We may mention here that atoms, being spherical, belong to the **full rotation group** (R_3).

Table 9 lists the point groups of some common molecules along with their geometry and general formulae.

TABLE 9

Point Groups and Geometry of Some Common Molecules

Molecule/Complex ion	General Formula	Point Group	Geometry
H_2	A_2	$D_{\infty h}$	Linear with *i*
HF	AB	$C_{\infty v}$	Linear without *i*
CO_2	AB_2	$D_{\infty h}$	Linear with *i*
COS	ABC	$C_{\infty v}$	Linear without *i*
H_2O	A_2B	C_{2v}	Angular
C_2H_2	A_2B_2	$D_{\infty h}$	Linear with *i*
CH_2Cl_2	AB_2C_2	C_{2v}	Tetrahedral
$CHCl_3$	ABC_3	C_{3v}	Tetrahedral
NH_3	AB_3	C_{3v}	Pyramidal
CH_4	AB_4	T_d	Tetrahedral
PCl_5	AB_5	D_{3h}	Trigonal bipyramidal
SF_4	AB_4	C_{2v}	Angular
$[PtCl_4]^{2-}$	$[AB_4]^{2-}$	D_{4h}	Square planar
BrF_5	AB_5	C_{4v}	Square pyramidal
SF_6	AB_6	O_h	Octahedral
IF_7	AB_7	D_{5h}	Pentagonal bipyramidal
$[B_{12}H_{12}]^{2-}$	$[A_{12}B_{12}]^{2-}$	I_h	Icosahedral

Example 5. List the symmetry elements and locate as many of them as possible (in the molecule) for the following molecules :

(*a*) CH_4, (*b*) $[PtCl_4]^{2-}$, (*c*) H_2, (*d*) HF, (*e*) HCN and (*f*) C_2H_2

Solution : (*a*) CH_4 (tetrahedral). It belongs to the T_d point group. The symmetry elements are E, $4C_3$, $3C_2$, $3S_4$ and $6\sigma_d$ (Fig. 8).

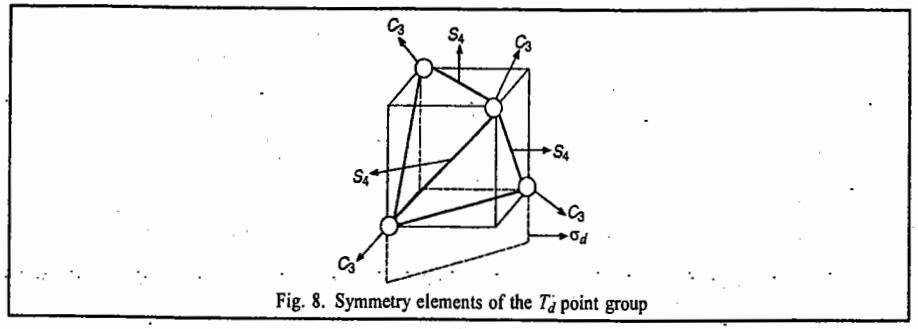

Fig. 8. Symmetry elements of the T_d point group

(*b*) $[PtCl_4]^{2-}$ (square planar). This molecule has the general formula AB_4 and belongs to the D_{4h} point group. The symmetry elements are E, C_4, S_4, $4C_2$, $4\sigma_v$, σ_h and i (Fig.9).

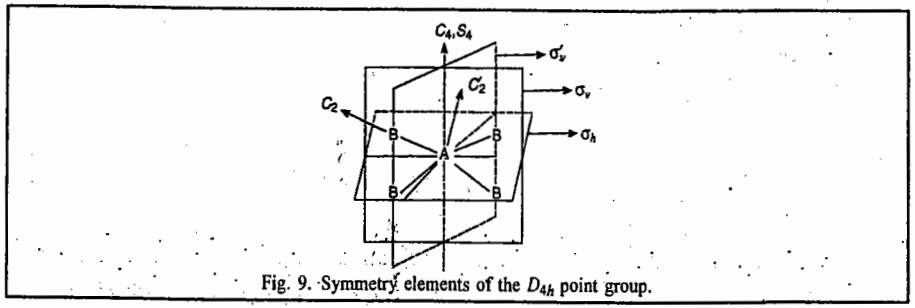

Fig. 9. Symmetry elements of the D_{4h} point group.

(*c*) H_2 (linear with a centre of symmetry, (*i*). It belongs to the $D_{\infty h}$ point group. It has the symmetry elements E, $2C_\infty$, $\infty\sigma_v$, σ_h, i, $2S_\infty$ and ∞C_2 (Fig. 10).

(*d*) HF (linear without centre of symmetry, (*i*). It belongs to the $C_{\infty v}$ point group and has the symmetry elements : E, C_∞ and $\infty\sigma_v$ (Fig. 11).

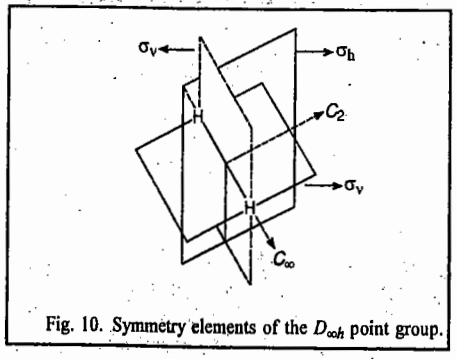

Fig. 10. Symmetry elements of the $D_{\infty h}$ point group.

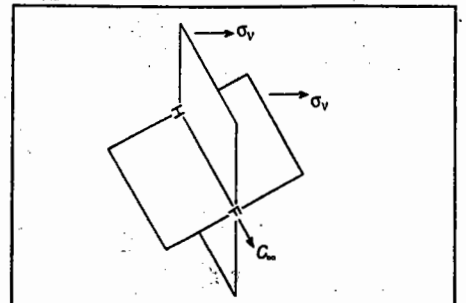

Fig. 11. Symmetry elements of the $C_{\infty v}$ point group.

(*e*) HC≡N (linear without centre of symmetry, (*i*). It belongs to $C_{\infty v}$ point group and possesses the symmetry elements : E, C_∞ and $\infty\sigma_v$ (Fig. 12).

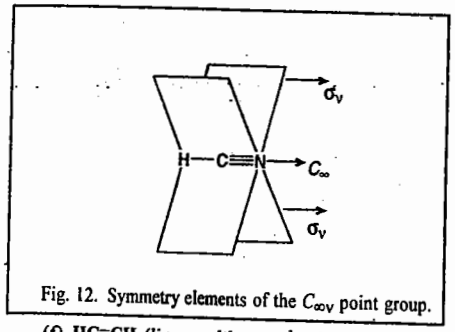

Fig. 12. Symmetry elements of the $C_{\infty v}$ point group.

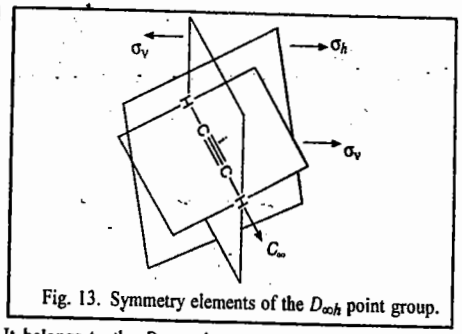

Fig. 13. Symmetry elements of the $D_{\infty h}$ point group.

(*f*) HC≡CH (linear with centre of symmetry, (*i*). It belongs to the $D_{\infty h}$ point group and has the symmetry elements : E, $2C_\infty$, $\infty\sigma_v$, σ_h, i, $2S_\infty$ and ∞C_2 (Fig. 13).

Example 6. Illustrate diagrammatically that H_2O molecule is Abelian whereas NH_3 molecule is non-Abelian.

Solution. A molecule is said to be Abelian if all the symmetry elements commute with one another and non-Abelian if they do not commute with one another.

H_2O molecule : See Fig. 14.

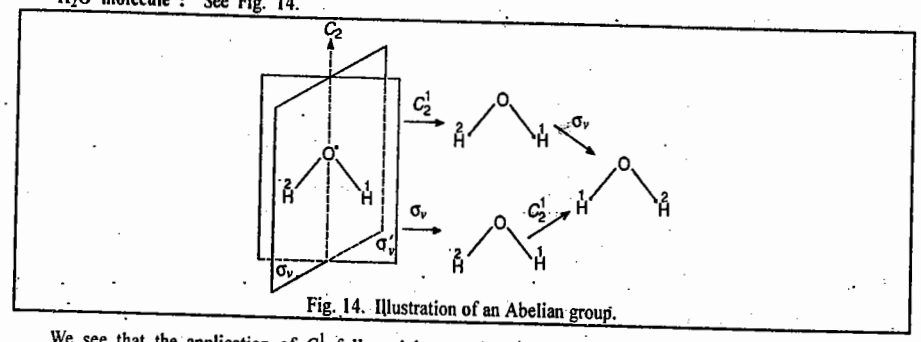

Fig. 14. Illustration of an Abelian group.

We see that the application of C_2^1 followed by σ_v gives the same configuration as the application of σ_v followed by C_2^1.

Hence, C_2^1 and σ_v commute, *i.e.*, $\sigma_v C_2^1 = C_2^1 \sigma_v$

Thus, H_2O molecule belongs to an Abelian point group (C_{2v}).

NH_3 molecule : See Fig. 15.

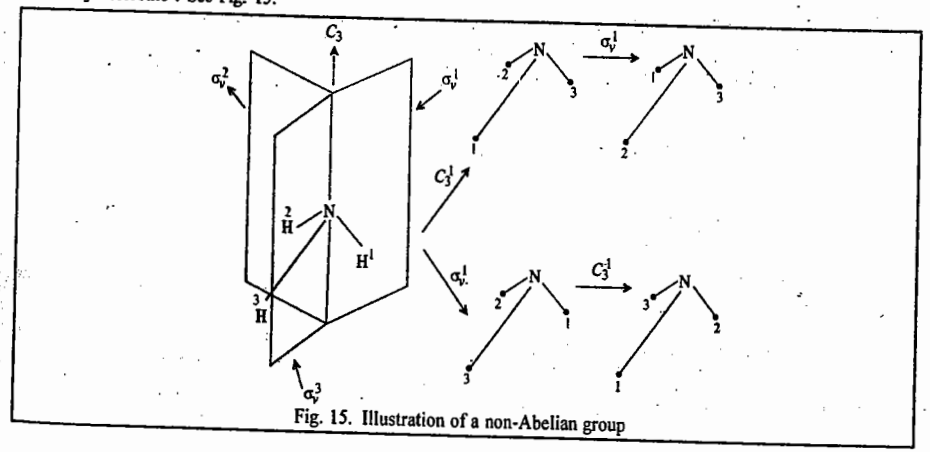

Fig. 15. Illustration of a non-Abelian group

Here we find that application of C_3^1 followed by σ_v^1 gives a different configuration of NH_3 molecule than the configuration obtained by the application of σ_v^1 followed by C_3^1, *i.e.*,

$$\sigma_v^1 C_3^1 \neq C_3^1 \sigma_v^1$$

so that the two symmetry operations do not commute. Thus, NH_3 molecule belongs to a non-Abelian point group (C_{3v}).

As an application of group theory to quantum mechanics, consider the Schrodinger equation for helium atom

$$\hat{H}\psi = E\psi \qquad \ldots (37)$$

where $\hat{H} = -\frac{1}{2}(\nabla_1^2 + \nabla_2^2) - \frac{2}{r_1} - \frac{2}{r_2} + \frac{1}{r_{12}}$ (in atomic units)

(see Fig. 16 for the description of the coordinates of the two electrons.)

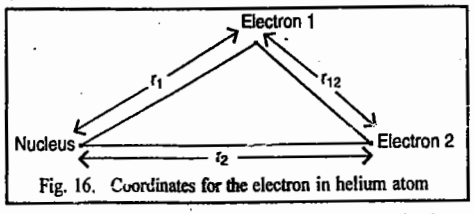

Fig. 16. Coordinates for the electron in helium atom

If we use a symmetry operation called **parity**, $\hat{P}$, which interchanges the coordinates of the two electrons, we find that $\hat{H}$ remains unchanged. This is expressed in group-theoretical language by saying that the Hamiltonian (and hence the energy E) is *invariant* under the symmetry operation $\hat{P}$. In fact, the Hamiltonian operator $\hat{H}$ is invariant under all the symmetry operations of the point group of an atom or a molecule since it commutes with them, *i.e.*,

$$[\hat{H}, \hat{P}] = \hat{H}\hat{P} - \hat{P}\hat{H} = 0 \qquad \ldots (38)$$

Applying the parity operation to both sides of Eq. 37 and using Eq. 38, we have

$$\hat{P}\hat{H}\psi = \hat{H}\hat{P}\psi \qquad \ldots (39)$$

Hence, $$\hat{H}(\hat{P}\psi) = E(\hat{P}\psi) \qquad \ldots (40)$$

This means that $\hat{P}\psi$ is also a solution of Eq. 37 with the eigenvalue E. Thus, assuming the absence of degeneracy (*i.e.*, no two wave functions have the same energy), we can say that there is no difference between $\hat{P}\psi$ and ψ.

Let us next consider the effect of parity on ψ. Consider the eigenvalue equation

$$\hat{P}\psi = \lambda\psi \qquad \ldots (41)$$

where λ is the eigenvalue of $\hat{P}$. Operating on Eq. 41 again with $\hat{P}$, we obtain

$$\hat{P}^2\psi = \hat{P}\lambda\psi \qquad \ldots (42)$$

or $$\psi = \lambda\hat{P}\psi = \lambda^2\psi \qquad \ldots (43)$$

i.e., $$\lambda^2 = 1 \qquad \ldots (44)$$

$\therefore$ $$\lambda = \pm 1$$

Substituting in Eq. 41, we find that

$$\hat{P}\psi = \pm\psi \qquad \ldots (45)$$

Eq. 45 implies that *ψ would either be symmetric (does not change sign) or antisymmetric (changes sign) to exchange of any pair of electrons.* Particles such as electrons and protons which have half-integral spin are classified as *fermions* because their wave function is *antisymmetric* to exchange of their coordinates and particles such as photons and phonons which have integral spin are classified as *bosons* since their wave function is symmetric to exchange of their coordinates. Fermions obey Fermi–Dirac statistics and bosons obey Bose–Einstein statistics.

From the above discussion we see that since ψ and $\hat{P}\psi$ both belong to the energy level E, the parity operation $\hat{P}$ transforms the eigenfunctions of E into each other. In the language of group theory this implies that we can choose the eigenfunctions of $\hat{H}$ with energy E as a basis set for the irreps of the point group.

Crystallographic Symmetry

We shall come across in the chapter on the Solid State that there are seven crystal systems, fourteen Bravais lattices, thirty two classes (or point groups) and 230 space groups. A crystallographer needs to determine to which crystal system, Bravais lattice, point group and space group a given unknown crystal belongs. This would be a very arduous task, indeed. The additional symmetry which ultimately produces space groups in crystals is a consequence of unique features not found in molecules.

It can be shown from purely geometrical considerations that a crystal can possess only 1-, 2-, 3-, 4- or 6-fold axis of symmetry but *not a 5-fold axis of symmetry*. Every crystal possesses external symmetry and internal symmetry. The former is determined by the symmetry elements and the interfacial angles of the crystal whereas the latter is determined by the arrangement of atoms in the lattice.

External Symmetry of Crystals. This symmetry is described by ten basic symmetry elements: n (where n=1, 2, 3, 4 and 6) and $\bar{n}$ (where $\bar{n} = \bar{1}, \bar{2}, \bar{3}, \bar{4}$ and $\bar{6}$). Here n is the n-fold proper axis and $\bar{n}$ is the n-fold proper axis combined with the operation of inversion through a central point on the axis. In other words, $\bar{n}$ is the n-fold *rotation-inversion axis*. On the basis of external symmetry, crystals are classified into 32 point groups which are listed in Table 10 in both the Hermann-Mauguin (HM) notation, (preferred by crystallographers) and in Schoenflies notation, reserved for molecules.

TABLE 10

The 32 Crystallographic Point Groups

Hermann-Mauguin Notation	Schoenflies Notation	Hermann-Mauguin Notation	Schoenflies Notation
n (1, 2, 3, 4, 6)	C_n(C_1, C_2, C_3, C_4, C_6)	n/m 2/m 2/m (n is even)	D_{nh} (n is even)
$\bar{n}$ ($\bar{1}$, $\bar{2}$, $\bar{3}$, $\bar{4}$, $\bar{6}$)	(C_i, C_s, S_6, S_4, S_3)	(2/m 2/m 2/m, 4/m 2/m 2/m,	
n 22 (n is even)	D_n (n is even)	6/m 2/m 2/m)	(D_{2h}, D_{4h}, D_{6h})
(222, 422, 622)	(D_2, D_4, D_6)	$\bar{6}$ 2m	D_{3h}
32	D_3	$\bar{4}$ 2m	D_{2d}
nmm (n is even)	C_{nv} (n is even)	$\bar{3}$ 2/m ($\bar{3}$ m)	D_{3d}
(2mm, 4mm, 6mm)	(C_{2v}, C_{4v}, C_{6v})	23	T
3m	C_{3v}	$\bar{4}$ 3m	T_d
n/m (n is even)	C_{nh} (n is even)	2/m $\bar{3}$	T_h
(2/m, 4/m, 6/m)	(C_{2h}, C_{4h}, C_{6h})	432	O
		4/m $\bar{3}$ 2/m	O_h

We shall now explain the rather unfamiliar Hermann-Mauguin (HM) notation for the crystallographic point groups. Crystals containing the proper axis of symmetry alone are denoted by the symbol n. The HM notation for crystals possessing the centre of symmetry alone is $\bar{1}$. The symbol $\bar{2}$ stands for the crystal having rotation-inversion axis of order 2. As shown below, $\bar{2}$ is equivalent to σ_h, the horizontal reflection plane :

$$\bar{2} = C_2^1 i = C_2^1 C_2^1 \sigma_h = E\sigma_h = \sigma_h \qquad \ldots (46)$$

The crystallographic point group having a mirror plane is denoted by the symbol m. A crystal which possesses a rotation-inversion axis of order 3 is denoted by the notation $\bar{3}$. $\bar{3}$ can be shown to be equivalent to the rotation-reflection axis of order 6 as follows :

$$\bar{3} = C_3^1 i = C_3^1 C_2^1 \sigma_h = C_6^2 C_6^3 \sigma_h = C_6^5 \sigma_h = S_6^5 \qquad \ldots (47)$$

A crystal possessing a rotation-inversion axis of order 4 is denoted by the symbol $\bar{4}$ which is equivalent to a rotation-reflection axis of order 4 :

$$\bar{4}=C_4^1 i = C_4^1 C_2^1 \sigma_h = C_4^1 C_4^2 \sigma_h = C_4^3 \sigma_h = S_4^3 \quad \ldots (48)$$

And finally, the $\bar{6}$ group has the rotation-inversion axis of order 6 :.

$$\bar{6}=C_6^1 i = C_6^1 C_2^1 \sigma_h = C_6^1 C_6^3 \sigma_h = C_6^4 \sigma_h = C_3^2 \sigma_h = S_3^5 \quad \ldots (49)$$

D_n groups are denoted by the symbol $n22$ when the principal axis is of even order; here n refers to the principal axis and 22 corresponds to two sets of C_2 axes in different classes. D_3 group is denoted by 32 which implies the presence of C_3 axis and 2-fold axes ; the 2-fold axes are in the same class.

C_{nv} groups are denoted by nmm when the principal axis n is of even order ; mm denotes two sets of vertical planes in different classes. C_{3v} group is denoted by $3m$; here 3 stands for 3-fold principal axis and m for vertical planes all of which are in the same class. C_{nh} symmetry is referred to as n/m when n is even (2, 4 or 6). The n/m point groups contain C_n axis and a horizontal plane σ_h. $\bar{6}$ is the HM notation for the C_{3h} point group.

If a crystal with D_{nh} symmetry contains a C_n axis of even order, then the HM notation is $n/m\ 2/m\ 2/m$. It denotes the presence of the C_n axis, two sets of C_2 axes in different classes and the horizontal plane. The notation $\bar{6}2m$ corresponds to D_{3h} point group. It means that the crystal has an $S_3(\bar{6})$ axis, C_2 axes and mirror planes. The $\bar{6}$ axis generates C_3 axis, σ_h and identity operation E. The HM notation for D_{2d} and D_{3d} point groups is $\bar{4}2m$ and $\bar{3}2/m$, respectively. The D_{2d} point group possesses a $\bar{4}$ axis, C_2 axes and dihedral planes, whereas the D_{3d} point group possesses the S_6 axis, C_2 axes and dihedral planes. A crystal cannot have the D_{4d} symmetry since $\bar{8}$ or S_8 axis cannot occur.

The T group is denoted by 23 which means the presence of 2-fold axes and 3-fold axes. If, in addition, i, C_2 and C_3 axes are also present, the point group obtained is T_h whose HM notation is $2/m\ \bar{3}$. T_d group is denoted by $\bar{4}3m$; it contains $\bar{4}$ axis, 3-fold axes and mirror planes. The point group O is represented by 432 ; it contains C_4, C_3 and C_2 axes whereas the HM notation for the point group O_h is $4/m\ \bar{3}2/m$; it implies the presence of C_4 axes, C_2 axes, S_6 axes and mirror planes.

Crystal Systems. It is known that the unit cell of a crystal is specified by the six unit cell parameters a, b, c, α, β and γ where a, b, c are the crystallographic axes and α, β, γ are the angles at which these axes intersect one another. The 32 point groups are grouped into seven crystal systems, *viz.*, cubic, tetragonal, hexagonal, rhombohedral (trigonal), orthorhombic, monoclinic and triclinic.

The cube which belongs to the O_h point group has the maximum symmetry and the triclinic system has the minimum symmetry. The cube and the octahedron are mutual polyhedra.

Table 11 lists the various n-fold rotation axes n and the n-fold rotation-inversion axes $\bar{n}$ possessed by the seven crystal systems :

TABLE 11

The n or $\bar{n}$-axes of the Seven Crystal Systems

Crystal System	n or $\bar{n}$-axis	Crystal System	n or $\bar{n}$-axis
Cubic	Many 3-fold or $\bar{3}$ axes	Orthorhombic	2 or many 2-fold axes
Tetragonal	4 or $\bar{4}$ axes	Monoclinic	2 or $\bar{2}$ axes
Hexagonal	6 or $\bar{6}$ axes	Triclinic	1 or $\bar{1}$ axis
Trigonal	3 or $\bar{3}$ axes		

Table 12 lists the 32 point groups corresponding to seven crystal systems :

TABLE 12

The 32 Point Groups Corresponding to the Seven Crystal Systems

System	Example	Unit Cell Parameters	Point Groups (HM Notation)
Cubic	NaCl	$a=b=c$, $\alpha=\beta=\gamma=90°$	23, $2/m\ \bar{3}$, $\bar{4}$, $3m$, 432, $4/m$, $\bar{3}\,2/m$
Tetragonal	SnO_2	$a=b\neq c$, $\alpha=\beta=\gamma=90°$	4, $\bar{4}/m$, $4mm$, $\bar{4}2m$, 422, $4/m\ 2/m\ 2/m$
Hexagonal	SiO_2	$a=b\neq c$, $\alpha=\beta=90°$, $\gamma=120°$	6, $\bar{6}$, $6/m$, $6mm$, 622, $\bar{6}2m$, $6/m\ 2/m\ 2/m$
Trigonal	$CaCO_3$	$a=b=c$, $\alpha=\beta=\gamma\neq 90°$	3, $\bar{3}$ $3m$, 32, $\bar{3}\,2/m$
Orthorhombic	KNO_3	$a\neq b\neq c$, $\alpha=\beta=\gamma=90°$	$2mm$, 222, $2/m\ 2/m\ 2/m$
Monoclinic	$CaSO_4.2H_2O$	$a\neq b\neq c$, $\alpha=\beta=90°$, $\gamma\neq 90°$	2, m, $2/m$
Triclinic	$K_2Cr_2O_7$	$a\neq b\neq c$, $\alpha\neq\beta\neq\gamma\neq 90°$	I, 1

Internal Symmetry of Crystals. On the basis of the arrangement of atoms or ions in the lattice, Auguste Bravais, the 19th century French crystallographer, determined that only fourteen space lattices, now referred to as the *Bravais Lattices*, are possible for the seven crystal systems. When combined with the symmetry operations, they generate 230 space groups (Table 13).

TABLE 13

14 Bravais Lattices and 230 Space groups

System	Number of Space Lattices*	Number of Space Groups
Cubic	3 (P, I, F)	36
Tetragonal	2 (P, I)	68
Hexagonal	1 (P)	27
Trigonal (Rhombohedral)	1 (R)	25
Orthorhombic	4 (P, F, I, C)	59
Monoclinic	2 (P, C)	13
Triclinic	1 (P)	2
	Total : 14	Total : 230

*P : Primitive ; I : Body-centered ; F : Face-centered ; C : End-centered ; R : Rhombohedral

Two types of space groups result depending upon the presence or absence of translational elements of symmetry in a crystal. It is found that the 230 space groups can be grouped into 73 space groups containing no translational elements of symmetry and 157 space groups involving translational elements of symmetry.

1. Space groups without translational elements of symmetry. The symbol for such a space group is described by mentioning the space lattice and the symmetry point group of the crystal in the Hermann-Mauguin (HM) notation.

A few examples of space groups are I 23 (in the cubic system), P 6 *mm* (in the hexagonal system), F $2/m\ 2/m\ 2/m$ (in the orthorhombic system) and C $2/m$ (in the monoclinic system). They denote, respectively, the body-centered Bravais lattice with point group 23, the primitive Bravais lattice with point group 6 *mm*, the face-centered Bravais lattice with point group $2/m\ 2/m\ 2/m$ and the side-centered Bravais lattice with point group $2/m$.

2. Space groups with translational elements of symmetry. In order to describe such space groups we must first describe what is translational symmetry. Translational symmetry is defined by two symmetry elements, *viz., the screw axis* and *the glide plane.*

Screw Axis. Let us consider a set of equivalent atoms, say, a_1, a_2, a_3, a_4, a_5, a_6 within a crystal structure. A screw axis is defined by an operation which combines a rotation corresponding to 2-, 3-, 4- or 6-fold axis with a translation parallel to the axis. Fig. 17(*a*) shows a normal 2-fold axis in which atom a_1 is related to atom a_2 by a rotation about the rotation axis through 180°. Fig. 17(*b*), on the other hand, shows a 2-fold screw axis, denoted by 2_t, in which atom a_1 is related to atom a_2 by rotation through 180° about the rotation axis followed by $t/2$ translation parallel to the axis. This is expressed by saying that a 2-fold axis generates a 2_t *screw axis*.

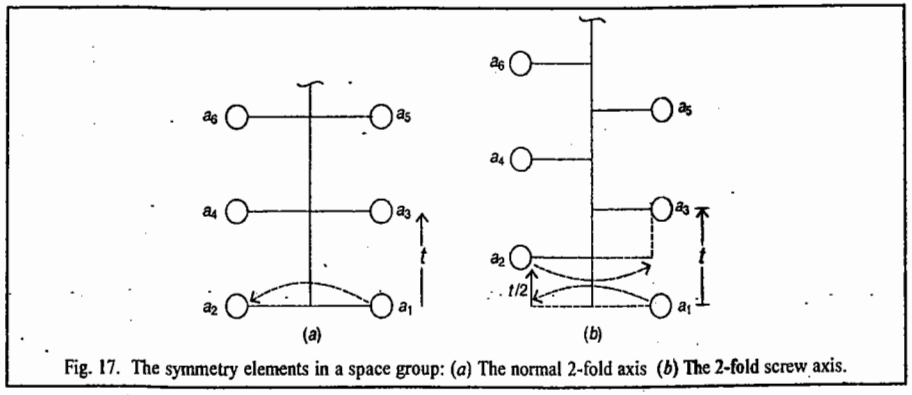

Fig. 17. The symmetry elements in a space group: (*a*) The normal 2-fold axis (*b*) The 2-fold screw axis.

Similarly, a 3-fold axis generates two screw axes : 3_1 and 3_2 ; the former corresponding to a 120° rotation about the axis followed by a translation $t/3$, and the latter corresponding to a 240° rotation about the axis followed by a translation $2t/3$. Similarly, a 4-fold axis generates three screws axes 4_1, 4_2 and 4_3 while a 6-fold axis generates 6_1, 6_2, 6_3, 6_4 and 6_5 screw axes.

Glide Planes. Consider again a set of equivalent atoms a_1, a_2, a_3, a_4, a_5, a_6, a_7, a_8 within a crystal structure. A glide plane is defined by an operation which involves a translation $t/2$ parallel to the reflection plane followed by reflection across the plane. Here t is the distance between the successive atoms. Fig. 18(*a*) shows a normal mirror plane and Fig. 18(*b*) shows the glide plane. The glide planes are further classified into three kinds, *viz., axial glides*, *diagonal glides* and *diamond glides*.

Axial glides are planes having glide component parallel to a crystallographic axis *a*, *b* or *c* and with length equal to $a/2$, $b/2$ or $c/2$. They are denoted as *a* glide, *b* glide or *c* glide. Diagonal glides, denoted by the symbol *n*, correspond to planes whose glide component is the vector sum of any of the two vectors $a/2$, $b/2$ or $c/2$. The diamond glides, denoted by the symbol *d*, correspond to planes whose glide component is the vector sum of any of the two vectors $a/4$, $b/4$ or $c/4$.

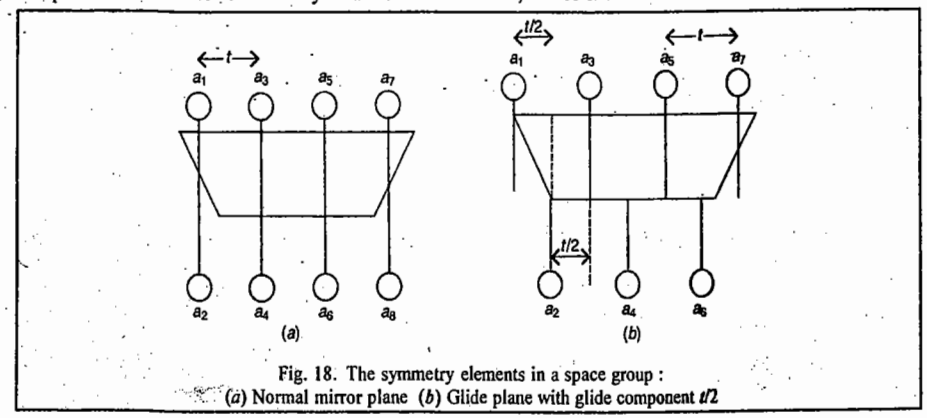

Fig. 18. The symmetry elements in a space group :
(*a*) Normal mirror plane (*b*) Glide plane with glide component $t/2$

The space group for a crystal containing translational symmetry elements is described by mentioning the Bravais lattice, the symmetry point group of the crystal in the HM notation and the translational symmetry elements. Thus, for instance, the space group $P\,2_1/b\,2_1/a\,2/m$ for an orthorhombic crystal has the following interpretation : It means that (*i*) the Bravais lattice is primitive ; (*ii*) the *a*-axis is a 2_1 screw axis having a *b*-glide plane normal to it ; (*iii*) the *b*-axis is also a 2_1 screw axis with an *a*-glide plane normal to it ; (*iv*) the *c*-axis is the ordinary 2-fold axis and (*v*) the ordinary mirror plane is normal to the 2-fold axis. All the 230 space groups have similar notation and interpretation.

Molecular Symmetry and Crystallographic Symmetry. Table 14 compares the two kinds of symmetry.

TABLE 14

Comparison between Molecular and Crystallographic Symmetry

Molecular Symmetry	Crystallographic Symmetry
1. C_n axis of order n (where n =1, 2, 3, 4,..., ∞) is present.	C_n axis of order n (n = 1, 2, 3, 4, 6) is present. Note that 5-fold axis is not present.
2. Rotation-reflection axis is present.	Rotation-inversion axis is present.
3. The number of point groups is not limited.	The number of point groups is 32.
4. Schoenflies notation is used to denote point groups.	Hermann-Mauguin (HM) notation is used to denote point groups.

Quasicrystals. Recently, quasicrystals have been prepared by metallurgists. A quasicrystal has 5-fold axis of symmetry. The best known quasicrystal is an alloy of solidified aluminium and a transition metal such as chromium, manganese or iron. It possesses the icosahedral symmetry (the icosahedral point group I_h consists of twelve 5-fold axes of symmetry). A quasicrystal occurs primarily as a metastable phase and its dimension is so small that it cannot be investigated by the conventional X-ray single crystal diffractometry. Quasicrystals can be prepared by techniques such as rapid solidification of alloys, rapid pressurization of the melt and precipitation from solid solutions. They can be studied by transmission electron microscopy. Quasicrystals having the symmetry of such polyhedra as icosahedron, pentagonal dodecahedron and triacontahedron have been prepared. They are very hard and are also very poor conductors of heat and electricity ; they are used as thermoelectric materials which convert heat into electricity. They were discovered by the Israeli scientist Daniel Shechtman who was awarded the 2011 Nobel Prize in Chemistry. Their discovery was a "shock" to crystallographers. Even Linus Pauling, the great colossus of science, had mounted a "crusade" against Shechtman, saying, "There is no such thing as quasicrystals, only quasi-scientists". However, nature has always the last laugh.

Problems

1. List the symmetry elements and the Schoenflies symbols for each of the following molecules :

(*a*) H_2S, (*b*) PCl_3 (pyramidal), (*c*) $\begin{matrix}H\\Cl\end{matrix}\!\!>\!C{=}O$, (*d*) IF_5 (square pyramidal), (*e*) B_2H_6, (*f*) p-Dichlorobenzene (*g*) Naphthalene, (*h*) Thiophene, (*i*) SiF_4, (*j*) NH_2Cl, (*k*) BF_4^-, (*l*) CO_3^{2-}(*m*) SiFClBrI, (*n*) trans-N_2F_2, (*o*) Cyclohexane, (*p*) $CHClBr(CH_3)$, (*q*) $CF_2{=}CF_2$, (*r*) 1,2-dichlorobenzene, (*s*) XeF_2(linear), (*t*) monosodium acetylide (H–C≡C–Na), (*u*) *trans*-$[CrBr_2(H_2O)_4]^+$ (ignore Hs), (*v*) gauche-CH_2Cl CH_2Cl, (*w*) Ketene ($CH_2{=}C{=}O$), (*x*) $CH_2{=}O$, (*y*) $[IO_6]^{5-}$ (octahedral), (*z*) 

[Ans. (*a*) C_{2v}, (*b*) C_{3v}, (*c*) C_s, (*d*) C_{4v}, (*e*) D_{2h}, (*f*) D_{2h}, (*g*) D_{2h}, (*h*) C_{2v}, (*i*) T_d, (*j*) C_s, (*k*) T_d, (*l*) D_{3h}, (*m*) C_1, (*n*) C_{2h}, (*o*) D_{3d}, (*p*) C_1, (*q*) D_{2h}, (*r*) C_{2v}, (*s*) $D_{\infty h}$, (*t*) $C_{\infty v}$, (*u*) D_{4h}, (*v*) C_2, (*w*) C_{2v}, (*x*) C_{2v}, (*y*) O_h, (*z*) C_{2v} **]**

2. Which of the following molecules and ions has (*i*) a centre of inversion, (*ii*) an S_4 axis, : (*a*) CO_2, (*b*) C_2H_2, (*c*) BF_3, (*d*) SO_4^{2-}? [Ans. (*i*) CO_2, C_2H_2, (*ii*) SO_4^{2-}]

3. Assuming that a molecule AB_6 belongs to O_h point group, determine the point groups that result if it is changed into (*a*) AB_5C, (*b*) trans-AB_4C_2, (*c*) *cis*-AB_4C_2 [Ans. (*a*) C_{4v}, (*b*) D_{4h}, (*c*) C_{2v}]

4. In the solid state, phosphorus(V) chloride exists as an ionic solid composed of PCl_4^+ cations and PCl_6^- anions but the vapour is molecular. To what point groups do the ionic species in the solid belong ? [Ans. T_d and O_h, respectively]

5. Draw the structures of three distinct isomers of $C_2H_2Cl_2$ and determine their point groups. Which of them is polar ?

[Ans.  (1, 1-dechloroethylene) (C_{2v}) ; polar  (*trans*-1, 2-dichloroethylene) (C_{2h}) ; nonpolar  (*cis*-1, 2-dichloroethylene) (C_{2v}) ; polar]

6. There are 10 distinct isomers of dichloronaphthalene, $C_{10}H_6Cl_2$. Two of them are nonpolar. Draw the structures of these nonpolar isomers and determine the point group to which they belong.

[Ans.  (C_{2h}) ;  (C_{2h})]

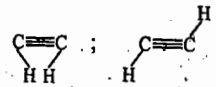
7. Explain why a set of numbers cannot form a group by the process of division.

[Ans. The reason is that the associative law of combination is not obeyed, *i.e.*, $A/(B/C) \neq (A/B)/C$. Thus, for example, 3/(4/5) = 15/4 ; and (3/4)/5 = 3/20]

8. Explain why the set of integers between 0 and ∞ do not form a group under the process of multiplication.

[Ans. The reason is that the inverse of every element is a fraction which is not a member of the set.]

9. In some of the electronic excited states, acetylene, a linear molecule, may exist as *cis*-bent or as *trans*-bent, as shown below :



(*cis*-bent) (*trans*-bent)

Determine the point groups of these geometries. [Ans. C_{2v} and C_{2h}]

10. State G.O.T. and list the properties of the irreps.

11. Using G.O.T., derive the character table for C_{2v} point group.

12. Using G.O.T., derive the character table for C_{3v} point group.

CHAPTER 5

GROUP THEORY–II. APPLICATIONS

The basic concepts of group theory have been discussed at length in the previous chapter. The ideas of symmetry described mathematically by the group theory find wide applications which will be discussed in this chapter. These applications include ; assigning the modes of molecular vibrations to the irreducible representations of the point groups to which a molecule belongs, determining which orbitals are used for hybridisation in chemical bonding, deriving the selection rules for spectral transitions, etc. The most spectacular application of group theory is in determining the vanishing of the integrals (matrix elements) in quantum mechanical calculations.

1. Decomposing a Reducible Representation into its Irreducible Representations

We shall derive an extremely important result which allows us to determine how many times the *j*th irrep is contained in a rep (reducible representation). In general, any rep Γ can be written as a linear combination of irreps as shown below :

$$\Gamma = n_1\Gamma_1 + n_2\Gamma_2 + n_3\Gamma_3 + \ldots\ldots \qquad \ldots(1)$$

where Γ_1, Γ_2, Γ_3, ... are the irreps and n_1, n_2, n_3, ... are the number of times each irrep occurs in Γ.

Recalling that the character of a matrix is unaltered by a similarity transformation, we can write

$$\chi(R) = \Sigma n_i \chi_i(R) \qquad \ldots(2)$$

where $\chi(R)$ is the character of the matrix corresponding to an operation R in the rep and n_i refers to the number of times the block constituting the irrep repeats itself in the diagonal; $\chi_i(R)$ is the character of the matrix for the operation R in the *i*th irrep. Multiplying Eq. 2 by $\chi_j(R)$ and summing over R, we obtain

$$\sum_R \chi_j(R)\chi(R) = \sum_R \sum_i n_i\chi_j(R)\chi_i(R) = \sum_i n_i \sum_R \chi_i(R)\chi_j(R) \qquad \ldots(3)$$

Using the property of the irreps, *viz.*,

$$\sum_R \chi_i(R)\chi_j(R) = h\delta_{ij}, \qquad \ldots(4)$$

we find that Eq. 3 becomes

$$\sum_R \chi_j(R)\chi(R) = \sum_i n_i h\delta_{ij} \qquad \ldots(5)$$

The term for which $i = j$ survives in the summation so that Eq. 5 reduces to

$$\sum_R \chi_j(R)\chi(R) = n_j h \qquad \ldots(6)$$

Hence,

$$n_j = \frac{1}{h}\sum_R \chi_j(R)\chi(R) \qquad \ldots(7)$$

If g_p is the number of operations in the *p*th class of the group, then Eq. 7 becomes

$$n_j = \frac{1}{h}\sum_{R_p} g_p\chi(R_p)\chi_j(R_p) \qquad \ldots(8)$$

where R_p denotes the symmetry operation in the pth class. Eq. 7 or Eq. 8, known as **the standard reduction formula**, gives the relation which determines the number of times the jth irrep occurs in the rep.

Example 1. Suppose that the characters of a reducible representation of the C_{2v} point group are $\chi(E) = 4$, $\chi(C_2) = 2$, $\chi(\sigma_v) = 0$ and $\chi(\sigma_v') = 2$. This is usually expressed by writing $\Gamma = 4\ 2\ 0\ 2$. Determine how many times each irreducible representation of C_{2v} is contained in $\Gamma = 4\ 2\ 0\ 2$.

Solution :
$$n_j = \frac{1}{h}\sum_R \chi_j(R)\chi(R) \qquad \text{(Eq. 7)}$$

The order h of the C_{2v} point group is 4. Hence, using the character table of the C_{2v} point group and the above equation, we get

$$n_{A_1} = \frac{1}{4}[1\times 4 + 1\times 2 + 1\times 0 + 1\times 2] = 2$$
$$n_{A_2} = \frac{1}{4}[1\times 4 + 1\times 2 + (-1)\times (0) + (-1)\times 2] = 1$$
$$n_{B_1} = \frac{1}{4}[1\times 4 + (-1)\times 2 + 1\times 0 + (-1)\times 2] = 0$$
$$n_{B_2} = \frac{1}{4}[1\times 4 + (-1)\times 2 + (-1)\times 0 + 1\times 2] = 1$$

Thus, $\Gamma = 2A_1 + A_2 + B_2$

Example 2. Suppose that the characters of a reducible representation of the C_{3v} point group are expressed as $\Gamma = 3\ 0\ -1$. Determine how many times each irreducible representation of C_{3v} is contained in the above rep.

Solution :
$$n_j = \frac{1}{h}\sum_{R_p} g_p\chi(R_p)\chi_j(R_p) \qquad \text{[Eq. 8]}$$

The order h of the C_{3v} point group is 6. Hence, using the character table of the C_{3v} point group and the above equation, we get

$$n_{A_1} = \frac{1}{6}[1\times 3\times 1 + 2\times 0\times 1 + 3\times (-1)\times 1] = 0$$
$$n_{A_2} = \frac{1}{6}[1\times 3\times 1 + 2\times 0\times 1 + 3\times (-1)\times (-1)] = 1$$
$$n_E = \frac{1}{6}[1\times 3\times 2 + 2\times 0\times (-1) + 3\times (-1)\times 0] = 1$$

Thus, $\Gamma = A_2 + E$

2. Group Theory and Normal Modes of Vibrations of Polyatomic Molecules

The normal modes of vibration that set a polyatomic molecule into a periodic oscillation in which the nuclei move in phase, that is, they all pass through the mean position at the same time, are of great importance in vibrational analysis since any arbitrary vibration of the molecule can be described by a superposition of the normal modes. We shall briefly review the normal mode analysis here.

The potential energy V of a molecule can be written as a Taylor's series :

$$V = V_0 + \sum_i \left(\frac{\partial V}{\partial q_i}\right)_0 q_i + \frac{1}{2}\sum_i\sum_j \left(\frac{\partial^2 V}{\partial q_i \partial q_j}\right)_0 q_i q_j + \cdots \qquad \ldots(9)$$

where q_i, q_j, ... are the coordinates of the nuclei i, j, ..., and the subscript zero refers to the equilibrium state of the molecule. Since V_0 is the potential energy in the equilibrium state and hence, a constant, we can arbitrarily call it zero. The term $(\partial V/\partial q)_0$ corresponds to the minimum of the potential energy curve and is, therefore, also set equal to zero. Neglecting all the higher terms except one in Eq. 9, Eq. 9 reduces to

$$V = \frac{1}{2}\sum_i\sum_j \left(\frac{\partial^2 V}{\partial q_i \partial q_j}\right)_0 q_i q_j = \frac{1}{2}\sum_i\sum_j b_{ij} q_i q_j \qquad \ldots(10)$$

where $b_{ij} = \left(\dfrac{\partial^2 V}{\partial q_i \partial q_j}\right)_0$

Similarly, the kinetic energy T of the molecule can also be written in the form of a Taylor's series. Thus,

$$T = \frac{1}{2}\sum_i\sum_j a_{ij}\,\dot{q}_i\,\dot{q}_j \qquad \ldots(11)$$

where $\dot{q} = dq/dt$ and the a_{ij} are functions of the mass of atoms.

Eqs. 10 and 11 can be used to construct the Hamiltonian operator, $\hat{H}$, for the Schrödinger wave equation. (Recall that $H = T + V$.) However, the cross products of the types q_iq_j prevent the separation of variables. This problem can be solved by using the normal coordinates Q such that

$$\left.\begin{aligned} q_1 &= c_{11}Q_1 + c_{12}Q_2 + c_{13}Q_3 + \cdots\cdots \\ q_2 &= c_{21}Q_1 + c_{22}Q_2 + c_{23}Q_3 + \cdots\cdots \\ &\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ q_i &= c_{i1}Q_1 + c_{i2}Q_2 + c_{i3}Q_3 + \cdots\cdots \end{aligned}\right\} \qquad \ldots(12)$$

By a suitable choice of the coefficients c_{ij} of this linear transformation, it is possible to write T and V in terms of the new coordinates as

$$T = \frac{1}{2}(\dot{Q}_1^2 + \dot{Q}_2^2 + \cdots\cdots + \dot{Q}_{3N}^2) = \frac{1}{2}\sum_i \dot{Q}_i^2 \qquad \ldots(13)$$

and
$$V = \frac{1}{2}(\lambda_1\dot{Q}_1^2 + \lambda_2\dot{Q}_2^2 + \cdots\cdots + \lambda_N\dot{Q}_{3N}^2) = \frac{1}{2}\sum_i \lambda_i Q_i^2 \qquad \ldots(14)$$

where $\lambda_i = 4\pi^2\nu_i^2$.

We can now proceed to solve the time-independent Schrödinger wave equation for the vibrational problem. For each normal coordinate Q_i, that is, for each normal mode, we have

$$\hat{H} = \hat{T} + \hat{V} \qquad \ldots(15)$$

so that the Schrödinger wave equation is

$$-\frac{\hbar^2}{2}\frac{\partial^2\psi(Q_i)}{\partial Q_i^2} + \frac{\lambda_i Q_i^2}{2}\psi(Q_i) = E_i\psi(Q_i) \qquad \ldots(16)$$

The total vibrational energy is given by

$$E_{vib} = E_1 + E_2 + E_3 + \cdots\cdots + E_{3N-5,6} = \sum_i^{3N-5,6} E_i \qquad \ldots(17)$$

where $E_i = \left(v + \dfrac{1}{2}\right)h\nu_i$. The total wave function is given by

$$\psi_{vib} = \psi_v(Q_1)\ \psi_v(Q_2)\ \cdots\cdots\ \psi_v(Q_{3N-5,6}) = \prod_i^{3N-5,6} \psi_v(Q_i) \qquad \ldots(18)$$

where the subscript v denotes the particular vibrational level and i the particular vibrational mode.

We know that the eigenfunctions of a simple harmonic oscillator are given by

$$\psi_v(\xi) = N_v H_v(\xi)\exp(-\xi^2/2) \qquad \ldots(19)$$

where $H_v(\xi)$ are the Hermite polynomials. Writing Q_i for ξ, we have, for the ground state ($v=0$),

$$\psi_0(Q_i) = \left(\frac{1}{\alpha_i\pi}\right)^{1/2}\exp\left(-\frac{1}{2}Q_i^2/\alpha_i\right) \qquad \ldots(20)$$

and for the first excited state ($v=1$),

$$\psi_1(Q_i) = \left(\frac{1}{\alpha_i^3\pi}\right)^{1/2} Q_i\exp\left(-\frac{1}{2}Q_i^2/\alpha_i\right) \qquad \ldots(21)$$

Thus, assuming the simple harmonic model, we have broken the vibrational motion of the molecule down into $3N$–5 or $3N$–6 S.H.O.s in the normal coordinates Q_i. Assuming the vibrational transition $v=0 \rightarrow 1$, as required by the selection rule, there will be $3N - 5$ fundamental vibrational frequencies for the linear and $3N - 6$ fundamental vibrational frequencies for the nonlinear molecules. The vibrational frequency for the ith normal mode is given by

$$\nu_i = \frac{1}{2\pi}\left(\frac{k}{\mu}\right)^{1/2} \qquad ...(22)$$

where k is the force constant and μ is some complicated function of masses. It should be noted that k is no longer associated with a single bond as in the diatomic case and there is no straightforward correlation between k and the strength of the chemical bond.

3. Procedure for Determining the Irreducible Representations of the Vibrational Modes in Nonlinear Molecules. The procedure involves the following steps :

1. Determine the point group of the molecule.
2. Obtain the reducible representations (reps) for all the symmetry operations of the point group.
3. Split the rep into the irreps using the standard reduction formula.
4. The irreps Γ_{3N} thus obtained correspond to the translational, rotational and vibrational degrees of freedom. By subtracting the irreps (corresponding to the translational and rotational degrees of freedom) from Γ_{3N}, the irreps corresponding to the vibrational motion, Γ_{vib}, are obtained.

We shall apply the above procedure to three molecules, *viz.*, H_2O, NH_3 and BF_3.

a. Normal Modes of Vibration of H_2O Molecule. H_2O belongs to the C_{2v} point group whose character table is given below :

TABLE 1

Character Table of the C_{2v} Point Group

C_{2v}	E	C_2	σ_v	σ_v'	$h = 4$	
A_1	1	1	1	1	z	x^2, y^2, z^2
A_2	1	1	–1	–1	R_z	xy
B_1	1	–1	1	–1	x, R_y	xz
B_2	1	–1	–1	1	y, R_x	yz

The coordinate axis system for H_2O and the symmetry elements in H_2O molecule are shown in Fig. 1.

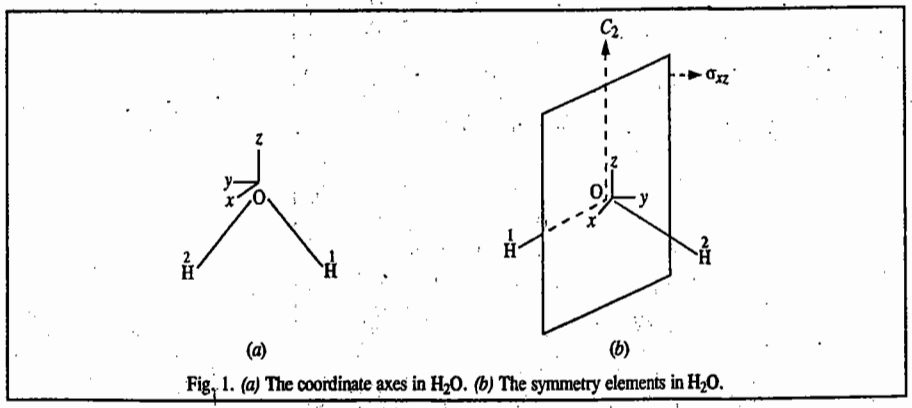


Fig. 1. *(a)* The coordinate axes in H_2O. *(b)* The symmetry elements in H_2O.

The three atoms in H_2O have 9 coordinates. Four 9×9 matrices can be constructed for the four symmetry operations (E, $C_2(z)$, $\sigma_v(x, z)$ and $\sigma_v'(y, z)$) of this molecule, as shown below :

***E* Matrix :**

$$\begin{bmatrix} x_1' \\ y_1' \\ z_1' \\ x_2' \\ y_2' \\ z_2' \\ x_3' \\ y_3' \\ z_3' \end{bmatrix} = \begin{bmatrix} 1&0&0&0&0&0&0&0&0 \\ 0&1&0&0&0&0&0&0&0 \\ 0&0&1&0&0&0&0&0&0 \\ 0&0&0&1&0&0&0&0&0 \\ 0&0&0&0&1&0&0&0&0 \\ 0&0&0&0&0&1&0&0&0 \\ 0&0&0&0&0&0&1&0&0 \\ 0&0&0&0&0&0&0&1&0 \\ 0&0&0&0&0&0&0&0&1 \end{bmatrix} \begin{bmatrix} x_1 \\ y_1 \\ z_1 \\ x_2 \\ y_2 \\ z_2 \\ x_3 \\ y_3 \\ z_3 \end{bmatrix} \qquad ...(23)$$

The character $\chi(E)$ of this matrix is equal to 9.

C_2 Matrix :

$$\begin{bmatrix} x_1' \\ y_1' \\ z_1' \\ x_2' \\ y_2' \\ z_2' \\ x_3' \\ y_3' \\ z_3' \end{bmatrix} = \begin{bmatrix} 0&0&0&-1&0&0&0&0&0 \\ 0&0&0&0&-1&0&0&0&0 \\ 0&0&0&0&0&1&0&0&0 \\ -1&0&0&0&0&0&0&0&0 \\ 0&-1&0&0&0&0&0&0&0 \\ 0&0&1&0&0&0&0&0&0 \\ 0&0&0&0&0&0&-1&0&0 \\ 0&0&0&0&0&0&0&-1&0 \\ 0&0&0&0&0&0&0&0&1 \end{bmatrix} \begin{bmatrix} x_1 \\ y_1 \\ z_1 \\ x_2 \\ y_2 \\ z_2 \\ x_3 \\ y_3 \\ z_3 \end{bmatrix} \qquad ...(24)$$

The character $\chi(C_2)$ of this matrix is equal to –1.

$\sigma_v(xz)$ Matrix :

$$\begin{bmatrix} x_1' \\ y_1' \\ z_1' \\ x_2' \\ y_2' \\ z_2' \\ x_3' \\ y_3' \\ z_3' \end{bmatrix} = \begin{bmatrix} 0&0&0&1&0&0&0&0&0 \\ 0&0&0&0&-1&0&0&0&0 \\ 0&0&0&0&0&1&0&0&0 \\ 1&0&0&0&0&0&0&0&0 \\ 0&-1&0&0&0&0&0&0&0 \\ 0&0&1&0&0&0&0&0&0 \\ 0&0&0&0&0&0&1&0&0 \\ 0&0&0&0&0&0&0&-1&0 \\ 0&0&0&0&0&0&0&0&1 \end{bmatrix} \begin{bmatrix} x_1 \\ y_1 \\ z_1 \\ x_2 \\ y_2 \\ z_2 \\ x_3 \\ y_3 \\ z_3 \end{bmatrix} \qquad ...(25)$$

The character $\chi(\sigma_v(x\,z))$ of this matrix is equal to 1.

$\sigma_v'(yz)$ Matrix :

$$\begin{bmatrix} x_1' \\ y_1' \\ z_1' \\ x_2' \\ y_2' \\ z_2' \\ x_3' \\ y_3' \\ z_3' \end{bmatrix} = \begin{bmatrix} -1&0&0&0&0&0&0&0&0 \\ 0&1&0&0&0&0&0&0&0 \\ 0&0&1&0&0&0&0&0&0 \\ 0&0&0&-1&0&0&0&0&0 \\ 0&0&0&0&1&0&0&0&0 \\ 0&0&0&0&0&1&0&0&0 \\ 0&0&0&0&0&0&-1&0&0 \\ 0&0&0&0&0&0&0&1&0 \\ 0&0&0&0&0&0&0&0&1 \end{bmatrix} \begin{bmatrix} x_1 \\ y_1 \\ z_1 \\ x_2 \\ y_2 \\ z_2 \\ x_3 \\ y_3 \\ z_3 \end{bmatrix} \qquad ...(26)$$

The character $\chi(\sigma_v(yz))$ of this matrix is equal to 3.

We thus obtain the following Γ_{3N} reducible representation (rep) for the $3N$ coordinates :

Operation	E	C_2	$\sigma_v(xz)$	$\sigma_v'(yz)$
Γ_{3N}	9	–1	1	3

A simple rule states that the character for the operation R in the rep $\chi_{xyz}(R)$ is equal to the product of the number of *unshifted* atoms, U_R and the character of the matrix for the operation R, $\chi(R)$.

Using the standard reduction formula (Eq. 8) and the character table for the C_{2v} point group, the above mentioned reducible representation is split into the various irreps as follows :

$$n_{A_1} = \frac{1}{4}[1 \times 9 \times 1 + 1 \times (-1) \times 1 + 1 \times 1 \times 1 + 1 \times 3 \times 1] = 3$$

$$n_{A_2} = \frac{1}{4}[1 \times 9 \times 1 + 1 \times (-1) \times 1 + 1 \times 1 \times (-1) + 1 \times 3 \times (-1)] = 1$$

$$n_{B_1} = \frac{1}{4}[1 \times 9 \times 1 + 1 \times (-1) \times (-1) + 1 \times 1 \times 1 + 1 \times 3 \times (-1)] = 2$$

$$n_{B_2} = \frac{1}{4}[1 \times 9 \times 1 + 1 \times (-1) \times (-1) + 1 \times 1 \times (-1) + 1 \times 3 \times 1] = 3$$

Hence, $\Gamma_{3N} = 3A_1 + A_2 + 2B_1 + 3B_2$ ...(27)

Now, Γ_{vib}, *i.e.*, the sum of the irreps of the vibrational modes, is related to Γ_{3N} by

$$\Gamma_{vib} = \Gamma_{3N} - (T_x + T_y + T_z + R_x + R_y + R_z) \quad ...(28)$$

where T_x, T_y, T_z refer to the representations of the translational degrees of freedom and R_x, R_y, R_z refer to the representations of the rotational degrees of freedom. Note that $x \to T_x$, $y \to T_y$ and $z \to T_z$ so that using the values of T_x, T_y, T_z and R_x, R_y, R_z from the section III of the C_{2v} point group, we obtain

$$\Gamma_{vib} = (3A_1 + A_2 + 2B_1 + 3B_2) - (B_1 + B_2 + A_1 + B_2 + B_1 + A_2) \quad ...(29)$$

or $\Gamma_{vib} \equiv \Gamma_{3N-6} = 2A_1 + B_2$

We thus find that the three normal modes of vibration of H_2O molecule belong to A_1 and B_2 symmetry species (irreps). The vibrations belonging to A_1 symmetry are called totally symmetric vibrations. (If a vibration is symmetric with respect to the highest-fold rotation axis, it is designated by A and if the vibration is antisymmetric about the same axis, it is designated by B. The letter E which is absent here, is for doubly degenerate vibrations).

b. Normal Modes of Vibration of NH_3 Molecule. NH_3 belongs to the C_{3v} point group whose character table is given below :

TABLE 2

Character Table of the C_{3v} Point Group

C_{3v}	E	$2C_3$	$3\sigma_v$	$h = 6$	
A_1	1	1	1	z	$x^2 + y^2, z^2$
A_2	1	1	–1	R_z	
E	2	–1	0	(x, y) (R_x, R_y)	$(x^2 - y^2, xy)$, (xz, yz)

Using the procedure given above, we obtain the following reducible representation (rep) for the NH_3 molecule (whose symmetry elements are shown in Fig. 2) :

Operation	E	$2C_3$	$3\sigma_v$
Γ_{3N}	12	0	2

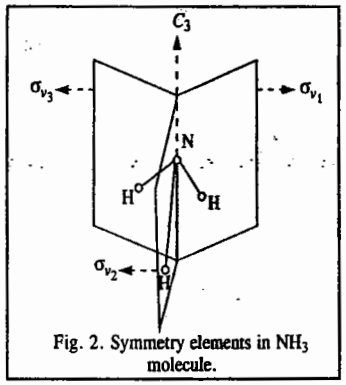

Fig. 2. Symmetry elements in NH_3 molecule.

Using the standard reduction formula (Eq. 8), this reducible representation is split into the following irreps :

$$\Gamma_{3N} = 3A_1 + A_2 + 4E \quad ...(30)$$

Now, Γ_{vib}, *i.e.*, the sum of the reps of the vibration modes, is related to Γ_{3N} by

$$\Gamma_{vib} = \Gamma_{3N} - (T_x + T_y + T_z + R_x + R_y + R_z) \quad ...(31)$$

From section III of the C_{3v} point group,

$$T_x + T_y + T_z = A_1 + E \text{ and } R_x + R_y + R_z = A_2 + E$$

Hence, $\Gamma_{vib} = (3A_1 + A_2 + 4E) - (A_1 + E + A_2 + E)$

$$= 2A_1 + 2E \quad ...(32)$$

We see that two normal modes of vibration of NH_3 molecule belong to the totally symmetric species A_1 and four modes belong to the doubly degenerate symmetry E.

c. Normal Modes of Vibration of BF_3 Molecule. BF_3 belongs to the D_{3h} point group whose character table is given below :

TABLE 3

Character Table of the D_{3h} Point Group

D_{3h}	E	$2C_3$	$3C_2$	σ_h	$2S_3$	$3\sigma_v$	$h=12$	
A_1'	1	1	1	1	1	1		$x^2 + y^2, z^2$
A_2'	1	1	–1	1	1	–1	R_z	
E'	2	–1	0	2	–1	0	(x, y)	$x^2 - y^2, xy$
A_1''	1	1	1	–1	–1	–1		
A_2''	1	1	–1	–1	–1	1	z	
E''	2	–1	0	–2	1	0	(R_x, R_y)	(xz, yz)

Using the procedure given above, we obtain the following reducible representation (rep) for the BF_3 molecule (whose symmetry elements are shown in Fig. 3) :

Operation	E	$2C_3$	$3C_2$	σ_h	$2S_3$	$3\sigma_v$
Γ_{3N}	12	0	–2	4	–2	2

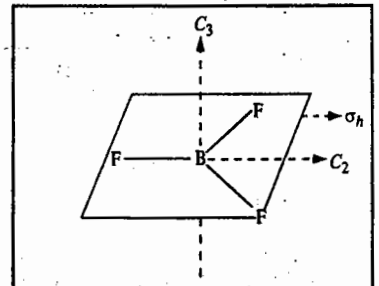

Fig. 3. The symmetry elements in BF_3 molecule

Using the standard reduction formula (Eq. 8), this reducible representation is split into the following irreps :

$$\Gamma_{3N} = A_1' + A_2' + 3E' + 2A_2'' + E'' \quad ...(33)$$

As before, $\Gamma_{vib} = \Gamma_{3N} - (T_x + T_y + T_z + R_x + R_y + R_z)$ ...(34)

From section III of the character table of the D_{3h} point group, we have

$$(T_x, T_y) = E' \text{ and } T_z = A_2'' \text{ (for translation)}$$

$$(R_x, R_y) = E'' \text{ and } R_z = A_2' \text{ (for rotations)}$$

Hence,
$$\Gamma_{vib} = (A_1' + A_2' + 3E' + 2A_2'' + E'') - (E' + A_2'' + E'' + A_2')$$
$$= A_1' + A_2'' + 2E' \quad ...(35)$$

Fig. 4 shows the normal modes of vibration of BF_3 molecule.

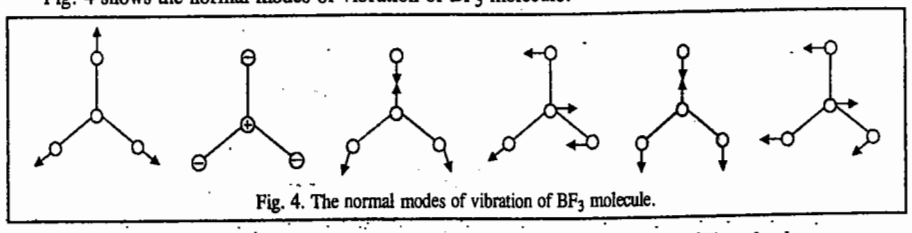

Fig. 4. The normal modes of vibration of BF_3 molecule.

Example 3. Establish the symmetry species of the normal modes of vibration of CH_4 molecule.

Solution : Refer to Fig. 5. There are $3\times5 = 15$ possible displacements, of which $3\times5 - 6 = 9$ are the normal modes of vibration.

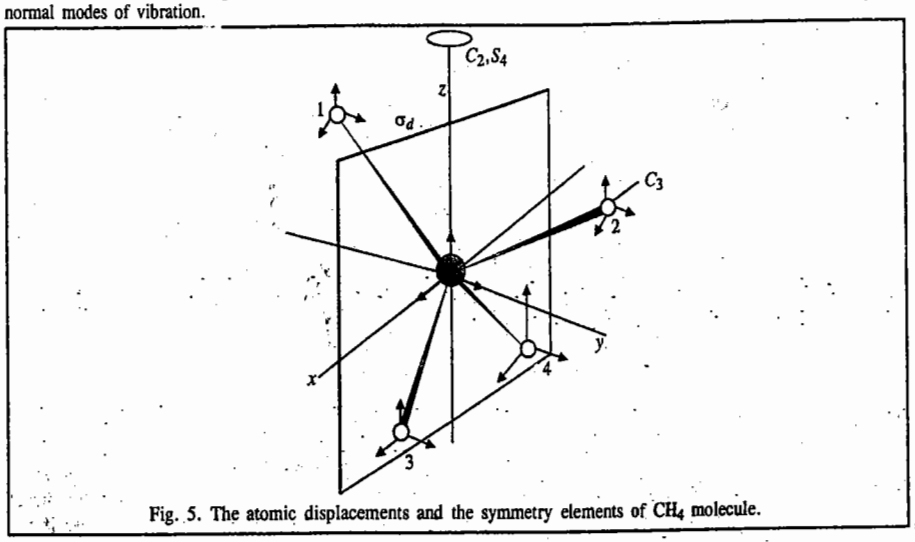

Fig. 5. The atomic displacements and the symmetry elements of CH_4 molecule.

The character table of the T_d point group to which CH_4 molecule belongs is given below :

TABLE 4

Character Table of the T_d Point Group

T_d	E	$8C_3$	$3C_2$	$6S_4$	$6\sigma_d$	$h = 24$	
A_1	1	1	1	1	1		$x^2 + y^2 + z^2$
A_2	1	1	1	-1	-1		
E	2	-1	2	0	0		$(2z^2 - x^2 - y^2, x^2 - y^2)$
T_1	3	0	-1	1	-1	(R_x, R_y, R_z)	
T_2	3	0	-1	-1	1	(x, y, z)	(xy, xz, yz)

Under the identity operation E, no displacement coordinates are changed. Hence, the character is 15. Under C_3, no. displacements are left unchanged, so the character is 0. Under a C_2 rotation, the z-displacement of the central atom is left unchanged while the x- and y-displacement components both change sign. Hence, $\chi(C_2) = 1 - 1 - 1 + 0 + 0 = -1$. Under S_4, the z-displacement of the central atom is reversed, so $S_4 = -1$. Under σ_d, the x- and z-displacements of C, H (3) and H (4) are left unchanged and the y-displacements are reversed. Hence, $\chi(\sigma_d) = 3 + 3 - 3 = 3$. Thus, we obtain the following reducible representation (rep) for the $3N$ coordinates :

Operation	E	$8C_3$	$3C_2$	$6S_4$	$6\sigma_d$
Γ_{3N}	15	0	-1	-1	3

Using the standard reduction formula (Eq. 8) and the character table for the T_d point group, we find that

$$\Gamma_{3N} = A_1 + E + T_1 + 3T_2 \quad ...(36)$$

Since the translations span T_2 and the rotations span T_1, we have

$$\Gamma_{vib} = (A_1 + E + T_1 + 3T_2) - (T_2 + T_1)$$
$$= A_1 + E + 2T_2 \quad ...(37)$$

The normal vibrational modes of CH_4, a tetrahedral molecule, are shown in Fig. 6.

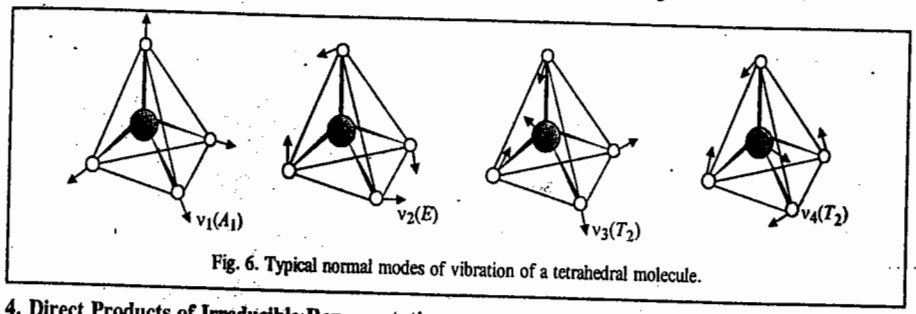

Fig. 6. Typical normal modes of vibration of a tetrahedral molecule.

4. Direct Products of Irreducible Representations

If ψ_i and ψ_j are the wave functions which form a basis for the irreps of a point group, then the product of these wave functions can also form a basis for the representation of the group. This representation is called the **direct product representation.** Let $\chi^{\mu}(R)$ and $\chi^{\nu}(R)$ denote the characters for operation R in the representations μ and ν, respectively. Then the character $\chi^{\mu\nu}(R)$ of the operation R in the direct product representation is given by

$$\chi^{\mu\nu}(R) = \chi^{\mu}(R)\, \chi^{\nu}(R) \quad ...(38)$$

An important application of this concept is that *the integral of the product of two or more functions over symmetric interval is nonzero if the direct product representation is totally symmetric.* If the direct product representation is reducible, then the integral of the product function is non-zero only if the direct product representation contains the totally symmetric species.

Let ψ_i and ψ_j be the wave functions of two energy states i and j and μ, the dipole moment vector whose components are μ_x, μ_y and μ_z is thus given by

$$\mu = \mu_x + \mu_y + \mu_z \quad ...(39)$$

Also, $\mu_x = ex$; $\mu_y = ey$ and $\mu_z = ez$ where e is the electronic charge. The transition will be allowed only if μ_{ij}, the matrix element (transition dipole moment integral) between the states i and j is nonzero :

$$\mu_{ij} = \langle \psi_i | \mu | \psi_j \rangle \equiv \int \psi_i \mu \psi_j \, d\tau \quad ...(40)$$

More specifically, the transition will be allowed if at least one of the components μ_{ij} is different from zero. Since μ_{ij} is a real physical property of the molecule, it must be invariant with respect to any

rotation, reflection or inversion about the molecular symmetry axis. In other words, a transition is allowed if the product $\psi_i \mu \psi_j$ is totally symmetric for at least one orientation of μ. That is to say, if the product $\psi_i \psi_j$ and at least one of the components of μ belongs to the same irrep (IR), the transition is allowed. This can be written as direct product of irrep (IR) as

$$\Gamma_{\psi_i} \times \Gamma_{\mu} \times \Gamma_{\psi_j} = \Gamma_1 \quad \text{or} \quad A_1 \text{ (totally symmetric)} \qquad ...(41)$$

Consider H_2O molecule which belongs to the C_{2v} point group. The irreps (IRs) of the dipole moment components are : $\mu_x = B_1$, $\mu_y = B_2$, $\mu_z = A_1$. The various other states are A_1, A_2, B_1, B_2 (which are the IRs of the C_{2v} point group). Consider the transition $A_1 \rightarrow A_1$. Now,

$$\Gamma_{\psi_i} = A_1, \quad \Gamma_{\psi j} = A_1 \qquad ...(42)$$

Thus, for the μ_x component, $A_1 \mu_x A_1 = A_1 \times B_1 \times A_1 = B_1$ ...(43)

for the μ_y component, $A_1 \mu_y A_1 = A_1 \times B_2 \times A_1 = B_2$ ...(44)

for the μ_z component, $A_1 \mu_z A_1 = A_1 \times A_1 \times A_1 = A_1$ ...(45)

As the z-component gives a symmetric irrep (IR) A_1, the transition $A_1 \rightarrow A_1$ is allowed.

Consider next the transition $A_1 \rightarrow A_2$. Then,

$$\Gamma_{\psi_i} = A_1, \Gamma_{\psi_j} = A_2 \text{ so that}$$

for the μ_x component, $A_1 \times B_1 \times A_2 = B_2$ ...(46)

for the μ_y component, $A_1 \times B_2 \times A_2 = B_1$ ...(47)

for the μ_z component, $A_1 \times A_1 \times A_2 = A_2$ ...(48)

As none of the components reduces to the symmetric irrep (*IR*) A_1, the transition $A_1 \rightarrow A_2$ is forbidden, *i.e.*, not allowed. We can similarly investigate the other transitions. (It should be noted that the acronym *IR* in the above discussion stands for irreducible representation (irrep) and not for infrared.)

Thus, we conclude that **the selection rule for infrared spectra is that a fundamental vibrational frequency will be infrared-active if the excited normal modes have the same symmetry as one of the Cartesian coordinates.**

Example 4. How do you justify that if the symmetry species of a normal mode is the same as any of the symmetry species of *x*, *y* or *z*, then the mode is infrared-active ?

Solution : Consider the transition dipole moment integral between the ground state vibrational wave function ψ_0 and the first excited state wave function ψ_1 :

$$\mu_{10} = e \int \psi_0 x \psi_1 \, d\tau \qquad ...(49)$$

for the *x*-component, with similar expressions for the two other components of the transition moment. The ground state vibrational wave function is a Gaussian function of the form e^{-x^2}, so it is symmetric in *x*. The wave function for the first excited state will give a non-vanishing integral only if it is proportional to *x*, because then the integrand is proportional to x^2 rather than to *xy* or *xz*. Consequently, the excited state wave function must have the same symmetry as the displacement *x* and hence the mode is infrared active.

Example 5. Which fundamental vibrational modes of CH_4 molecule are infrared-active ?

Solution : We have shown in Example 3 that the vibrational modes of CH_4 molecule span $A_1 + E + 2T_2$, *i.e.*,

$$\Gamma_{vib} = A_1 + E + 2T_2 \qquad \text{[Eq. 37]}$$

Referring to the character table of the T_d point group (Table 4), we find that the symmetry species (irrep) of *x*, *y* and *z* is T_2. Using the selection rule stated earlier, *viz.*, the vibrational mode is infrared-active if its symmetry species is the same as any of the symmetry species of *x*, *y*, or *z*, we conclude that only the T_2 modes are infrared-active.

Example 6. Which normal modes of H_2O molecule are infrared-active ?

Solution : The normal modes of H_2O molecule are sketched in Fig. 7.

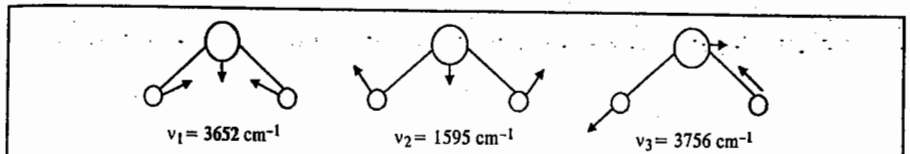

Fig. 7. The three normal modes of H_2O molecule.

The symmetric stretch and the bending mode belong to A_1 and the asymmetric stretch belongs to B_2. From the character table of C_{2v} point group to which H_2O belongs we see that *x* belongs to B_1, *y* to B_2 and *z* to A_1. Therefore, **all the three modes of H_2O molecule are infrared-active.**

Example 7. Which of the three vibrations of an AB_2 molecule are infrared or Raman-active when it is *(a)* bent *(b)* linear ?

Solution : Refer to the vibrational modes of H_2O molecule (bent) and CO_2 molecule (linear). Decide which modes correspond to *(i)* a changing electric dipole moment *(ii)* a changing polarizability and take note of the mutual exclusion rule.

(a) Nonlinear : All modes both infrared and Raman-active.

(b) Linear : The symmetric stretch is infrared-inactive but Raman-active. The antisymmetric stretch is infrared-active and (by the mutual exclusion rule) Raman-inactive. The two bending modes are infrared-active and, therefore, Raman-inactive.

Example 8. Consider the vibrational mode that corresponds to the uniform expansion of the benzene ring. Is the mode *(a)* Raman-active *(b)* infrared-active ?

Ans. The uniform expansion is as shown 
Benzene is centrosymmetic and so the mutual exclusion rule applies. The mode is infrared-inactive (symmetic breathing leaves the molecular dipole moment unchanged at zero) and, therefore, the mode may be Raman-active (and it is). In group theoretical terms, the breathing mode has symmetry A_{1g} in D_{6h} which is the point group to which benzene belongs and the quadratic terms $x^2 + y^2$ and z^2 have this symmetry (see the character table for C_{6h}, a subgroup of D_{6h}). Hence, the mode is Raman-active.

Example 9. Determine the infrared activity (active or inactive) of the normal modes of vibration of SO_3 molecule shown in Fig. 8.

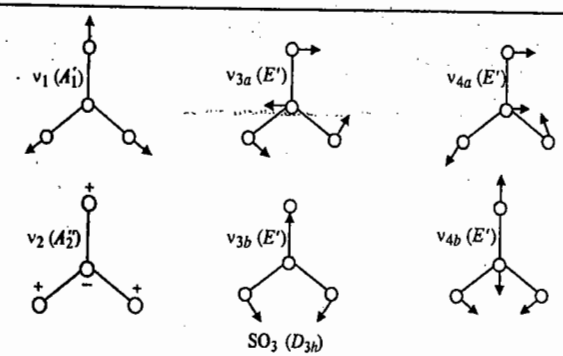

Fig. 8. The normal modes of vibration of SO_3 molecule.

Solution : SO_3 belongs to the D_{3h} point group. From its character table (Table 3), we see that x and y belong to E' and that z belongs to A_2''. Referring to the normal modes shown above we see that the ν_1 mode (which belongs to A_1') is infrared-inactive and others (which belong to A_2'' and E') are infrared-active.

We shall now state the **selection rule for vibrational Raman spectra of molecules.** A fundamental vibrational mode of a molecule will show Raman spectrum, *i.e.*, will be Raman-active if the polarizability of the molecule changes during the vibration. The transition integral in this case is

$$\int_{-\infty}^{\infty} \psi_v'' \alpha \psi_v' d\tau \qquad ...(50)$$

where α is the molecular polarizability operator which is one of the following quadratic functions of the Cartesian coordinates : x^2, y^2, z^2, xy, yz, zx, $(x^2 - y^2)$. The functions ψ_v are the vibrational wave functions, double prime ('') referring to the ground state and the single prime (') referring to the excited state. A vibration is Raman-active if it has the same irrep as one of the quadratic or binary cartesian coordinates listed above.

For **centrosymmetric molecules** (*i.e.*, molecules such as CO_2, C_2H_2, which contain a centre of symmetry) the infrared and Raman activity of fundamental vibrations is determined by the **mutual exclusion rule** which states that any vibration which is infrared-active is Raman-inactive and vice versa. This rule can be derived from group theory. The centrosymmetric molecules have point groups with two sets of irreps. The irreps which are symmetric with respect to the centre of inversion, i, are called gerade (g) representations and the irreps which are antisymmetric with respect to i are called ungerade (u) representations. Now the coordinate x, when operated upon by i, changes sign, *i.e.*, $x \rightarrow -x$; similarly, $y \rightarrow -y$ and $z = -z$ through inversion. Hence, all representations generated by the Cartesian coordinates x, y or z must belong to the u representation. However, the product of two coordinates x and y does not change sign on inversion ; thus, $(-x)(-y) = xy$. We see that the binary product xy generates a g representation. In fact, all the binary or quadratic coordinates generate the g representation. Hence, from group theory we conclude that in centrosymmetric molecules, the vibrational modes belonging to the u symmetry species (irreps) are infrared-active and those belonging to the g symmetry are Raman-active (Table 5). For H_2O and NH_3 molecules, which are non-centrosymmetric molecules, all the vibrations are both IR-active and Raman-active.

TABLE 5

Infrared and Raman Activity in Some Molecules

Molecule	Point group	Symmetry species	IR-active species	Raman-active species
CO_2	$D_{\infty h}$	A_{1g}, A_{1u}, E_{1u}	A_{1u}, E_{1u}	A_{1g}
C_2H_2	$D_{\infty h}$	$2A_{1g}, E_{1g}, E_{1u}, A_{1u}$	A_{1u}, E_{1u}	A_{1g}, E_{1g}
H_2O	C_{2V}	$2A_1, B_2$	A_1, B_2	A_1, B_2
NH_3	C_{3V}	$2A_1, 2E$	A_1, E	A_1, E
BF_3	D_{3h}	$A_1', 2E', A_2''$	A_2'', E'	A_1', E'

5. Selection Rules for Atomic Spectra

Since the intensity of a spectral line is proportional to the square of the transition (dipole) moment integral,

$$\text{Intensity} \propto |\langle \psi_n |\mu| \psi_m \rangle|^2 \qquad ...(51)$$

i.e.,

$$\text{Intensity} \propto \left| \int \psi_n \mu \psi_m d\tau \right|^2 \qquad ...(52)$$

the intensity is zero if the transition moment integral between the states ψ_n and ψ_m vanishes and is non-zero if it does not vanish. This integral determines the selection rules for all branches of spectroscopy.

The three components of the dipole moment μ are μ_x, μ_y and μ_z (in Cartesian coordinates) where $\mu_x = ex$, $\mu_y = ey$ and $\mu_z = ez$, where e is the electronic charge. A transition between the states ψ_n and ψ_m of an atom is allowed if one of the components of the transition moment integral

$$\langle \psi_n |\mu_x| \psi_m \rangle, \langle \psi_n |\mu_y| \psi_m \rangle, \langle \psi_n |\mu_z| \psi_m \rangle \qquad ...(53)$$

is non-zero, *i.e.*, does not vanish. In group theory language, the transition moment integral

$$e \int \psi_n x \psi_m d\tau \qquad ...(54)$$

will be nonzero if the direct product representation of ψ_n, x and ψ_m has even symmetry (or belongs to the totally symmetric representation). Since the Cartesian coordinates x, y and z have odd symmetry, it is evident that the direct product representation of ψ_n and ψ_m, also, should have odd symmetry. This means that if ψ_n is odd, ψ_m must be even. (Here ψ_n and ψ_m are AOs.). Now from the contours of s, p, d and f atomic orbitals in a hydrogenic atom we know that the s and d orbitals have even symmetry whereas the p and f orbitals have odd symmetry. Thus, the transition $1s \rightarrow 2p$ is allowed whereas the transition $1s \rightarrow 3d$ is forbidden in the hydrogen atom spectrum, using the above mentioned argument. This is the basis of the $\Delta l = \pm 1$ selection rule in atomic spectra. For multi-electron atoms, the selection rules for spectral transitions are more elaborate, being determined by the Russell-Saunders coupling scheme and jj coupling scheme of angular momenta.

Example 10. Using the result that the integral $\int f_1 f_2 f_3 \, d\tau$ is non-zero if the direct product representation of the integrand is symmetric, determine if the integral $\int (3d_{xy})(x)(3d_{z^2}) d\tau$ will vanish in a C_{2V} molecule.

Solution : Referring to the character table of the C_{2v} point group (Table 1) and recalling that the orbitals transform as their subscripts, we draw up the following table :

	E	C_2	$\sigma_v(xz)$	$\sigma_v'(yz)$	
$f_1 = d_{xy}$	1	1	-1	-1	A_2
$f_2 = x$	1	-1	1	-1	B_1
$f_3 = d_{z^2}$	1	1	1	1	A_1
$f_1 f_2 f_3$	1	-1	-1	1	

The characters are those of B_2. Hence, the given integral is necessarily zero.

6. Use of Group Theory for Determining the Selection Rules for the $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ Transitions in Formaldehyde

The electronic transitions in the carbonyl chromophore $>C=O$ of aldehydes and ketones have been investigated experimentally and theoretically. The typical energy level diagram involving the MOs σ, π, n, π^* and σ^* and the possible electronic transitions between them, *viz.*, ($\sigma \rightarrow \sigma^*$, $\pi \rightarrow \pi^*$, $n \rightarrow \pi^*$ and $n \rightarrow \sigma^*$) are shown in Fig. 9.

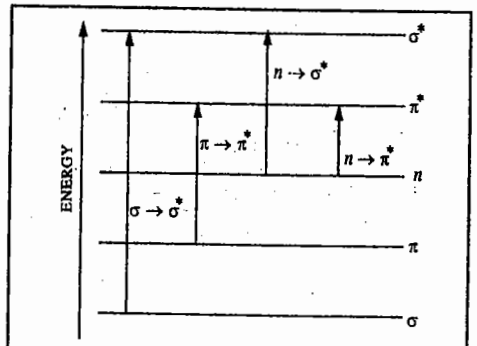

Fig. 9. Various electronic transitions in the carbonyl group.

We are primarily interested in the electronic transitions $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ in formaldehyde, $CH_2=O$. The MO energy level diagram for the carbonyl group in this molecule is shown in Fig. 10.

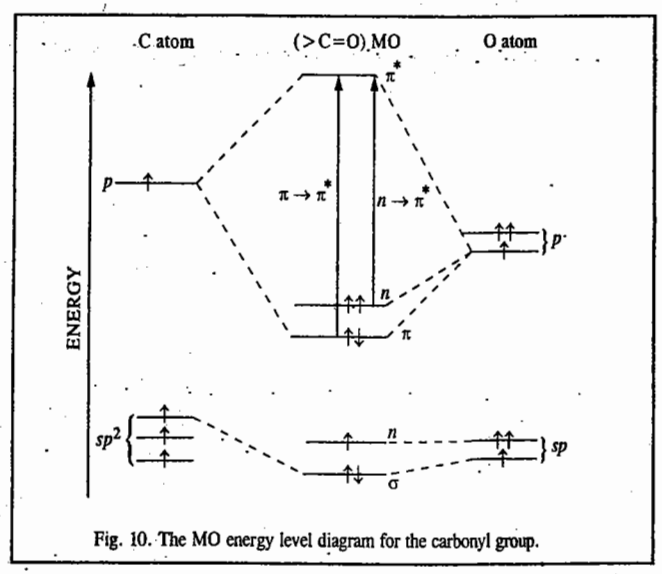

Fig. 10. The MO energy level diagram for the carbonyl group.

Fig. 11 shows the electron distribution in the relevant MOs involved in the $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ transitions.

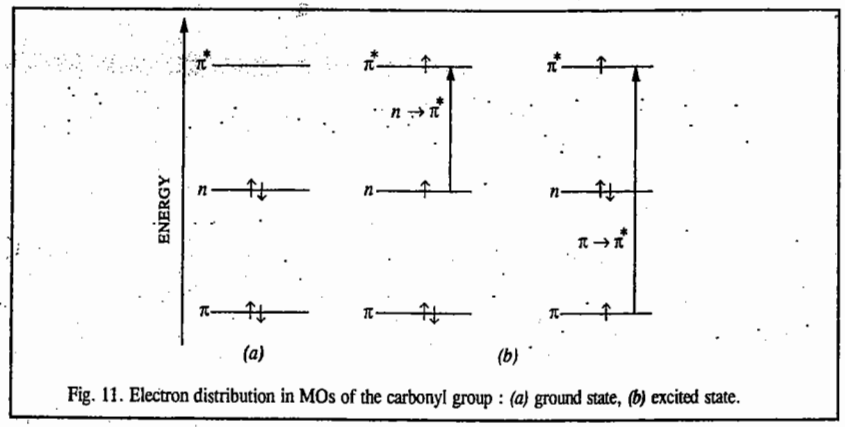

Fig. 11. Electron distribution in MOs of the carbonyl group : *(a)* ground state, *(b)* excited state.

The $n \rightarrow \pi^*$ Transition. This transition will be allowed if any one of the following three transition moment integrals, *viz.*,

$$e\int \psi_g x \psi_e \, d\tau, \quad e\int \psi_g y \psi_e \, d\tau, \quad e\int \psi_g z \psi_e \, d\tau$$

is non-zero. Here, as usual, e is the electronic charge ; x, y, z are the Cartesian coordinates and ψ_g and ψ_e are the wave functions for the ground state and excited state, respectively. The ground state wave function is given by

$$\psi_g = (\pi^2)(n^2) \qquad ...(55)$$

The excited state wave function is given by

$$\psi_e = (\pi^2)(n)(\pi^*) \qquad ...(56)$$

The coordinate system and the shapes of MOs of interest in formaldehyde are shown in Fig. 12.

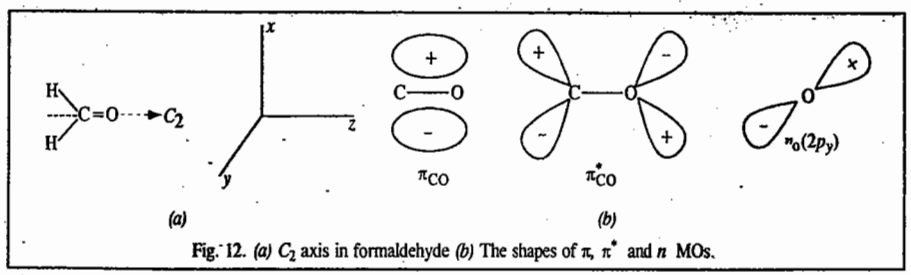

Fig. 12. *(a)* C_2 axis in formaldehyde *(b)* The shapes of π, π^* and n MOs.

Now, the $n \rightarrow \pi^*$ transition will be allowed if the direct product representation of ψ_g and ψ_e has the same symmetry as one of the Cartesian coordinates x, y or z. To determine the direct product representation of ψ_g and ψ_e we proceed as follows : The $CH_2=O$ molecule belongs to the C_{2v} point group. We perform the symmetry operations of this group on the MOs π, n and π^* to obtain the reducible representations of ψ_g and ψ_e. The representation Γ_g for the ground state wave function ψ_g is given by

$$\Gamma_g = (\Gamma_\pi^2)(\Gamma_n^2) \qquad ...(57)$$

Γ_π^2 or Γ_n^2 corresponds to A_1 since two electrons are present in the π or n MO. Thus, Γ_g is totally symmetric. The representation Γ_e for the excited state wave function ψ_e is given by

$$\Gamma_e = (\Gamma_\pi^2)\Gamma_n\Gamma_{\pi^*} = A_1\Gamma_n\Gamma_{\pi^*} \qquad ...(58)$$

Γ_n and Γ_{π^*} can be obtained by performing the symmetry operations of the C_{2v} point group on the n and π^* orbitals of the carbonyl group of $CH_2=O$. These are tabulated as follows :

	E	$C_2(z)$	$\sigma_v(xz)$	$\sigma_v'(yz)$
Γ_n	1	–1	–1	1
Γ_{π^*}	1	–1	1	–1

Referring to the character table of the C_{2v} point group (Table 1), we see that Γ_n and Γ_{π^*} correspond to the irreps B_2 and B_1, respectively. Thus, substitution of these irreps for Γ_n and Γ_{π^*} in Eq. 58, we obtain

$$\Gamma_e = A_1B_2B_1 = A_2 \qquad ...(59)$$

The direct product representation of ψ_g and ψ_e is given by

$$\Gamma_g\Gamma_e = A_1A_2 = A_2 \qquad ...(60)$$

From the character table of the C_{2v} point group (Table 1), we find that A_2 does not correspond to the representation of any one of the Cartesian coordinates. Hence, the $n \rightarrow \pi^*$ transition is not allowed in formaldehyde.

The $\pi \rightarrow \pi^*$ Transition. As we have noted above, the representation of the ground state wave function ψ_g is A_1. The excited state wave function is

$$\psi_e = (\pi)(n^2)(\pi^*) \qquad ...(61)$$

Performing the symmetry operations of the C_{2v} point group on the π orbital of the carbonyl group,

we obtain the following representation :

	E	$C_2(z)$	$\sigma_v(xz)$	$\sigma_v'(yz)$
Γ_π	1	–1	1	–1

From the character table for the C_{2v} point group we see that Γ_π corresponds to the B_1 irreducible representation. Thus, the representation of ψ_e is given by

$$\Gamma_e = \Gamma_\pi(\Gamma_{n^2})\Gamma_{\pi^*} = B_1A_1B_1 = A_1 \qquad ...(62)$$

The direct product representation of ψ_g and ψ_e is

$$\Gamma_g\Gamma_e = A_1A_1 = A_1 \qquad ...(63)$$

From the character table of the C_{2v} point group (Table 1) we find that A_1 corresponds to the symmetry species (irrep) of the z-coordinate. Hence, $\pi \rightarrow \pi^*$ transition in the carbonyl group of formaldehyde is allowed. Experimentally, it is found that the λ_{max} for $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ transitions is 280 nm and 160 nm, respectively. The former transition, being forbidden, is very weak whereas the latter transition, being allowed, is very strong, *i.e.*, intense.

7. Use of Group Theory in Constructing Hybrid Orbitals in Simple Molecules

Hybridisation plays a very important role in chemical bonding. We know, for instance, that the C—H bonds in CH_4 involve sp^3 hybrid orbitals and the B—F sigma bonds in BF_3 involve sp^2 hybrid orbitals. Group theory can help us in predicting the possible combinations of AOs in hybridisation. To do this, we need to know the **transformation properties** of AOs, which can be described in terms of the transformation properties of the Cartesian components. These are listed in sections III and IV of all the character tables. In fact, *an orbital transforms just as its subscripts*. Thus, in any point group, a p_x orbital transforms as the Cartesian coordinate x does and a d_{xy} orbital transforms as the function xy and so on. Since an s orbital is spherically symmetric and possesses no angular dependence, it is invariant to all the symmetry operations of a point group. This is expressed in group theory language by saying that the s orbital forms a *basis* for the totally symmetric representation of each point group. Consider, for instance, the tetrahedral CH_4 molecule. Here the s orbital belongs to the A_1 representation and the three $2p$ orbitals ($2p_x$, $2p_y$, $2p_z$) form a basis for the triply degenerate irrep T_2.

We employ the following procedure for constructing the hybrid orbitals for sigma bonds in molecules:

1. Obtain the point group to which the molecule belongs.

2. Obtain the rep as follows : Treat each sigma bond as a vector and perform the symmetry operations of the point group on each vector. *The number of unshifted vectors by each symmetry operation gives the character of the operation in the reducible representation.* The set of characters thereby obtained for all the symmetry operations of the point group constitutes the reducible representation.

3. Using the standard reduction formula (Eq. 8), reduce this representation into the set of irreps of the point group.

4. From sections III and IV of the character table, identify the coordinates and products of coordinates, or binary products of coordinates, which correspond to these irreps.

5. Identify the orbitals corresponding to these coordinates and products of coordinates.

6. The orbitals so identified are combined to form the hybrid orbitals. The s orbital should be included in the hybrid if the totally symmetric irrep occurs in the reducible representation.

We shall illustrate the above procedure for the construction of hybrid orbitals for sigma bonds in CH_4 and $[PtCl_4]^{2-}$.

Methane Molecule, CH_4

The tetrahedral CH_4 molecule belongs to the T_d point group whose character table has already been given (Table 4). We obtain the reducible representation of CH_4 by applying the symmetry operations, *viz.*, E, $8C_3$, $3C_2$, $6S_4$ and $6\sigma_d$ on the four vectors (C—H bonds). Fig. 13 *(a)* shows the molecular geometry of CH_4 while Fig. 13*(b)* shows the four vectors r_1, r_2, r_3, r_4 representing the four

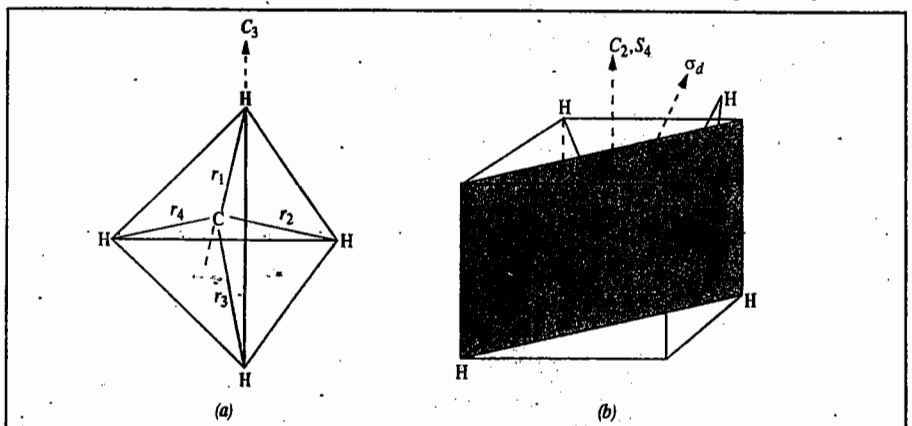

Fig. 13. *(a)* The molecular geometry of CH_4 molecule showing the four C—H sigma bonds ; *(b)* The four vectors representing the four C—H sigma bonds, along with some symmetry elements in CH_4 molecule.

C—H sigma bonds, along with some symmetry elements in CH_4. All the four vectors (C—H sigma bonds) in CH_4 remain unshifted by the identity operation, E. A rotation about the C_3 axis passing through r_1 leaves it unshifted. Symmetry operation C_2 interchanges vector r_1 with vector r_2. Similarly, vectors r_3 and r_4 are interchanged. The σ_d operation leaves vectors r_3 and r_4 unshifted. The S_4 operation shifts all the vectors. Accordingly, we obtain the reducible representation, Γ_R as follows :

Operation	E	$8C_3$	$3C_2$	$6S_4$	$6\sigma_d$
Γ_R	4	1	0	0	2

Using the standard reduction formula (Eq. 8), this rep is reduced to the sum of irreps as follows:

$$n_{A_1} = (1/24)\,[(1 \times 4 \times 1) + (8 \times 1 \times 1) + (3 \times 0 \times 1) + (6 \times 0 \times 1) + (6 \times 2 \times 1)] = 1$$

$$n_{T_2} = (1/24)\,[(1 \times 4 \times 3) + (8 \times 1 \times 0) + (3 \times 0 \times (-1)) + (6 \times 0 \times (-1)) + (6 \times 2 \times 1)] = 1$$

Similarly, we can show that

$$n_{A_2} = n_E = n_{T_1} = 0$$

Hence,
$$\Gamma_R = A_1 + T_2 \qquad ...(64)$$

Using sections III and IV of the character table for the T_d point group (Table 4), we find the possible combinations of orbitals with A_1 and T_2 symmetry as shown below :

Irreducible Representation	A_1	T_2
Coordinates or products of coordinates or binary products of coordinates	$x^2 + y^2 + z^2$	(x,y,z) ; (xy, xz, yz)
Orbitals	s	(p_x, p_y, p_z) ; (d_{xy}, d_{xz}, d_{yz})

We find that there are two possible types of hybrid orbitals with T_d symmetry, *viz.*, sp^3 and sd^3. Since, however, carbon atom does not have d orbitals, so the natural choice is sp^3 hybridisation for the four C—H sigma bonds.

Tetrachloroplatinate (II) anion, $[PtCl_4]^{2-}$

This complex anion belongs to the D_{4h} point group. It is square planar. The character table for the D_{4h} point group is given below.

TABLE 6

Character Table for the D_{4h} Point Group

D_{4h}	E	$2C_4$	C_2	$2C_2'$	$2C_2''$	i	$2S_4$	σ_h	$2\sigma_v$	$2\sigma_v'$	$h = 16$	
A_{1g}	1	1	1	1	1	1	1	1	1	1		$x^2 + y^2, z^2$
A_{2g}	1	1	1	−1	−1	1	1	1	−1	−1	R_z	
B_{1g}	1	−1	1	1	−1	1	−1	1	1	−1		$x^2 - y^2$
B_{2g}	1	−1	1	−1	1	1	−1	1	−1	1		xy
E_g	2	0	−2	0	0	2	0	−2	0	0	(R_x, R_y)	(xz, yz)
A_{1u}	1	1	1	1	1	−1	−1	−1	−1	−1		
A_{2u}	1	1	1	−1	−1	−1	−1	−1	1	1	z	
B_{1u}	1	−1	1	1	−1	−1	1	−1	−1	1		
B_{2u}	1	−1	1	−1	1	−1	1	−1	1	−1		
E_u	2	0	−2	0	0	−2	0	2	0	0	(x, y)	

The four vectors representing the Pt–Cl sigma bonds and some symmetry elements in $[PtCl_4]^{2-}$ are shown in Fig. 14.

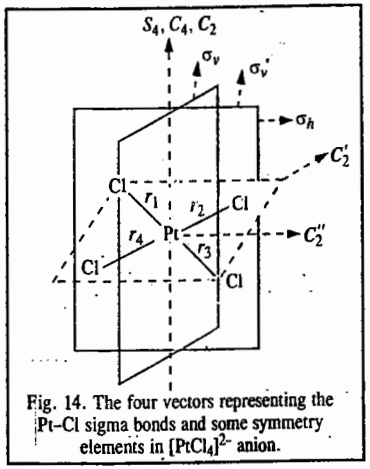

Fig. 14. The four vectors representing the Pt–Cl sigma bonds and some symmetry elements in $[PtCl_4]^{2-}$ anion.

We obtain the following reducible representation, Γ_R, by finding the number of unshifted vectors by each of the symmetry operations (E, $2C_4$, C_2, $2C_2'$, $2C_2''$, i, $2S_4$, σ_h, $2\sigma_v$ and $2\sigma_v'$) of the D_{4h} point group :

Operation	E	$2C_4$	C_2	$2C_2'$	$2C_2''$	i	$2S_4$	σ_h	$2\sigma_v$	$2\sigma_v'$
Γ_R	4	0	0	2	0	0	0	4	2	0

Using the standard reduction formula (Eq. 8), this rep is reduced to the following sum of irreps :

$$\Gamma_R = A_{1g} + B_{1g} + E_u \qquad ...(65)$$

Using sections III and IV of the character table for the D_{4h} point group, we find the possible combinations of orbitals with A_{1g}, B_{1g} and E_u symmetry as shown in the following table :

Irreducible Representation	A_{1g}	B_{1g}	E_u
Orbitals	(s, d_{z^2})	$d_{x^2-y^2}$	(p_x, p_y)

We find that there are two possible types of hybrid orbitals with D_{4h} symmetry, *viz.*, dsp^2 and d^2p^2. Since the $[PtCl_4]^{2-}$ anion is diamagnetic, the hybridisation is dsp^2.

8. Use of Group theory in Factoring the Secular Equation in MOT

In MOT we encounter the secular equation in our attempt to solve the Schrödinger wave equation for many-electron molecules. For a molecule containing π electrons in conjugated systems, for instance, the direct solution of the secular (determinantal) equation involves considerable labour and the problem can be solved speedily only on the digital computer. However, symmetry properties of such a molecule enable the reduction of the $n \times n$ determinant to a set of smaller order determinants so that the energy eigenvalues can be easily obtained without using a computer. The steps involved in this procedure are given below :

1. Determine the point group of the molecule.
2. Use the rotational subgroup of the point group to obtain the rep for the π MOs in the molecule.
3. Using the standard reduction formula, reduce this rep and obtain the symmetries of the orbitals
4. Determine the symmetry orbitals and use them to solve the secular equation of the conjug π-electron system.
5. Solve the resulting smaller order determinant and determine the energy of the π-electron syste

Let us apply these steps to two best known conjugated π-electron systems, *viz.*, *trans*-1,3-butadie and benzene.

Trans-1,3-Butadiene. In the HMO theory discussed in Chapter on Chemical Bonding we have fou nd that the secular determinant for this molecule is :

$$\begin{vmatrix} \alpha - E & \beta & 0 & 0 \\ \beta & \alpha - E & \beta & 0 \\ 0 & \beta & \alpha - E & \beta \\ 0 & 0 & \beta & \alpha - E \end{vmatrix} = 0 \qquad ...(66)$$

where α is the Coulomb integral and β is the resonance integral. We use group theory to simplify the determinant and obtain the energy values.

Steps 1 and 2. Trans-1,3-butadiene molecule belongs to the C_{2h} point group whose character table is given below (Table 7).

TABLE 7

Character Table for the C_{2h} Point Group

C_{2h}	E	C_2	i	σ_h	$h = 4$	
A_g	1	1	1	1	R_z	x^2, y^2, z^2, xy
B_g	1	−1	1	−1	R_x, R_y	xz, yz
A_u	1	1	−1	−1	z	
B_u	1	−1	−1	1	x, y	

We choose the rotational subgroup C_2 of the point group C_{2h} and perform its operations on the four $p\pi$ orbitals of the carbon atoms. The identity operation E leaves all the orbitals unshifted. The symmetry operation C_2 interchanges the atomic orbital ϕ_1 with ϕ_4 and ϕ_2 with ϕ_3. (The numbering of the atoms and the AOs of the given molecule are shown in Fig. 15).

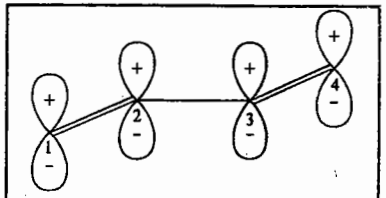

Fig. 15. The *trans*-1,3-butadiene molecule.

The following table lists these transformations :

Symmetry operation	Orbital			
	1	2	3	4
E	1	2	3	4
C_2	4	3	2	1

The character of each symmetry operation in the rep is equal to the number of orbitals unshifted by the operation so that we obtain the rep Γ_R in which $\chi(E)=4$ and $\chi(C_2)=0$. This is written schematically as

	E	C_2
Γ_R	4	0

Steps 3 and 4. Using the standard reduction formula (Eq. 8), we find out how many times each of the irreps A and B occur in Γ (which we write as Γ_π). Thus,

$$n_A = \frac{1}{2}(1\times 4 + 1\times 0) = 2$$

$$n_B = \frac{1}{2}(1\times 4 - 1\times 0) = 2$$

$$\text{This gives } \Gamma_\pi = 2A + 2B \qquad ...(67)$$

where A and B are the symmetry species (irreps) of the C_2 point group whose partial character table is as shown below :

C_2	E	C_2
A	1	1
B	1	-1

Eq. 67 means that A contains two *symmetry orbitals* ψ_1' and ψ_2' and B contains two *symmetry orbitals* ψ_3' and ψ_4'. These symmetry orbitals are obtained by using the so-called basis-generating machine procedure as follows :

We apply each symmetry operation in turn to each non-equivalent atomic orbital and multiply the atomic orbital by the character. (In fact, we are here making use of the so-called projection operators to obtain SALCs, *i.e.*, symmetry adapted linear combinations of atomic orbitals. Thus,

$$\psi_1' = \sum_R R\,\phi_j\,\chi_i(R)$$

For *trans*-1,3-butadiene we have, for the A irrep,

For ϕ_1 : $\psi_1' = E\phi_1\chi(E) + C_2\phi_1\chi(C_2) = \phi_1 + \phi_4$ ...(68)

For ϕ_2 : $\psi_2' = E\phi_2\chi(E) + C_2\phi_2\chi(C_2) = \phi_2 + \phi_3$ ...(69)

Thus, we get the following four linear combinations of atomic orbitals :

$$\phi_1 + \phi_4,\ \phi_2 + \phi_3,\ \phi_3 + \phi_2, \text{ and } \phi_4 + \phi_1$$

The two *independent* symmetry orbitals are

$$\phi_1 + \phi_4 \text{ and } \phi_2 + \phi_3$$

These orbitals correspond to the A_u irrep of the C_{2h} point group.

Similarly, for the B irrep, we have

For ϕ_1 : $\psi_3' = E\phi_1\chi(E) + C_2\phi_1\chi(C_2) = \phi_1 - \phi_4$ ...(70)

For ϕ_2 : $\psi_4' = E\phi_2\chi(E) + C_2\phi_2\chi(C_2) = \phi_2 - \phi_3$ ...(71)

These orbitals belong to the B_g irrep in the C_{2h} point group. After normalization the four symmetry orbitals are :

$$\psi'_{A_u}(1) = \left(\frac{1}{\sqrt{2}}\right)(\phi_1+\phi_4)\ ;\quad \psi'_{A_u}(2) = \left(\frac{1}{\sqrt{2}}\right)(\phi_2+\phi_3) \qquad ...(72)$$

$$\psi'_{B_g}(3) = \left(\frac{1}{\sqrt{2}}\right)(\phi_1-\phi_4)\ ;\quad \psi'_{B_g}(4) = \left(\frac{1}{\sqrt{2}}\right)(\phi_2-\phi_3) \qquad ...(73)$$

Using these four symmetry orbitals, the Hückel secular determinant for 1,3-butadiene can be written as

$$\begin{vmatrix} H^s_{11}-E & H^s_{12} & H^s_{13} & H^s_{14} \\ H^s_{12} & H^s_{22}-E & H^s_{23} & H^s_{24} \\ H^s_{13} & H^s_{23} & H^s_{33}-E & H^s_{34} \\ H^s_{14} & H^s_{24} & H^s_{34} & H^s_{44}-E \end{vmatrix} = 0 \qquad ...(74)$$

where $H^s_{ii} = \int \psi_i' \hat{H} \psi_i'\, d\tau$; $H^s_{ij} = \int \psi_i' \hat{H} \psi_j'\, d\tau$ ...(75)

We can use the direct product representation to show which matrix elements H_{ij} in Eq. 74 vanish. Recall that the integral of the product of two or more functions over symmetric interval is nonzero (*i.e.*, does not vanish) if the direct product representation is totally symmetric. Consider, for instance, the matrix element H^s_{14}.

$$H^s_{14} = \int \psi_1' \hat{H} \psi_4'\, d\tau = \int \psi'_{A_u}(1)\, \hat{H}\, \psi'_{B_g}(4) d\tau \qquad ...(76)$$

Now, the Hamiltonian operator, $\hat{H}$, belongs to the totally symmetric irrep since it is unaffected by any symmetry operation. The symmetry orbital ψ_1' belongs to the symmetry species A_u and the symmetry orbital ψ_4' belongs to the symmetry species B_g. Thus, the direct product representation of ψ_1', ψ_4' and $\hat{H}$ is not totally symmetric so that the matrix element (integral) H^s_{14} vanishes. Similarly, we can show that the matrix elements (integrals) H^s_{13}, H^s_{14}, H^s_{23} and H^s_{24} vanish, *i.e.*, are equal to zero, since the two symmetry orbitals involved in each of them do not have the same symmetry. Grouping all the orbitals of the same symmetry, we obtain the symmetry-factored secular determinant given below :

$$\left|\begin{array}{cc:cc} H^s_{11}-E & H^s_{12} & 0 & 0 \\ H^s_{12} & H^s_{22}-E & 0 & 0 \\ \hdashline 0 & 0 & H^s_{33}-E & H^s_{34} \\ 0 & 0 & H^s_{34} & H^s_{44}-E \end{array}\right| = 0 \qquad ...(77)$$

We see that the symmetry considerations of group theory enable the reduction of the 4×4 secular determinant (Eq. 66) of butadiene to two 2×2 secular determinants :

Symmetry	Determinant	
A_u	$\begin{vmatrix} H^s_{11}-E & H^s_{12} \\ H^s_{12} & H^s_{22}-E \end{vmatrix} = 0$	...(78)
B_g	$\begin{vmatrix} H^s_{33}-E & H^s_{34} \\ H^s_{34} & H^s_{44}-E \end{vmatrix} = 0$	...(79)

Step 5. The A_u and B_g secular determinants can now be solved to obtain the energy values. Let us evaluate the matrix elements H^s_{11}, H^s_{12} and H^s_{22} of the A_u determinant.

$$H^s_{11} = \int \psi'_{A_u}(1)\hat{H}\psi_{A_u}(1)d\tau = \int\left(\frac{1}{\sqrt{2}}\right)(\phi_1+\phi_4)\hat{H}\left(\frac{1}{\sqrt{2}}\right)(\phi_1+\phi_4)d\tau$$

$$= \left(\frac{1}{2}\right)\left[\int\phi_1\hat{H}\phi_1 d\tau + \int\phi_4\hat{H}\phi_1 d\tau + \int\phi_1\hat{H}\phi_4 d\tau + \int\phi_4\hat{H}\phi_4 d\tau\right]$$

$$= (1/2)\,[\alpha + 0 + 0 + \alpha] = \alpha \qquad ...(80)$$

$$H^s_{12} = \int \psi'_{A_u}(1)\hat{H}\psi_{A_u}(2)d\tau = \int\left(\frac{1}{\sqrt{2}}\right)(\phi_1+\phi_4)\hat{H}\left(\frac{1}{\sqrt{2}}\right)(\phi_2+\phi_3)d\tau$$

$$= \left(\frac{1}{2}\right)\left[\int\phi_1\hat{H}\phi_2 d\tau + \int\phi_4\hat{H}\phi_2 d\tau + \int\phi_1\hat{H}\phi_3 d\tau + \int\phi_4\hat{H}\phi_3 d\tau\right]$$

$$= (1/2)\,[\beta + 0 + 0 + \beta] = \beta \qquad ...(81)$$

We can similarly show that

$$H^s_{22} = \alpha + \beta \qquad ...(82)$$

(Here α is the Coulomb integral and β is the resonance integral of the HMO theory.)

Substituting the values of H^s_{11}, H^s_{12} and H^s_{22}, the A_u determinant becomes

$$\begin{vmatrix} \alpha - E & \beta \\ \beta & \alpha + \beta - E \end{vmatrix} = 0 \qquad ...(83)$$

Consider next the B_g determinant. Proceeding as above, we find that the matrix elements (integrals) H^s_{33}, H^s_{34} and H^s_{44} are :

$$H^s_{33} = \alpha\ ;\ H^s_{34} = \beta\ ;\ H^s_{44} = \alpha - \beta \qquad ...(84)$$

so that the B_g determinant becomes

$$\begin{vmatrix} \alpha - E & \beta \\ \beta & \alpha - \beta - E \end{vmatrix} = 0 \qquad ...(85)$$

Dividing by β and making the substitution $(\alpha - E)/\beta = x$, where x is the dimensionless parameter, the A_u determinant becomes

$$\begin{vmatrix} x & 1 \\ 1 & x+1 \end{vmatrix} = 0 \qquad ...(86)$$

which, on expansion, gives the quadratic equation $x^2 + x - 1 = 0$ whose solution is

$$x = \frac{(-1 \pm \sqrt{5})}{2} \qquad ...(87)$$

Now $(\alpha - E)/\beta = x$ so that $E = \alpha - x\beta$. Hence, the energy eigenvalues of the two A_u orbitals are

$$E_{A_u}(1) = \alpha - \frac{(-1+\sqrt{5})\beta}{2} = \alpha - 0{\cdot}618\,\beta \qquad ...(88)$$

$$E_{A_u}(2) = \alpha - \frac{(-1-\sqrt{5})\beta}{2} = \alpha + 1{\cdot}168\,\beta \qquad ...(89)$$

Similarly, the B_g determinant is modified to

$$\begin{vmatrix} x & 1 \\ 1 & x-1 \end{vmatrix} = 0 \qquad ...(90)$$

which, on expansion, gives the quadratic equation $x^2 - x - 1 = 0$ whose solution is

$$x = (1 \pm \sqrt{5})/2 \qquad ...(91)$$

Hence, the energy eigenvalues of the two B_g orbitals are

$$E_{B_g}(3) = \alpha - \frac{(1+\sqrt{5})\beta}{2} = \alpha - 1{\cdot}618\,\beta \qquad ...(92)$$

$$E_{B_g}(4) = \alpha - \frac{(1-\sqrt{5})\beta}{2} = \alpha + 0{\cdot}618\,\beta \qquad ...(93)$$

Notice that the four energy levels of 1,3-butadiene, obtained above using symmetry considerations, are the same which were obtained in the HMO theory of this molecule discussed in Chapter 3 on Chemical Bonding. These are redrawn in the HMO diagram (in Fig. 16) with the appropriate designations of the symmetry species (irreps) to which they belong. We have already shown that the delocalization energy (DE) of this molecule is equal to 0·472 β :

$$DE = (4\alpha + 4{\cdot}472\,\beta) - (4\alpha + 4\beta) = 0{\cdot}472\beta \qquad ...(94)$$

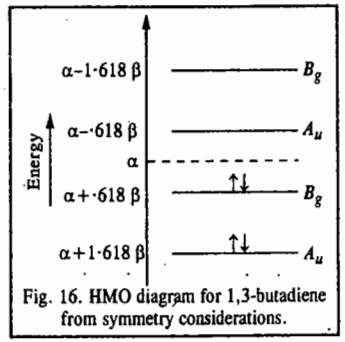

Fig. 16. HMO diagram for 1,3-butadiene from symmetry considerations.

Benzene, C_6H_6. We shall briefly summarize the symmetry classification of the MOs of benzene which belongs to D_{6h} point group. In the HMO theory discussed in Chapter 2 on Chemical Bonding, we have found that the secular determinant for benzene molecule is

$$\begin{vmatrix} \alpha-E & \beta & 0 & 0 & 0 & \beta \\ \beta & \alpha-E & \beta & 0 & 0 & 0 \\ 0 & \beta & \alpha-E & \beta & 0 & 0 \\ 0 & 0 & \beta & \alpha-E & \beta & 0 \\ 0 & 0 & 0 & \beta & \alpha-E & \beta \\ \beta & 0 & 0 & 0 & \beta & \alpha-E \end{vmatrix} = 0 \qquad ...(95)$$

where, as usual, α is the Coulomb integral and β is the resonance integral. Using group theory, this determinant can be simplified to obtain the energy levels. The character table for the D_{6h} point group is shown in Table 8.

TABLE 8

Character Table for the D_{6h} Point Group

A_{1u}	1	1	1	1	1	1	-1	-1	-1	-1	-1	-1		
A_{2u}	1	1	1	1	-1	-1	-1	-1	-1	-1	1	1	z	
B_{1u}	1	-1	1	-1	1	-1	-1	1	-1	1	-1	1		
B_{2u}	1	-1	1	-1	-1	1	-1	1	-1	1	1	-1		
E_{1u}	2	1	-1	-2	0	0	-2	-1	1	2	0	0	(x, y)	
E_{2u}	2	-1	-1	2	0	0	-2	1	1	-2	0	0		

We choose the rotational subgroup C_6 of the point group D_{6h} and perform its symmetry operations on the six $p\pi$ orbitals of the carbon atoms in benzene (Fig. 17).

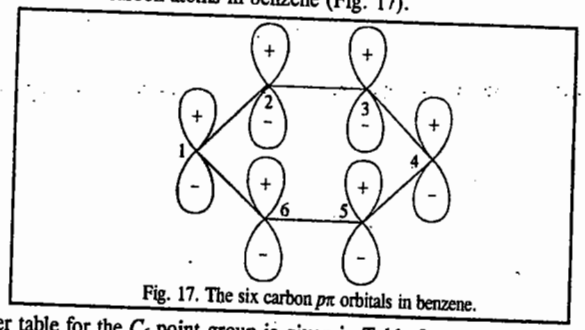

Fig. 17. The six carbon $p\pi$ orbitals in benzene.

The character table for the C_6 point group is given in Table 9.

TABLE 9

Character Table for the C_6 Point Group

C_6	E	C_6	C_3	C_2	C_3^2	C_6^5	$\epsilon = \exp(2\pi i/6)$	
A	1	1	1	1	1	1		
B	1	-1	1	-1	1	-1	z, R_z	x^2+y^2, z^2
E_1	1	ϵ	$-\epsilon^*$	-1	$-\epsilon$	ϵ^*		
	1	ϵ^*	$-\epsilon$	-1	$-\epsilon^*$	ϵ	$(x, y)\ (R_x, R_y)$	(xz, yz)
E_2	1	$-\epsilon^*$	$-\epsilon$	1	$-\epsilon^*$	$-\epsilon$		
	1	$-\epsilon$	$-\epsilon^*$	1	$-\epsilon$	$-\epsilon^*$		(x^2-y^2, xy)

The character of each symmetry operation is given by the number of unshifted $p\pi$ orbitals by the operation. The identity operation E leaves all the orbitals unshifted. Every symmetry operation of the C_6 subgroup shifts every orbital to a different place. Thus, we obtain the following rep :

	E	C_6	C_3	C_2	C_3^2	C_6^5
Γ_π	6	0	0	0	0	0

Using the standard reduction formula (Eq. 8), we find that

$$\Gamma_\pi = A + B + E_1 + E_2 \qquad \text{...(96)}$$

In the parent D_{6h} point group, this becomes

$$\Gamma_\pi = A_{2u} + B_{2g} + E_{1g} + E_{2u} \qquad \text{...(97)}$$

Thus we find that in a cyclic hydrocarbon having the general formula $(CH)_n$ there will always be n π-MOs, one belonging to each symmetry species of the subgroup C_n. It is also known from group theory that in a conjugated cyclic π-system the coefficients of the MOs in the LCAO-MO approximation are the characters of the irreps of the rotation subgroup. Thus, using the sets of the characters of the irreps of the rotation subgroup C_6, we can write the symmetry orbitals (*i.e.*, SALCs) for benzene :

$$A \to A_{2u}: \quad \phi_1 + \phi_2 + \phi_3 + \phi_4 + \phi_5 + \phi_6 \qquad \text{...(98)}$$

$$B \to B_{2g}: \quad \phi_1 - \phi_2 + \phi_3 - \phi_4 + \phi_5 - \phi_6 \qquad \text{...(99)}$$

$$E_1 \to E_{1g}\begin{cases} E'_{1g}: \phi_1 + \epsilon\phi_2 - \epsilon^*\phi_3 - \phi_4 - \epsilon\phi_5 + \epsilon^*\phi_6 \\ \epsilon^*\phi_2 - \epsilon\phi_3 - \phi_4 - \epsilon^*\phi_5 + \epsilon\phi_6 \end{cases} \qquad \text{...(100)}$$

$$E_2 \to E_{2g}\begin{cases} E^1_{2u}: \phi_1 - \epsilon^*\phi_2 - \epsilon\phi_3 + \phi_4 - \epsilon^*\phi_5 - \epsilon\phi_6 \\ E^2_{2u}: \phi_1 - \epsilon\phi_2 - \epsilon^*\phi_3 + \phi_4 - \epsilon\phi_5 - \epsilon^*\phi_6 \end{cases} \qquad \text{...(101)}$$

The normalized symmetry orbitals, *i.e.*, SALCs, belonging to the various symmetry species (irreps) can be shown to be given by

$$\psi'(A_{2u}) = (1/\sqrt{6})\ (\phi_1 + \phi_2 + \phi_3 + \phi_4 + \phi_5 + \phi_6) \qquad \text{...(102)}$$

$$\psi'(B_{2g}) = (1/\sqrt{6})\ (\phi_1 - \phi_2 + \phi_3 - \phi_4 + \phi_5 - \phi_6) \qquad \text{...(103)}$$

$$\psi'(E^1_{1g}) = (1/\sqrt{12})\ (2\phi_1 + \phi_2 - \phi_3 - 2\phi_4 - \phi_5 + \phi_6) \qquad \text{...(104)}$$

$$\psi'(E^2_{1g}) = (1/2)\ (\phi_2 + \phi_3 - \phi_5 - \phi_6) \qquad \text{...(105)}$$

$$\psi'(E^1_{2u}) = (1/\sqrt{12})\ (2\phi_1 - \phi_2 - \phi_3 + 2\phi_4 - \phi_5 - \phi_6) \qquad \text{...(106)}$$

$$\psi'(E^2_{2u}) = (1/2)\ (\phi_2 - \phi_3 + \phi_5 - \phi_6) \qquad \text{...(107)}$$

Using these symmetry orbitals, the secular determinant for benzene can be written as

A_{2u}	B_{2g}	E_{1g}		E_{2u}	
$H^s_{11}-E$	0	0	0	0	0
0	$H^s_{22}-E$	0	0	0	0
0	0	$H^s_{33}-E$	H^s_{34}	0	0
0	0	H^s_{34}	$H^s_{44}-E$	0	0
0	0	0	0	$H^s_{55}-E$	H^s_{56}
0	0	0	0	H^s_{56}	$H^s_{66}-E$

$= 0$ ...(108)

Thus, the 6×6 Hückel secular determinant is factored as follows :

Symmetry	Determinant	
A_{2u}	$H^s_{11}-E = 0$	...(109)
B_{2g}	$H^s_{22}-E = 0$	...(110)
E_{1g}	$\begin{vmatrix} H^s_{33}-E & H^s_{34} \\ H^s_{34} & H^s_{44}-E \end{vmatrix} = 0$	...(111)
E_{2u}	$\begin{vmatrix} H^s_{55}-E & H^s_{56} \\ H^s_{56} & H^s_{66}-E \end{vmatrix} = 0$	...(112)

To determine the energy of the MO belonging to the A_{2u} irrep, we have

$$H^s_{11} - E = 0$$

or

$$H^s_{11} = E \qquad \text{...(113)}$$

where

$$H^s_{11} = \int \psi'(A_{2u})\, \hat{H}\, \psi'(A_{2u})\, d\tau \qquad \text{...(114)}$$

Substituting for the symmetry orbital $\psi'(A_{2u})$ from Eq. 102, we find that

$$H^s_{11} = \frac{1}{6}\int (\phi_1+\phi_2+\phi_3+\phi_4+\phi_5+\phi_6)\,\hat{H}(\phi_1+\phi_2+\phi_3+\phi_4+\phi_5+\phi_6)\,d\tau \qquad \text{...(115)}$$

$$= \frac{1}{6}\Big[\int \phi_1\hat{H}\phi_1 d\tau + \int \phi_2\hat{H}\phi_2 d\tau + \int \phi_3\hat{H}\phi_3 d\tau + \int \phi_4\hat{H}\phi_4 d\tau + \int \phi_5\hat{H}\phi_5 d\tau + \int \phi_6\hat{H}\phi_6 d\tau$$
$$+ \int \phi_1\hat{H}\phi_2 d\tau + \int \phi_2\hat{H}\phi_1 d\tau + \int \phi_2\hat{H}\phi_3 d\tau + \int \phi_3\hat{H}\phi_2 d\tau + \int \phi_3\hat{H}\phi_4 d\tau + \int \phi_4\hat{H}\phi_3 d\tau$$
$$+ \int \phi_4\hat{H}\phi_5 d\tau + \int \phi_5\hat{H}\phi_4 d\tau + \int \phi_5\hat{H}\phi_6 d\tau + \int \phi_6\hat{H}\phi_5 d\tau + \int \phi_1\hat{H}\phi_6 d\tau + \int \phi_6\hat{H}\phi_1 d\tau\Big] \qquad \text{...(116)}$$

or $$H_{11}^s = \left(\frac{1}{6}\right)(6\alpha + 12\beta) = \alpha + 2\beta \quad \ldots(117)$$

Thus, $$E(A_{2u}) = \alpha + 2\beta \quad \ldots(118)$$

Similarly, $$E(B_{2g}) = \alpha - 2\beta \quad \ldots(119)$$

We next consider the E_{1g} and E_{2u} determinants.

$$E_{1g}: \begin{vmatrix} H_{33}^s - E & H_{34}^s \\ H_{34}^s & H_{44}^s - E \end{vmatrix} = 0; \quad E_{2u}: \begin{vmatrix} H_{55}^s - E & H_{56}^s \\ H_{56}^s & H_{66}^s - E \end{vmatrix} = 0 \quad \ldots(120)$$

Since $H_{33}^s = H_{44}^s$; $H_{55}^s = H_{66}^s$; $H_{34}^s = H_{56}^s = 0$, the E_{1g} and E_{2u} determinants become

$$E_{1g}: \begin{vmatrix} H_{33}^s - E & 0 \\ 0 & H_{33}^s - E \end{vmatrix} = 0; \quad E_{2u}: \begin{vmatrix} H_{55}^s - E & 0 \\ 0 & H_{55}^s - E \end{vmatrix} = 0 \quad \ldots(121)$$

Expansion of the determinants yields

$$\left(H_{33}^s - E\right)^2 = 0 \quad \text{and} \quad \left(H_{55}^s - E\right)^2 = 0 \quad \ldots(122)$$

The solution of these equations gives the following values of the energies of E_{1g} and E_{2u} MOs :

$E(E_{1g}) = \alpha + \beta$; $E(E_{2u}) = \alpha - \beta$ ...(123)

Notice that the energies $E(A_{2u})$, $E(B_{2g})$, $E(E_{1g})$ and $E(E_{2u})$ of benzene obtained using symmetry arguments, are the same which were obtained in the HMO theory of this molecule discussed in Chapter 3. These are redrawn in the HMO diagram (Fig. 18) with the appropriate designations of the symmetry species (irreps) to which they belong. We have already shown that the delocalization energy (DE) of benzene molecule is equal to 2β :

$$DE = (6\alpha + 8\beta) - (6\alpha + 6\beta) = 2\beta \quad \ldots(124)$$

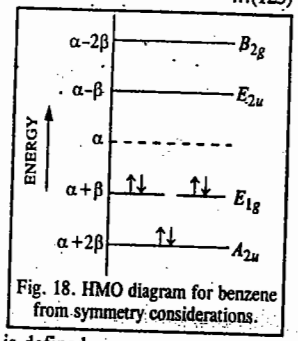

Fig. 18. HMO diagram for benzene from symmetry considerations.

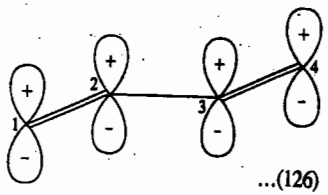
9. Use of Generating Operators (Projection Operators) to Determine Linear Combinations of AOs that are Basis for Irreducible Representations

The generating operator or the projection operator for the jth irrep is defined as

$$\hat{P}_j = \frac{l_j}{h} \sum_{\hat{R}} \chi_j(\hat{R})\,\hat{R} \quad \ldots(125)$$

where l_j is the dimensionality of the jth irrep. Though Eq. 125 looks somewhat formidable, it is easy to use. In fact, we have already made use of the projection operators to determine SALCs. What follows is a slightly brief treatment.

Let us consider the *trans*-1,3-butadiene molecule which belongs to C_{2h} point group :



Denoting the $2p_z$ orbital on carbon atom i by ϕ_i, Eq. 125 yields

$$\hat{P}_{A_g}\phi_1 = \frac{1}{4}\sum_{\hat{R}} \chi_{A_g}(R)\,R\phi_1 \quad \ldots(126)$$

$$= \frac{1}{4}\left[(1)E\phi_1 + (1)\,C_2\phi_1 + (1)i\phi_1 + (1)\,\sigma_h\phi_1\right]$$

$$= \frac{1}{4}\left(\phi_1 + \phi_4 - \phi_4 - \phi_1\right) = 0 \quad \ldots(127)$$

$$\hat{P}_{A_g}\phi_2 = \frac{1}{4}(\phi_2 + \phi_3 - \phi_3 - \phi_2) = 0 \quad \ldots(128)$$

with similar results for ϕ_3 and ϕ_4.

Similarly, using ϕ_1 and ϕ_2, we obtain

$$\left.\begin{aligned} \hat{P}_{B_g}\phi_1 &= \frac{1}{4}(\phi_1 - \phi_4 - \phi_4 + \phi_1) \propto \phi_1 - \phi_4 \\ \hat{P}_{B_g}\phi_2 &= \frac{1}{4}(\phi_2 - \phi_3 - \phi_3 + \phi_2) \propto \phi_2 - \phi_3 \\ \hat{P}_{A_u}\phi_1 &= \frac{1}{4}(\phi_1 + \phi_4 + \phi_4 + \phi_1) \propto \phi_1 + \phi_4 \\ \hat{P}_{A_u}\phi_2 &= \frac{1}{4}(\phi_2 + \phi_3 + \phi_3 + \phi_2) \propto \phi_2 + \phi_3 \end{aligned}\right\} \quad \ldots(129)$$

$$\hat{P}_{B_u}\phi_1 = \hat{P}_{B_u}\phi_2 = 0 \quad \ldots(130)$$

Here we have ignored the numerical factors in front of the various symmetry orbitals since we are interested only in their functional form. Normalization of the orbitals can be easily carried out.

Eq. 129 gives four symmetry orbitals, two belonging to B_g symmetry species and two belonging to A_u symmetry species. Using these symmetry orbitals, the HMO theory secular determinant of 1, 3-butadiene factors into two 2×2 blocks :

$$\left|\begin{array}{cc:cc} x & 1 & 0 & 0 \\ 1 & x+1 & 0 & 0 \\ \hdashline 0 & 0 & x & 1 \\ 0 & 0 & 1 & x-1 \end{array}\right| = 0 \quad \ldots(131)$$

which, upon expansion, gives $(x^2 + x - 1)(x^2 - x - 1) = 0$, whence ...(132)

$$x = \frac{-1 \pm \sqrt{5}}{2} \quad \text{and} \quad x = \frac{1 \pm \sqrt{5}}{2} \quad \ldots(133)$$

or $x = 0{\cdot}6180$, $-1{\cdot}6180$, $1{\cdot}6180$ and $-0{\cdot}6180$. These are the same values which we obtained in the HMO treatment of butadiene.

Notice that no symmetry orbital belongs to A_g or B_u. As a matter of fact, we did not really have to apply the generating operators for A_g and B_u to learn this. Let us apply the four group operations E, C_2, i, and σ_h to the four $2p_z$ AOs. For the identity operation E, $E\phi_j = \phi_j$ for each j. This result can be written in the matrix form :

$$E\begin{bmatrix}\phi_1\\ \phi_2\\ \phi_3\\ \phi_4\end{bmatrix} = \begin{bmatrix}1&0&0&0\\0&1&0&0\\0&0&1&0\\0&0&0&1\end{bmatrix}\begin{bmatrix}\phi_1\\ \phi_2\\ \phi_3\\ \phi_4\end{bmatrix} \quad \ldots(134)$$

The character of this matrix is $\chi(E) = 4$. Similarly, $C_2\phi_1 = \phi_4$, $C_2\phi_2 = \phi_3$, $C_2\phi_3 = \phi_2$, and $C_2\phi_4 = \phi_1$, or in the matrix form :

$$C_2\begin{bmatrix}\phi_1\\ \phi_2\\ \phi_3\\ \phi_4\end{bmatrix} = \begin{bmatrix}0&0&0&1\\0&0&1&0\\0&1&0&0\\1&0&0&0\end{bmatrix}\begin{bmatrix}\phi_1\\ \phi_2\\ \phi_3\\ \phi_4\end{bmatrix} \quad \ldots(135)$$

Thus, $\chi(C_2) = 0$.

Similarly,

$$i\begin{bmatrix}\phi_1\\ \phi_2\\ \phi_3\\ \phi_4\end{bmatrix} = \begin{bmatrix}0 & 0 & 0 & -1\\ 0 & 0 & -1 & 0\\ 0 & -1 & 0 & 0\\ -1 & 0 & 0 & 0\end{bmatrix}\begin{bmatrix}\phi_1\\ \phi_2\\ \phi_3\\ \phi_4\end{bmatrix} \quad ...(136)$$

Thus, $\chi(i) = 0$.

Again,

$$\sigma_h\begin{bmatrix}\phi_1\\ \phi_2\\ \phi_3\\ \phi_4\end{bmatrix} = \begin{bmatrix}-1 & 0 & 0 & 0\\ 0 & -1 & 0 & 0\\ 0 & 0 & -1 & 0\\ 0 & 0 & 0 & -1\end{bmatrix}\begin{bmatrix}\phi_1\\ \phi_2\\ \phi_3\\ \phi_4\end{bmatrix} \quad ...(137)$$

so that $\chi(\sigma_h) = -4$. Thus, we have

	E	C_2	i	σ_h
Γ_R	4	0	0	-4

We see from these results that the four $2p_z$ AOs belong to the reducible representation Γ_R.

We can write Γ_R without writing out all the matrices. Recall that there is a 1 on a diagonal in a representation if the $2p_z$ orbital is unchanged, a -1 if it remains on the original atom but changes direction and a 0 if it is moved to another atom. The operation E leaves all four unchanged ; the operations C_2 and i move all of them to different atoms and σ_h changes the direction of all four but does not move them otherwise.

Using the standard reduction formula, the above rep can be reduced to a sum of irreps as follows :

$$n_{A_g} = \frac{1}{4}[1\times4 + 1\times0 + 1\times0 + 1\times(-4)] = 0$$

$$n_{B_g} = \frac{1}{4}[1\times4 + (-1)\times0 + 1\times0 + (-1)\times(-4)] = 2$$

$$n_{A_u} = \frac{1}{4}[1\times4 + 1\times0 + (-1)\times0 + (-1)\times(-4)] = 2$$

$$n_{B_u} = \frac{1}{4}[1\times4 + (-1)\times0 + (-1)\times0 + 1\times(-4)] = 0$$

Thus, $\Gamma_R = 2B_g + 2A_u$, in agreement with our earlier result that no symmetry orbital belongs to A_g or B_u.

MISCELLANEOUS SOLVED EXAMPLES

Example 11. List the symmetry elements of $CHCl_3$ molecule which belongs to the C_{3v} point group and locate them in the molecule.

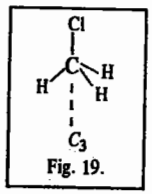


Fig. 19.

Solution : The elements, other than the identity E are a C_3 axis and three vertical mirror planes σ_v. The symmetry axis passes through the C—Cl nuclei. The mirror planes are defined by the three ClCH planes (see Figure 19).

Example 12. Which of the following molecules may be polar : *(a)* pyridine (C_{2v}) *(b)* CH_3Cl(C_{3v}) *(c)* $SnCl_4$(I_d) *(d)* gas phase $HgBr_2$(D_{4h}) *(e)* $B_3N_3H_6$(D_{3h}) *(f)* nitroethane (C_s) ?

Solution : A molecule is *nonpolar* if it has a centre of symmetry or perpendicular C_2 axes. This means that only molecules belonging to C_n, C_{nv} and C_s may be *polar*. Hence, of the listed molecules, only *(a)* pyridine *(b)* CH_3Cl and *(f)* nitroethane are polar.

Example 13. The group C_{2h} consists of the elements E, C_2, σ_h, i. Construct the group multiplication table and give an example of a molecule that belongs to the group.

Solution : See Fig. 20 showing the symmetry operation of the C_{2h} point group.

Note that $R^2 = E$ for all the operations of the group ; $ER = RE = R$ and $RR' = R'R$ for this group. Since $C_2\sigma_h = i$; $\sigma_h i = C_2$ and $iC_2 = \sigma_h$, we can draw up the following multiplication table :

	E	C_2	σ_h	i
E	E	C_2	σ_h	i
C_2	C_2	E	i	σ_h
σ_h	σ_h	i	E	C_2
i	i	σ_h	C_2	E

Hence, the trans-CHCl=CHCl molecule belongs to the C_{2h} point group.

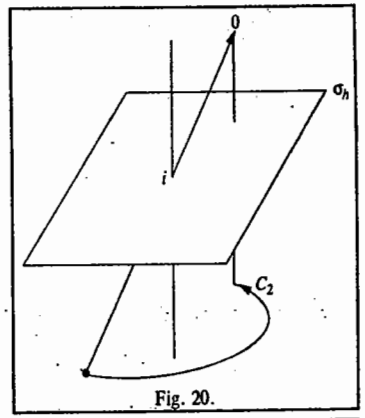

Fig. 20.

Example 14. The point group D_{2h} has a C_2 axis perpendicular to the principal axis and a horizontal mirror plane. Show that the group must, have a centre of inversion, i.

Solution : Refer to Fig. 21.

The effect of σ_h on a point P is to generate $\sigma_h P$ and the effect of C_2 on $\sigma_h P$ is to generate the point $C_2\sigma_h P$. The same point is generated from P by the inversion i so that $C_2\sigma_h P = iP$ for all points P. Hence, $C_2\sigma_h = i$ and i must be a number of the group.

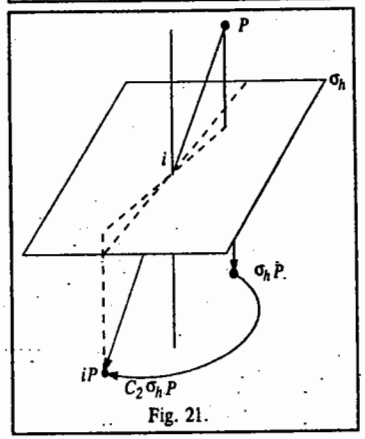

Fig. 21.

Example 15. List the symmetry elements of the following molecules and name the point groups to which they belong : *(a)* staggered ethane, *(b)* chair and boat cyclohexane, *(c)* diborane B_2H_6, *(d)* $[Co(en)_3]^{3+}$, where *en* is ethylenediamine (ignore its detailed structure), *(e)* crown-shaped S_8. Which of these molecules can be *(i)* polar *(ii)* chiral ?

Solution : *(a)* Staggered CH_3CH_3 : E, C_3, C_2, $3\sigma_d$; D_{3d}

(b) Chair C_6H_{12} : E, C_3, C_2, $3\sigma_d$; D_{3d}; Boat C_6H_{12} : E, C_2, σ_v, σ_v' ; C_{2v}

(c) B_2H_6 : E, C_2, $2C_2'$, σ_h ; D_{2h}

(d) $[Co(en)_3]^{3+}$: E, $2C_3$, $3C_2$; D_3

(e) Crown S_8 : E, C_4, C_2, $4C_2'$, $4\sigma_d$, $2S_8$; D_{4d}

Only boat C_6H_{12} may be polar since all others are D point groups. Only $[Co(en)_3]^{3+}$ belongs to a group without any improper axis of rotation ($S_1 = \sigma$), and hence is chiral.

Example 16. Molecules belonging to the point groups D_{2h}, C_{3h}, T_h and T_d cannot be chiral. Which elements of these rule out chirality ?

Solution : A molecule cannot be chiral if it has an improper rotation axis S_n of any order (look for such an axis even in a disguised form : $S_1 = \sigma$, $S_2 = i$) or a centre of inversion or a plane of symmetry. D_{2h} and T_h contain i, C_{3h} contains σ_h, T_d contains S_4. Therefore, molecules belonging to these point groups cannot be chiral.

Example 17. List the symmetry elements in the followiug molecules and name the point groups to which they belong : *(a)* naphthalene, $C_{10}H_8$, *(b)* anthracene, $C_{14}H_{10}$ and *(c)* the three dichlorobenzenes.

Solution. *(a)* Naphthalene : E, C_2, C_2', σ_h ; D_{2h}

(b) Anthracene : E, C_2, C_2', σ_h ; D_{2h}

(c) Dichlorobenzenes :

(i) 1, 2-dichlorobenzene : E, C_2, σ_v, σ_v' ; C_{2v}

(ii) 1, 3-dichlorobenzene : E, C_2, σ_v, σ_v' ; C_{2v}

(iii) 1, 4-dichlorobenzene : E, C_2, C_2', σ_h ; D_{2h}

Example 18. List the symmetry elements of the following molecules and name the point groups to which they belong : (a) NO_2 (b) N_2O (c) $CHCl_3$ (d) $CH_2=CH_2$ (e) *cis*-CHCl=CHCl (f) *trans*-CHCl=CHCl.

Solution : (a) NO_2 : E, C_2, σ_v, σ_v' ; C_{2v} (b) N_2O : E, C_∞, C_2, σ_v ; $C_{\infty v}$

(c) $CHCl_3$: E, C_3, $3\sigma_v$; C_{3v} (d) $CH_2=CH_2$: E, C_2, $2C_2'$, σ_h ; D_{2h}

(e) *cis*-CHCl=CHCl : E, C_2, σ_v, σ_v' ; C_{2v} (f) *trans*-CHCl=CHCl : E, C_2, σ_h, i ; C_{2h}

Example 19. The group C_{2v} consists of the elements E, C_2, $\sigma_v(xz)$ and $\sigma_v'(yz)$. Construct the group multiplication table for this group.

Solution : We draw up the following group multiplication table :

	E	C_2	$\sigma_v(xz)$	$\sigma_v'(yz)$
E	E	C_2	$\sigma_v(xz)$	$\sigma_v'(yz)$
C_2	C_2	E	$\sigma_v'(yz)$	$\sigma_v(xz)$
$\sigma_v(xz)$	$\sigma_v(xz)$	$\sigma_v'(yz)$	E	C_2
$\sigma_v'yz)$	$\sigma_v'(yz)$	$\sigma_v(xz)$	C_2	E

Example 20. The group C_{3v} consists of the symmetry operations E, C_3, C_3^2, $\sigma_v(1)$, $\sigma_v(2)$ and $\sigma_v(3)$. Construct the group multiplication table for this group.

Solution : We draw up the following group multiplication table :

	E	C_3	C_3^2	$\sigma_v(1)$	$\sigma_v(2)$	$\sigma_v(3)$
E	E	C_3	C_3^2	$\sigma_v(1)$	$\sigma_v(2)$	$\sigma_v(3)$
C_3	C_3	C_3^2	E	$\sigma_v(2)$	$\sigma_v(3)$	$\sigma_v(1)$
C_3^2	C_3^2	E	C_3	$\sigma_v(3)$	$\sigma_v(1)$	$\sigma_v(2)$
$\sigma_v(1)$	$\sigma_v(1)$	$\sigma_v(3)$	$\sigma_v(2)$	E	C_3^2	C_3
$\sigma_v(2)$	$\sigma_v(2)$	$\sigma_v(1)$	$\sigma_v(3)$	C_3	E	C_3^2
$\sigma_v(3)$	$\sigma_v(3)$	$\sigma_v(2)$	$\sigma_v(1)$	C_3^2	C_3	E

Example 21. Identify the point group to which the following objects belong : (a) a sphere (b) an isosceles triangle (c) an equilateral triangle (d) an unsharpened cylindrical pencil (e) a sharpened cylindrical pencil (f) a three-balanced propellor (g) a four-legged table (h) yourself approximately.

Solution : Refer to Fig. 22.

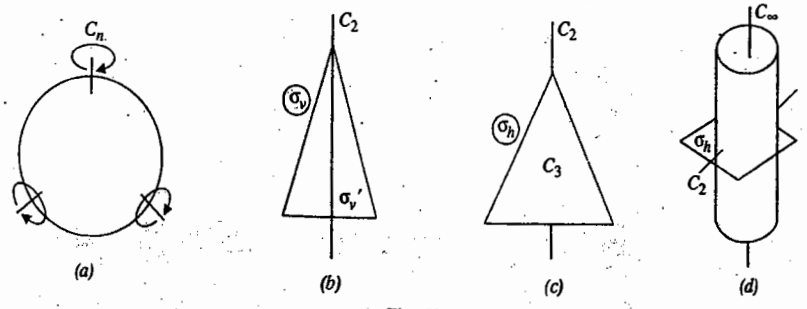

Fig. 22

(a) Sphere : An infinite number of summetry axes ; therefore, R_3.
(b) Isosceles triangle : E, C_2, σ_v, σ_v' ; therefore, C_{2v}.
(c) Equilateral triangle : E, C_3, C_2, σ_h ; therefore, D_{3h}
(d) Cylinder : E, C_∞, C_2, σ_h ; therefore, $D_{\infty h}$.

Cont.

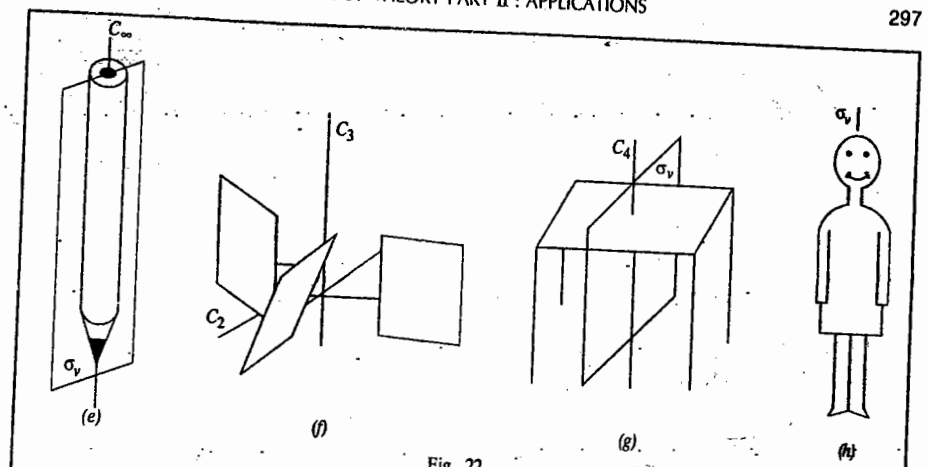

Fig. 22.

(e) Sharpened pencil : E, C_∞, σ_v ; therefore, $C_{\infty v}$
(f) Propellor : E, C_3, $3C_2$; therefore, D_3
(g) Square Table : E, C_4, $4\sigma_4$; therefore, C_{4v} ; Rectangular table : E, C_2, $2\sigma_v$; therefore, C_{2v}
(h) Person : E, σ_v (approximately) ; therefore, C_s

Example 22. Using similarity transformation show that the six elements of the C_{3v} point group (to which NH_3 molecule belongs) can be divided into three classes.

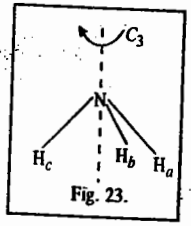

Fig. 23.

Solution : The NH_3 molecule is shown in Fig. 23.

Two elements, say, A and B, of a group are said to be conjugate if

$$A = X^{-1}BX$$

where X is another element of the same group. Such a transformation is known as similarity transformation. The six symmetry operations of NH_3 are E, C_3, C_3^2, σ_{v_a}, σ_{v_b} and σ_{v_c}. The identity E is a class by itself since for every other element of the group $X^{-1}EX = E$. We can show that C_3 and C_3^2 form a class by examining their similarity transformation with every other element of the group.

$$E^{-1}C_3E = EC_3E = C_3$$

$$C_3^{-1}C_3C_3 = C_3^2C_3C_3 = C_3^2C_3^2 = C_3$$

$$(C_3^2)^{-1}C_3C_3^2 = C_3C_3C_3^2 = C_3C_3^3 = C_3$$

$$(\sigma_{v_a}^{-1})C_3\sigma_{v_a} = \sigma_{v_a}C_3\sigma_{v_a} = \sigma_{v_a}\sigma_{v_c} = C_3^2$$

$$(\sigma_{v_b}^{-1})C_3\sigma_{v_b} = \sigma_{v_b}\sigma_{v_a} = C_3^2$$

$$(\sigma_{v_c}^{-1})C_3\sigma_{v_c} = \sigma_{v_c}\sigma_{v_b} = C_3^2$$

Similarly, we can show that the similarity transformation of C_3^2 by E, C_3 and C_3^2 gives C_3^2 and by σ_{v_a}, σ_{v_b} and σ_{v_c} gives C_3. Hence, C_3^2 and C_3 are conjugate and belong to the same class. We can similarly show that the three σ_v planes belong to a class. The three classes of the C_{3v} point group are written as

E, (C_3 and C_3^2), (σ_{v_a}, σ_{v_b}, σ_{v_c})

or, in a compact manner as E, $2C_3$, $3\sigma_v$.

Example 23. Define isomorphism in group theory.

Solution : Two groups G and G' of the same order are said to be *isomorphous* if we can establish a one-to-one correspondence between their elements such that, if the element A of the group G corresponds to the element A' of G' and B of G to B' of G', then AB corresponds to $A'B'$. Two such groups have identical properties though the actual meaning of their elements may be different.

Example 24. From the character table for the D_{6h} point group, determine the direct product $E_{1u}\times E_{1u}$. Show that its irreducible components are A_{1g}, A_{2g} and E_{2g}.

Solution : Refer to the character table of the D_{6h} point group (Table 8). The information we get is tabulated below :

	E	$2C_6$	$2C_3$	C_2	$3C_2'$	$3C_2''$	i	$2S_3$	$2S_6$	σ_h	$3\sigma_d$	$3\sigma_v$
$\chi(E_{1u}\times E_{1u})$	4	1	1	4	0	0	4	1	1	4	0	0

Using the standard reduction formula (Eq. 8), *viz.*,

$$n_j = \frac{1}{h}\sum_{R_p} g_p \chi(R_p)\chi_j(R_p)$$

and the characters of the direct product representation obtained above, we obtain

$$n_{A_{1g}} = \frac{1}{24}[1\times4\times1+2\times1\times1+2\times1\times1+1\times4\times1+3\times0\times1+3\times0\times1+1\times 4\times1+2\times1\times1+2\times1\times1+1\times4\times1+3\times0\times1+3\times0\times1] = 0$$

$$n_{A_{2g}} = \frac{1}{24}[4+2+2+4+4+2+2+4] = 1$$

$$n_{E_{2g}} = \frac{1}{24}[8-2-2+8+8-2-2+8] = 1$$

Hence, $$E_{1u}\times E_{1u} = A_{1g} + A_{2g} + E_{2g}$$

Example 25. Use symmetry properties to determine whether or not the integral $\int p_x z p_z d\tau$ is necessarily zero in a molecule with symmetry C_{4v}.

Solution : The character table for the C_{4v} point group is given below :

Table 10

Character Table for the C_{4v} Point Group

C_{4v}	E	$2C_4$	C_2	$2\sigma_v$	$2\sigma_d$	$h = 8$	
A_1	1	1	1	1	1	z	x^2+y^2, z^2
A_2	1	1	1	−1	−1	R_z	
B_1	1	−1	1	1	−1		x^2-y^2
B_2	1	−1	1	−1	1		xy
E	2	0	−2	0	0	$(x, y)(R_x, R_y)$	(xz, yz)

$$I = \int f_1 f_2 f_3 \, d\tau \quad \text{where } f_1 = p_x, \quad f_2 = z, \quad f_3 = p_z$$

For the integral to be non-zero, it is necessary that the product $f_1f_2f_3$ spans A_1. We draw up the following table of characters and their products :

	E	$2C_4$	C_2	$2\sigma_v$	$2\sigma_d$	
$f_3 = p_z$	1	1	1	1	1	A_1
$f_2 = z$	1	1	1	1	1	A_1
$f_1 = p_x$	2	0	−2	0	0	E
$f_1f_2f_3$	2	0	−2	0	0	

The number of times that A_1 appears is 0 (since 2, 0, −2, 0, 0 are the characters of E itself). Hence the integral is necessarily zero.

Example 26. Show that the transition $A_1 \rightarrow A_2$ is forbidden for electric dipole transitions in a C_{3v} molecule.

Solution : Refer to the character table of the C_{3v} point group (Table 2).

consider all the components of the electric dipole moment operator and draw up the following table :

Component of μ	x			y			z		
A_1	1	1	1	1	1	1	1	1	1
$\Gamma(\mu)$	2	−1	0	2	−1	0	1	1	1
A_2	1	1	−1	1	1	−1	1	1	−1
$A_1\Gamma(\mu)A_2$	2	−1	0	2	−1	0	1	1	−1
		E			E			A_2	

Since A_1 is not present in any product, the transition dipole moment must be zero and hence the transition $A_1 \rightarrow A_2$ is forbidden.

Example 27. Does the product xyz necessarily vanish when integrated over *(a)* a cube *(b)* a tetrahedron *(c)* a hexagonal prism each centred on the origin ?

Solution :

(a) xyz changes sign under the inversion operation (one of the symmetry operations of the cube). Hence, it does not span A_{1g} and its integral must vanish.

(b) xyz spans A_1 in T_d and so its integral need not be zero.

(c) $xyz \rightarrow -xyz$ under $z \rightarrow -z$ (the σ_h operation in D_{6h}) and so its integral must vanish.

Example 28. The ClO_2 molecule, which belongs to the C_{2v} point group, was trapped in a solid. Its ground state is known to be B_1. Light polarized parallel to the y-axis (parallel to the OO separation) excited the molecule to an upper state. What is the symmetry of that state ?

Solution : Refer to the character table for the C_{2v} point group. For the transition to occur, the direct product representation of the integrand must be A_1 or must contain A_1. Now the direct product representation is $\Gamma_f \times \Gamma(\mu) \times \Gamma_i$ (where i refers to the initial state and f refers to the final state). Then, since $\Gamma_i = B_1$, $\Gamma(\mu) = \Gamma(y) = B_2$, we can draw up the following table of characters :

	E	C_2	σ_v	σ_v'	
B_2	1	−1	−1	1	
B_1	1	−1	1	−1	
B_1B_2	1	1	−1	−1	$= A_2$

Hence, the upper state is A_2 because $A_2\times A_2 = A_1$.

Example 29. What states (irreps or symmetry species) of *(a)* benzene *(b)* naphthaleue may be reached by electric dipole transitions from their (totally symmetric) ground states ?

Solution : *(a)* Refer to the character table for D_{6h} point group to which benzene belongs. In D_{6h}, μ spans $E_{1u}(x, y)$ and $A_2(z)$ and the ground term is A_{1g}. Then using $A_{2u}\times A_{1g}=A_{2u}$, $E_{1u}\times A_{1g} = E_{1u}$; $A_{2u}\times A_{2u}=A_{1g}$ and $E_{1u}\times E_{1u}=A_{1g}+A_{2g}+E_g$, we conclude that the upper term is either E_{1u} or A_{2u}. This is in agreement with the requirement that the transition moment integral is non-zero if the direct product representation of the integrand spans the totally symmetric representation or, if reducible, contains the totally symmetric representation (A_{1g}).

(b) Refer to the character table for the D_{2h} point group to which naphthalene belongs. In D_{2h} itself the dipole moment μ components span $B_{3u}(x)$, $B_{2u}(y)$ and $B_{1u}(z)$ and the ground term is A_g. Hence, since $A_g \times \Gamma = \Gamma$ in this point group, the upper terms are B_{3u} (x-polarized), B_{2u} (y-polarized) and B_{1u} (z-polarized).

Example 30. Using symmetry arguments determine which overlap integrals in the secular determinant for the molecular orbital theory treatment of H_2O will vanish and which will not vanish.

Solution : As we have said, an integral is non-zero if the direct product representation of the integrand is symmetric. This is expressed by saying that (at least for one-dimensional irreducible representations) the overlap integral, S_{ij}, must necessarily be zero if the orbitals ϕ_i and ϕ_j belong to (or are basis of) different irreducible representations.

The coordinate system for H_2O molecule is shown in Fig. 24.

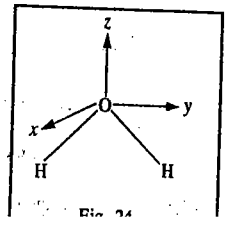

Fig. 24

H_2O molecule lies in the y—z plane. Let us evaluate S_{ij} for a $2p_x$ orbital on the oxygen atom ($2p_{xO}$) and the sum of the 1s orbitals on the hydrogen atoms ($1s_{H_A} + 1s_{H_B}$). The linear combination of 1s orbitals of H is symmetric under all operations of the C_{2v} point group and so transforms as A_1. We choose $1s_{H_A} + 1s_{H_B}$ rather than $1s_{H_A}$ or $1s_{H_B}$ individually for this reason. Referring to the character table for C_{2v} point group, we see that the $2p_x$ orbital on the oxygen atom transforms as x which transforms as (*i.e.*, belongs to) B_2. Hence, we can say that the overlap integral of $2p_{xO}$ and $1s_{H_A} + 1s_{H_B}$, *viz.*,

$$\int (2p_{x_O})(1s_{H_A} + 1s_{H_B})d\tau = 0$$

since the two orbitals belong to different irreducible representations. The same argument shows that

$$\int (2p_{y_O})(1s_{H_A} + 1s_{H_B})d\tau = 0$$

However,

$$\int (2p_{z_O})(1s_{H_A} + 1s_{H_B})d\tau \neq 0.$$

Example 31. Show that the overlap integral involving $2p_{xN}$ and $(1s_{H_A} + 1s_{H_B} + 1s_{H_C})$ in NH_3 molecule (C_{3v}) is equal to zero.

Solution. The overlap integral, S_{ij} must necessarily be zero if the orbitals ϕ_i and ϕ_j belong to (or are basis of) different irreducible representations. The linear combination $(1s_{H_A} + 1s_{H_B} + 1s_{H_C})$ belongs to the totally symmetric irreducible representation A_1 since it is symmetric under all operations of the C_{3v} point group. Referring to the character table for the C_{3v} point group, we see that the nitrogen atom orbital ($2p_{xN}$) transforms as x, which transforms as (or belongs to) E. Hence, the overlap integral

$$\int (2p_{xN})(1s_{H_A} + 1s_{H_B} + 1s_{H_C})d\tau = 0$$

Example 32. If we carry out a molecular orbital calculation on H_2O molecule using the minimal basis set atomic orbitals (AOs), $1s_{H_A}$, $1s_{H_B}$, $1s_{H_C}$, $2s_O$, $2p_{x_O}$, $2p_{y_O}$ and $2p_{z_O}$ without using group theory, we would obtain a 7×7 secular determiuant. How will this determinant look if we use group theory to generate symmetry orbitals ?

Solutiou : H_2O molecule belongs to the C_{2v} point group. We shall first determine the reducible representation of the seven AOs (as we did above for butadiene). We picture the s orbitals as spheres on each hydrogen atom and the $2p$ orbitals on the oxygen atom, like the coordinate axis system shown earlier. Clearly $\chi(E)=7$. The symmetry operation C_2 moves the $1s_H$ orbitals to different atoms, does not alter $1s_O$, $2s_O$ and $2p_{zO}$ and changes the direction of $2p_{xO}$ and $2p_{yO}$; hence, $\chi(C_2)=3-2=1$. Similarly, σ_v moves the $1s_H$ to different atoms, does not alter $1s_O$, $2s_O$, $2p_{xO}$ and $2p_{zO}$ and changes the direction of $2p_{yO}$. Therefore, $\chi(\sigma_v) = 4-1 = 3$. Finally, $\chi(\sigma_v') = 6 - 1 = 5$. Hence, the reducible representation is

Symmetry operation	E	C_2	$\sigma_v(xz)$	$\sigma_v'(yz)$
Γ	7	1	3	5

Using the standard reduction formula (Eq. 8), this rep can be reduced to sum of irreps as follows :

$$n_j = \frac{1}{h}\sum_{R_p} g_p \chi_j(R_p)\chi(R_p) \; ; \; h = 4$$

$$n_{A_1} = \frac{1}{4}[1\times 7 + 1\times 1 + 1\times 3 + 1\times 5] = 4$$

$$n_{A_2} = \frac{1}{4}[1\times 7 + 1\times 1 + (-1)\times 3 + (-1)\times 5] = 0$$

$$n_{B_1} = \frac{1}{4}[1\times 7 + (-1)\times 1 + 1\times 3 + (-1)\times 5] = 1$$

$$n_{B_2} = \frac{1}{4}[1\times 7 + (-1)\times 1 + (-1)\times 3 + 1\times 5] = 2$$

Thus, $\Gamma = 4A_1 + B_1 + 2B_2$. We see that four combinations belong to A_1, none to A_2, one to B_1 and two to B_2. The original 7×7 secular determinant blocks into a 1×1, a 2×2, and a 4×4 determinant. The energies obtained for the 1×1, 2×2, and 4×4 determinants correspond to the molecular orbitals of B_1, B_2 and A_1 symmetry, respectively. We can easily show that $1s_{H_A} + 1s_{H_B}$, $1s_O$, $2s_O$ and $2p_{z_O}$ belong to A_1 ; that $2p_{x_O}$ belongs to B_1 and that $2p_{y_O}$ and $1s_{H_A} - 1s_{H_B}$ belong to B_2.

Concluding Remarks. The 1963 Physics Nobel Laureate E.P. Wigner, whose monumental contributions to group theory have revolutionized mathematical physics, brought group theory from the realm of mathematics to physics and chemistry. Though books by Bishop, Cotton, Kettle, Ladd, Harris and Bertolucci, Tinkham and others deal with various aspects of the subject, the beginner can obtain a good insight into elements of group theory and of quantum chemistry by referring to books by K.V. Raman and A.K. Chandra, respectively. The student who intends to savour the excitement of physical chemistry and quantum chemistry will have to read the fabulous books written by the Oxford University Professor, the inimitable P.W. Atkins (there are a host of them, each different from the other). I.N. Levine's books on physical chemistry, quantum chemistry and spectroscopy are edifying, too. D.A. McQuarrie's books on quantum chemistry, statistical mechanics and physical chemistry are in the same league as those of Atkins and Levine. And finally, to delve into physics (whence physical chemistry and chemical physics are primarily derived), there are the great *Feynman Lectures on Physics*, renowned as much for their content as for Feynman's wit and wisdom. Richard Feynman (1918-1988), the 1965 Physics Nobel Laureate, who has contributed to several areas of physics, *viz.*, QED, path integral approach to quantum mechanics, theory of partons in elementary particle physics and theory of liquid helium, was an exceptionally brilliant teacher as well. The Feynman diagrams, have invaded theoretical chemistry, too! H.A.Bethe (1906-2005), the 1967 Physics Nobel Laureate was to the second half of the twentieth century what Einstein was to the first half.

Problems

1. Derive the standard reduction formula for the number of times an irrep occurs in a reducible representation.
2. Using the character table for the C_{2v} point group and the standard reduction formula, determine the symmetry species (irreps) to which the three normal modes of vibration of H_2O belong.
3. Repeat problem 2 for NH_3 molecule which belongs to the C_{3v} point group.
4. Repeat problem 2 for BF_3 molecule which belongs to D_{3h} point group.
5. Using group theory, factorise the Hückel secular equation for trans-1,3-butadiene (C_{2h} point group), and determine the SALCs for this molecule. Also, solve the Hückel secular equation for the energy levels, labelling them with the appropriate symmetry species (irresp) and draw the HMO diagram.
6. The first singlet excited state of ethylene is tested so that the two hydrogens and carbon on one side are in a plane perpendicular to the plane containing the other three atoms. To which symmetry group does it belong ? Does it have a dipole moment ? (Ans. D_{2d} ; no dipole moment)
7. Consider the three distinct isomers of dichlorobenzene. To which symmetry group does each belong ? Which can have a dipole moment ?

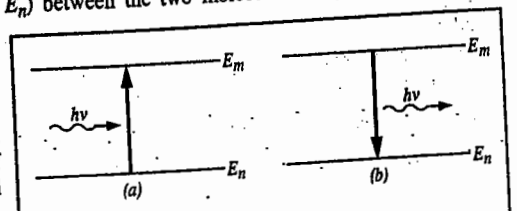
   (Ans. 1, 2-Dichlorobenzene, C_{2v}, dipole ; 1,3-dichlorobenzene, C_{2v}, dipole ; 1,4-dichlorobenzene, D_{2h}, no dipole)
8. Suppose the characters of a reducible representation (rep) of the C_{2v} point group are $\Gamma = 27 \; -1 \; 1 \; 5$. Determine how many times each irrep of C_{2v} is contained in the rep. Γ. (Ans. $\Gamma = 8A_1 + 5A_2 + 6B_1 + 8B_2$)
9. Suppose the characters of a reducible representation (rep) of the D_{3h} point group are $\Gamma = 12 \; 0 \; -2 \; 4 \; -2 \; 2$. Determine how many times each irrep of D_{3h} is contained in the rep. Γ. (Ans. $\Gamma = A_1' + A_2' + 3E' + 2A_2'' + E''$)
10. Consider a tetrahedral molecule xy_4 whose point group is T_d. Show that for constructing its hybrid orbitals, $\Gamma_R = 4 \; 1 \; 0 \; 0 \; 2$, which reduces to $\Gamma = A_1 + T_2$. Now argue that hybrid orbitals with T_d symmetry can be formed from an s orbital and p_x, p_y and p_z orbitals (or the d_{xy}, d_{yz} and d_{zx} orbitals) to give sp^3 (or sd^3) hybrid orbitals.

CHAPTER 6

MOLECULAR SPECTROSCOPY–I
(ROTATIONAL, VIBRATIONAL AND ELECTRONIC SPECTRA)

What is Spectroscopy ? Chemists, physicists, biochemists and other scientists are deeply interested in knowing the structure of molecules. If one could actually 'see' a molecule, there would probably be little fun in investigating it further. However, these systems are of so infinitesimal dimensions that it is not possible to see them, though some progress has of late been made in 'photographing' these species. Our knowledge about molecular structure is derived indirectly from the technique known as **spectroscopy**. *which deals with the transitions that a molecule undergoes between its energy levels upon absorption of suitable radiations determined by quantum mechanical selection rules.*

Quantum mechanics tells that the energy levels of all systems are *quantized* and are designated by appropriate quantum numbers. These energy levels are obtained by the solutions of the time-independent Schrödinger equation, the details of which are not really essential to the understanding of spectroscopy. Let us consider how a spectrum arises. Consider two molecular energy levels E_n and E_m, as shown in Fig. 1. If a photon of frequency ν falls on a molecule in the ground state and its energy $h\nu$ is exactly equal to the energy difference ΔE ($= E_m - E_n$) between the two molecular energy levels, then the molecule undergoes a **transition** from the lower energy level to the higher energy level with the *absorption* of a photon of energy $h\nu$. The spectrum thus obtained is called the **absorption spectrum**. If the molecule falls from the excited state to the ground state with the *emission* of a photon of energy $h\nu$, the spectrum obtained is called the **emission spectrum.**



(a) Absorption spectrum *(b)* Emission spectrum.

Fig. 1. Spectroscopic transitions between molecular energy levels.

Basic Features of a Spectrometer

The schematic diagram of the spectrometer used for absorption spectroscopy is given in Fig. 2.

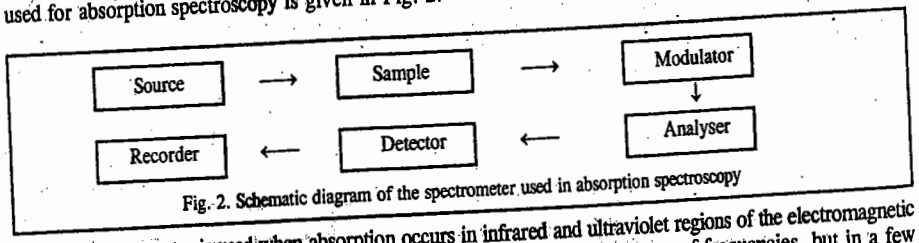


Fig. 2. Schematic diagram of the spectrometer used in absorption spectroscopy

This spectrometer is used when absorption occurs in infrared and ultraviolet regions of the electromagnetic spectrum. The source in a spectrometer produces radiation spanning a range of frequencies, but in a few cases (such as lasers), it is almost a monochromatic radiation. The radiation source in an absorption spectrometer is a heated ceramic filament coated with rare-earth oxides (a Nernst emitter or filament) for the infrared region. The source for the visible region of the spectrum is a tungsten filament which gives out intense white light ; for the ultraviolet region the source is a hydrogen discharge lamp. A

klystron (which is also used in radar installations and microwave ovens) or, more commonly, a semiconductor device called *Gunn diode*, is used to generate microwaves. The radiofrequency radiation is generated by causing an electric current to oscillate in a coil of wire.

The variation of absorption with frequency is determined, traditionally, by analyzing the spectral radiation by means of a *dispersing element* which separates different frequencies into rays that travel in different directions. The simplest dispersing element is a glass or a quartz prism but a diffraction grating is more widely used. A *diffraction grating* consists of a glass or ceramic plate into which fine grooves have been cut about 1000 nm apart (a spacing comparable to the wave length of visible light) and covered with a reflective aluminium coating. The grating causes interference between waves reflected from its surface and constructive interference occurs at specific angles that depend on the frequency of the radiation being used. Thus, each wave length of light is directed into a specific direction.

The third component of the spectrometer is the *detector*, a device that converts the spectral radiation into an electrical signal that is passed on to a recording device operating synchronously with the analyzer, thus producing either a trace on a chart recorder or a computer record of the spectrum. Common detectors are the radiation-sensitive semiconductors. The radiation is chopped by a shutter that rotates in the beam so that an alternating signal is obtained from the detector (an oscillating signal is easier to amplify than a steady signal). A modulator is introduced to convert the signal to an alternating character. This procedure enables more AC electronics to be employed in the recording stages. In the microwave region the source frequency is varied and the analyser is not necessary.

The highest resolution is obtained when the sample is gaseous and at such low pressure that collisions between molecules are infrequent. Gaseous samples are essential for microwave (pure rotational) spectroscopy since molecules can freely rotate only in the gaseous state. In order to achieve sufficient absorption, the path lengths of gaseous samples must be very long, of the order of metres. Long path lengths are achieved by multiple passage of the beam between two parallel mirrors at each end of the sample cavity. For infrared spectroscopy, the sample is typically a liquid held between windows of sodium chloride (which is transparent down to 700 cm^{-1}) or potassium bromide (down to 400 cm^{-1}). Other ways of preparing the sample include grinding it into a paste with 'Nujol', a hydrocarbon oil, or pressing it into a solid disk, with powdered potassium bromide.

Nowadays it is a common practice to use **Fourier-transform technique in spectroscopy**, particularly with infrared (IR) and nuclear magnetic resonance (NMR) spectroscopies. In Fourier-transform infrared (FTIR) spectroscopy, a Michelson-type interferometer is used to analyse the spectrum. It functions by producing an interferogram which is the superposition of a series of waves, each of which represents a component in the spectrum in terms of intensity and wave number. A Fourier transformation of the interferogram then produces a well-resolved absorption spectrum of the species, with a good signal-to-noise (S/N) ratio, also abbreviated as SNR.

The molecular spectra are governed by the so-called **selection rules** which specify the changes in the quantum numbers accompanying a particular transition. The chemist is lucky that selection rules exist which determine a spectrum. If there were no selection rules, the resulting spectrum would have been very chaotic indeed ! The selection rules are, in fact, the 'backbone' of spectroscopy and are obtained from the quantum theory of interaction of radiation with matter. Let us enumerate a few examples which would later be elucidated. For a diatomic molecule, such as H_2, NO, CO, etc., the selection rule for a pure *rotational transition* is $\Delta J = \pm 1$, where J is the rotational quantum number. The selection rule for a pure *vibrational transition* is $\Delta v = \pm 1$, where v is the vibrational quantum number.

The selection rules, however, are not always obeyed strictly. This is because certain approximations which have been used in the derivation of the selection rules are not valid strictly. The spectral transitions which obey a given selection rule are called **allowed transitions** whereas those which violate a selection rule are called **forbidden transitions.** In general, the allowed transitions are more intense (stronger) than the forbidden transitions which are weak. The selection rules for spectral transitions are derived from time-dependent perturbation theory (TDPT), discussed in Chapter 2.

The **natural linewidth** (or **life-time broadening**) of a spectral line is determined by the Heisenberg uncertainty principle, $\Delta E \Delta t \geq h/4\pi$, where ΔE is the uncertainty in the energy and Δt is the uncertainty in the life-time of the energy level. Since for a photon $E = h\nu$ so that $\Delta E = h\Delta\nu$, hence the natural linewidth, $\Delta\nu$, is given by

$$\Delta\nu \geq (4\pi\Delta t)^{-1} \qquad ...(1)$$

Width and Intensity of Spectral Lines. When we analyse the spectrum of a molecule, the first thing we wish to know is how sharp and how intense (strong) is the spectral line. In other words, we are interested in the width and intensity of a spectral line. These two quantities are common to all branches of spectroscopy. Fig. 3*(a)* shows a sharp spectral line having no width while Fig. 3*(b)* shows a spectral line having a width ΔE at half-height. The chemist would, indeed, be a happy person if the spectral lines were all very sharp and very intense. In practice, this is not so.

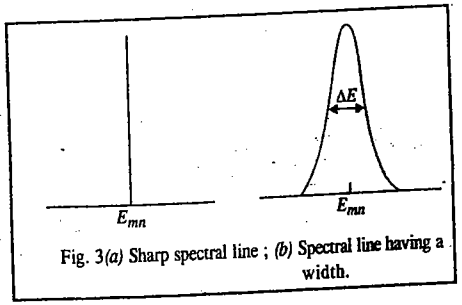

Fig. 3*(a)* Sharp spectral line ; *(b)* Spectral line having a width.

Two factors contribute to broadening of a spectral line : *(i)* The **collision broadening** and *(ii)* the **Doppler broadening**. The collision broadening is largely responsible for the width of spectral lines in the ultraviolet (UV) and visible regions. These transitions mostly take place between electrons in the outer shells in a molecule. When molecules in the gaseous or liquid phase collide with one another, they deform the charge clouds of the outer electrons thereby slightly perturbing the energy levels of these electrons. Hence, the spectral transitions between these perturbed energy levels are broadened.

Doppler broadening arises when the molecule under investigation has a velocity relative to the observer or observing instrument. This is generally the case with gaseous samples where the molecules are undergoing random motion according to the postulates of the kinetic theory of gases. If the molecule is moving *towards* the measuring instrument with velocity u, then the frequency ν' of radiation 'seen' by the molecule is given by

$$\nu' = \nu (1 + u/c) \qquad ...(2a)$$

where ν is the radiation frequency and c is the velocity of light. If, on the other hand, the molecule is moving *away* from the measuring instrument, the frequency of radiation 'seen' by the molecule is given by

$$\nu' = \nu (1 - u/c) \qquad ...(2b)$$

Rearranging Eq. 2*a*, we obtain

$$(\nu - \nu')/\nu = \Delta\nu/\nu = -u/c \qquad ...(3a)$$

Similarly, rearranging Eq. 2*b*, we obtain

$$(\nu - \nu')/\nu = \Delta\nu/\nu = u/c \qquad ...(3b)$$

The quantity $\Delta\nu$ is the *Doppler broadening*. We see that, depending upon the direction of motion of the molecule relative to the instrument, the observed frequency becomes either higher or lower than the actual radiation frequency. From the kinetic theory of gases, it can be shown that the Doppler broadening of the spectral line of a molecule of mass m is given by

$$\Delta\nu/\nu = (2/c)(2kT \ln 2/m)^{1/2} \qquad ...(4)$$

Since $\Delta\nu/\nu$ is directly proportional to $T^{1/2}$, Doppler broadening can be reduced (and spectral lines of maximum sharpness can be obtained) by working with cold gaseous samples.

We now turn to the **intensity of spectral lines.** The intensity of a spectral line is determined by

(i) the **Boltzmann population** of the energy levels and *(ii)* the **transition probability** between them.

According to Boltzmann, if, at temperature T, N_0 is the number of molecules in the ground state, then the number of molecules, N, in the excited state is given by

$$N = N_0 e^{-\Delta E/kT} \qquad ....(5)$$

where ΔE is the energy difference between the ground and excited states and k is the Boltzmann constant. The relative population at equilibrium is, thus, given by

$$N/N_0 = e^{-\Delta E/kT} \qquad ...(6)$$

Evidenty, if ΔE is large, N/N_0 is small, *i.e.*, the number of molecules in the excited state is less than that in the ground state. In fact, at room temperature, most of the molecules are in the ground state. Hence, the spectral lines originating from transitions from the ground state to a higher, say, third excited state would be more intense than those originating from transitions from the first excited state to the third excited state. The term transition probability, as the name implies, means the probability of transition between two given energy levels. We have said earlier that a molecule, upon absorption of a photon, does not just go anywhere it pleases ; it ends up in an energy level determined by the *selection rules* for that particular transition. The selection rules, in turn, determine the allowed transitions and the forbidden transitions. Clearly, the allowed transitions yield spectral lines which have greater intensity than the forbidden ones. The quantum theory of radiation was put forth by Einstein in 1916.

We may mention parenthetically that atomic spectra (discussed in Chapter 2) are the simplest spectra, consisting of sharp lines arising from electronic transitions, and are called **line spectra.** They are distinguished from molecular spectra (to be discussed in this chapter), which consist of bands arising from rotational and vibrational transitions accompanying electronic transitions ; they are called **band spectra.**

Molecular Spectra. In contrast to atomic spectra which arise from the transitions of an electron between the atomic energy levels, the molecular spectra arise from three types of transitions, *viz.*, *rotational, vibrational* and *electronic transitions*. Broadly speaking, the total energy of a molecule, according to the Born-Oppenheimer approximation, is given by

$$E = E_{tr} + E_{rot} + E_{vib} + E_{el} \qquad ...(7)$$

i.e., the energy is the sum of translational energy, E_{tr} ; rotational energy, E_{rot} ; vibrational energy, E_{vib} and electronic energy, E_{el}. The translational energy is, however, not quantized. Furthermore,

$$E_{el} >> E_{vib} >> E_{rot} >> E_{tr}$$

Since the translational energy is negligibly small, we can write the Born-Oppenheimer approximation as

$$E = E_{rot} + E_{vib} + E_{el} \qquad ...(8)$$

Let us illustrate these energies with reference to a diatomic molecule. Rotational energy arises when the molecule rotates about an axis perpendicular to the internuclear axis and passing through the centre of gravity of the molecule. Vibrational energy is associated with the to and fro motion of the nuclei of the molecule such that the centre of gravity does not change. And finally, electronic energy is associated with the transition of an electron from the ground state energy level to an excited state energy level of the molecule due to the absorption of a photon of suitable frequency.

Associated with each electronic state are a series of vibrational energy levels (designated by the vibrational quantum number v) and associated with each vibrational energy level are a series of rotational energy levels (designated by the rotational quantum number J), as shown in Fig. 4. It is customary to use a single prime superscript to designate a higher energy level and a double prime superscript to designate a lower energy level.

The rotational spectra of a molecule are observed in the microwave region ; the vibrational spectra in the infrared (IR) region and the electronic spectra in the ultraviolet (UV) and/or visible regions of the

electromagnetic spectrum.

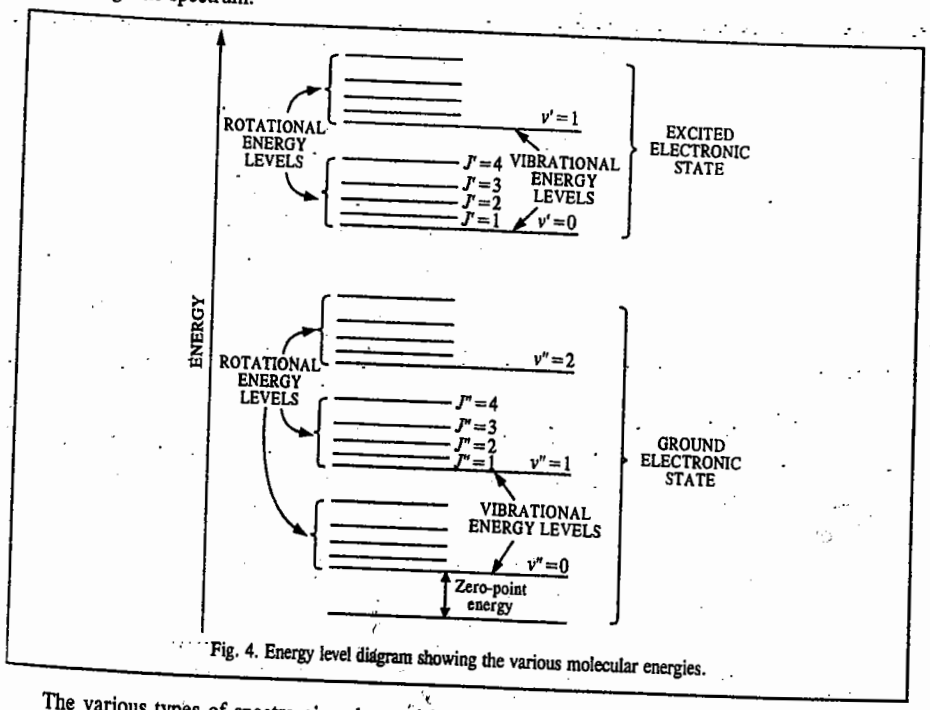

Fig. 4. Energy level diagram showing the various molecular energies.

The various types of spectra given by a molecule, the regions in which these spectra lie and the energy changes that take place in the molecule on absorption of radiation, are listed below.

1. Rotational (Microwave) Spectra. These spectra result from transitions between the rotational energy levels of a *gaseous* molecule on the absorption of radiations falling in the microwave region. These spectra are shown by molecules which *possess a permanent dipole moment, e.g.*, HCl, CO, H_2O vapour, NO, etc. Homonuclear diatomic molecules such as H_2, Cl_2, etc., and linear polyatomic molecules such as CO_2, which do not possess a dipole moment, do not show microwave spectra. Microwave spectra occur in the spectral range of 1 – 100 cm^{-1}.

2. Vibrational and Vibration-Rotation (Infrared) Spectra. These spectra originate from transitions induced between the vibrational energy levels of a molecule on the absorption of radiations belonging to the infrared region. IR spectra are shown by molecules when vibrational motion is accompanied by a *change in the dipole moment of the molecule*. These spectra occur in the spectral range of 500 – 4000 cm^{-1}.

3. Raman Spectra. Raman spectra relate to vibrational and/or rotational transitions in molecules but in a different manner. In this case, what we measure is the *scattering* and not the absorption of radiation. An intense beam of monochromatic radiation in the *visible region* is allowed to fall on a sample and the intensity of scattered light is observed at right angles to the incident beam. Most of the scattered light has the same frequency as the incident beam (this is called *Rayleigh scattering*). However, some of the scattered light has different frequencies than the incident beam. This is called *Raman scattering*. The energy differences between these weak lines and the main Rayleigh line correspond to vibrational and/or rotational transitions in the molecule under investigation. Raman spectra are observed in the visible region, *viz.*, 12,500 – 25,000 cm^{-1}.

4. Electronic Spectra. Electronic spectra arise from electronic transitions in a molecule by absorption of radiations falling in the visible and ultraviolet regions. While electronic spectra in the visible region span 12,500 – 25,000 cm^{-1}, those in the ultraviolet region span 25,000 – 70,000 cm^{-1}. Since electronic transitions in a molecule are invariably accompanied by vibrational and rotational transitions, the eletronic spectra of molecules are highly complex.

5. Photoelectron Spectra (PES). These spectra help in the determination of ionization energies of molecules. If a light photon falling on a molecule possesses very high energy, it can cause ionization of the molecule, *i.e.*, the removal of the electron from the molecule. If the energy of the incident photon is greater than the ionization energy, the ejected electron will possess excess kinetic energy. In PES, a beam of photons of known energy is allowed to fall on the sample and the kinetic energy of the ejected electrons is measured. The difference between the photon energy and the excess kinetic energy gives the **binding energy** of the electron. PES offers one of the most accurate methods for determining the ionization energies of molecules. Photoelectron spectra can be studied either using the X-ray photons or the UV photons. In the former case, they are called XPES spectra and in the latter case, the UVPES (or UPES) spectra.

6. Nuclear Magnetic Resonance (NMR) and Nuclear Quadrupole Resonance (NQR) Spectra. NMR spectra result from transitions induced between the nuclear spin energy levels of a molecule in an applied magnetic field. NQR spectra result from the transitions between the nuclear spin energy levels of a molecule arising from the interaction of the unsymmetrical charge distribution in nuclei with the electric field gradients (EFG) which arise from the bonding and non-bonding electrons in the molecule. NMR and NQR spectra span the radiofrequency regions, *viz.*, 5 – 100 MHz.

7. Electron Spin Resonance (ESR) or Electron Paramagnetic Resonance (EPR) Spectra. ESR spectra result from transitions induced between the electron spin energy levels of a molecule in an applied magnetic field. These spectra are exhibited by systems which contain odd (unpaired) electrons such as free radicals, transition metal ions and rare-earth ions. Molecules such as nitric oxide and oxygen and other paramagnetic systems also show ESR spectra. This branch of spectroscopy falls in the microwave region, *viz.*, 2 – 9·6 GHz.

8. Mössbauer Spectra (also called Nuclear Gamma Resonance Fluorescence (NRF) Spectra). Mössbauer spectra constitute a type of nuclear resonance spectra like nuclear magnetic resonance spectra. However, while NMR spectra result from absorption of low energy photons of frequency around 60 MHz, Mössbauer spectra result from absorption of high energy γ-photons of frequency around 10^{13} MHz by the nuclei. Gamma ray spectra have been used specifically for the study of compounds of iron and tin. In this case, γ-radiations from ^{57}Co source are allowed to fall on a sample in which the iron nuclei are in an environment identical with that of the source atoms. This results in resonant absorption of γ-rays. The splittings in Mössbauer lines are found to be of the same order as in NMR spectroscopy.

ROTATIONAL (MICROWAVE) SPECTRA OF DIATOMIC MOLECULES

Consider a diatomic molecule in which m_1 and m_2 are the masses of the two atoms and r is the equilibrium bond length, rotating about an axis passing through its centre of gravity, c.g. (Fig. 5).

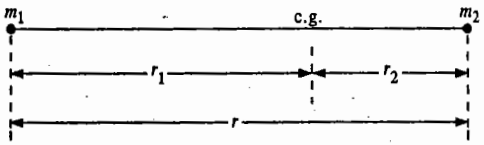

Fig. 5. Rotation of a diatomic molecule about its centre of gravity.

The centre of gravity is defined by the equality of the moments about it, *i.e.*,

$$m_1 r_1 = m_2 r_2 \qquad \ldots(9)$$

The **moment of inertia** I of a **molecule** (rotating as a rigid rotor, not subject to contrifugal forces that tend to distort the molecular geometry and change the moments of inertia) is defined as

$$I = \sum_i m_i r_i^2 \qquad ...(10)$$

where r_i is the distance of the ith particle of mass m_i from the centre of gravity. Since a diatomic molecule has two atoms, we have

$$I = m_1 r_1^2 + m_2 r_2^2 = m_2 r_2 r_1 + m_1 r_1 r_2 \quad \text{(using Eq. 9)} = r_1 r_2 (m_2 + m_1) \qquad ...(11)$$

Also, as seen from Fig. 5, $r = r_1 + r_2$ ...(12)

Therefore, from Eqs. 9 and 13, ...(13)

$$m_1 r_1 = m_2 r_2 = m_2 (r - r_1) \qquad ...(14)$$

Hence,

$$r_1 = \frac{m_2 r}{m_1 + m_2} \quad \text{and} \quad r_2 = \frac{m_1 r}{m_1 + m_2}$$

Substituting the above values of r_1 and r_2 in Eq. 11, we have

$$I = \frac{m_1 m_2^2}{(m_1 + m_2)^2} r^2 + \frac{m_1^2 m_2}{(m_1 + m_2)^2} r^2 \qquad ...(15)$$

$$= \frac{m_1 m_2 (m_1 + m_2)}{(m_1 + m_2)^2} r^2 = \frac{m_1 m_2}{m_1 + m_2} r^2 = \mu r^2 \qquad ...(16)$$

where $\mu = m_1 m_2/(m_1 + m_2)$ is called the **reduced mass** of the molecule.

Classically, the angular momentum L of a rotating molecule is given by $L = I\omega$ where ω is its angular velocity. However, the angular momentum is quantized, being given by

$$L = \sqrt{J(J+1)}\ \hbar\ ; \quad J = 0, 1, 2, ... \qquad ...(17)$$

where J is the rotational quantum number. The energy of a rotating molecule is given by $\frac{1}{2} I\omega^2$. Hence, the quantized rotational energy levels of a rigid diatomic rotor (rotating molecule) are given by

$$E_J = \tfrac{1}{2} I\omega^2 = (I\omega)^2/2I = L^2/2I \qquad ...(18)$$

Using the expression for L from Eq. 17, we have

$$E_J = J(J+1)\frac{\hbar^2}{2I}\ ; \text{ where } J = 0, 1, 2, ... \qquad ...(19)$$

Eq. 19 is also obtained by solving the Schrödinger wave equation for a rigid diatomic rotor (Chapter 1). It is customary to express the energy in cm^{-1} rather than in joules. This is done by dividing energy in joules by hc when we get

Here Total rotational energy, written as

$$F(J) = E_J/hc = J(J+1)\frac{\hbar}{4\pi cI}\ ; J = 0, 1, 2, ... \qquad ...(20)$$

$F(J)$, is called the **rotational term**. Defining the **rotational constant** B as

$$B = \frac{\hbar}{4\pi cI}\ \text{cm}^{-1}, \qquad ...(21)$$

we have

$$F(J) = BJ(J+1)\ ;\ J = 0, 1, 2, ... \qquad ...(22a)$$

and

$$E_J = hcBJ(J+1)\ ;\ J = 0, 1, 2, ... \qquad ...(22b)$$

If we want to take into account **centrifugal distortion** whose effect on the diatomic rotor is to stretch the bond and hence to increase the moment of inertia, and thereby to reduce the rotational constant and hence bring the energy levels closer than in the rigid-rotor approximation, then the energy level expression (22*a*) becomes

$$F(J) = BJ(J+1) - D_J J^2 (J+1)^2 \qquad ...(22c)$$

where D_J is the centrifugal distortion constant given by $D_J = 4B^3/\bar{\nu}^2$, where $\bar{\nu}$ is the vibrational frequency of the molecule.

Next we need a ***selection rule*** to determine the radiative transitions between the rotational energy levels. The derivation of the selection rule is a quantum-mechanical problem ; its details need not concern us here. Suffice it to mention that the rotational transitions for a rigid diatomic molecule are governed by the selection rule

$$\Delta J = \pm 1 \qquad ...(23)$$

i.e., only those transitions are allowed in which the rotational quantum number changes by unity. The + sign refers to absorption and the – sign to emission of radiation. Microwave spectra are usually observed as absorption spectra so that the operative part of the selection rule is $\Delta J = +1$. For a transition taking place from J to $J + 1$, the rotational frequency is given by

$$\nu_{(J \to J+1)} = B(J+1)(J+2) - BJ(J+1) \qquad ...(24)$$

$$= B(J^2 + 3J + 2) - B(J^2 + J) \qquad ...(25)$$

$$= 2B(J+1)\ \text{cm}^{-1} \qquad ...(26)$$

Thus, $\nu_{(0 \to 1)} = 2B$; $\nu_{(1 \to 2)} = 4B$;

$\nu_{(2 \to 3)} = 6B$; $\nu_{(3 \to 4)} = 8B$, etc.

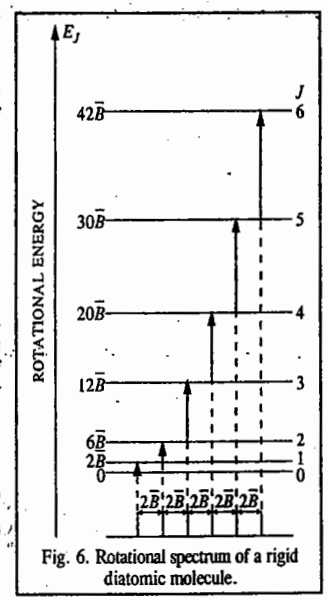

Fig. 6. Rotational spectrum of a rigid diatomic molecule.

We see that the rotational spectrum of a rigid diatomic molecule consists of a series of lines at $2B$, $4B$, $6B$, $8B$, etc. Evidently, these lines are equally spaced by an amount of $2B$ (Fig. 6) called **frequency separation.**

Example 1. The internuclear distance (*i.e.*, bond length) of carbon monoxide molecule is 1·13 Å. Calculate the energy (in joules and in eV) and angular velocity of this molecule in the first excited rotational level. The atomic masses are : $^{12}C = 1{\cdot}99 \times 10^{-26}$ kg ; $^{16}O = 2{\cdot}66 \times 10^{-26}$ kg.

Solution :

$$r = 1{\cdot}13\ \text{Å} = 1{\cdot}13 \times 10^{-8}\ \text{cm} = 1{\cdot}13 \times 10^{-10}\ \text{m}$$

$$\mu = \frac{m_1 m_2}{m_1 + m_2} = \frac{(1{\cdot}99 \times 10^{-26}\ \text{kg})(2{\cdot}66 \times 10^{-26}\ \text{kg})}{(1{\cdot}99 + 2{\cdot}66) \times 10^{-26}\ \text{kg}} = 1{\cdot}14 \times 10^{-26}\ \text{kg}$$

$$I = \mu r^2 = (1{\cdot}14 \times 10^{-26}\ \text{kg})\ (1{\cdot}13 \times 10^{-10}\ \text{m})^2 = 1{\cdot}46 \times 10^{-46}\ \text{kg m}^2$$

$$E_1 = \hbar^2/I\ \text{joule} \quad \text{[Eq. (19)]}$$

$$= \frac{(1{\cdot}054 \times 10^{-34}\ \text{Js})^2}{(1{\cdot}46 \times 10^{-46}\ \text{kg m}^2)} = 7{\cdot}61 \times 10^{-23}\ \text{joule} = \frac{7{\cdot}61 \times 10^{-23}\ \text{J}}{1{\cdot}602 \times 10^{-19}\ \text{J/eV}} = 4{\cdot}76 \times 10^{-4}\ \text{eV}$$

Since from Eq. 18, $E_1 = \frac{1}{2} I\omega^2$, where ω is the angular velocity, hence

$$\omega = \sqrt{\frac{2E_1}{I}} = \sqrt{\frac{2 \times (7{\cdot}61 \times 10^{-23}\ \text{J})}{1{\cdot}46 \times 10^{-46}\ \text{kg m}^2}} = 3{\cdot}23 \times 10^{11}\ \text{radians s}^{-1}$$

Example 2. Compare the first excited state rotational energy of CO molecule obtained in the last example with its thermal energy at room temperature and comment on the result.

Solution : Thermal energy of CO molecule at room temperature, *i.e.*, 25°C = kT

$$= \frac{1{\cdot}38\times10^{-23}\,\text{J K}^{-1}(298\,\text{K})}{1{\cdot}602\times10^{-19}\,\text{J / eV}} = 2{\cdot}6\times10^{-2}\ \text{eV}$$

Comparing it with the first excited state rotational energy of CO (*viz*, $4{\cdot}76\times10^{-4}$ eV), obtained in the last example, we find that the thermal energy is far greater. Hence, we conclude that at room temperature, all the molecules in the gaseous sample of carbon monoxide are in the excited rotational energy levels.

Example 3. The pure rotational (microwave) spectrum of the gaseous molecule CN consists of a series of equally spaced lines separated by 3·7978 cm^{-1}. Calculate the internuclear distance (*i.e.*, equilibrium bond length) of the molecule. The molar masses are : ^{12}C = 12·011 g mol^{-1} and ^{14}N = 14·007 g mol^{-1}

Solution : The spacing between the lines = $2B$ = 3·7978 cm^{-1}

$$\therefore \quad B = 3{\cdot}7978/2 = 1{\cdot}8989\ \text{cm}^{-1}$$

$$B = \frac{\hbar}{4\pi cI}\ \text{cm}^{-1} \qquad \text{(Eq. 21)}$$

$$\therefore \quad I = \frac{\hbar}{4\pi Bc} = \frac{1{\cdot}054\times10^{-34}\,\text{J s}}{(4\pi)(1{\cdot}8989\,\text{cm}^{-1})(3\times10^{10}\,\text{cm s}^{-1})}$$

$$= 1{\cdot}4742\times10^{-46}\ \text{kg m}^2 \qquad (\text{J} = \text{kg m}^2\,\text{s}^{-2})$$

The reduced mass is given by

$$\mu = \frac{(M_1/N_A)(M_2/N_A)}{(M_1/N_A)+(M_2/N_A)} = \frac{M_1M_2}{(M_1+M_2)N_A}$$

where N_A is Avogadro's number and M_1, M_2 are the molar masses of C and N, respectively. Thus,

$$\mu = \frac{(12{\cdot}011\,\text{g mol}^{-1})(14{\cdot}007\,\text{g mol}^{-1})}{(26{\cdot}018\,\text{g mol}^{-1})(6{\cdot}022\times10^{23}\,\text{mol}^{-1})} = 1{\cdot}0737\times10^{-23}\ \text{g}$$

$$= 1{\cdot}0737\times10^{-26}\ \text{kg}$$

Since $I = \mu r^2$, hence, $r = \left(\frac{I}{\mu}\right)^{1/2} = \left[\frac{1{\cdot}4742\times10^{-46}\,\text{kg m}^2}{1{\cdot}0737\times10^{-26}\,\text{kg}}\right]^{1/2} = 1{\cdot}1717\times10^{-10}\ \text{m} = \mathbf{117\ pm}$

Example 4. The pure rotational (microwave) spectrum of gaseous HCl consists of a series of equally spaced lines separated by 20·80 cm^{-1}. Calculate the internuclear distance of the molecule. The atomic masses are : ^{1}H = $1{\cdot}673\times10^{-27}$ kg : ^{35}Cl = $58{\cdot}06\times10^{-27}$ kg.

Solution : The spacing between the lines = $2B$ = 20·80 cm^{-1}

$$\therefore \quad B = 20{\cdot}80/2 = 10{\cdot}40\ \text{cm}^{-1}$$

$$B = \frac{\hbar}{4\pi cI}\ \text{cm}^{-1}$$

$$I = \frac{\hbar}{4\pi Bc} = \frac{1{\cdot}054\times10^{-34}\,\text{J s}}{(4\pi)(10{\cdot}40\,\text{cm}^{-1})(3\times10^{10}\,\text{cm s}^{-1})}$$

$$= 0{\cdot}2689\times10^{-46}\ \text{kg m}^2 \qquad (\text{J} = \text{kg m}^2\,\text{s}^{-2})$$

$$\mu = \frac{(1{\cdot}673\times10^{-27}\,\text{kg})(58{\cdot}06\times10^{-27}\,\text{kg})}{(1{\cdot}673+58{\cdot}06)\times10^{-27}\,\text{kg}} \qquad \text{(From Eq. 16)}$$

$$= \frac{(1{\cdot}673\times58{\cdot}06)10^{-27}}{59{\cdot}73}\ \text{kg} = 1{\cdot}626\times10^{-27}\ \text{kg}$$

$$\frac{(1{\cdot}673\times58{\cdot}06)10^{-27}}{59{\cdot}73}\ \text{kg} = 1{\cdot}626\times10^{-27}\ \text{kg}$$

Since $I = \mu r^2$, hence, $r = 1{\cdot}29\times10^{-10}$ m = **129 pm**

Relative Intensities of Rotational Spectral Lines. The relative intensities of spectral lines depend upon the relative populations of the energy levels. As we see from Example 2, even at room temperature many of the diatomic molecules are present in the excited state energy levels. Since the energy level population is given by the Boltzmann distribution, the intensity of rotational lines is evidently proportional to the Boltzmann distribution of molecules in the rotational energy levels, *i.e.*,

$$\text{Intensity} \propto N_J/N_0 = e^{-E_J/kT} \qquad \ldots(27)$$

Rotational energy levels are, however, degenerate, their degeneracy (g_J) for a diatomic molecule being given by

$$g_J = 2J+1 \qquad \ldots(28)$$

In other words, for a given value of J, the energy level is $(2J+1)$-fold degenerate. For $J=0$, $g_J=1$; for $J=1$, $g_J=3$; for $J=2$, $g_J=5$ and so on.

Thus, the intensity of the rotational spectral lines is determined by the product of the degeneracy factor and the Boltzmann exponential factor. Hence,

$$\text{Intensity} \propto N_J/N_0 = (2J+1)e^{-E_J/kT} \qquad \ldots(29)$$

Since $$E_J = hcF(J) \qquad \ldots(30)$$

and $$F(J) = BJ(J+1), \qquad \ldots(31)$$

hence, $$N_J/N_0 = (2J+1)\,e^{-BJ(J+1)\,hc/kT} \qquad \ldots(32)$$

The quantity N_J/N_0 is plotted versus J for a diatomic molecule at room temperature in Fig. 7.

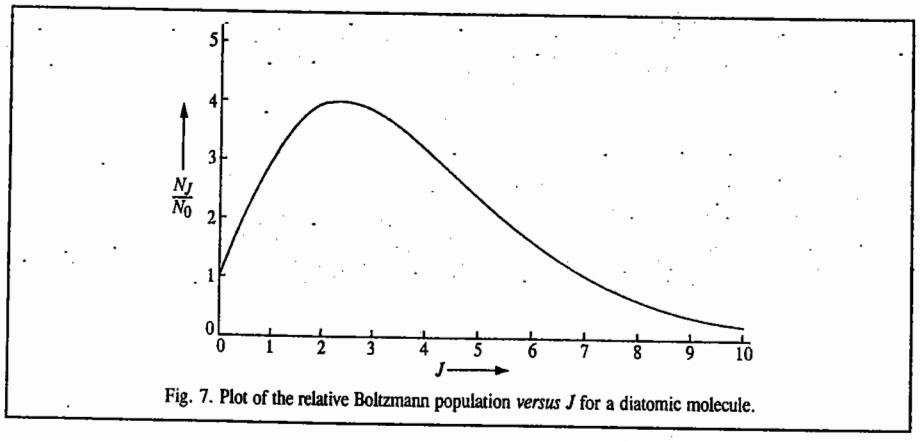

Fig. 7. Plot of the relative Boltzmann population *versus* J for a diatomic molecule.

We see that the relative intensity passes through a maximum. It can be shown that the value of J corresponding to the maximum in population is given by

$$J_{max} = \left(\frac{kT}{2hcB}\right)^{1/2} - \frac{1}{2} \qquad \ldots(33)$$

The J_{max} should be rounded off to the nearest integral value.

Example 5. Calculate J_{max} for a rigid diatomic molecule for which at 300 K, the rotational constant is 1·566 cm^{-1}.

Solution : $$J_{max} = \left(\frac{kT}{2hcB}\right)^{1/2} - \frac{1}{2} \qquad \text{(Eq. 33)}$$

$$\simeq \left[\frac{(1{\cdot}38 \times 10^{-23}\ \text{J K}^{-1})(300\ \text{K})}{2(6{\cdot}626 \times 10^{-34}\ \text{J s})(3 \times 10^{10}\ \text{cm s}^{-1})(1{\cdot}566\ \text{cm}^{-1})}\right]^{1/2} - \frac{1}{2} = 7{\cdot}56 \simeq 8$$

Application of Microwave Spectroscopy for the Determination of Bond Distances in Polyatomic Molecules. For the sake of simplicity, consider the gaseous linear triatomic molecule O=C=S for which we want to determine the two bond distances O—C and C—S. This can be done by **isotopic substitution method.** Consider first the molecule $^{16}O{=}^{12}C{=}^{32}S$ (Fig. 8).

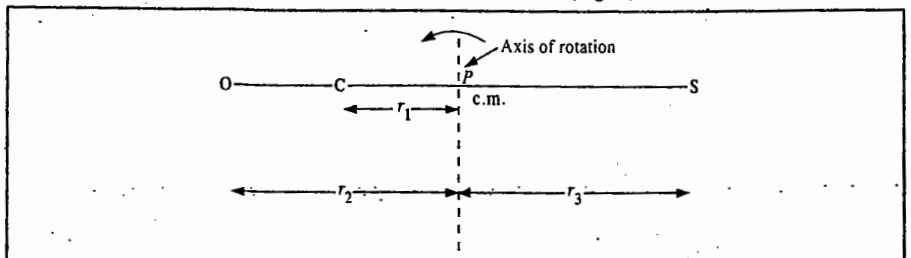

Fig. 8. The rotation of $^{16}O{=}^{12}C{=}^{32}S$ molecule about an axis of rotation passing through its centre of mass (c.m.)

Since the centre of mass is at P (from where the various distances are measured),

$$\therefore \qquad m_C r_1 + m_O r_2 = m_S r_3 \qquad \text{...(34)}$$

The moment of inertia is given by

$$I = m_C r_1^2 + m_O r_2^2 + m_S r_3^2 \qquad \text{...(35)}$$

Also, $$r_2 = r_{CO} + r_1\ ;\ r_3 = r_{CS} - r_1 \quad \text{(Fig. 8)} \qquad \text{...(36)}$$

where r_{CO} and r_{CS} are the two interatomic distances to be determined. Substituting Eq. 36 into Eq. 34, we have

$$m_C r_1 + m_O (r_{CO} + r_1) = m_S (r_{CS} - r_1) \qquad \text{...(37)}$$

or, rearranging,

$$(m_C + m_O + m_S)\, r_1 = m_S\, r_{CS} - m_O\, r_{CO} \qquad \text{...(38)}$$

Since $m_C + m_O + m_S = M$ (the mass of the O=C=S molecule), hence,

$$Mr_1 = m_S\, r_{CS} - m_O\, r_{CO}$$

$$r_1 = (m_S\, r_{CS} - m_O\, r_{CO})/M \qquad \text{...(39)}$$

Substituting Eq. 36 into Eq. 35, we have

$$I = m_C\, r_1^2 + m_O\, (r_{CO} + r_1)^2 + m_S\, (r_{CS} - r_1)^2 \qquad \text{...(40)}$$

Substituting for r_1 from Eq. 39 into Eq. 40 and simplifying, we obtain

$$I = (m_S\, r_{CS}^2 - m_O\, r_{CO}^2 + 2m_O m_S\, r_{CO}\, r_{CS} - m_S\, r_{CS}^2)/M \qquad \text{...(41)}$$

Eq. 44 contains the unknowns r_{CO} and r_{CS}.

Now we make an important assumption *that isotopic substitution does not alter the interatomic distances.* Applying this assumption to the $^{16}O{=}^{12}C{=}^{34}S$ molecule, we obtain a similar expression for the moment of intertia I' of the molecule :

$$I' = (m_S'\, r_{CS}^2 - m_O\, r_{CO}^2 + 2m_O\, m_S'\, r_{CO}\, r_{CS} - m_S'\, r_{CS}^2)/M \qquad \text{...(42)}$$

Thus, we can obtain both I and I' from the microwave spectra of $^{16}O{=}^{12}C{=}^{32}S$ and $^{16}O{=}^{12}C{=}^{34}S$ molecules and from these moments of inertia, the unknowns r_{CO} and r_{CS} can be determined.

The interatomic distances in gaseous O=C=S, using several pairs of isotopes are given in Table 1.

TABLE 1

Interatomic Distances in O=C=S Molecule

Pairs of Isotopic Molecules	r_{C-O} (in Å)	r_{C-S} (in Å)
$^{16}O{=}^{12}C{=}^{32}S$ and $^{16}O{=}^{12}C{=}^{34}S$	1·1647	1·5576
$^{16}O{=}^{12}C{=}^{32}S$ and $^{16}O{=}^{13}C{=}^{32}S$	1·1629	1·5591
$^{16}O{=}^{12}C{=}^{34}S$ and $^{16}O{=}^{13}C{=}^{34}S$	1·1625	1·5594
$^{16}O{=}^{12}C{=}^{32}S$ and $^{18}O{=}^{12}C{=}^{32}S$	1·1652	1·5653

Notice that there are small differences in bond lengths caused by changing the isotopes. These differences are due to *zero-point vibrations* whose amplitudes depend upon the masses of the atoms. Thus, measured bond lengths change upon isotopic substitution.

Microwave Oven. In recent years, the microwave oven has become a very familiar and useful cooking device in the kitchen. Its mode of operation depends upon the absorption by the food of the microwave radiation in which it is placed. The water molecules in the food absorb the microwave radiation and are thereby raised to the higher rotational states. The biological molecules in the food, on the other hand, are far too big to be able to rotate. The heating in the microwave oven is entirely *internal,* in contrast to the conventional oven where the food is cooked by *external* heating. In internal heating, the water molecules in the food are excited and the excess rotational energy is re-emitted as heat with the help of which the food gets cooked.

Unfortunately, the microwave radiation also affects the human body. Hence, the door seal of the microwave oven must be in good condition to ensure that no radiation leaks out.

ROTATIONAL SPECTRA OF POLYATOMIC MOLECULES

The rotational spectra of polyatomic molecules show features not found in the spectra of diatomic molecules. Whereas the diatomics have only one bond distance and hence only one moment of inertia, polyatomic molecules have more than one bond distance and hence several moments of inertia. In fact, in the Cartesian coordinate system (x, y, z), there are *nine* components of the moment of inertia.

However, in the so-called principal axis system (A, B, C), these components reduce to three moments of inertia, I_A, I_B, I_C, where I_A, I_B and I_C are, respectively, the principal moments of inertia about the A, B and C axes. Thus, polyatomic molecules in microwave spectroscopy are classified into different types of rotators (rotors) as shown in Table 2.

1. Linear Rotor. The energy of a linear rotor such as O=C=S is given by Eq. 22, *viz.*, the same as that for a diatomic rotor. In this case, isotopic substitution method is used to determine the bond distances, as discussed above.

TABLE 2

Classification of Polyatomic Molecules

Moment of Inertia	Type of Rotor	Examples
$I_A = I_B,\ I_C = 0$	Linear	HX, O=C=S, H—C≡N
$I_A = I_B = I_C$	Spherical top	CH_4, SF_6, UF_6
$I_A > I_B = I_C$	Prolate symmetric top	NH_3, $CHCl_3$, CH_3Cl
$I_A < I_B = I_C$	Oblate symmetric top	
$I_A \neq I_B \neq I_C$	Asymmetric top	H_2O

2. Spherical Top Molecules. Since a spherical top molecule such as CH_4 or SF_6 does not possess a permanent dipole moment, it is not microwave-active and is of only academic interest.

3. Symmetric Top Molecules. The solution of the Schrödinger wave equation for a symmetric top molecule gives the following expression for the energy levels of this rotor :

$$E_{J,K} = BJ(J+1) + (A - B)K^2 \quad ...(43)$$

where K is the component of J about the unique axis and the rotational constants A and B (in cm^{-1}) are defined as

$$A = h/(8\pi^2 I_A c) \text{ and } B = h/(8\pi^2 I_B c) \quad ...(44)$$

For every value of J, there are $2J+1$ values of K given by

$$K = 0, \pm 1, \pm 2, \cdots\cdots, \pm J \quad ...(45)$$

The selection rules for rotational transitions are

$$\Delta J = 0, \pm 1; \ \Delta K = 0 \quad ...(46)$$

4. Asymmetric Top Molecules. The solution of the Schrödinger wave equation for an asymmetric top rotor is a very difficult problem and there is no simple expression for the energy levels. We shall, therefore, not discuss this rotor here.

Stark Effect in Microwave Spectra. The splitting of molecular rotational energy levels in the presence of the external electric field E is called the **Stark effect,** after the German physicist, J. Stark (1874–1957) who was awarded the 1919 Physics Nobel Prize for his discovery of Doppler effect in canal rays and the splitting of spectral lines in electric fields. The shift of rotational frequency, $\Delta\nu$, for a linear gaseous molecule in the Stark effect is given by

$$\Delta\nu \propto (\mu E)^2 \quad ...(47)$$

where μ is the electric dipole moment of the molecule. Thus, knowing E and measuring $\Delta\nu$, μ can be determined. The Stark effect is extremely useful for determining the dipole moments of gaseous molecules.

Other Applications of Microwave Spectroscopy

The two most important applications of microwave spectroscopy are the study of internal rotation and the inversion spectrum of NH_3.

1. Internal Rotation. If a part of a molecule can rotate about a *single bond* then the internal potential energy of the molecule depends on the orientation of this part with respect to the rest of the molecule. Consider $F_3C—CH_3$ (*i.e.*, 1,1,1-trifluoroethane) molecule. The variation of the potential energy of this molecule when CF_3 group rotates about the C—C single bond, as a function of the angle θ is given by

$$V(\theta) = V_0(1 - \cos 3\theta) \quad ...(48)$$

where V_0 is the height of the potential energy barrier (Fig. 9). For low potential energy barriers, free rotation takes place. The potential energy barriers of a number of compounds have been determined using microwave spectroscopy. However, the origin of these barriers still remains obscure.

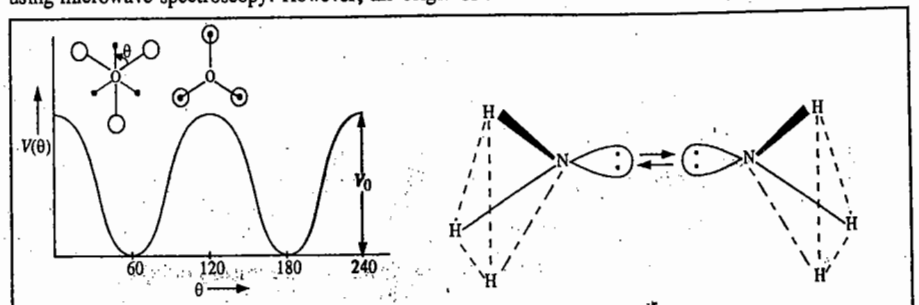

Fig. 9. Potential energy as a function of θ in internal rotation.

Fig. 10. The inversion of NH_3 molecule.

2. Inversion Spectrum of NH_3. Consider the inversion of the N atom through the plane of the three H atoms (Fig. 10).

The new configuration is the mirror image of the original configuration; it cannot be obtained by the rotation of the molecule. The two configurations have the same energy. A plot of the potential energy curve shows two minima with a hump in between (Fig. 11). The height of the hump, *i.e.*, the potential energy barrier, represents the *restriction to inversion*. Its value for NH_3 is about 25 kJ mol^{-1}.

Classically, it is impossible for the molecule to invert if it is in one of the first two vibrational levels. However, quantum mechanically it can 'tunnel' through the barrier. The inversion, in principle, is a vibrational motion. However, since it is hindered, it is observed in the microwave region. The splitting of the vibrational levels shown in Fig. 11 is a result of the *resonance interaction* between the two identical configurations. This **inversion doubling** causes the rotational lines to split.

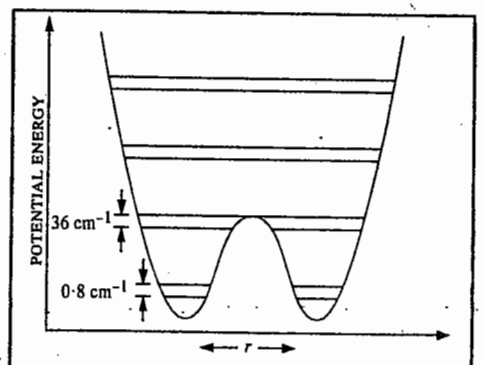

Fig. 11. A plot of the potential energy curve of NH_3 molecule.

VIBRATIONAL (INFRARED) SPECTRA OF DIATOMIC MOLECULES

A diatomic molecule with atomic masses m_1 and m_2 joined by a chemical bond vibrates as a one-dimensional simple harmonic oscillator (S.H.O.). Classically, the vibrational frequency of a mass point m connected by a spring of force constant k is given by

$$\nu = \frac{1}{2\pi}\left(\frac{k}{m}\right)^{1/2} \quad ...(49)$$

In the case of a diatomic molecule, the masses m_1 and m_2 vibrate back and forth relative to their centre of mass in opposite directions (Fig. 12).

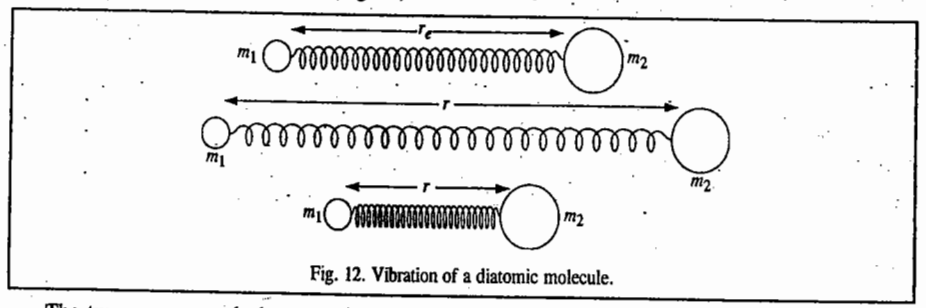

Fig. 12. Vibration of a diatomic molecule.

The two masses reach the extreme of their respective motions at the same time. The vibrational frequency of the molecule is given by a relation analogous to that of Eq. 49 with mass m replaced by the reduced mass μ :

$$\nu = \frac{1}{2\pi}\left(\frac{k}{\mu}\right)^{1/2} s^{-1} \quad ...(50)$$

To convert the frequency ν from s^{-1} (hertz) to cm^{-1}, we divide by c, the velocity of light. Thus,

$$\bar{\nu} = \frac{1}{2\pi c}\left(\frac{k}{\mu}\right)^{1/2} cm^{-1} \quad ...(51)$$

The units of the force constant are N m^{-1}. The potential energy of the simple harmonic oscillator (S.H.O.) as a function of displacement from the equilibrium configuration is given by the parabolic Hooke's law equation, *viz.*,

$$V(x) = \tfrac{1}{2}k(r - r_e)^2 = \tfrac{1}{2}kx^2 \qquad ...(52)$$

where x $(= r - r_e)$ is the displacement, r_e being the equilibrium bond length. The Hooke's law potential energy is shown in Fig. 13.

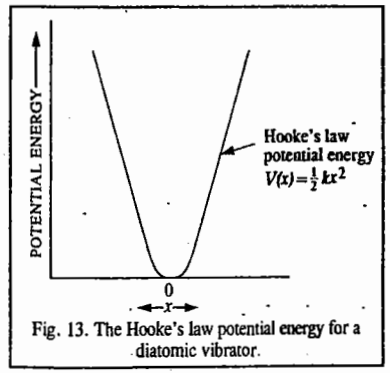

Fig. 13. The Hooke's law potential energy for a diatomic vibrator.

The solution of the Schrödinger equation for a simple harmonic oscillator gives the quantized vibrational energy levels

$$E_v = (v + \tfrac{1}{2})\,h\nu\,;\ v = 0, 1, 2, 3, \qquad .....(53)$$

where v is the **vibrational quantum number** and ν is the vibrational frequency given by Eq. 50. Notice that the energy of the lowest vibrational level of the oscillator is not zero but is equal to $\frac{1}{2}h\nu$; this is called **zero-point energy (Z.P.E.).** The energy levels of the S.H.O. are equally spaced, the spacing being equal to $h\nu$. To convert the energy from joules to cm^{-1} we divide by hc, obtaining

$$G(v) = E_v/hc = (v + \tfrac{1}{2})\,\nu/c = (v + \tfrac{1}{2})\omega_e \qquad ...(54)$$

where ω_e is the equilibrium vibrational frequency. $G(v)$ is called the **vibrational term.**

The selection rule for a vibrational transition in the simple harmonic oscillator is

$$\Delta v = \pm 1 \qquad ...(55)$$

The operative part of the selection rule for the absorption spectrum is $\Delta v = +1$, *i.e.*, the vibrational quantum number changes by unity. Using the selection rule, the frequency of the vibrational transition is given by

$$\bar{\nu} = G(v \to v+1) = (v+1+\tfrac{1}{2})\,\omega_e - (v+\tfrac{1}{2})\,\omega_e = \omega_e \qquad ...(56)$$

At room temperature, most of the molecules are in the ground vibrational state (v=0) so that the only transition of interest is that which takes place from v=0 to v=1. The vibrational frequency corresponding to this transition is called **fundamental vibrational frequency.** Diatomic molecules have only one vibrational frequency. This is a stretching vibrational frequency. Diatomic molecules do not have a bending vibrational frequency.

Vibrational spectra are observed in the infrared (IR) region. There is a very important requirement for a molecule to show an infrared spectrum. It states that the *dipole moment of the molecule must change during the vibration.* Homonuclear diatomic molecules such H_2, O_2, N_2, etc., do not have a permanent dipole moment nor does the stretching of the bond between the two atoms change the dipole moment from zero. Hence, homonuclear diatomics do not show IR spectra. On the other hand, heteronuclear diatomic molecules such as CO, NO, CN, HCl, do possess a dipole moment which changes when the bond length changes. Hence they show IR spectra. Thus, *homonuclear diatomics are IR-inactive while heteronuclear diatomics are IR-active.*

In practice, the molecule does not always vibrate as a simple harmonic oscillator ; there is present what is called **anharmonicity.** In 1929, P.M. Morse suggested an empirical expression for the potential energy of an anharmonic diatomic oscillator, given by

$$V(r) = D_e\,[1 - \exp(-a\{r - r_e\})]^2 \qquad ...(57)$$

Here a is a constant and D_e is the dissociation energy of the molecule. The **Morse potential energy** is sketched in Fig. 14.

It may be pointed out that the dissociation energy D_e in the Morse potential energy curve is measured from the bottom of the potential well. The experimentally measured dissociation energy D_0 is the one that is measured from the ground level (v = 0) to the top. Thus,

$$D_e = D_0 + h\nu/2 \qquad ...(58)$$

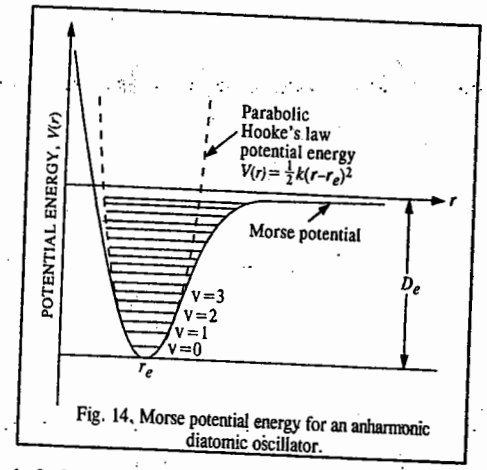

Fig. 14. Morse potential energy for an anharmonic diatomic oscillator.

When the Schrödinger equation for an *anharmonic oscillator* is solved using the Morse potential energy, the energy levels are given by

$$G(v) = (v + \tfrac{1}{2})\,\omega_e - (v + \tfrac{1}{2})^2\,\omega_e x_e\ ;\ (v = 0, 1, 2, 3,...) \qquad ...(59)$$

where $\omega_e x_e$ is called the **anharmonicity constant.** As expected, $\omega_e x_e \ll \omega_e$. The consequence of anharmonicity is that the vibrational energy levels of the S.H.O. are all slightly lowered and the spacing between them is no longer constant but goes on steadily decreasing with increase in vibrational quantum number. Also, because of anharmonicity, the rule for vibrational transitions is no longer $\Delta v = \pm 1$. Instead, transitions corresponding to $\Delta v = \pm 2, \pm 3$, etc., are also observed in the IR spectra. These are called the first overtone, the second overtone, etc., respectively. The *intensity of an overtone is dependent on the anharmonicity of the vibration.* Compared with the highly intense fundamental vibrational frequency, the overtones are very weak, *i.e.*, of considerably low intensity.

Example 6. The fundamental vibrational frequency of HCl is 2,890 cm^{-1}. Calculate the force constant of this molecule. The atomic masses are $^1H = 1{\cdot}673\times10^{-27}$ kg ; $^{35}Cl = 58{\cdot}06\times10^{-27}$ kg.

Solution. The reduced mass of HCl is given by

$$\mu = \frac{m_1 m_2}{m_1 + m_2} = \frac{(1{\cdot}673\times10^{-27}\,\text{kg})(58{\cdot}06\times10^{-27}\,\text{kg})}{(1{\cdot}673+58{\cdot}06)\times10^{-27}\,\text{kg}} = 1{\cdot}626\times10^{-27}\ \text{kg}$$

Since from Eq. 51, $\bar{\nu} = \dfrac{1}{2\pi c}\left(\dfrac{k}{\mu}\right)^{1/2}$ cm^{-1},

$$\therefore\quad k = 4\pi^2 c^2\,(\bar{\nu})^2\,\mu = 4\pi^2\,(3\times10^{10}\ \text{cm})^2\,(2890\ \text{cm}^{-1})^2\,(1{\cdot}626\times10^{-27}\ \text{kg})$$
$$= 4{\cdot}83\times10^2\ \text{kg s}^{-2} = 4{\cdot}83\times10^2\ \text{kg m s}^{-2}\times\text{m}^{-1} = 483\ \text{N m}^{-1}$$

Example 7. The force constant of CO is 1840 N m^{-1}. Calculate the vibrational frequency in cm^{-1} and the spacing between the vibrational energy levels in eV. Compare this spacing with the thermal energy at room temperature and comment on your result. The atomic masses are $^{12}C = 19{\cdot}9\times10^{-27}$ kg ; $^{16}O = 26{\cdot}6\times10^{-27}$ kg; 1 eV = 8066 cm^{-1}

Solution. The reduced mass of CO is given by

$$\mu = \frac{m_1 m_2}{m_1 + m_2} = \frac{(19{\cdot}9\times10^{-27}\,\text{kg})\times(26{\cdot}6\times10^{-27}\,\text{kg})}{(19{\cdot}9+26{\cdot}6)\times10^{-27}\,\text{kg}} = 11{\cdot}4\times10^{-27}\ \text{kg}$$

$$\bar{\nu} = \frac{1}{2\pi c}\left(\frac{k}{\mu}\right)^{1/2} = \frac{1}{2(3{\cdot}1416)(3\times10^{10}\,\text{cm s}^{-1})}\left(\frac{1840\ \text{kg s}^{-2}}{11{\cdot}4\times10^{-27}\,\text{kg}}\right) = 2140\ \text{cm}^{-1}$$

The spacing between energy levels $= \Delta E = E_{v+1} - E_v = h\nu$ joules $= h\nu/hc = \nu/c = \bar{\nu} = 2140\ \text{cm}^{-1}$

Since $1\ eV = 8066\ cm^{-1}$

$$\therefore \quad \Delta E = \frac{2140\ cm^{-1}}{8066\ cm^{-1}/eV} = 0{\cdot}265\ eV$$

$$\text{Thermal energy} = kT = \frac{(1{\cdot}38\times10^{-23}\ JK^{-1})(300\ K)}{1{\cdot}602\times10^{-19}\ J/eV} = 2{\cdot}6\times10^{-2}\ eV = 0{\cdot}026\ eV$$

We see that $kT < \Delta E$. Hence, we conclude that most of the molecules are in the ground vibrational state at room temperature. This situation is in contrast with the rotational states where $kT > \Delta E$ and consequently most of the molecules are in the excited rotational states at room temperature.

The force constant for a diatomic molecule can be calculated with the help of Eq. 51. Table 3 gives the calculated force constants for some diatomic molecules which contain triple bonds (N≡N), double bonds (O=O), single bonds (H—Cl) and ionic bonds (Na^+Cl^-).

TABLE 3

Observed Vibrational Frequencies and Calculated Force Constants for Some Diatomic Molecules

Molecules	$\bar{\nu}$ (cm^{-1})	Reduced mass μ (kg)	k ($N\ m^{-1}$)
N_2	2331	$1{\cdot}1625\times10^{-26}$	2240
CO	2141	1·1384	1860
NO	1776	1·2397	1550
O_2	1556	1·3279	1140
HF	3958	0·15658	870
H_2	4159	0·08367	510
HCl	2886	0·16272	480
F_2	892	1·5773	450
I_2	213	10·536	170
NaCl	378	2·3162	120

Example 8. For the molecule BH, $\omega_e = 2368\ cm^{-1}$ and the anharmonicity constant $\omega_e x_e = 49\ cm^{-1}$. Calculate the vibrational terms of the first four vibrational levels and determine the spacing between them.

Solution. From Eq. 59,

$$G(v) = (v + \tfrac{1}{2})\,\omega_e - (v + \tfrac{1}{2})^2\,\omega_e x_e$$

$$G(0) = (0 + \tfrac{1}{2})\times2368 - (0 + \tfrac{1}{2})^2\times49 = 1184 - 12 = 1172\ cm^{-1}$$

$$G(1) = (1 + \tfrac{1}{2})\times2368 - (1 + \tfrac{1}{2})^2\times49 = 3552 - 110 = 3442\ cm^{-1}$$

$$G(2) = (2 + \tfrac{1}{2})\times2368 - (2 + \tfrac{1}{2})\times49 = 5920 - 306 = 5614\ cm^{-1}$$

$$G(3) = (3 + \tfrac{1}{2})\times2368 - (3 + \tfrac{1}{2})\times49 = 8288 - 600 = 7688\ cm^{-1}$$

The spacings between the energy levels are :

$$G(1) - G(0) = 3442 - 1172 = 2270\ cm^{-1}$$

$$G(2) - G(1) = 5614 - 3442 = 2172\ cm^{-1}$$

$$G(3) - G(2) = 7688 - 5616 = 2074\ cm^{-1}$$

Notice that the energy levels are not equally spaced and the spacing goes on steadily decreasing with increase in the vibrational quantum number.

Example 9. The force constant of H_2 is 510 N m^{-1} and its dissociation energy is 4·5 eV. Assuming that it vibrates as a simple harmonic oscillator, calculate the vibrational quantum number corresponding to its dissociation energy.

Solution. From the given value of the force constant, the frequency of vibration can be easily calculated ; it is found to be 4159 cm^{-1}. Since vibrational levels of an S.H.O. are equally spaced, the dissociation energy of 4·5 eV (*i.e.*, $4{\cdot}5\times8066\ cm^{-1} = 36{,}297\ cm^{-1}$) corresponds to

$$\frac{36297\ cm^{-1}}{4159\ cm^{-1}} = 8{\cdot}7 = 9\text{th energy level}$$

Hence, the vibrational quantum number corresponding to the given dissociation energy is **8.**

ROTATION–VIBRATION (IR) SPECTRA OF DIATOMIC MOLECULES

Pure vibrational spectra can be observed only in liquids where interactions between molecules inhibit rotation. Since rotational energies are considerably smaller than vibrational energies, the freely moving molecules in the gaseous state are almost always rotating regardless of their vibrational state. Hence, molecules in gaseous state show rotation–vibration spectra. The rotation and vibration are, to a first approximation, independent of each other. Ignoring the effect of centrifugal distortion and taking into account the anharmonicity, the **rotation-vibration term,** S (v, J), for vibrating rotator is given by

$$S(v, J) = F(J) + G(v) \qquad \ldots(60)$$

$$= BJ(J+1) + (v + \tfrac{1}{2})\,\omega_e - (v + \tfrac{1}{2})^2\,\omega_e x_e\ cm^{-1} \qquad \ldots(61)$$

where we have used Eq. 31 for $F(J)$ and Eq. 59 for G(v).

The selection rules for combined vibrational and rotational transitions are

$$\Delta v = \pm1 \text{ and } \Delta J = \pm1 \qquad \ldots(62)$$

It is customary to designate the lower energy state by double prime and the upper energy state by a single prime. Using the energy level expression (61) and the selection rule (62), we have

$$\Delta S(v, J) = [B'J'(J'+1) + \tfrac{3}{2}\,\omega_e - \tfrac{9}{4}\,\omega_e x_e] - [B''J''(J''+1) + \tfrac{1}{2}\,\omega_e - \tfrac{1}{4}\,\omega_e x_e]$$

$$= \omega_0 + B(J' - J'')(J' + J'' + 1)\ cm^{-1}$$

where $\omega_0 = \omega_e(1 - 2x_e)$. $\qquad \ldots(63)$

Here we have assumed that the rotational constant B is the same in the upper and lower vibrational states, an assumption that is justified by the fact that rotation and vibration are, to a first approximation, independent. Since most of the molecules are in the ground vibrational state at room temperature, only the v = 0 to v = 1 transition is of interest.

(i) For the $\Delta J = +1$ transition, $J' = J''+1$, *i.e.*, $J' - J'' = +1$ so that

$$\Delta S(v, J) = \omega_0 + 2B(J''+1)\ cm^{-1};\ J'' = 0, 1, 2, 3,\ldots \qquad \ldots(64)$$

(ii) For the $\Delta J = -1$ transition, $J'' = J'+1$, *i.e.*, $J' - J'' = -1$ so that

$$\Delta S(v, J) = \omega_0 + 2B(J'+1)\ cm^{-1};\ J' = 0, 1, 2, 3,\ldots \qquad \ldots(65)$$

Combining the expressions 64 and 65,

$$\Delta S(v, J) = \bar{\nu}_{spec} = \omega_0 + 2Bm\ cm^{-1};\ m = \pm1, \pm2, \pm3,\ldots \qquad \ldots(66)$$

Notice that $m = J''+1$ in Eq. 64 and $= J'+1$ in Eq. 65 ; it is positive for $\Delta J = +1$ and negative for $\Delta J = -1$. The frequency ω_0, called the **band centre,** does not appear in the rotation–vibration spectrum which consists of equally spaced lines with spacing equal to $2B$ on each side of the band centre (Fig. 15).

The lines corresponding to $\Delta J = -1$ are called the **P branch** while those corresponding to $\Delta J = +1$ are called the **R branch.**

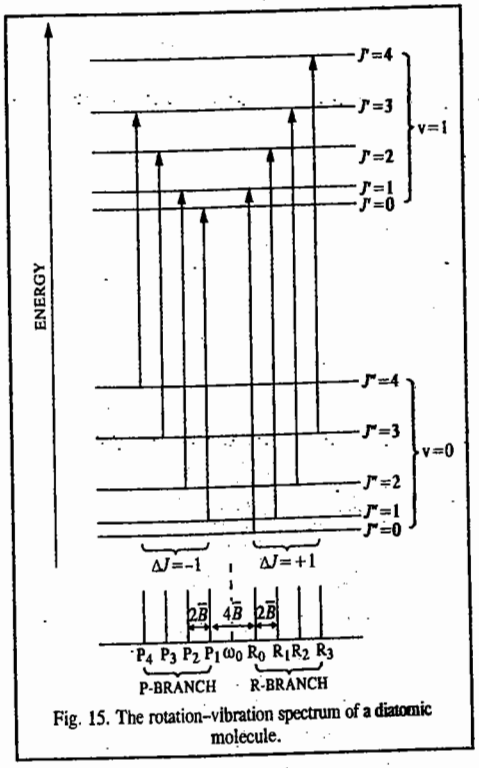

Fig. 15. The rotation–vibration spectrum of a diatomic molecule.

VIBRATIONAL SPECTRA OF POLYATOMIC MOLECULES

In order to study the vibrational spectra of polyatomic molecules, we have to investigate the vibrations of polyatomic molecules for which we start with the classical model of a molecule where the atoms (or nuclei) are represented by mathematical mass points. Each point requires three coordinates (such as x, y, z in a Cartesian coordinate system) to define its position. This is expressed by saying that there are *three* independent *degrees of freedom* in the x, y and z directions. For a molecule containing N atomic nuclei, there will be $3N$ degrees of freedom for all the nuclear masses in the molecule.

We need three coordinates to specify the centre of gravity of the molecule. Thus, the centre of gravity of the molecule has *three* independent *translational* degrees of freedom. For a non-linear molecule in its equilibrium configuration, three rotational coordinates are needed to specify the molecular orientation about the centre of gravity. These can be the three angular coordinates specifying rotation about three mutually perpendicular axes, each passing through the centre of gravity. Thus, a non-linear molecule has *three* independent *rotational* degrees of freedom. On the other hand, a linear molecule has only *two* independent *rotational* degrees of freedom about the two mutually perpendicular axes which are perpendicular to the molecular axis.

If we subtract the translational and rotational degrees of freedom from the total $3N$ degrees of freedom, we find that we are left with $3N - 6$ *internal* degrees of freedom for a non-linear molecule and $3N - 5$ *internal* degrees of freedom for a linear molecule. The $3N - 6$ internal degrees of freedom of motion of a non-linear molecule correspond to its $3N - 6$ independent *normal modes of vibration.* Similarly, the $3N - 5$ internal degrees of freedom of motion of a linear molecule correspond to its $3N - 5$ independent normal modes of vibration (or simply, normal vibrations). A **normal mode of vibration** is *defined as a molecular motion in which all the atoms in the molecule vibrate with same frequency and all the atoms pass through their equilibrium positions simultaneously.* The relative vibrational amplitudes of individual atoms may be different in magnitude and direction but the centre of gravity of the molecule does not change.

As has been stated earlier, in order for a molecule to be IR-active, *i.e.*, to show vibrational spectrum, it must either possess a permanent dipole moment μ or the dipole moment must change during a vibration, *i.e.*,

$$d\mu/dr \neq 0 \qquad ...(67)$$

The three normal modes of vibration (*i.e.*, fundamental vibrational frequencies) of H_2O molecule are shown in Fig. 16. They are all IR-active since each of them is accompanied by a change in dipole moment. The displacement vectors attached to the various nuclei in the molecule show the direction and relative amplitude of vibration of each nucleus. The symmetric stretching frequency is labelled as $\bar{\nu}_1$;

the symmetric bending frequency as $\bar{\nu}_2$ and the antisymmetric (asymmetric) stretching frequency as $\bar{\nu}_3$. The values of the three frequencies for water are $\bar{\nu}_1 = 3651{\cdot}7\ cm^{-1}$; $\bar{\nu}_2 = 1595{\cdot}0\ cm^{-1}$ and $\bar{\nu}_3 = 3755{\cdot}8\ cm^{-1}$. It is easier to bend a molecule than to stretch it. Hence, the bending frequency is generally lower than the stretching frequency. Also, it is easier to stretch a molecule symmetrically than to stretch it asymmetrically. Hence, the symmetric stretching frequency is lower than the asymmetric stretching frequency.

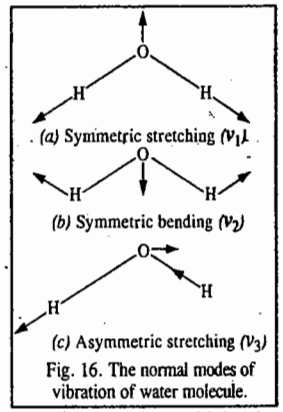

Fig. 16. The normal modes of vibration of water molecule.

The determination of the exact form of normal vibrations of a polyatomic molecule requires the solution of a system of simultaneous mathematical equations of motion (known as the **Lagrangian equations of motion**), involving the atomic masses, the bond force constants and parameters of molecular geometry. This mathematical analysis of molecular vibrations, called the **Normal Coordinate Analysis**, was carried out in 1935 by E.B. Wilson Jr., of Harvard University in the U.S.A. The best reference on the subject is E.B. Wilson, Jr., J.C. Decius, and P.C. Cross, *Molecular Vibrations*, McGraw Hill, 1955.

The linear CO_2 molecule has $3\times3 - 5 = 4$ fundamental vibrational frequencies while the linear acetylene molecule has $3\times4-5 = 7$ fundamental vibrational frequencies. These are shown in Fig. 17 and Fig.18, respectively. Of the four fundamental vibrations of CO_2 molecule two have the same frequency and are said to be *degenerate.* The symmetric stretching frequency $\bar{\nu}_1$ is not observed in the IR spectrum of CO_2 since it is not accompanied by a change in the dipole moment of the molecule with vibration.

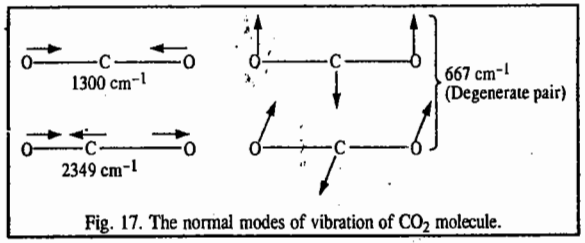

Fig. 17. The normal modes of vibration of CO_2 molecule.

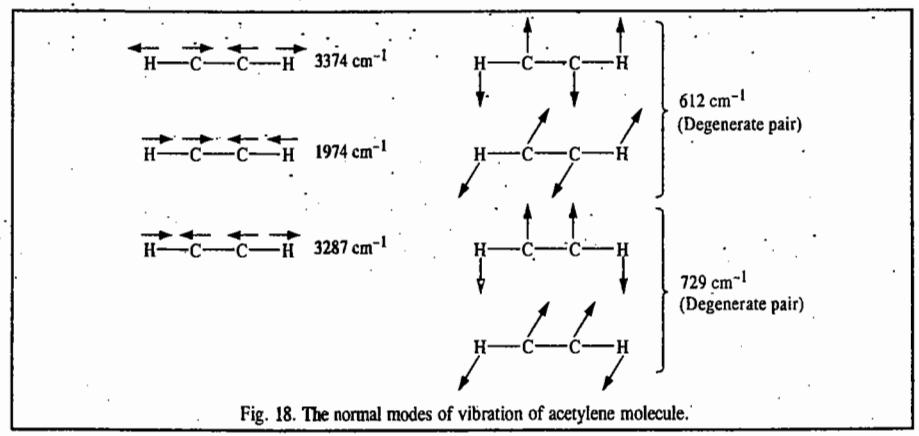

Fig. 18. The normal modes of vibration of acetylene molecule.

For acetylene, there are two degenerate pairs of frequencies at 612 cm^{-1} and 729 cm^{-1} (Fig.18). The former is not observed in IR region since it does not involve a change in dipole moment with vibration. The symmetric stretching frequencies (3374 cm^{-1} and 1974 cm^{-1}) are also IR-inactive for the same reason.

In general, a **normal mode of vibration** is an independent, synchronous motion of atoms or groups of atoms that may be excited without leading to the excitation of any other normal mode and without involving transtation or rotation of the molecule as a whole. The N_{vib} normal modes of polyatomics in general, are the key to the description of molecular vibrations. Each normal mode, q, behaves like an independent, harmonic oscillator (if anharmonicities are neglected), so each has a series of vibrational terms

$$G_q(v) = \left(v + \frac{1}{2}\right)\bar{\nu}_q, \quad \bar{\nu}_q = \frac{1}{2\pi c}\left(\frac{k_q}{m_q}\right)^{1/2}$$

where $\bar{\nu}_q$ is the wave number of the q mode and depends on the force constant k_q for the mode and on the effective mass m_q of the mode. The effective mass of the mode is a measure of the mass that is swung about by the vibration and in general is a complicated function of the masses of the atoms. For example, in the symmetric stretch of CO_2, the C atom is stationary and the effective mass depends on the masses of only O atoms. In the antisymmetric stretch and in the bends, all the three atoms move ; so all contribute to the effective mass. For the three normal modes of H_2O (Fig. 16) the predominantly bending mode (ν_2) has lower frequency than the others, which are predominantly stretching modes. It is generally the case that the frequencies of the bending motions are lower than those of the stretching modes. One point that must be appreciated is that only in special cases (such as the CO_2 molecule) are the normal modes purely stratches or purely bends. In general, a normal mode is a composite motion of simultaneous stretching and bending of bonds. Another point to note is that heavy atoms generally move less than light atoms in normal modes.

Since the nuclei in a polyatomic molecule do not always vibrate in a simple harmonic manner, there arises **anharmonicity** in molecular vibrations. The harmonic vibrations give rise to $3N-5$ (or $3N-6$) fundamental vibrational frequencies as stated above. On the other hand, the anharmonic vibrations give rise to the so called **overtones** and **combination bands.** The overtones occur as multiples of a given fundamental frequency. Thus, for H_2O molecule which has three fundamental vibrational frequencies $\bar{\nu}_1$, $\bar{\nu}_2$ and $\bar{\nu}_3$, the overtones would occur at (or near) $2\bar{\nu}_1, 3\bar{\nu}_1, \ldots, 2\bar{\nu}_2, 3\bar{\nu}_2 \ldots, 2\bar{\nu}_3, 3\bar{\nu}_3, \ldots$, etc. The first overtone of $\bar{\nu}_1$ is designated as $2\bar{\nu}_1$, the second as $3\bar{\nu}_1$, the third as $4\bar{\nu}_1$ and so on. The **combination bands** are merely the sum of two or more fundamental frequencies or overtones while the **difference bands** are the differences of two or more fundamental frequencies or overtones. Thus, combination bands are $\bar{\nu}_1 + \bar{\nu}_2$, $2\bar{\nu}_1 + \bar{\nu}_2$, $\bar{\nu}_1 + \bar{\nu}_2 + \bar{\nu}_3$, etc., while the difference bands are $\bar{\nu}_1 - \bar{\nu}_2$, $2\bar{\nu}_1 - \bar{\nu}_2$, $\bar{\nu}_1 - \bar{\nu}_2 + \bar{\nu}_3$, $\bar{\nu}_1 + \bar{\nu}_2 - \bar{\nu}_3$, etc. The overtones and combination bands have low intensity.

The complete IR spectrum of a polyatomic molecule, therefore, consists of the highly intense fundamental vibrational frequencies and the less intense overtones, combination bands and difference bands. *The overtones, combination bands and difference bands arise as a result of the violation of the selection rule for harmonic vibrations.* The analysis of the IR spectrum of water vapour is given in Table 4.

TABLE 4

IR Spectrum of H_2O Vapour

$\bar{\nu}$ (cm^{-1})	Intensity	Assignment
1595·0	Very strong	$\bar{\nu}_2$
3151·4	Medium	$2\bar{\nu}_2$
3651·6	Strong	$\bar{\nu}_1$
3755·8	Very Strong	$\bar{\nu}_3$
5332·0	Medium	$\bar{\nu}_2 + \bar{\nu}_3$
6874·0	Weak	$2\bar{\nu}_2 + \bar{\nu}_3$

Sometimes it may happen that a fundamental mode of vibration becomes *accidentally degenerate* with an overtone or a combination band. As a result, the intensity of the overtone or the combination band which is otherwise very low is enhanced by a resonance

phenomenon, known as **Fermi resonance,** after E. Fermi who first observed it. The classic example of Fermi resonance is furnished by CO_2 molecule where $\bar{\nu}_1 = 1330\ cm^{-1}$ and $2\bar{\nu}_2 = 1334\ cm^{-1}$. Quantum mechanically it can be shown that, as a result of Fermi resonance, the higher frequency is raised whereas the lower frequency is depressed. The two bands of CO_2 mentioned above are not observed in IR but they are observed in the Raman spectrum at 1285 cm^{-1} and 1385 cm^{-1}, respectively. Their mean is near 1330 cm^{-1}.

In fact, the consequence of anharmonic interactions is that the energy levels change as a result of their mixing under the perturbative anharmonic potential energy. Also, the transitions take on different intensities because wavefunctions mix and so acquire characteristics of one another. This is most striking in the case of an allowed fundamental vibration and a forbidden combination, for the latter may acquire intensity by virtue of the component of the allowed fundamental that the anharmonicity mixes into it. Fermi resonance represents the type of mode mixing in which the interaction is between a fundamental and a combination band or overtone. In fact, Fermi resonance can be viewed as the vibrational analogue of configuration interaction in molecular quantum mechanics.

We shall now consider an entirely different kind of force, known as the **Coriolis force** (which was studied by the 19th century French physicist G.G. Coriolis and has important implications for the movements of the oceans and the atmopshere resulting from earth's rotation). This force brings about a different kind of interaction between vibrational and rotational modes of a molecule. Let us consider how the Coriolis force affects a rotating molecule when its antisymmetrical vibrational mode has been excited (Fig. 19). When one of the bonds stretches, it experiences a retarding Corioils force; at the same time, the bond that is shortening experiences an accelerating Coriolis force. As a result, the molecule tends to bend. As the bonds next contract and lengthen, respectively, the Coriolis force acts in the opposite way, and the molecule is forced to bend in the opposite direction. This effect of the rotation on the antisymmetric stretch, therefore, is to induce one of the bending modes. This is expressed quantum mechanically by saying that rotation provides a perturbation that mixes the antisymmetric stretch with one of the components of the doubly degenerate pair of bending modes. As a result, the two levels move apart in energy, and the bending mode in the plane of rotation is no longer degenerate with the bending mode perpendicular to the plane. Transitions to these two levels no longer fall at the same energy and so the lines are doubled by the rotation. This effect is called *l*-**type doubling.**

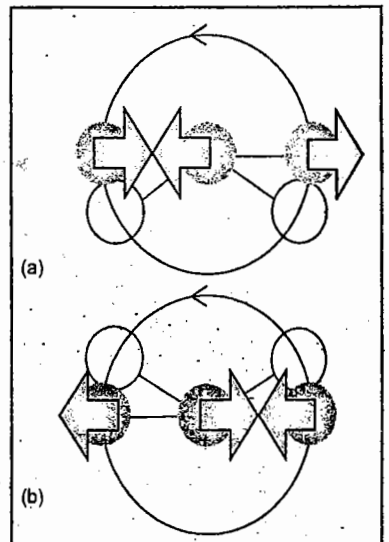

Fig. 19. Normal mode coupling in a rotating molecule : (*a*) and (*b*) show different stages of the antisymmetric stretch.

We may mention parenthetically that in the case of pyramidal molecules AB_3 (belonging to the C_{3v} point group), when the potential energy barrier is high, the inversion of the pyramid is difficult but when the barrier is low, the inversion is easy and the molecule (NH_3, for instance) can invert and take on the character of H_3N. In this case, the mixing of the wavefunctions on the left and right side of the barrier, $\psi_L \pm \psi_R$, leads to the phenomenon called **inversion doubling** of the energy levels. Details can be found in advanced books on quantum mechanics.

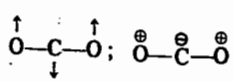
ROTATION-VIBRATION (*IR*) SPECTRA OF POLYATOMIC MOLECULES

1. Linear Molecules. Linear molecules such as CO_2 and HCN, whether they possess permanent electric dipole moment or not, are IR-active if some of their vibrations produce an oscillating dipole moment. Consider CO_2 molecule. It has two types of IR-active vibrations :

(i) The oscillating dipole is parallel to the molecular axis :

Such a vibration produces the so-called **parallel band.** The selection rules are $\Delta v = \pm 1$ and $\Delta J = \pm 1$.

(ii) The oscillating dipole is perpendicular to the molecular axis :



(Here $\ominus$ indicates vibration of C atom perpendicular to the plane of the paper downwards and $\oplus$ indicates vibration of O atom perpendicular to the plane of the paper upwards). Such a vibration gives rise to a **perpendicular band.** The selection rules are $\Delta v = \pm 1$ and $\Delta J = 0, \pm 1$.

2. Symmetric Top Molecules (Symmetric Rotors). Ignoring anharmonicity and centrifugal distortion, the energy levels of a symmetric top molecule such as CH_3Cl are given by

$$E_{J,K} = \left(v + \frac{1}{2}\right)\omega_e + B_v J(J+1) + (A - B)K^2$$

where A and B are defined in Eq. 44 and the values of K are given in Eq. 45. The selection rules are :

Parallel band : $\Delta J = 0, \pm 1, \Delta K = 0$

Perpendicular band : $\Delta J = 0, \pm 1, \Delta K = \pm 1$

3. Asymmetric Top Molecules (Asymmetric Rotors). Since the solution of the Schrödinger wave equation for the asymmetric top molecules is very difficult, we shall not deal with that here.

Vibrational Frequencies of Different Functional Groups

In general, the bond lengths and bond angles for given moieties of various compounds remain approximately constant. However, small changes occur in these parameters due to other species present in the molecule. These changes give rise to characteristic ranges of vibrational wave numbers and intensities for functional groups in molecules. Assignment of these wave numbers in an infrared spectrum often provides a rapid method for the identification of a compound. Some normal modes of vibration of organic molecules can be regarded as motions of individual functional groups ; others are regarded as the collective motions of the molecule as a whole. The latter are generally of low frequency and occur below about 1500 cm^{-1} in the spectrum. The resulting whole-molecule region of the absorption spectrum is called a **fingerprint region** of the spectrum since it is characteristic of the molecule. The matching of the fingerprint region with the spectrum of a known compound in a library of infrared spectra is a very powerful way of confirming the presence of a particular substance.

From studies over a range of compounds, charts have been developed that give the vibrational wave number ranges for most functional groups in different compounds. These wave numbers that occur outside the fingerprint region are very useful for the identification of an unknown compound. Table 5 lists some of

the assignments for a selection of the commoner functional groups encountered in organic chemistry. Lower frequency bending modes usually occur in the fingerprint region and so are less easily identified. The IR of a molecule can be regarded as made of several regions :

TABLE 5
Typical Vibrational Wave Numbers for Functional Groups

Group	Mode	Range (cm^{-1})	Intensity
>CH_2 $-CH_3$ >C–H	C–H(s)	3000–2850	*s*
>CH_2		2900–2880	*w*
$-CH_3$	C–H(b)	1470–1430	*m*
$-CH_3$	CH_3(sb)	1390–1370	*m*
>CH_2	CH_2(r)	700–750	*w*
$-C\equiv C-H$	CH(s)	3300	*s*
R, H, C=C, H, R	CH(s)	960–980	*s*
>C=C<	C=C(s)	1680–1620	*s*
–O–H	O–H(b)	1410–1260	*s*
–O–H	O–H(s)	3650–3590	*s*
>C–OH	C–OH(s)	1150–1050	*s*
>N–H =N–H	N–H(ss/as)	3500–3300	*m*
>C=O	C=O(s)	1780–1680	*vs*
Hydrogen bonds	O–H(s)	3570–3200	*s*

Key : s, stretch ; b, bend ; sb, symmetric bend ; r, rock ; ss, symmetric stretch ; as, asymmetric stretch ; *vs*, very strong; *s*, strong ; *m*, medium ; *w*, weak.

1. *Hydrogen stretching vibrations,* 3700–2500 cm^{-1}. These vibrations occur at higher wave numbers because of the low mass of the hydrogen atom. If H atom is replaced by D atom (*i.e.,* deuterium atom), the vibrational wave number falls by a factor of $1/\sqrt{2}$ because of the greater reduced mass of the deuterium molecule. If an –OH group is not involved in hydrogen bonding, it usually has a vibrational wave number in the vicinity of 3700–3600 cm^{-1}. Hydrogen bonding causes this wave number to drop by 300–1000 cm^{-1} or more.

2. *Triple-bond region,* 2500–2000 cm^{-1}. These bonds have high vibrational wave numbers because of the large force constants. The C ≡ C group usually causes absorption between 2300 and 2050 cm^{-1} but this absorption may be weak or absent because of the symmetry of the molecule. The C ≡ N group absorbs near 2300–2200 cm^{-1}.

3. *Double-bond region,* 2000–1600 cm^{-1}. Absorption bands of substituted aromatic compounds fall in this range and are a good indicator of the position of the substitution. Carbonyl groups of ketones, aldehydes, acids, amides and esters usually show strong absorption in the vicinity of 1700 cm^{-1}. Alkenes may show absorption in the vicinity of 1650 cm^{-1}.

4. *Single-bond stretch and bend region,* 500–1700 cm^{-1}. This region is not diagnostic for particular functional groups but it is a useful fingerprint region since it shows differences between similar molecules.

RAMAN SPECTROSCOPY

Quantum Theory of Raman Scattering. In contrast with other branches of spectroscopy, Raman spectroscopy deals with the *scattering of light* and not with its absorption. Consider a photon of frequency ν falling on a molecule. If the collision is *elastic*, then the scattered photon will have the same energy as the incident photon. If, however, the collision is *inelastic*, the scattered photon will have either a higher or a lower energy than the incident photon. If we further assume that the total kinetic energy of the photon and the molecule remains unchanged before and after the collision, then, from the law of conservation of energy,

$$h\nu + E = h\nu' + E' \qquad ...(68)$$

where $h\nu$ is the energy of the incident photon and $h\nu'$ is the energy of the scattered photon after collision; E is the energy of the molecule (rotational, vibrational and electronic) before collision and E' is the molecular energy after collision. Rearranging Eq. 68, we obtain

$$(E' - E)/h = \nu - \nu' \qquad ...(69)$$

Consider now the following cases ;

Case I : $\nu = \nu'$ so that $E = E'$

Case II*(a)* : $\nu < \nu'$ so that $E > E'$

Case II*(b)* : $\nu > \nu'$ so that $E < E'$

Case I is referred to as *Rayleigh scattering* and cases II*(a)* and II*(b)* as *Raman scattering*. Thus, in the Rayleigh scattering, the scattered photon has the same frequency (or energy) as the incident photon while in the Raman scattering, when the photon collides with the molecule, the energy is either transferred to, or taken away from, the molecule. The Rayleigh scattering and the Raman scattering are shown schematically in Fig. 20.

The Raman scattering had been predicted by the German physicist A. Smekel in 1923. It was observed by C.V. Raman and K.S. Krishnan in 1928. The Indian physicist C.V. Raman (1888 - 1970) won the Nobel Prize for Physics in 1930 for his work on the scattering of light and for the discovery of Raman effect.

When the molecule, excited to the higher unstable vibrational state, returns to the original vibrational state, we get Rayleigh scattering. If it returns to a different vibrational state, this gives rise to Raman scattering (Stokes lines). When the molecule, initially in the *first excited vibrational state*, is promoted to a higher unstable vibrational state and returns to the *ground state*, this again gives rise to Raman scattering (anti-Stokes lines). Thus, *the Raman spectrum of a molecule consists of Stokes lines and anti-Stokes lines, situated symmetrically about the Rayleigh line.*

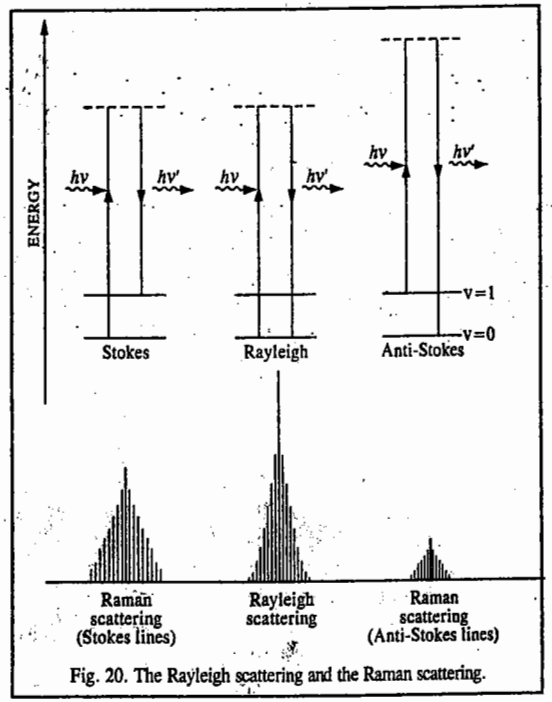


Fig. 20. The Rayleigh scattering and the Raman scattering.

The Rayleigh line is far more intense than the Stokes lines which, in turn, have greater intensity than the anti-Stokes lines. The anti-Stokes lines are very difficult to observe in the conventional Raman spectroscopy because they correspond to the return of a molecule from the unstable excited vibrational state to the ground state and initially there are very few molecules in the excited vibrational state. We can write Eq. 68 as

$$E' - E = h(\nu - \nu') = h\Delta\nu_{\text{Raman}} = hc\Delta\bar{\nu}_{\text{Raman}} \qquad ...(70)$$

The shifts in frequency $(\nu - \nu')$ are called **Raman shifts.** The Raman shifts fall in the range 100–4,000 cm^{-1} for vibrational energy changes. Their values are smaller for rotational energy changes. Since $\bar{\nu} = 1/\lambda$, we have

$$\bar{\nu}\ (\text{in cm}^{-1}) = \frac{10^8}{\lambda(\text{in Å})}$$

Hence, Raman shift (in cm^{-1}) is given by

$$\Delta\bar{\nu}_{\text{Raman}}\ (\text{in cm}^{-1}) = \frac{10^8}{\lambda_{\text{exc}}(\text{in Å})} - \frac{10^8}{\lambda_{\text{Raman}}(\text{in Å})} \qquad ...(71)$$

where λ_{exc} is the wave length corresponding to the exciting (incident) frequency.

Classical Theory of Raman Scattering. The classical theory of Raman effect, also called the polarizability theory, was developed by G. Placzek in 1934. We will discuss it briefly here. It is known from electrostatics that the electric field E associated with the electromagnetic radiation induces a dipole moment μ in the molecule, given by

$$\mu = \alpha E \qquad ...(72)$$

where α is the polarizability of the molecule. The electric field vector E itself is given by

$$E = E_0 \sin 2\pi\nu t \qquad ...(73)$$

where E_0 is the amplitude of the vibrating electric field vector and ν is the frequency of the incident light radiation. Thus, from Eqs. 72 and 73,

$$\mu = \alpha E_0 \sin 2\pi\nu t \qquad ...(74)$$

Such an oscillating dipole emits radiation of its own oscillation with a frequency ν, giving the Rayleigh scattered beam, If, however, the polarizability varies slightly with molecular vibration, we can write

$$\alpha = \alpha_0 + (\partial\alpha/\partial q)\, q \qquad ...(75)$$

where the coordinate q describes the molecular vibration. We can also write q as

$$q = q_0 \sin 2\pi\nu_m t \qquad ...(76)$$

where q_0 is the amplitude of the molecular vibration and ν_m is its frequency. From Eqs. 75 and 76, we have

$$\alpha = \alpha_0 + (\partial\alpha/\partial q)\, q_0 \sin 2\pi\nu_m t \qquad ...(77)$$

Substituting for α in Eq. 74, we have

$$\mu = \alpha_0 E_0 \sin 2\pi\nu t + (\partial\alpha/\partial q)\, q_0 E_0 \sin 2\pi\nu t \sin 2\pi\nu_m t \qquad ...(78)$$

Making use of the trigonometric relation $\sin x \sin y = \frac{1}{2}[\cos(x-y) - \cos(x+y)]$, this equation reduces to

$$\mu = \alpha_0 E_0 \sin 2\pi\nu t + \tfrac{1}{2}(\partial\alpha/\partial q)\, q_0 E_0 \cos 2\pi(\nu - \nu_m)\, t - \tfrac{1}{2}(\partial\alpha/\partial q)\, q_0 E_0 \cos 2\pi(\nu + \nu_m)t \quad ...(79)$$

$$= \alpha_0 E_0 \sin 2\pi\nu t + \tfrac{1}{2}(\partial\alpha/\partial q)\, q_0 E_0 \times [\cos 2\pi(\nu - \nu_m)\, t - \cos 2\pi(\nu + \nu_m)\, t] \quad ...(80)$$

Thus, we find that the oscillating dipole has three distinct frequency components : *(i)* the exciting frequency ν with amplitude $\alpha_0 E_0$ *(ii)* $\nu - \nu_m$ and *(iii)* $\nu + \nu_m$ with very small amplitudes = (1/2) $(\partial\alpha/\partial q)\, q_0 E_0$. Hence, the Raman spectrum of a vibrating molecule consists of a relatively intense band at the incident frequency and two very weak bands at frequencies slightly above and below that of the intense band.

If, however, the molecular vibration does not change the polarizability of the molecule, then $(\partial\alpha/\partial q) = 0$ so that the dipole oscillates only at the frequency of the incident (exciting) radiation. The same is true of the molecular rotation. We conclude that *for a molecular vibration or rotation to be active in the Raman spectrum, it must cause a change in the molecular polarizability, i.e.,*

$$\partial\alpha/\partial r \neq 0. \quad ...(81)$$

Homonuclear diatomic molecules such as H_2, N_2, O_2, which do not show IR spectra since they do not possess a permanent dipole moment, *do show Raman spectra since their vibration is accompanied by a change in polarizability of the molecule.* As a consequence of the change in polarizability, there occurs a change in the induced dipole moment at the vibrational frequency.

The selection rule for the vibrational Raman spectrum of a diatomic molecule is

$$\Delta v = \pm 1 \quad ...(82)$$

Rotational Raman Spectrum of a Diatomic Molecule

The selection rule for pure rotational Raman spectrum of a diatomic molecule is

$$\Delta J = 0, \pm 2 \quad ...(83a)$$

The operative part of the rotational selection rule is

$$\Delta J = +2 \quad ...(83b)$$

since $\Delta J = 0$ corresponds to Rayleigh scattering and $\Delta J = -2$ transition can be ignored as the rotational quantum number of the upper state must be greater than that of the lower state. Using the selection rule (Eq. 83*b*) with the energy level expression for rigid diatomic rotor, *viz.*,

$$F(J) = BJ(J+1)\ \text{cm}^{-1}\ (J = 0, 1, 2, 3...), \quad \text{(Eq. 31)}$$

we find that $\Delta F(J) = F(J+2) - F(J) = B(4J+6)\ \text{cm}^{-1}$ ...(84)

It is customary to call the $\Delta J = +2$ transitions as **S-branch lines.** Thus,

$$\Delta F(J) = B(4J+6)\ \text{cm}^{-1}\ (J = 0, 1, 2, 3,...) \quad ...(85)$$

where J is the quantum number of the *lower* rotational energy level. Hence, the Raman spectral lines appear at the wave numbers given by the following equation :

$$\bar{\nu}_S = \bar{\nu}_{exc} \pm \Delta F(J) = \bar{\nu}_{exc} \pm B(4J+6)\ \text{cm}^{-1} \quad ...(86)$$

where ν_{exc} is the exciting (incident) frequency, the negative sign refers to the Stokes lines and the positive sign to the anti-Stokes lines.

The energy level diagram and the rotational Raman spectrum for a diatomic molecule are shown in Fig. 21. We see that the first Stokes line (or the first anti-Stokes line) appears at a distance of $6B$ from the exciting Rayleigh line. This is evident from Eq. 85, where putting $J=0$ we obtain $\Delta F(J) = 6B$. The separation of the successive Raman lines is, however, $4B$, as can be easily verified by putting $J=1, 2, 3$, etc., in Eq. 86.

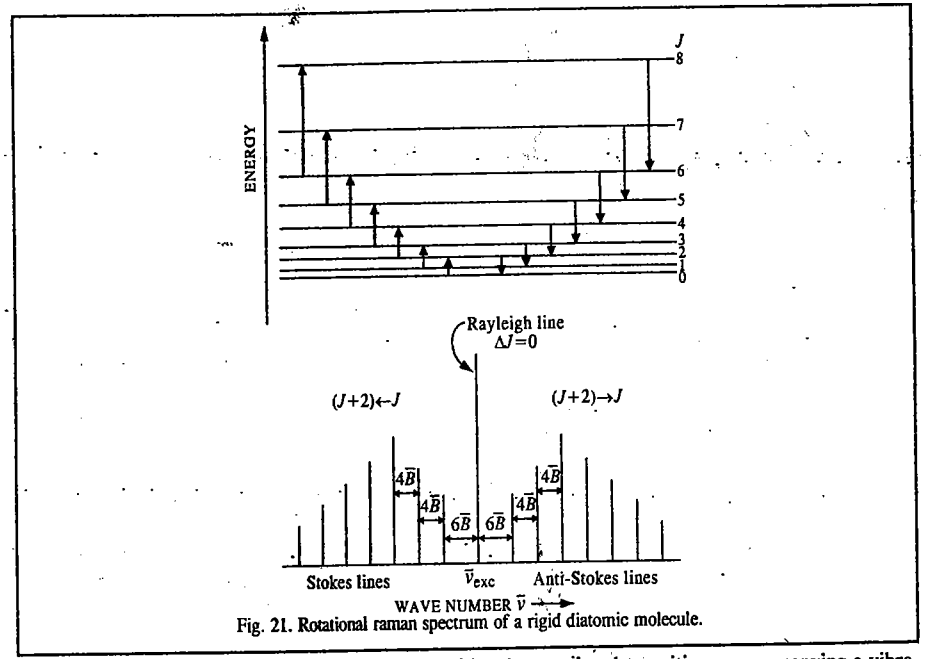

Fig. 21. Rotational raman spectrum of a rigid diatomic molecule.

Rotation–Vibration Raman Spectrum. Consider the rotational transitions accompanying a vibrational Raman transition of a diatomic molecule. The selection rules now involve the changes in both the vibrational and the rotational quantum numbers. For a diatomic molecule, the selection rules are :

$$\Delta v = +1\ ;\ \Delta J = 0, \pm 2 \quad ...(87)$$

Since at room temperature most of the molecules are in the ground vibrational state (v=0), only the vibrational transition, v=0 to v=1, is of interest. The transitions with $\Delta J = 0$ form a Q-branch ; those with $\Delta J = +2$ form an S-branch and those with $\Delta J = -2$ form an O-branch. The rotational Raman transitions accompanying a $0 \rightarrow 1$ vibrational transition are shown in Fig. 22. Here, $\Delta\bar{\nu}$ measures the displacement from the exciting mercury line. The Q-branch exhibits an intense 'narrow line' at $\bar{\nu}_{exc}$ that is usually unresolved while the S and O branches form weak wings which extend to lower and higher wave numbers, respectively, from the intense narrow line.

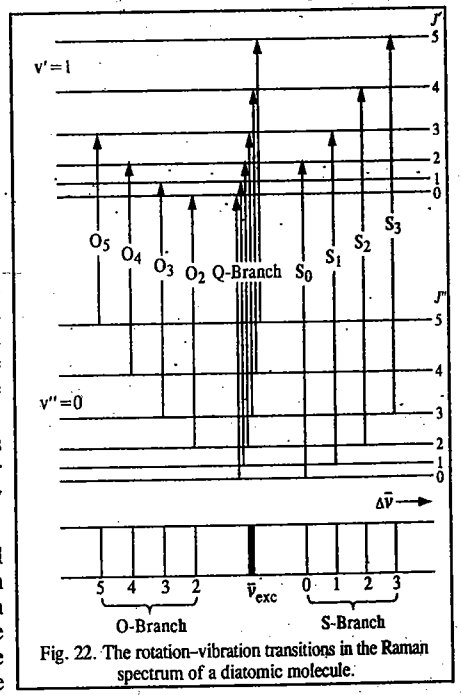

Fig. 22. The rotation–vibration transitions in the Raman spectrum of a diatomic molecule.

Experimental Raman Spectroscopy. The original experimental set-up for Raman spectroscopy is shown in Fig. 23. Intense monochromatic radiation from a source consisting of a large spiral discharge tube with mercury electrodes is allowed to fall on the cell containing a gaseous or liquid sample. When the

electric discharge passes through the tube, mercury emits lines in its spectrum the most intense of which at 4358 Å (*i.e.*, 435·8 nm) serves as the exciting line. The scattered light is observed at right angles to the direction of incident radiation. The detector is either a photographic plate or a photomultiplier. The horn shape of the cell helps in reducing the direct reflection of the source from the back of the cell.

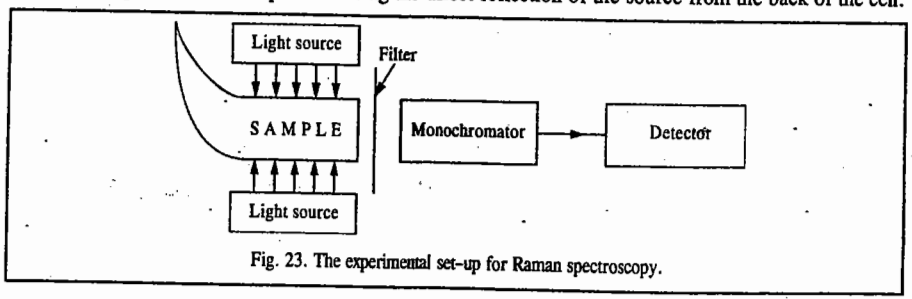

Fig. 23. The experimental set-up for Raman spectroscopy.

The Raman spectra of gases are generally weaker than those of liquids. It is necessary to use very long discharge lamps and cells, the latter containing mirrors at both ends arranged so as to increase the effective path length of the cell.

Between 1930 and 1960, Raman spectroscopy was not used for analytical work as was the case with IR spectroscopy. However, with the discovery of the 'LASER' (light amplification by stimulated emission of radiation) by Townes, Basov and Prokhorov in the late 1950s, Raman spectroscopy has become an extremely important analytical tool. The laser has replaced Hg as the source of radiation. The laser radiation is coherent and monochromatic, *i.e.*, it is a radiation of very high intensity in a narrow beam with a well-defined frequency. Thus, it can be easily focussed and collimated. The line width of the laser line is also far smaller than that of the mercury-excited line. Modern scientific laboratories are now equipped with laser Raman spectrometers. Using a laser Raman spectrometer, the spectrum of a sample can be recorded quickly.

Raman spectroscopy, despite difficulties with sensitivity, has several advantages. It gives information about molecular vibrations that are inactive in the infrared region because of molecular symmetry. According to the **'mutual exclusion rule'**, for centrosymmetric molecules (*i.e.*, molecules such as H_2, CO_2, C_2H_2, etc., that possess a centre of symmetry), the vibration which is active in IR is inactive in Raman and the vibration which is inactive in IR is active in Raman spectra. Raman spectroscopy, in fact, complements IR spectroscopy. Thus, the stretching vibrations of homonuclear diatomic molecules (such as H_2, O_2, N_2, etc.,) which are inactive in IR (since they are not accompanied by a change in dipole moment which is already zero) are observed in Raman spectra. Also, the symmetric stretching vibration of CO_2, that is inactive in IR, is active in Raman spectra. Another example is that of planar dichloroethylene, $C_2H_2Cl_2$, which consists of *cis* and *trans* configurations in equilibrium proportions. Only the *trans* configuration has a centre of symmetry. Thus, the coincident frequencies observed in IR and Raman spectra of the sample can be assigned to the *cis* configuration. In this manner the analysis of the mixture of *cis* and *trans* isomers can be carried out. Again, for CS_2, all the vibrations that are Raman-active are infrared-inactive and vice versa, whereas for N_2O, the vibrations are simultaneously Raman and infrared-active. From the spectral data we conclude that CS_2 has a centre of symmetry whereas N_2O has no centre of symmetry. Thus, the CS_2 structure is of the type S—C—S while the N_2O structure must be N—N—O rather than N—O—N.

Raman spectroscopy has another advantage in that it uses visible or ultraviolet radiation rather than infrared radiation. Hence, the walls of the sample cell and other units of the optical system can be made of glass or quartz rather than of special materials that are transparent to IR radiation. Also, the experimentalist can work very conveniently with aqueous media since water is far more transparent in the visible and UV regions than in the IR region. Thus, Raman spectroscopy can be utilized for the investigation of biological systems such as the polypeptides and the proteins in aqueous solution.

Example 10. A sample was excited by the 4358 Å line of mercury. A Raman line was observed at 4447 Å. Calculate the Raman shift in cm^{-1}.

Solution : Since the Raman line is observed at longer wave length (shorter frequency) than the exciting line, it is evidently a Stokes line in the Raman spectrum. From Eq. 71, the Raman shift is given by

$$\Delta\bar{\nu}_{\text{Raman}}\ (\text{cm}^{-1}) = \frac{10^8}{\lambda_{\text{exc}}(\text{Å})} - \frac{10^8}{\lambda_{\text{Raman}}(\text{Å})}$$

$$= \frac{10^8}{4{\cdot}358\times10^3} - \frac{10^8}{4{\cdot}447\times10^3} = (2{\cdot}295 - 2{\cdot}249)\times10^4$$

$$= 0{\cdot}046\times10^4 = \mathbf{460\ cm^{-1}}$$

Example 11. At what wave length in Å would the anti-Stokes line appear in the Raman spectrum of the sample in Example 10 ?

Solution : The anti-Stokes line will appear at a frequency 460 cm^{-1} higher than the frequency (in cm^{-1}) associated with 4358 Å Hg line used as a source of excitation. Now,

$$\bar{\nu}_{\text{exc}}\ (\text{cm}^{-1}) = \frac{10^8}{\lambda_{\text{exc}}(\text{Å})} = \frac{10^8}{4{\cdot}358\times10^3} = 2{\cdot}295\times10^4\ \text{cm}^{-1}$$

Hence, $\bar{\nu}_{\text{anti-Stokes}} = (2{\cdot}295\times10^4\ \text{cm}^{-1}) + (460\ \text{cm}^{-1}) = 2{\cdot}341\times10^4\ \text{cm}^{-1}$

$$\therefore\quad \lambda\ (\text{in Å}) = \frac{10^8}{\bar{\nu}\ (\text{cm}^{-1})} = \frac{10^8}{2{\cdot}341\times10^4} = \mathbf{4272\ Å}$$

RESONANCE RAMAN SPECTROSCOPY

Ordinarily, a Raman spectrum is excited using light of frequency that is not absorbed by the sample. (Recall that the conventional Raman technique involves the *inelastic scattering* of a radiation photon by a molecule.) The probability of absorption is very low and excitation is to a virtual excited state whose lifetime is very short and whose energy is correspondingly poorly defined. If we use light whose absorption probability is high, the effects of local heating by the laser beam are usually so great that the sample decomposes. If we can avoid this local heating, possibly by spinning the sample rapidly under the laser spot so that different parts of the sample are heated in turn, we observe stronger Raman signals as the exciting radiation is absorbed by the sample. This effect is called **resonance Raman effect**. The intensity of this effect is very high. However, in general, only a few vibrational modes are involved and often only one is detectable. It is usual to find a progression indicating significant transition probabilities to many vibrational levels of the modes concerned. The energy levels of the resonance Raman effect are shown in Fig. 24.

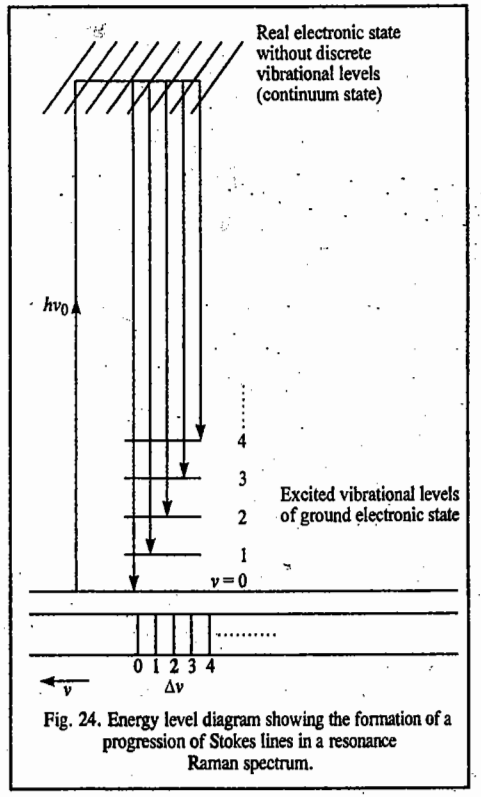

Fig. 24. Energy level diagram showing the formation of a progression of Stokes lines in a resonance Raman spectrum.

The particular vibrations excited are often found to be closely associated with the electronic transition within whose band the exciting radiation

falls and this can sometimes be useful in assigning electronic transitions. The use of a tunable laser may be helpful since the excitation profiles, which show the intensity of resonance-enhancement as a function of exciting frequency, may allow overlapping electronic bands to be distinguished from one another. In terms of vibrational spectroscopy, resonance Raman spectroscopy has the following three advantages over simple Raman spectroscopy :

1. Enhancement of intensity, enabling weakly scattering or very dilute samples to be investigated.
2. Greatly simplified spectrum, as only a few vibrations are enhanced.
3. The experimental observation of the spectrum enables the vibrational potential function (such as the Morse potential energy function) to be specified over a wide range of vibrational quantum numbers.

The resonance Raman effect can be observed with a normal Raman spectrometer and is independent of any special properties of laser excitation . The intensity enhancement relies on the electronic transition being allowed by symmetry. Thus, the vibrations whose intensities are enhanced are almost always usually symmetric.

The resonance Raman technique has enabled spectra to be obtained from the metallic cores of biological molecules such as haemoglobin and some enzymes, where the low concentration of the metal and the low solubility of the substance itself make it difficult to study vibrational spectra in any other way. The IR or normal Raman spectrum of these biological molecules, too, is very complex but the resonance Raman spectrum can be easily interpreted because of its simplicity. Fig. 25 shows the resonance Raman spectrum of the tetrahedral chromate ion present in solid potassium chromate, K_2CrO_4. A clear-cut progression of peaks due to the totally symmetric stretching mode of the anion is seen, upto the ninth or tenth member. Excitation carried out was by UV laser line within the absorption band whose low frequency wing in the blue/violet region is responsible for the yellow colour of the salt. The sample is rotated rapidly to reduce the effects of local heating for absorbed laser light. The broadening of the higher bands reflects progressively shorter lifetimes for the al highly excited vibrational states.

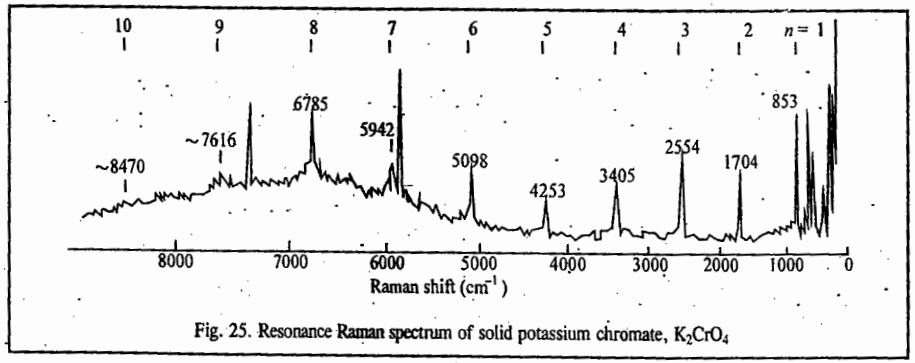

Fig. 25. Resonance Raman spectrum of solid potassium chromate, K_2CrO_4

Laser Raman Spectroscopy

The large intensity possessed by lasers leads to nonlinear polarization of the medium which is responsible for the observation of nonlinear phenomena such as nonlinear Raman spectroscoy, multiphoton spectroscopy, saturation spectroscopy, second harmonic generation (SHG), etc. Lasers are also used in **stimulated Raman spectroscopy (SRS).** In this form of spectroscopy, there is multiple scattering resulting in the emission of larger number of Stokes and anti-stockes lines. A brief description of SRS and some other forms of laser Raman spectroscopy is given here. When a laser pulse is focussed into a sample and the scattered radiation is observed along the laser beam direction at small angles to it,

it is found to consist of the incident frequency ν_0 and the Stokes and anti-Stokes lines at $\nu_0 \pm n\nu_m$, $n=1, 2, 3, \ldots$, where ν_m corresponds to Raman-active vibration of the scattering molecule. This phenomenon is called **stimulated Raman scattering (SRS).** The process involving stimulation is shown schematically in Fig.26. In SRS there is no need for population inversion of the states.

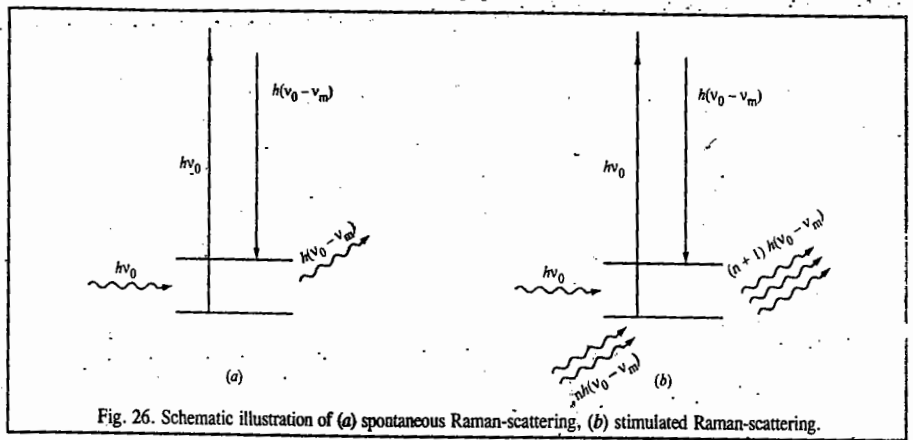

Fig. 26. Schematic illustration of (*a*) spontaneous Raman-scattering, (*b*) stimulated Raman-scattering.

The Stokes line produced by spontaneous Raman scattering at frequency $\nu_0 - \nu_m$ becomes intense enough quickly to act as powerful source to produce a Stokes line at $(\nu_0 - 2\nu_m)$. This is illustrated in Fig. 27. As this line gains in intensity, it acts as a source and so on.

Stimulated Raman scattering differs from normal Raman scattering not only in its wave number pattern and angular dependence but also on its intensity. The ν_0–ν_m line will be very intense, ν_0–$2\nu_m$ slightly less intense, and so on. At least upto n=3 or 4, the intensity will be larger than found in normal Raman scattering. The width of lines in SRS is also much less than that found in normal Raman scattering. The high conversion efficiency of SRS means that it can be used to generate intense coherent laser-like sources over a wide range of wave numbers by judicious selection of scattering material.

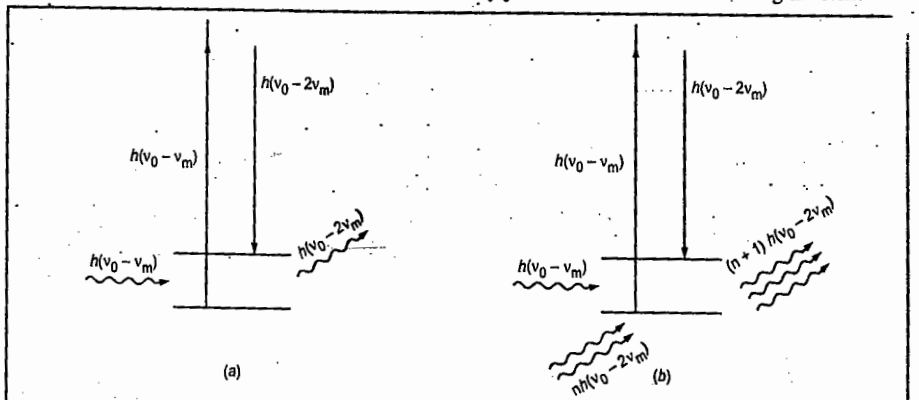

Fig. 27. Illustration of (*a*) spontaneous Raman scattering at $(\nu_0 - 2\nu_m)$, (*b*) stimulated Raman scattering at $(\nu_0 - 2\nu_m)$.

Raman scattering is inelastic scattering of photons of energy $h\nu_0$ by molecules. If the scattered photon has an energy $h(\nu_0+\nu_m)$, the incident photon gains an energy by an amount $h\nu_m$ from the molecule. The energy balance equation for this normal anti-Stokes-Raman scattering is shown in Fig. 28*a*. If this process is inverted, the scattering molecule absorbs radiation of frequency $(\nu_0+\nu_m)$,

resulting in the molecule going to a higher energy level and the emission of radiation of frequency ν_0. This phenomenon is called the inverse **anti-Stokes Raman effect** (Fig. 27*b*).

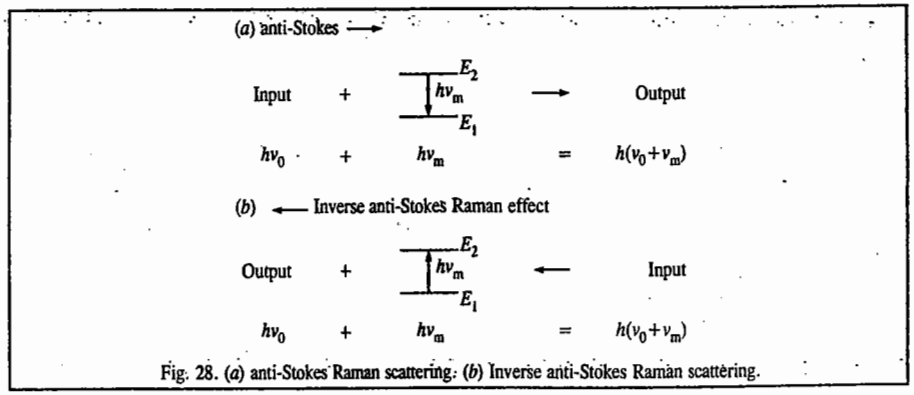

Fig. 28. (*a*) anti-Stokes Raman scattering. (*b*) Inverse anti-Stokes Raman scattering.

The absorption of radiation of frequency $\nu_0 - \nu_m$ by the molecule would result in a decrease in the energy of the scattering molecule by $h\nu_m$ and emission of radiation of energy $h\nu_0$. This is inverse anti-Stokes Raman scattering. This complementary effect requires appropriate population of the upper state. It is found that absorption at frequencies $\nu_0 \pm \nu_m$ can occur only in the presence of a very intense radiation at frequency ν_0. Thus, the essential requirements for the observation of inverse Raman scattering are the simultaneous irradiation of the sample with a giant pulse laser beam of frequency ν_0 and a strong continuum covering the Stokes and anti-Stokes regions in which absorptions are expected. With improved experimental techniques, inverse Raman spectroscopy, offers a potential method for the study of very short-lived species and the measurement of very short lifetimes.

Coherent antiStokes-Raman scattering (CARS) which combines the advantages of SRS and the general applicability of normal Raman scattering. When coherent radiation of frequency ν_1 is mixed with coherent radiation of frequency ν_2 ($\nu_1 > \nu_2$) in a molecular medium, coherent radiation of frequency $\nu_3 = 2\nu_1 - \nu_2 = \nu_1 + (\nu_1 - \nu_2)$ is generated, if the irradiances of the two frequencies are sufficiently large. Here mixing implies spatial and temporal coincidence of the two beams. If ν_1 is fixed and ν_2 is varied so that $\nu_1 - \nu_2 = \nu_m$, a Raman active vibration of the molecule under investigation, then $\nu_3 = \nu_1 + \nu_m$, which is an anti-Stokes Raman frequency. Radiation produced in this way is called CARS. Fig. 29 illustrates a typical CARS set-up where the two incident radiations are provided by the 514·5 nm argon laser line (ν_1) and a continuous wave (CW) dye laser (ν_2) pumped by the same argon laser.

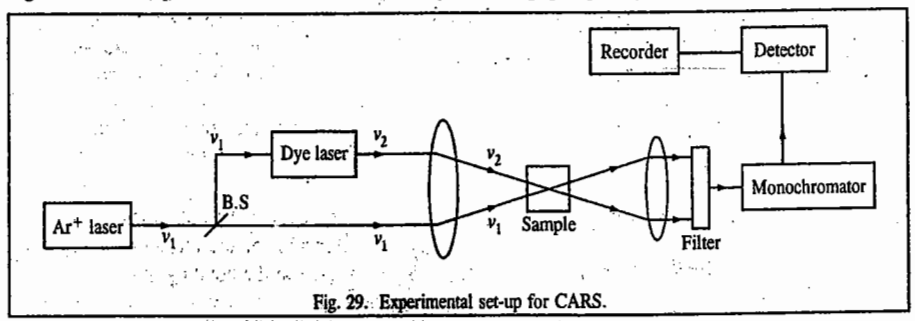

Fig. 29. Experimental set-up for CARS.

With CARS, the conversion efficiency to $\nu_3 = (\nu_1 + \nu_m)$ is several orders of magnitude greater than the conversion frequencies in the normal Raman scattering. The radiations resulting from CARS form a highly coherent collimated beam whereas normal Raman scattering is incoherent and extends over a

solid angle 4π. Since CARS is highly collimated, fluorescence and thermal radiation from hot samples can effectively be filtered by placing a screen with a hole of a few mm diameter between the detector and the sample which just passes only the CARS beam. Moreover, in principle, no dispersing medium is needed for CARS experiment. The fluorescence-free nature of CARS makes it an ideal tool for high resolution spectroscopic studies and analysis of biological samples.

ELECTRONIC SPECTRA

The electronic band spectra of molecules are generally very complex and are, investigated with considerable difficulty. They are observed in the ultraviolet and visible regions of the electromagnetic spectrum. Their complexity arises from the fact that a transition between two electronic states is almost invariably accompanied by simultaneous transitions between the vibrational and rotational energy levels as well. This is expressed by saying that electronic spectra have **vibrational fine structure and rotational fine structure.** As discussed earlier, according to the Born-Oppenheimer approximation, the total energy of a molecule in the lower (ground) state is given by

$$E'' = E''_{el} + E''_{vib} + E''_{rot} \qquad ...(88)$$

neglecting the translational energy, E''_{tr}, which is not quantized. Here, E''_{el}, E''_{vib} and E''_{rot} are, respectively, the electronic, vibrational and rotational energies. Assuming that the Born-Oppenheimer approximation is valid in the upper (excited) state as well, the excited state energy E' is given by

$$E' = E'_{el} + E'_{vib} + E'_{rot} \qquad ...(89)$$

The energy change for an electronic transition is given by

$$\Delta E = E' - E'' = (E'_{el} - E''_{el}) + (E'_{vib} - E''_{vib}) + (E'_{rot} - E''_{rot}) \qquad ...(90)$$

$$= \Delta E_{el} + \Delta E_{vib} + \Delta E_{rot} \qquad ...(91)$$

Considerable simplification of spectra results by recognizing that

$$\Delta E_{el} >> \Delta E_{vib} >> \Delta E_{rot} \qquad ...(92)$$

The frequency for the electronic transition is given by the **Bohr frequency condition,** *viz.*,

$$\bar{\nu} = \frac{\Delta E}{hc} = \frac{\Delta E_{el} + \Delta E_{vib} + \Delta E_{rot}}{hc} \text{ cm}^{-1} \qquad ...(93)$$

Eq. 93 shows how an electronic transition possesses the vibrational and rotational fine structures.

A very useful guiding principle for investigating the vibrational structure of electronic spectra is provided by the well known **Franck-Condon principle** which states that *an electronic transition takes place so rapidly that a vibrating molecule does not change its internuclear distance appreciably during the transition.* This principle is, to a first approximation, true since the electrons move so much faster than the nuclei that during the electronic transition the nuclei do not change their position. Hence, *an electronic transition may be represented by a vertical line on a plot of potential energy versus the internuclear distance.*

Let us demonstrate the Franck-Condon principle for the electronic transition of a diatomic molecule. Consider Fig. 30. where we have shown two potential energy curves for the molecule in the ground electronic state (E_0) and in the first excited electronic state (E_1). Since the bonding in the excited state is weaker than in the ground state, the minimum in the potential energy curve for the excited state occurs at a slightly greater internuclear distance than the corresponding minimum in the ground electronic state. Also, quantum mechanically it is known that the molecule is in the *centre* of the ground vibrational level of the ground electronic state. Thus, when a photon falls on the molecule, the most probable electronic transition, according to the Franck-Condon principle, takes place from $v''=0$ to

$v'=2$ (written schematically as $0 \rightarrow 2$). Transitions to other vibrational levels of the excited electronic state occur with lower probabilities so that their relative intensities are smaller than the intensity of the $0 \rightarrow 2$ transition, as shown in Fig. 31.

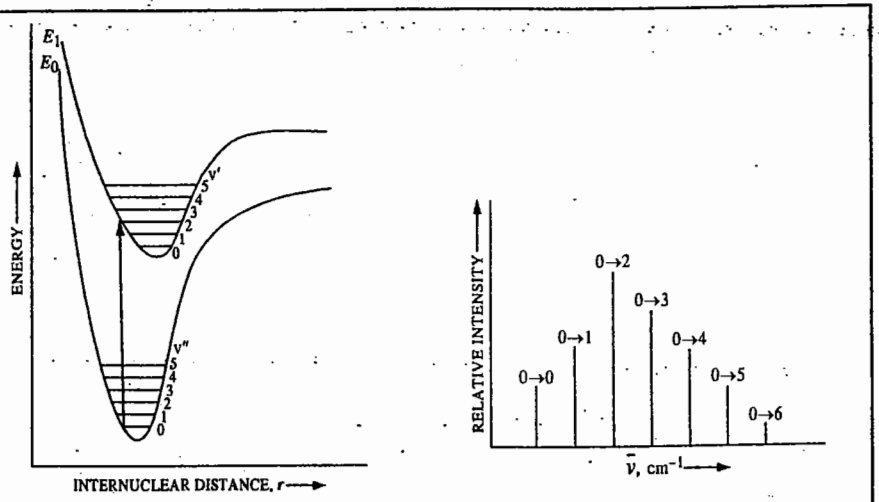

Fig. 30. Electronic transition in a diatomic molecule.

Fig. 31. Electronic spectrum of a diatomic molecule.

Consider now a slightly different case of a diatomic molecule which has a potential energy curve E_0 in ground state and two potential energy curves E_1 and E_2 in excited states. The potential energy curve E_2 does not have a minimum, as shown in Fig. 32.

The equilibrium internuclear distance is longer in E_1 than in E_0 since the bond is weaker in the excited state. The transition indicated by arrow a has, according to the Franck-Condon principle, maximum intensity. Other possible transitions are from the first excited vibrational level of the ground electronic state; they are indicated by the duplication of the vertical arrows b_1 and b_2. The transition b_1 ends in the lowest vibrational level of the first excited electronic state where the molecule is still held firmly. However, the transition b_2 promotes the molecule to a point where its energy is far above the potential energy plateau of state E_1 at large distance with the result that the molecule dissociates.

The molecule will also dissociate if it is excited to a level below the plateau in E_1 but above point c where the potential energy curves for E_1 and E_2

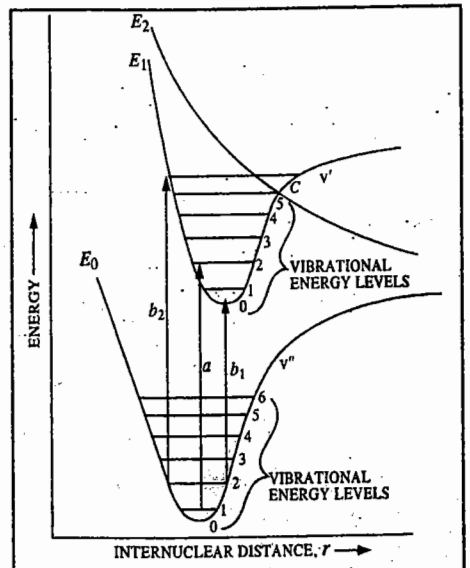

Fig. 32. Potential energy curves for the ground state and two excited states of a diatomic molecule. The curve E_2 crosses the curve E_1.

cross. At an internuclear distance corresponding to the point c, the molecule may undergo a crossover from one state to the other without energy change and continue to dissociate.

In the case of homonuclear diatomic molecules such as H_2 and N_2, the highest occupied molecular orbital (HOMO) in the ground state is a bonding molecular orbital (BMO) whereas the lowest unoccupied molecular orbital (LUMO) is an antibonding molecular orbital (ABMO). The HOMO and LUMO orbitals are collectively referred to as **frontier molecular orbitals** (FMOs). The electronic transition HOMO → LUMO takes place, *i.e.*, the electron, upon absorption of a photon, undergoes a transition from HOMO to LUMO. This lies in the short wave length side of the ultraviolet (UV) region. An exception is provided by the oxygen molecule O_2 that has two unpaired electrons in the ground state which is thus a triplet state. The electronic transition occurs from the triplet ground state to the triplet excited state (rather than to the singlet excited state). The electronic spectrum of O_2 molecule is, of course, complex.

Though the heteronuclear diatomic molecules such as CO, HCl, NO, BH, etc., have more complex structures in terms of the molecular orbitals occupied by the various electrons in them, their electronic spectra are essentially similar to those of the homonuclear diatomics, consisting of absorption bands in the near ultraviolet region.

Electronic Spectra of Polyatomic Molecules

The electronic spectra of polyatomic molecules show greater degree of complexity. The vibrational structure and the rotational fine structure of electronic spectra can only be observed in the gaseous states of small molecules. In solution, the rotational energy levels are not well defined; moreover, large molecules have very high moments of inertia. Hence, the rotational fine structure is totally wiped out in solution. Even vibrational transitions are broad, as shown by the Franck-Condon principle. Thus, the electronic spectra of molecules in solution appear as large unresolved bands rather than as sharp peaks. This is a characteristic feature of electronic spectra in condensed media and must be borne in mind. It also follows that if the rotational and vibrational structure of an electronic band can be fully resolved in the gaseous state, considerable information can be obtained from the electronic spectrum.

Organic compounds, particularly those containing groups like C=C, C=O, -N=N- and extensively conjugated systems, form a special class of polyatomic molecules whose electronic spectra are amenable to simple interpretation even though the investigation of their detailed spectral features may require knowledge of quantum mechanics and group theory. On the basis of the molecular orbital theory (MOT), the electrons can be classified as σ, π or *n*(non-bonding) depending upon the MOs they occupy. For organic carbonyl compounds, the electronic transitions involve promotion of the electrons in *n*, σ and π orbitals in the ground state to σ* and π* ABMOs in the excited state (Fig. 33). In other words, only the transitions of the type $\sigma^* \leftarrow \sigma$, $\pi^* \leftarrow \pi$ and $\pi^* \leftarrow n$ are allowed. Since electrons in the *n* orbitals are not involved in bond formation, there are no ABMOs associated with them.

The $\sigma^* \leftarrow \sigma$ transitions occurring in saturated hydrocarbons and other types of compounds in which all valence shell electrons are involved in single bonds, are found in ultraviolet region since they involve very high energy. The $\pi^* \leftarrow \pi$ and the $\pi^* \leftarrow n$ transitions, on the other hand, are found either in the UV or visible regions. The unsaturated molecules containing C=C and C=O groups (such as aldehydes and ketones) show $\pi^* \leftarrow n$ and $\pi^* \leftarrow \pi$ transitions. For aldehydes and ketones the more intense band near 1800 Å (180 nm) is due to $\pi^* \leftarrow \pi$ transition and the weaker band around 2850 Å (285 nm) is due to $\pi^* \leftarrow n$ transition. Olefinic hydrocarbons show a $\pi^* \leftarrow \pi$ transition in the wave length 160 - 170 nm. Acetylene shows an absorption near 180 nm.

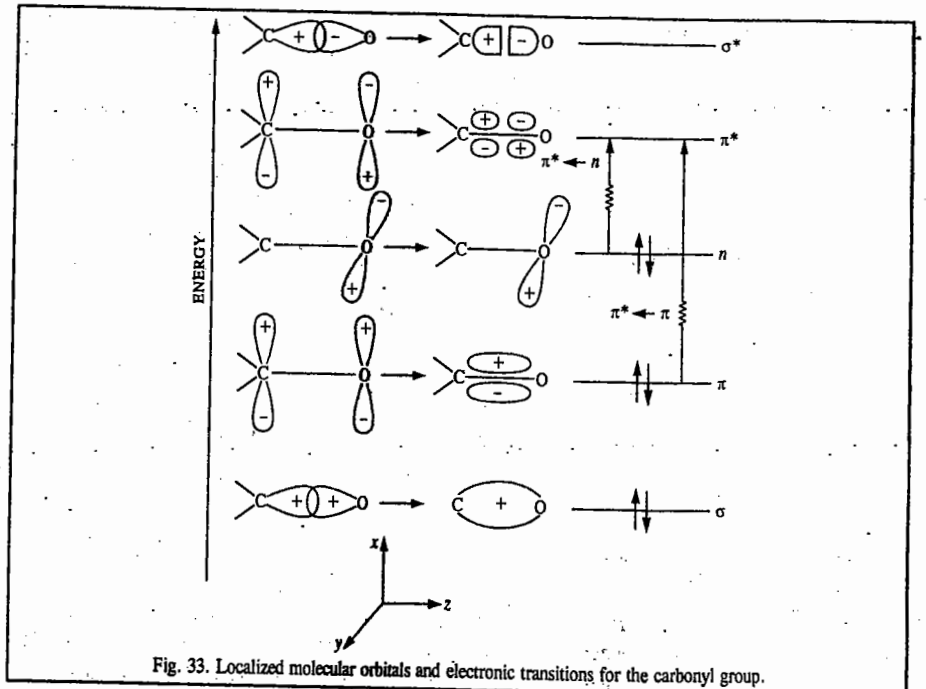

Fig. 33. Localized molecular orbitals and electronic transitions for the carbonyl group.

Functional groups such as C=C, -N=N- which absorb at wave lengths longer than 180 nm, are called **chromophores.** Other chromophores are nitro, nitroso, carbonyl, thiocarbonyl, sulphoxide groups as well as aromatic rings. Molecules such as CH_3NH_2 and CH_3I which do not contain a π orbital, show $\sigma^* \leftarrow n$ transitions.

In extensively conjugated systems, the π-electrons are delocalized over the entire skeletal framework. Such systems are treated in terms of the 'free-electron model' and it is found that *the absorption bands shift to longer wave lengths as the extent of conjugation increases.* Thus, in the compound C_6H_5–$(CH=CH)_n$–C_6H_5, the $\pi^* \leftarrow \pi$ transition lies in the UV region when $n=1$ or 2. As n increases, the electronic transition shifts to the visible region. This aspect is dealt with later in this chapter. This phenomenon is shown schematically in Fig. 34. Thus, λ_{max} is proportional to the extent of conjugation.

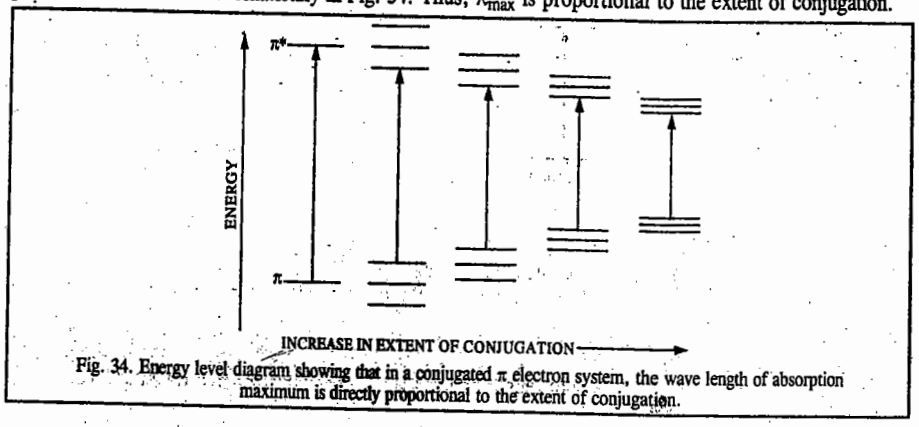

Fig. 34. Energy level diagram showing that in a conjugated π electron system, the wave length of absorption maximum is directly proportional to the extent of conjugation.

The intensity of an electronic band is determined by the extent of overlap of the wave functions in the ground and excited states. Since there is very poor overlap of wave functions of the ground and excited states in the $\pi^* \leftarrow n$ transition and there is considerable overlap of the corresponding wave functions in the $\pi^* \leftarrow \pi$ transitions, the $\pi^* \leftarrow n$ transitions are less intense (*i.e.*, weaker) than the $\pi^* \leftarrow \pi$ transitions. Also, in strongly acidic media, the $\pi^* \leftarrow n$ band disappears due to the protonation of lone pair of electrons. In fact, the protonation may increase the excitation energy to such an extent that the $\pi^* \leftarrow n$ transition may shift far out into the UV region and may not be observed.

The protonation of a functional group introduces profound changes in the spectra. Thus, the spectra in such cases are strongly dependent upon *p*H. Solvent effects, too, are useful in identifying the nature of these transitions. The $\pi^* \leftarrow n$ transitions are altered by the solvent effects in cases where the lone pair electrons in oxygen or nitrogen-containing systems interact with polar solvents. It is customary in spectroscopic literature to refer to the shifts in absorption bands and their intensity changes as follows :

1. **Bathochromic shift** (or the **red shift**) : a shift of λ_{max} to longer wave lengths.
2. **Hypsochromic shift** (or the **blue shift**) : a shift of λ_{max} to shorter wave lengths.
3. **Hyperchromic shift** : an increase in the intensity of an absorption band with reference to its molar extinction coefficient.
4. **Hypochromic shift** : a decrease in the intensity of an absorption band with reference to its molar extinction coefficient.

The term **auxochrome** refers to an atom or a group of atoms which does not give rise to an absorption band on its own but, when in conjugation with a chromophore, causes a bathochromic shift and a hyperchromic effect. For instance, $\rangle C=C\langle$ group is a chromophore in ethylene; when one of the hydrogens is replaced by a halogen atom, a bathochromic shift and a hyperchromic effect are produced. This is because the lone pair on the halogen atom conjugates with the alkene double bond. We conclude that the halogen atom acts as an auxochrome.

As said earlier, solvent effects are important in identifying $\pi^* \leftarrow \pi$ and $\pi^* \leftarrow n$ transitions. Polar solvents often stabilize the ground state of $\pi^* \leftarrow n$ transitions more than they stabilise the excited state, causing blue shifts (Fig. 35*a*). On the other hand, for $\pi^* \leftarrow \pi$ transitions, the excited state is stabilized more than the ground state, causing red shifts (Fig. 35*b*).

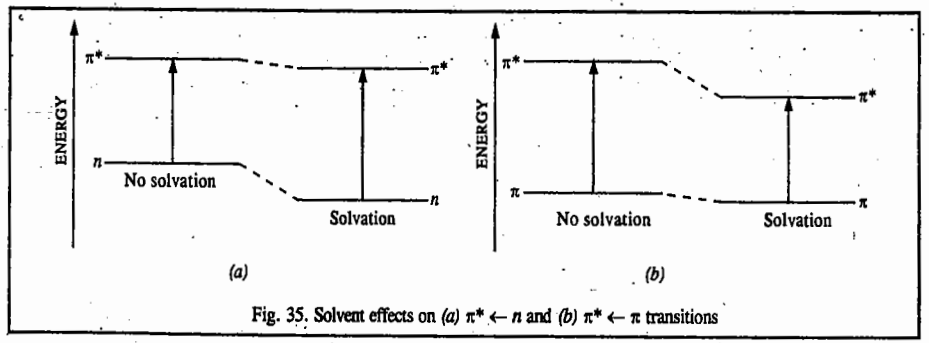

Fig. 35. Solvent effects on *(a)* $\pi^* \leftarrow n$ and *(b)* $\pi^* \leftarrow \pi$ transitions

One of the most important applications of UV spectroscopy, based on the Lambert-Beer law, is in quantitative analysis. According to the Lambert-Beer law, the absorbance A of a compound of concentration c is given by $A = \varepsilon bc$ where b is the path length and ε is the molar extinction coefficient. Consider the

equilibrium $X \rightleftarrows Y$. If X and Y have absorption bands that overlap and if at some wave length over the overlapped region both X and Y have equal absorbance, then there will be no change in the absorbance at this wave length as the ratio $[Y]/[X]$ is varied. This gives rise to the so called **isosbestic point.** When there is more than one isosbestic point present, we have

$$A_1 = b(\varepsilon_X^{(1)} c_X + \varepsilon_Y^{(1)} c_Y)$$

$$A_2 = b(\varepsilon_X^{(2)} c_X + \varepsilon_Y^{(2)} c_Y)$$

where 1 and 2 indicate the two wave lengths. Since A_1 and A_2 can be measured, the concentrations of X and Y, *viz.*, c_X and c_Y (and hence the equilibrium constant $K = [Y]/[X]$) can be calculated if the various extinction coefficients $\varepsilon_X^{(1)}, \varepsilon_X^{(2)}, \varepsilon_Y^{(1)}$ and $\varepsilon_Y^{(2)}$ are known.

Finally, we may mention that UV spectroscopy has an advantage over IR spectroscopy as far as applications to biological systems are concerned. Most biological systems have high water contents and since water absorbs strongly in the IR, its use is severely limited. On the other hand, aqueous solutions can be conveniently investigated by UV spectroscopy. UV spectra have also better resolution than IR spectra of biochemical systems.

CHARGE-TRANSFER (CT) SPECTRA

The theory of charge-transfer spectra was proposed by R.S. Mulliken who won the 1966 Chemistry Nobel Prize. The charge-transfer complexes (also called donor-acceptor complexes) are generally highly coloured. Thus, hydroquinone is colourless and quinone is yellow but quinhydrone crystals possess a highly green metallic colour. According to Mulliken, when two molecules which form loose complexes are mixed together, one of them acts as an electron-donor (D) while the other as an electron-acceptor (A) and they give rise to a donor-acceptor complex :

$$D + A \rightleftharpoons \underset{\text{Complex}}{(DA)} \overset{h\nu}{\rightleftarrows} \underset{\text{Donor-Acceptor Complex}}{(\overset{+}{D}-\overset{-}{A})}$$

Typical examples of donor-acceptor complexes are the quinhydrone, benzene/iodine solution and the compound $BF_3 \rightarrow NH_3$. The charge-transfer band for the complex formed between tetracyanoethylene and 1,2,4,5-tetramethyl benzene is shown in Fig. 36. It arises from the transition of an electron from the highest occupied molecular orbital (HOMO) of the donor molecule to the lowest unoccupied molecular orbital (LUMO) of the acceptor molecule (Fig. 37). Excitation of the electron to the higher unoccupied molecular orbitals of the acceptor gives rise to additional charge-transfer (CT) absorption bands.

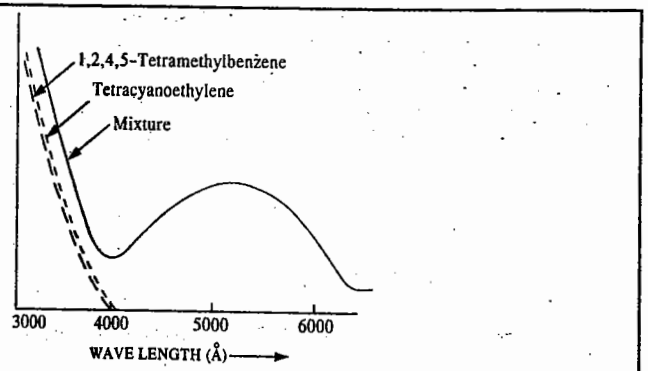

Fig. 36. The charge-transfer spectrum.

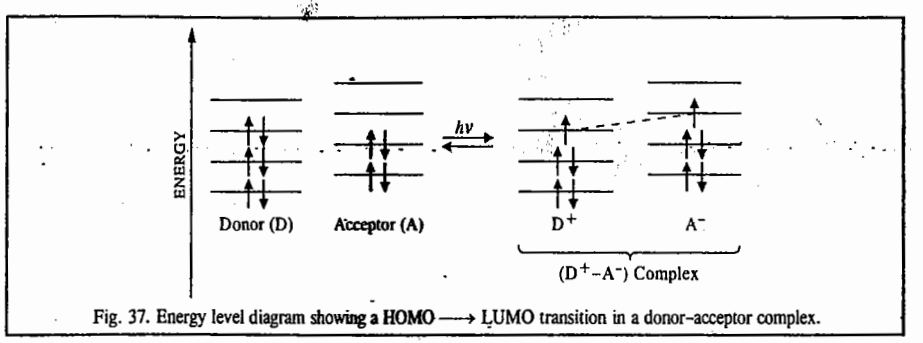

Fig. 37. Energy level diagram showing a HOMO ⟶ LUMO transition in a donor-acceptor complex.

The donor molecules are of two types : π-donors and n-donors. In the π-donors (such as aromatic hydrocarbons, alkenes, alkynes), the electron available for donation occupies the π MO of the molecule. In the n-donors (*e.g.*, alcohols, ethers, amines, etc.) the non-bonding electron is donated. The acceptor molecules are, on the other hand, of many types. The acceptor molecules are tetracyanoethylene, trinitrobenzene and other compounds containing highly electronegative substituents. The inorganic acceptors are the halogens, metal halides, etc. One of the best known CT complexes is that of benzene/iodine. It shows an absorption band at 3000 Å which has no counterpart in the spectrum of either benzene or iodine. In the quinhydrone complex, the donor and the acceptor orbitals are delocalized π molecular orbitals and the chemical bond between the two components of the complex is a delocalized bond.

The aromatic carbonyl compounds have absorption bands which can be identified as $\pi^* \leftarrow \pi$, $\pi^* \leftarrow n$ transistions and charge transfer (CT) transitions. Of these transitions, the CT transitions have the highest intensity, which means that they have the highest value of the extinction coefficient and of the oscillator strength. The **oscillator strength** of a transition is defined as the ratio of the experimental intensity to the theoretical intensity. In the complexes of the transition metal ions, intramolecular CT transitions may be observed where the electron is transferred from the ligand (L) to the metal ion (M), *i.e.*, the $L \rightarrow M$ transition can be a CT transition. The CT transitions are prominent in biological systems, too.

We must emphasize the difference between a normal electronic transition and a charge-transfer transition. In the former, the electron is promoted from the ground state to the excited state of the *same* molecule ; in the latter, the electron is promoted from the BMO of the donor (D) to the ABMO of the acceptor (A). The CT transition is determined by the ionization potential of the donor and the electron affinity of the acceptor.

ELECTRONIC SPECTRA OF TRANSITION METAL COMPLEXES*

The valence shell electrons in a transition metal complex are arbitrarily divided into : those in orbitals primarily associated with the metal, those in orbitals associated with ligands and those responsible for the metal-ligand bonding. Fig. 38 shows a simple energy level diagram for a transition metal complex. For instance, in a simple hexa-aquo ion such as $[Ni(H_2O)_6]^{2+}$, there are partly filled metal 3*d* orbitals containing eight electrons. We thus speak of this as a d^8 species. There are also electrons associated with the O–H bonds in H_2O molecules and others in BMOs formed by the overlap of lone-pair filled orbitals on oxygen atom with vacant *s*, *p* and *d* orbitals on the metal. The metal-ligand BMOs are ordinarily full, as are the bonding orbitals of the ligands themselves. There are also lone-pair orbitals not involved in metal-ligand bonding. Again, some ligands, such as organic ligands

*For detailed information, refer to the sister publication, **Principles of Inorganic Chemistry** by Puri, Sharma & Kalia.

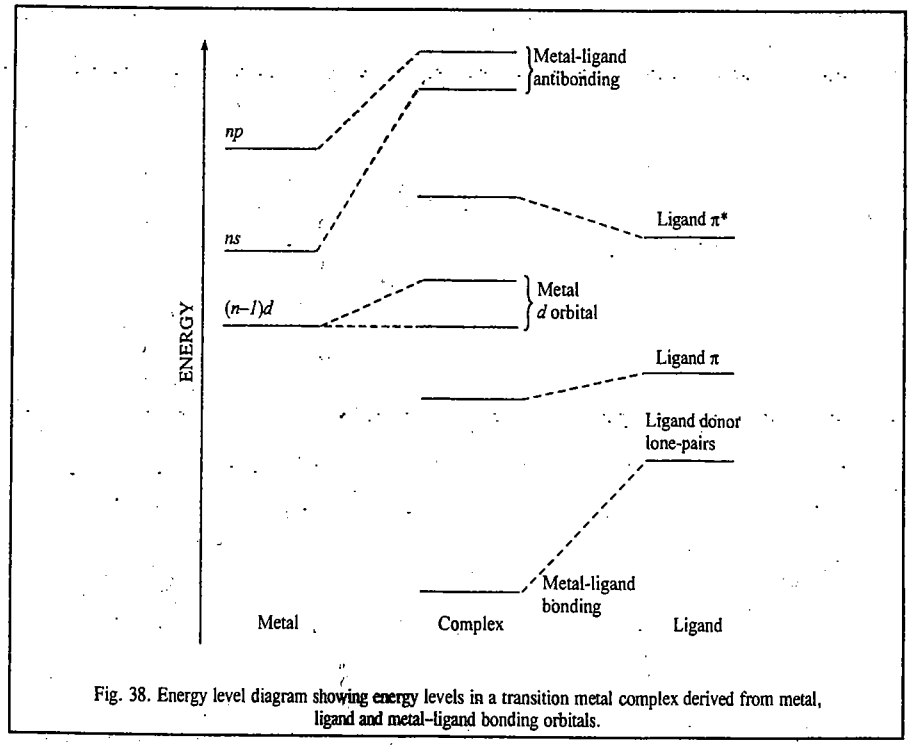

Fig. 38. Energy level diagram showing energy levels in a transition metal complex derived from metal, ligand and metal–ligand bonding orbitals.

containing π-systems, exemplified by pyridine and other aromatic amines, have low-lying empty orbitals, generally weakly antibonding in character. Since metal–ligand bonding is likely to involve the very orbitals that are the lower energy levels in such transitions, the transition energies are greatly affected by the metal centre, usually shifting to higher energy compared with those in the free ligand. More subtle effects are found to occur when we compare one complex with another. Thus, ligand–ligand transition energies will be found to vary with the nature and the charge on the central metal ion.

We shall now briefly comment on two important topics, *viz.*, 1. high-spin and low-spin states and 2. Jahn-Teller distortion.

1. High-spin and low-spin states. When a metal centre has more than enough electrons to half fill the lower set of d orbitals arising from ligand field splitting (the t_{2g} set for an octahedral complex, for instance), a complication arises through a competition between the tendency of all electrons to enter the lowest possible energy level and the tendency for as many electrons as possible to occupy different orbitals so that they may have the same spin. If the gap due to the ligand field splitting, Δ, is large, the first tendency will win and we will find as many electrons as possible in the lower set of d orbitals, even though the spins have to be paired when the electrons occupy the same orbital. This is called a **low-spin state.** If, on the other hand, the second tendency wins because the energy gap Δ is small, we will find electrons occupying some or all of the upper d orbitals (in the e_g set) as well as the lower t_{2g} set, thereby resulting in a higher total spin. This is called a **high-spin state.** This is illustrated in Fig.39 for a d^5 metal centre, such as Fe^{3+} in an octahedral environment. Here the low-spin case can be written as $t_{2g}^5 e_g^0$, with only one unpaired electron. The high-spin case is $t_{2g}^3 e_g^2$ with five unpaired electrons.

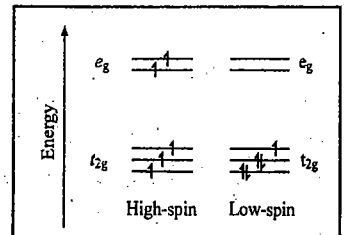

Fig. 39. High-spin and low-spin electron configurations of a d^5 metal centre in an octahedral environment.

2. Jahn-Teller Distortion. Theoretical treatment carried out in 1937 by H.A. Jahn and E. Teller and borne out experimentally shows that any complex with a degenerate (e or t) set of orbitals which is occupied unsymmetrically (*i.e.*, neither completely filled nor half filled) distorts its ligand environment spontaneously in such a way as to remove the degeneracy. For example, an octahedral d^7 ion with a filled t_{2g} (lower) set of d orbitals and a single electron in the doubly degenerate e_g upper set would distort in such a way that the e_g levels split, such as by an elongation along the z-axis, giving a tetragonal ligand arrangement as in Fig 40*(c)*. The single electron then occupies the lower orbital d_{z^2}, thereby reducing the overall energy pattern of the system. This clearly allows a new transition from the d_{z^2} to the empty $d_{x^2-y^2}$ level. As a consequence, the number of bands associated with an excitation of an electron from the t_{2g} to the e_g set of levels will increase—both sets are now split, so several extra bands will appear in the electronic spectrum.

We thus see that the high-spin/low-spin states and Jahn–Teller distortion have profound effects on the analysis of the d–d bands to which we now turn our attention.

Metal–Metal Transitions (d – d Bands)

The most characteristic transitions of transition metal complexes, known as the d–d transitions are those involving partly filled d subshells. These are formally forbidden in a strictly octahedral environment. According to the symmetry selection rules, the d levels separate into t_{2g} (lower) and e_g (upper) sets (Fig. 40) and the excitation of an electron from one set to the other is forbidden by the g → u selection rule (as well as the **Laporte rule** which prohibits transitions between levels which have the same orbital angular momentum quantum number, l ($\Delta l = \pm 1$). In a tetrahedral system, the d shell separates into e (lower) and t_2 (upper) sets (Fig. 40). Nor only is there no g/u distinction in this case, as there is no inversion centre, but even the Laporte rule can be circumvented, as the metal p subshell also has symmetry t_2, so that the upper d set can acquire some p orbital (l=1) character and the $e \rightarrow t_2$ transition becomes fully allowed. Even in truly octahedral systems, d – d transitions do occur, though only weakly, usually because of vibronic coupling involving vibrations though of low symmetry.

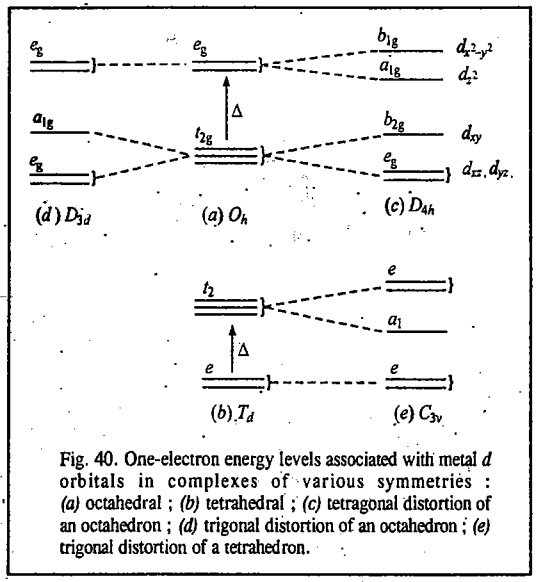

Fig. 40. One-electron energy levels associated with metal d orbitals in complexes of various symmetries : *(a)* octahedral ; *(b)* tetrahedral ; *(c)* tetragonal distortion of an octahedron ; *(d)* trigonal distortion of an octahedron ; *(e)* trigonal distortion of a tetrahedron.

For complexes with lower symmetry, the two-fold degeneracy of the e levels and/or the three-fold degeneracy of the t_2 levels is lost giving rise to more complex patterns of d levels thereby allowing more transitions to be observed. Figs. 39*(c)*, *(d)* and *(e)* show the energy level diagrams resulting from the more important distorted environments. The energy level diagrams of Fig. 40 refer strictly to the energy of a single electron, much as the energy level diagram for a hydrogen atom gives the possible energies for the single electron. For complexes with only a single d electron (such as those of Ti^{III}, V^{IV},

Cr^{V}, Mn^{VI}, etc.), such diagrams give a fairly good idea of the spectra to be expected in various complexes and Δ, the ligand field splitting parameter which gives the energy of the single transition for an octahedral or tetrahedral complex, depends on only a single parameter, *viz.*, the ligand field strength. Most transition metal complexes, however, have more than one *d* electron and the one-electron energy levels become less appropriate because of the importance of couplings between the spin and orbital angular momenta of the electrons. In this case, it is convenient to start with the electronic states (term symbols) of the free ion and then to consider the effects of the symmetry of the complex on the energy levels.

Let us, for illustrative purposes, consider the d^3 system. The lowest energy state for the free atom or ion is usually the quartet ^4F, with another quartet state, ^4P, of higher energy. In an octahedral environment, the ^4P state remains single, having symmetry $^4T_{1g}$, but the ^4F state gives rise to three levels whose energies diverge as the ligand field strength increases (Fig. 40). All the levels involved are still *g* (symmetric to the inversion centre), so all transitions are formally forbidden by both the $g \rightarrow u$ and the Laporte selection rules, but there are three possible excitations, from the lowest level to the three higher ones. These give bands in simple systems of this type, such as VCl_6^{4-} in molten $AlCl_3$. Fig. 41 is called an Orgel diagram for a d^3 system in an octahedral environment. Similar diagrams can be drawn up for any number of *d* electrons in environments of any symmetry, showing the nature and energies of the transitions expected for a given ligand field strength. L.E. Orgel was the first to introduce these diagrams in the 1950s.

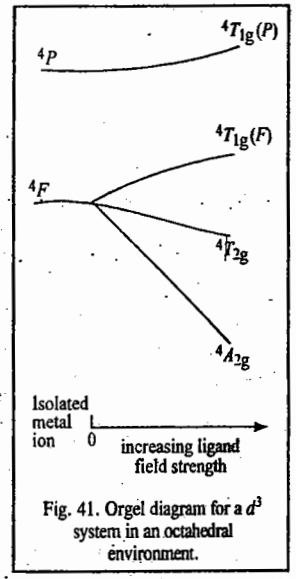

Fig. 41. Orgel diagram for a d^3 system in an octahedral environment.

The positions (energies) and intensities of the *d–d* bands can be used to infer the nature of the central metal and its surrounding ligands. We might, however, mention that although the information derived from the analysis of *d–d* band spectra is not formally 'structural' in the same sense as that derived from diffraction methods, from XPS or (indirectly) from the analysis of a vibrational spectrum, this may be all that can be obtained for a species in solution. Thus, it plays a valuable role in elucidating the structures of transition metal complexes. For an excellent treatment, see B.N. Figgis, *Introduction to Ligand Fields*, Wiley, 1966.

The Tanabe-Sugano diagrams, introduced by the two Japanese chemical physicists in 1954, give a more rigorous treatment of the electronic spectra of transition metal complexes than the Orgel diagrams. These are discussed at length in inorganic chemistry books.

Charge Transfer Bands

Because of the close approach of metal atom and ligand it is often possible for transitions to occur between a metal-based level and a ligand-based level. As these formally involve transfer of an electron from metal to ligand or from ligand to metal, they are called charge transfer (CT) transitions. These are particularly important for Second and Third row transition metal complexes where they tend to dominate the spectra so that the weak *d–d* bands and even ligand bands are obscured by the much stronger charge transfer bands. There are two kinds of charge transfer bands, *viz.*, ligand-to-metal charge transfer (LMCT) band and the metal-to-ligand charge transfer (MLCT) band. In an LMCT transition, a lone pair of the ligand is promoted into a predominantly metal orbital. Charge transfer bands in the visible region of the spectrum (and hence contributing to the intense colours of the complexes) may occur if the ligands have lone pairs of relatively high energy or if the metal has low-lying empty orbitals. In an MLCT transition, a transfer of charge from metal to ligand is observed in complexes with ligands that have low-lying π^* orbitals, especially aromatic ligands, such as bipyridine and phenanthroline.

An example of a CT band is provided by the permanganate ion. Here we formally write the ground state as $[Mn^{7+}(O^{2-})_4]$, in which case the charge transfer transition involves transferring one electron from O^{2-} ligand to Mn^{7+}, giving $[Mn^{6+}(O^{2-})_3O^-]$ as the upper state. This is an example of an LMCT and may be regarded as an *internal redox reaction*. The reverse MLCT is possible, as, for example, in organic amine complexes of low-valent metals, such as $[TiCl_3(bipy)]$, where bipy is 2,2′-bipyridine. Here the ground state is $[Ti^{3+}(Cl^-)_3bipy^0]$ and the excited state is $[Ti^{4+}(Cl^-)_3bipy^-]$. CT bands may overlap with *d – d* bands and with bands corresponding to excitation within ligands themselves, and it is often hard to make unambiguous assignments. Fig. 42 shows the electronic energy levels and CT transitions.

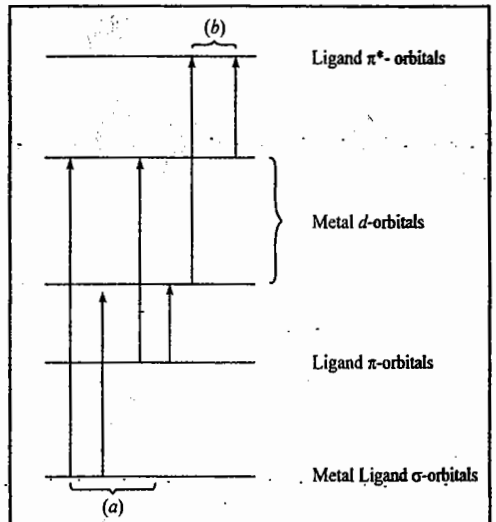

Fig. 42. Some possible LMCT transitions *(a)* and MLCT transitions *(b)*. Note that the metal-ligand σ-bond orbitals are derived primarily from ligand-based orbitals.

Electronic Spectra of Lanthanides and Actinides

The 4*f* electrons in the lanthanides and the 5*f* electrons in the actinides and their compounds are well screened from external effects by the filled shells of higher quantum numbers. This has important consequences, the first being that the *f–f* bands of such species are characteristic of the element concerned and are hardly affected by even the ligands in the immediate vicinity. All compounds of a particular ion are expected to have very similar spectra though species with different numbers of *f* electrons will have different states and hence different transitions. The lanthanide elements are generally found in the form of complexes of M^{3+} ions, each element having its own characteristic colour. The actinide elements have more varied colours since they are found in variable oxidation states. However, the spectra of actinide compounds derived from a given oxidation state are generally very similar.

The second consequence of this insulation of *f* electrons from external influences is that the *f–f* bands are sharp—in fact, much narrower than the typical *d–d* bands. They are also characteristically weak, the effects of deviations from perfect inversion symmetry (which is often found for complexes of lanthanide elements) being insufficient to relax the $g \rightarrow u$ selection rule. All *f* levels are of *u* symmetry in a centrosymmetric environment so that *f–f* transitions are forbidden. The colours of lanthanide compounds are, therefore, pale. The actinides have rather strong colours because of the effect of spin-orbit coupling which is greater for heavier atoms. Charge transfer transitions are less important for the *f*-block elements than for the *d*-block elements, mainly because they are less likely to form complexes with ligands having suitable donor orbitals. The Canadian physicist, G. Herzberg (1904-1999), known for his great monographs on spectroscopy, was awarded the 1971 Chemistry Nobel Prize for contributions to electronic structure, spectroscopy and geometry of molecules and free radicals.

ELECTRONIC SPECTRA OF CONJUGATED MOLECULES

The electronic spectra of conjugated systems using free-electron molecular orbital (FEMO) theory is based on the theory proposed in the 1930s by Pauling and, independently, by Kathleen Lonsdale and H. Kuhn, that the pi electrons are delocalized over the entire carbon skeletal framework. Thus, there is no true carbon–carbon single bond or carbon–carbon double bond and we can use the particle-in-a-one dimensional box approach for such systems. For this model, we have

$$E_n = n^2h^2/(8m_ea^2) \qquad (n = 1, 2, 3,\ldots) \qquad \ldots(94)$$

The electrons in the π MOs are filled according to the Pauli principle and Hund's rule. Thus, if N is the number of π orbitals, only $N/2$ π orbitals are filled in the ground state.

The *longest wave length* transition involves the excitation of the π electron from the $N/2$ HOMO to $(N/2)+1$ LUMO. Hence, the frequency of the electronic transition is given by

$$\nu = \frac{E_{(N/2)+1} - E_{N/2}}{h} = \frac{h}{8m_e a^2}\left[\left(\frac{N}{2}+1\right)^2 - \left(\frac{N}{2}\right)^2\right]$$

$$= h\,(N+1)/8m_e a^2 \qquad ...(95)$$

$$\therefore \quad \bar{\nu} = \nu/c = h\,(N+1)/(8m_e a^2 c) \qquad ...(96)$$

Let us now estimate the value of the chain length a of the conjugated system (*i.e.*, the width of the box). Since there is a residual free valence at each of the two terminal carbon atoms, hence

a = number of actual C—C bonds between N carbon atoms + 2

$$= (N - 1 + 2)\,l = (N + 1)\,l \qquad ...(97)$$

where l is the C—C bond length, assumed to be equal to 139 pm. Here we have made allowance for the molecular orbitals to extend one bond length l past each terminal carbon atom which is a very plausible assumption. Substituting for a in Eq. 96, we have

$$\bar{\nu}\,(\text{cm}^{-1}) = \frac{h(N+1)}{8m_e c(N+1)^2 l^2} = \frac{h}{8m_e c(N+1)l^2}$$

$$= 148{,}137{\cdot}6/(N+1) \text{ (after substituting various constants)} \qquad ...(98)$$

A more realistic approach is the use of sinusoidal form of potential energy with a minimum at the centre of the double bond considered. Eq. 98 is then modified to

$$\bar{\nu}\,(\text{cm}^{-1}) = \frac{153{,}000}{N+1} + 16{,}000\left(1 - \frac{1}{N}\right) \qquad ...(99)$$

Example 12. Using the FEMO theory, estimate the wave number of the lowest energy transition in the 1, 3, 5-hexatriene molecule.

Solution : The 1, 3, 5-hexatriene molecule is

$$CH_2=CH-CH=CH-CH=CH_2 \quad \textit{i.e.,} \quad CH_2{=}CH{=}CH{=}CH{=}CH{=}CH_2$$

Here $N = 6$. Hence,

$$\bar{\nu}(\text{cm}^{-1}) = 148{,}137{\cdot}6/(N+1) = 148{,}137{\cdot}6/7 = 21{,}162{\cdot}5 \qquad \text{[Eq. 98]}$$

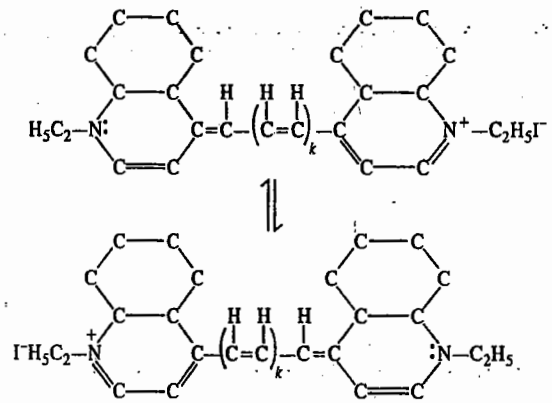
Using the modified FEMO theory,

$$\bar{\nu}(\text{cm}^{-1}) = \frac{153{,}000}{N+1} + 16{,}000\left(1 - \frac{1}{N}\right) = 34{,}495{\cdot}83 \qquad \text{[Eq. 99]}$$

(The experimental value is 37,313·4 cm)

Example 13. Derive an expression for the lowest frequency (*i.e.*, highest wave length) transition from HOMO to LUMO for polymethine dyes.

Solution : The general formula of polymethine dyes is



Using the FEMO theory,

$$\bar{\nu}(\text{cm}^{-1}) = \frac{h(N+1)}{8m_e a^2 c} \qquad \text{[Eq. (96)]}$$

If n_c is the number of carbon atoms in the polymethine dye, then N (the total number of π-electrons) = n_c+3. The three electrons are due to two nitrogen atoms, two due to one and one due to the other N atom. Assuming, as before, that the molecular orbitals extend by one bond length on either side and all bonds are equal

$$a = (n_c + 2 - 1 + 2)l \quad \text{or} \quad a = (n_c + 3)l \qquad ...(i)$$

Substituting the values of a and N, Eq. 96 becomes

$$\bar{\nu} = \frac{h(n_c + 3 + 1)}{8m_e c(n_c + 3)^2 l^2} = \frac{(n_c + 4) \times 1{\cdot}48 \times 10^5}{(n_c + 3)^2}\ \text{cm}^{-1} \qquad ...(ii)$$

Example 14. Assuming that $k = 1$ in the polymethine dye given above, calculate the wave number and the wave length of the lowest energy HOMO-to-LUMO electronic transition.

Solution : If $k = 1$, then $n_c = 9$.

Hence, from Eq. *(ii)* of Example 13, we obtain

$$\bar{\nu} = 1{\cdot}3361 \times 10^4\ \text{cm}^{-1} \quad \text{and} \quad \lambda = 748{\cdot}4\ \text{nm}$$

MISCELLANEOUS SOLVED EXAMPLES IN SPECTROSCOPY

Example 15. The selection rules for spectral transitions in atomic spectra are : *(i)* Δn = 1, 2, 3, 4,..., and *(ii)* $\Delta l = \pm 1$. Using these selection rules, determine which of the following transitions are allowed and which are forbidden :

(a) $1s \rightarrow 2p$ *(b)* $2s \rightarrow 3s$ *(c)* $2p \rightarrow 3s$

(d) $3d \rightarrow 4f$ *(e)* $4p \rightarrow 5f$ *(f)* $3p \rightarrow 3d$

Solution : For allowed transitions, both selection rules should be obeyed simultaneously. Accordingly,

Allowed transitions are : *(a)*, *(c)*, *(d)* and *(f)*

Forbidden transitions are : *(b)* and *(e)*.

Example 16. Obtain an expression for the natural line-width of a spectral transition. Using this expression calculate the natural line-width (in cm^{-1}) of a spectral line which results when a quantum system in an

excited state of life time 0·1 ns (nanosecond) makes a transition to the ground state.

Solution : We know from the Heisenberg uncertainty principle that

$$\Delta E \times \Delta t \approx h/4\pi \qquad \ldots(i)$$

where ΔE is the uncertainty in the energy and Δt is the uncertainty in lifetime of the quantum system—an atom or a molecule. Since for a photon of frequency ν, $E = h\nu$, hence,

$$\Delta E = h\Delta\nu \qquad \ldots(ii)$$

From Eqs. *(i)* and *(ii)*,

$$h\Delta\nu \times \Delta t = h/4\pi$$

$$\therefore \quad \Delta\nu = 1/4\pi\Delta t$$

If $\Delta t \approx \tau$, the life time, then

$$\Delta\nu = 1/4\pi\tau \qquad \ldots(iii)$$

Now $\tau = \Delta t = 0{\cdot}1 \text{ ns} = 0{\cdot}1 \times 10^{-9} \text{ s} = 1{\cdot}0 \times 10^{-10} \text{ s}$,

hence $$\Delta\nu = \frac{1}{4(3{\cdot}1416)(1{\cdot}0 \times 10^{-10}\,\text{s})} = 0{\cdot}8 \times 10^{9}\ \text{s}^{-1}$$

$$\therefore \quad \Delta\bar{\nu} = \frac{\Delta\nu}{c} = \frac{0{\cdot}8 \times 10^{9}\,\text{s}^{-1}}{3 \times 10^{10}\,\text{cm}^{-1}} = 0{\cdot}0267\ \text{cm}^{-1}$$

Example 17. Using the Heisenberg unertainty principle, estimate the lifetime of an energy state which gives rise to a line-width of *(a)* 0·1 cm *(b)* 1 cm *(c)* 60 MHz.

Solution : As shown in the last example,

$$\tau \approx 1/4\pi\Delta\nu = 1/4\pi c\Delta\bar{\nu} \qquad (\because\ \nu = c\bar{\nu})$$

(a) $$\Delta\bar{\nu} = 0{\cdot}1\ \text{cm}^{-1}\ ; \quad \tau \approx \frac{1}{(4\pi)(3 \times 10^{10}\,\text{cm s}^{-1})(0{\cdot}1\,\text{cm}^{-1})} = 2{\cdot}5 \times 10^{-11}\ \text{s}$$

(b) $$\Delta\bar{\nu} = 1{\cdot}0\ \text{cm}^{-1}\ ; \quad \tau \approx 2{\cdot}7 \times 10^{-12}\ \text{s}$$

(c) $$\Delta\bar{\nu} = 60\ \text{MHz}\ ; \quad \tau \approx \frac{1}{(4\pi)(60 \times 10^{6}\,\text{s}^{-1})} = 1{\cdot}35 \times 10^{-9}\ \text{s} = 1{\cdot}35\ \text{ns}$$

Example 18. In a certain fluxional molecule two groups that are interchanged by the conversion have vibrational absorption bands at 1650 cm^{-1} and 1655 cm^{-1}. Calculate, using the Heisenberg uncertainty principle, the minimum lifetime of the states for which the separate absorptions could be distinguished.

Solution : The absorptions are indistinguishable if the lifetimes are less than $1/4\pi\Delta\nu$, or in terms of the wave number, *less than*

$$\tau = \frac{1}{4\pi c\Delta\bar{\nu}} = \frac{1}{(4\pi)(3 \times 10^{10}\,\text{cm s}^{-1})(5\,\text{cm}^{-1})} = 0{\cdot}5 \times 10^{-12}\ \text{s} = 0{\cdot}5\ \text{ps}$$

0·5 ps is the time for the molecule to undergo about 10 oscillations in each conformation.

Example 19. Experimentally it is found that a molecule in a liquid undergoes approximately 10^{13} collisions per second. Calculate the linewidth (in cm^{-1}) of a spectral transition between a vibrationally excited state and the ground state assuming *(a)* that every collision deactivates the molecule vibrationally *(b)* that one in fifty collisions is effective in deactivating the molecule.

Solution : $\Delta\bar{\nu} = 1/(4\pi c\tau)$, where τ is the lifetime of the state.

(a) $$\tau = (1/10^{13})\ \text{s} = 10^{-13}\ \text{s}$$

$$\Delta\bar{\nu} \approx \frac{1}{(4\pi)(3 \times 10^{10}\,\text{cm s}^{-1})(10^{-13}\,\text{s})} = 25\ \text{cm}^{-1}$$

(b) $$\tau = (50/10^{13})\ \text{s} = 5 \times 10^{-12}\ \text{s}$$

$$\Delta\bar{\nu} \approx \frac{1}{(4\pi)(3 \times 10^{10}\,\text{cm s}^{-1})(5 \times 10^{-12}\,\text{s})} = 0{\cdot}5\ \text{cm}^{-1}$$

Example 20. Which of the following molecules will show a pure rotational (microwave) spectrum and why: H_2, HCl, CO, CH_3Cl, H_2O (liquid), NH_3, NH_4Cl (s) ?

Solution : Pure rotational spectra are shown by a *gaseous* molecule which possesses a permanent dipole moment, μ. Thus, the microwave-active molecules are : HCl, CO, CH_3Cl and NH_3.

Example 21. Which of the following molecules will show a vibrational infrared spectrum and why : H_2, HCl, CO, CH_3Cl, H_2O, NH_3, NH_4Cl, CH_3–CH_3, C_6H_6, CCl_4, CO_2.

Solution : Vibrational spectra are shown by a molecule when the vibrational motion is accompanied by a *change* in dipole moment *i.e.*, $d\mu/dr \neq 0$. All the molecules (except H_2) will be infrared-active. H_2 does not have a dipole moment, nor is the vibrational motion accompanied by a change in dipole moment. Again, although CO_2 is a symmetric molecule with no dipole moment, the *asymmetric* stretching motion and *bending* mode of vibration do result in a change in dipole moment.

Example 22. Which of the following molecules will show a rotational Raman spectrum and why : H_2HCl, CO, CH_4, CH_3Cl, H_2O, NH_3, C_2H_6, SF_6 ?

Solution : Rotational Raman spectra are shown by a molecule in which the rotational motion is accompanied by a *change* in the *polarizability i.e.*, $d\alpha/dr \neq 0$. Here all the molecules (except CH_4 and SF_6) will show rotational Raman spectrum.

Example 23. Which of the following molecules will show a vibrational Raman spectrum and why : H_2, HCl, CO, CH_4, CH_3Cl, H_2O, NH_3, C_2H_6, SF_6 ?

Solution : Vibrational Raman spectra are shown by a molecule in which the vibrational motion is accompanied by a *change* in the *polarizability*. Here all the molecules will show vibrational Raman spectrum.

Example 24. Give the quantum mechanical description of the Franck-Condon principle with special reference to the Franck-Condon factor and derive an expression for the relative intensity of the 0–0 vibronic transition as a function of ΔR, the change in nuclear coordinates.

Solution : Quantum mechanically, the vibronic transition (as described by the Franck-condon principle) is a vertical transition which qualitatively occurs from the ground vibrational state of the lower electronic state to the vibrational state that it most resembles in the upper electronic state. In that way, the vibrational wavefunctions undergo least change, which corresponds to the preservation of the dynamical state of the nuclei as required by the Franck–Condon principle. The vibrational state with a wavefunction that most resembles the original bell-shaped Gaussian function of the vibrational ground state is one with a peak immediately above the ground state. Thus, the wavefunction corresponds to the energy level that lies in much the same position as in the vertical transition of the classical description. It can be shown that the transition dipole moment between the ground vibronic state, $|\varepsilon\, \upsilon>$ and the upper vibronic state $|\varepsilon'\upsilon'>$ is given by

$$<\varepsilon'\upsilon'|\mu|\,\varepsilon\upsilon> = \mu_{\varepsilon'\varepsilon}\int \psi^{*}_{\upsilon'}(R)\,\psi_{\upsilon}(R)\,d\tau_N = \mu_{\varepsilon'\varepsilon}S(\upsilon',\upsilon)$$

where $$S(\upsilon',\upsilon) = \int \psi^{*}_{\upsilon'}(R)\,\psi_{\upsilon}(R)\,d\tau_N$$

is the overlap integral between the two vibrational states in their respective electronic states. Here R refers to the nuclear coordinates. The transition dipole moment is therefore largest between vibrational states that have the greatest overlap. This is the quantitative version of the previous qualitative discussion, where we looked for the upper vibrational state that had a local bell-shaped region above the gaussian function of the ground vibrational state of the lower electronic state. Here $\mu_{\varepsilon'\varepsilon}$ may be treated as a constant.

Several vibrational states have similar values of $S(\upsilon',\upsilon)$, and so transitions occur to all of them. Thus, a *progression* of transitions is stimulated and a series of lines are observed in the electronic spectrum. The relative intensities of the lines are proportinal to the square of the transition dipole moments and hence to the **Franck-Condon factors,** $|S(\upsilon',\upsilon)|^2$. The 0–0 transition refers to the transition from the ground vibrational level ($\nu = 0$) of the ground electronic state to the vibrational state with $\upsilon' = 0$ of the upper electronic state.

We need to evaluate the Franck-Condon factor $|S(0,0)|^2$. To do so we calculate the overlap integral $S(0,0)$ using harmonic oscillator wavefunctions,one centred on $x=0$ and the other on $x=\Delta R$. We shall need the following standard integral :

$$\int_{-\infty}^{\infty} e^{-ax^2}dx = \left(\frac{\pi}{a}\right)^{1/2}$$

The wavefunctions for the two states are

$$\psi_0 = \left(\frac{\alpha}{\pi}\right)^{1/4} e^{-\alpha x^2/2}, \psi_0' = \left(\frac{\alpha}{\pi}\right)^{1/4} e^{-\alpha(x-\Delta R)^2/2}$$

where $\alpha = m\omega/\hbar$ and the wavefunctions are normalized in the sense

$$\int_{-\infty}^{\infty} |\psi_0|^2 \, dx = 1$$

Hence,

$$S(0,0) = \left(\frac{\alpha}{\pi}\right)^{1/2} \int_{-\infty}^{\infty} e^{-\alpha x^2/2 - \alpha(x-\Delta R)^2/2} dx$$

$$= \left(\frac{\alpha}{\pi}\right)^{1/2} e^{-\alpha(\Delta R/2)^2} \int_{-\infty}^{\infty} e^{-\alpha(x-\Delta R/2)^2} dx = e^{-\alpha(\Delta R/2)^2}$$

The Franck-Condon factor for the transition is therefore

$$|S(0,0)|^2 = e^{-\alpha(\Delta R)^2/2}$$

This function is plotted in Fig. 43. Strong dependence of the function on ΔR is clearly evident.

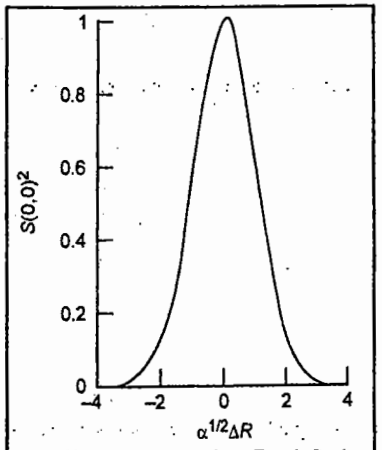


Fig. 43. The variation of the Franck-Condon factor with displacement of the minimum of the upper electronic state. Note that the factor is a maximum (1) when the two curves lie exactly over one another.

I. Review Questions

1. Discuss the factors which determine the width and intensity of spectral lines.
2. Show that for a rigid diatomic rotor the moment of inertia is given by $I = \mu r^2$.
3. Using the energy level expression and the selection rules draw an energy level diagram and the spectral transitions for the microwave (pure rotational) spectrum of a rigid diatomic rotor. Also show the appearance of the spectrum. No discussion is required.

4. Using the energy level expression and the appropriate selection rules draw an energy level diagram and the spectral transitions for the rotation–vibration spectrum of a diatomic molecule. Also show the appearance of the spectrum consisting of the P and R branches. No discussion is required.
5. Discuss the quantum theory of Raman spectroscopy and show how the Stokes and anti-Stokes lines appear in the Raman spectrum of a molecule.
6. Using the energy level expression and the appropriate selection rules draw an energy level diagram and the spectral transitions for the rotational Raman spectrum of a rigid diatomic rotor. Also show the appearance of the spectrum. No discussion is required.
7. Why are the anti-Stokes lines less intense than the Stokes lines in the Raman spectrum ? How has the use of the laser source of exciting radiation helped in Raman spectroscopy ?
8. State and illustrate with suitable potential energy curves the Franck–Condon principle in the vibronic spectrum of a diatomic molecule. Discuss briefly.
9. Which factors govern the intensities of rotational spectral lines in a rigid diatomic rotor ? Illustrate using the appropriate curve.
10. What is the Stark effect in microwave spectra ?
11. How is microwave spectroscopy used in investigating (*i*) internal rotation and (*ii*) the inversion spectrum of NH_3 ?
12. What is the effect of (*i*) centrifugal distortion on the rotational energy levels of a rigid diatomic rotor and of (*ii*) anharmonicity on the vibrational energy levels of a diatomic S.H.O. ?
13. Sketch the normal modes of vibration of (*a*) H_2O and (*b*) CO_2 and determine which are IR-active/inactive and why?
14. Why do overtones and combination bands appear in IR spectra ? Also, how does the phenomenon of Fermi resonance appear in IR spectra ?
15. Discuss briefly, using an energy level diagram, the resonance Raman spectroscopy. What are its advantages over simple Raman spectroscopy ?
16. Show diagrammatically the $\sigma^* \leftarrow \sigma$, $\sigma^* \leftarrow n$, $\sigma^* \leftarrow \pi$ transitions in the electronic spectra of polyatomic molecules.
17. Discuss briefly the change-transfer (CT) spectra of molecules.
18. Discuss briefly (*a*) Jahn-Teller distortion (*b*) metal–metal transition *d–d* bands and (*c*) charge-transfer bands in the electronic spectra of transition metal complexes.
19. How is the particle-in-a-box model applied to FEMO theory of the electronic spectra of conjugated molecules ?
20. Discuss SRS, Inverse Raman scattering and CARS, emphasizing the salient features.

II. Problems

1. Calculate the energy in joules per quantum, joules per mole, and in electron-volts (eV) of photons of wave length 300 nm.
   [Ans. $6{\cdot}62\times10^{-19}$ J; $3{\cdot}98\times10^{5}$ J mol^{-1}, 4·13 eV]
2. Calculate the frequency (in cm^{-1}) and wave length (in cm) of the rotational transition ($J' = 0 \rightarrow 1$) for $D^{35}Cl$
   [Ans. 10·89 cm^{-1} ; 0·9183 cm]
3. The far infrared spectrum of HI consists of a series of equally spaced lines with spacing equal to 12·8 cm^{-1}. Calculate (*a*) the moment of inertia and (*b*) the internuclear distance.
   [Ans. (*a*) $4{\cdot}37\times10^{-47}$ kg m^2 (*b*) 0·163 nm]
4. Calculate the relative Boltzmann populations of the first five rotational levels of the ground vibrational state of $H^{35}Cl$ at 300 K. Given the rotational constant is 10·4398 cm^{-1}.
   [Ans. N_J/N_0 for J = 0, 1, 2, 3, 4, 5 = 1·00, 2·71, 3·70, 3·84, 3·31 and 2·45]
5. The force constant of HF molecule is 970 N m^{-1}. Calculate the fundamental vibrational frequency as well as the zero-point energy.
   [Ans. $1{\cdot}247\times10^{14}$ s^{-1} ; $4{\cdot}129\times10^{-20}$ J]
6. Why is it that in the excited state of a molecule, the vibrational frequency, ν, is smaller than in the ground state ?
   [Ans. The reason is that ν is proportional to force constant, k, which is smaller in the excited state.]

7. The hydrogen halides have the following fundamental vibrational frequencies : HF (4141·3 cm^{-1}), $H^{35}Cl$ (2988·9 cm^{-1}), $H^{81}Br$ (2649·7 cm^{-1}), HI (2309·5 cm^{-1}). Calculate the force constants of the hydrogen–halogen bonds.
[Ans. 967, 516, 412, 314 N m^{-1}]

8. From the data in the last problem predict the fundamental vibrational frequencies of the deuterium halides.
[Ans. 3002, 2144, 1886, 1640 cm^{-1}]

9. Calculate the relative Boltzmann population of the $v = 1$ and $v = 0$ vibrational energy levels of a diatomic molecule, at 25°C, if they are separated by 1,000 cm^{-1}. **[Ans. $N_{v=1}/N_{v=0}$ = 0·008]**

10. The anharmonicity constant for $^{35}Cl^{19}F$ is $\omega_e x_e$ = 9·9 cm^{-1} and the fundamental vibrational frequency is 793·2 cm^{-1}. Calculate the energies of the first four vibrational energy levels.
[Ans. 1167·52 cm^{-1}, 1921·13 cm^{-1}, 2654·23 cm^{-1}, and 3368·93 cm^{-1}]

11. How many fundamental vibrational frequencies (*i.e.*, fundamental vibrational degrees of freedom) are expected for the following molecules :

(a) CO_2 (linear) *(b)* H_2O (bent) *(c)* SO_2 (bent) *(d)* O_2 *(e)* CH_3Cl *(f)* $CHCl_3$ *(g)* CH_4 *(h)* C_6H_6 *(i)* trans-N_2F_2 *(j)* C_2F_2 (linear) *(k)* N_2O *(l)* NO_2 ?

[Ans. *(a)* 4, *(b)* 3, *(c)* 3, *(d)* 1, *(e)* 9, *(f)* 9, *(g)* 9, *(h)* 30, *(i)* 6, *(j)* 7, *(k)* 3, *(l)* 3]

12. The infrared and Raman spectra of a triatomic molecule of the type MX_2 show two infrared frequencies and one Raman frequency. Determine whether the molecule is linear or bent. **[Ans. linear]**

13. The triatomic molecule AB_2 shows three strong infrared absorption bands. What is the structure of molecule ?
[Ans. ABB bent or BAB bent]

14. The fundamental vibrational frequencies of SO_2 are 1151·38, 517·69, and 1361·76 cm^{-1}. Account for the absorption bands at 1875·55, 2295·88 and 2499·55 cm^{-1}. **[Ans. $\bar{\nu}_2 + \bar{\nu}_3$, $2\bar{\nu}_1$ and $\bar{\nu}_1 + \bar{\nu}_3$]**

15. If $H^{35}Cl$ is irradiated with 435·8 nm mercury line, calculate the Raman line in nm if the fundamental vibrational frequency of $H^{35}Cl$ is $8·667 \times 10^{13}$ s^{-1}. **[Ans. 498·57 nm]**

16. List all the electronic transitions possible for *(a)* CH_4 *(b)* CH_3Cl *(c)* $H_2C{=}O$.
[Ans. *(a)* $\sigma^* \leftarrow \sigma$, *(b)* $\sigma^* \leftarrow \sigma$ and $\sigma^* \leftarrow n$ (there are no π or π^* MO's),
(c) $\sigma^* \leftarrow \sigma$, $\pi^* \leftarrow \sigma$, $\sigma^* \leftarrow \pi$, $\pi^* \leftarrow n$, $\pi^* \leftarrow \pi$ and $\pi^* \leftarrow n$]

17. Identify the two geometric isomers of stilbene, $C_6H_5CH{=}CHC_6H_5$, from their λ_{max} values, 294 nm and 278 nm.
[Ans. The higher the energy *cis*-isomer has, the shorter the λ_{max}. Steric strain prevents full coplanarity of the *cis* phenyl groups and the conjugative effect is attenuated.]

18. Predict the kind of electronic transitions in *(a)* Cl_2 and *(b)* C=O group. Also give their intensity.
[Ans. *(a)* $\sigma^* \leftarrow \sigma$ (allowed transition, strong) $\sigma^* \leftarrow n$ (forbidden transition, weak)
***(b)* $\pi^* \leftarrow \pi$ and $\sigma^* \leftarrow \sigma$ (both allowed, strong) $\pi^* \leftarrow n$, and $\sigma^* \leftarrow n$ (both forbidden, weak)]**

CHAPTER 7

MOLECULAR SPECTROSCOPY–II
(NMR, ESR, NQR, NRF and PES)

MAGNETIC RESONANCE SPECTROSCOPY

Molecular spectra including rotational (microwave) spectra, vibrational and vibration-rotation (infrared) spectra, Raman spectra and electronic (visible and ultraviolet) spectra have been discussed in the last chapter. In this chapter, we shall discuss some very important spectoscopies which are of interest in structural chemistry. NMR is an indispensable tool in the hands of an organic chemist in his synthetic investigations; ESR tells us about the transience of extremely short-lived free radicals; both NQR and NRF are useful in determining the strong electric field gradients (EFGs) found in metals and alloys and PES helps us in verifying quantum mechanical calculations on atoms and molecules and in determining their ionisation potentials.

NMR SPECTROSCOPY

NMR was independently discovered in 1946 by the American physicists F. Bloch (1905–1983) of Stanford University and E.M. Purcell (1912–1997) of Harvard University ; they shared the 1952 Physics Nobel Prize. The first application of NMR to chemistry was made in 1951 when NMR spectrum of ethanol was recorded. Since then NMR technique has almost completely been monopolized by chemists, biochemists and molecular biologists, for structural elucidation, physicists being primarily interested in its theoretical aspects.

All atomic nuclei possess nuclear spin, I, which may be integral (*i.e.*, 1, 2, 3, etc.) or half-integral (*i.e.*, 1/2, 3/2, 5/2, 7/2 etc.). The proton and the neutron each has spin 1/2. Since a nucleus contains nucleons (collective term for protons and neutrons), it is evident that the spin of the nucleus may be considered as the resultant of the spins of protons and neutrons comprising it. Consider, for instance, the deuteron nucleus, ^2D, which contains one proton and one neutron. Now, depending upon whether the spins of the proton and the neutron are aligned parallel (↑↑) or antiparallel (↑↓), the deuteron is expected to have a spin of 1 or 0. It is, however, found that in the ground state, deuteron has spin of 1 which means that the proton and neutron spins are aligned parallel to each other.

It is difficult to predict the spin of a nucleus. The following rules are, however, helpful in predicting the nuclear spin :

(i) If the mass number A is odd, nuclear spin I is *half integral*. Thus, in the case of ^1H, ^{15}N, ^{19}F, ^{31}P, I = 1/2 and in the case of ^{11}B, I = 3/2.

(ii) If the mass number A and the atomic number Z are both even, the spin is *zero*. Thus, in the case of ^4_2He, $^{12}_6C$, $^{16}_8O$, $I = 0$.

(iii) If the mass number A is even but the atomic number Z is odd, the spin is *integral*. Thus, the spin of ^2_1H and $^{14}_7N$ is 1 while that of $^{10}_5B$ is 3.

Since a nucleus possesses an electric charge, *the spinning nucleus gives rise to a magnetic field whose axis coincides with the axis of spin*. Thus, each nucleus can be thought of being equivalent to a minute magnet having a magnetic moment μ. Each nucleus with $I > 0$ has magnetic moment.

However, $^{12}_{6}C$ and $^{16}_{8}O$ having $I=0$ do not possess a magnetic moment, *i.e.*, they are non-magnetic.

Nuclei possessing $I \geq 1$ have also a ***nuclear electric quadrupole moment, Q,*** which is a measure of the deviation of the nuclear charge distribution from spherical symmetry. Some common quadrupolar nuclei are $^{2}_{1}H$ (deuteron) and $^{14}_{7}N$ both of which have $I=1$. The nuclear quadrupole moment interacts with the electric field gradient (EFG) created at the nucleus by the bonding and non-bonding electrons in a molecule. The quantity e^2Qq (where e is the electronic charge and q the EFG) is known as the *nuclear quadrupole coupling constant*. Suffice it to mention here, avoiding mathematical details, that quadrupolar nuclei not only 'spoil' their own NMR spectra but also the NMR spectra of nuclei attached to them in a molecule. Thus, the NMR spectra of quadrupolar nuclei are generally very broad and not at all sharp.

When a magnetic nucleus is placed in a uniform magnetic field, the magnetic dipole associated with the magnetic moment assumes only ***a discrete set of orientations.*** This is expressed by saying that the nuclear spin (and hence the magnetic moment associated with it) is *quantized* with respect to the direction of the applied magnetic field. The magnetic nucleus assumes any one of the $2I+1$ orientations with respect to the direction of the applied magnetic field. Suppose that a nucleus with spin I is placed in an external magnetic field B_z, applied along the z-direction. Then, as a result of quantization of spin, the observable component m_I of the spin I along the direction of the field is given by

(i) $m_I = I, I-1, I-2, \ldots, 0, \ldots, -(I-2), -(I-1), -I$ *(for integral spins)*

(ii) $m_I = I, I-1, I-2, \ldots, 1/2, -1/2, -3/2, \ldots, -I$ *(for half-integral spins)*

In each case, there are $(2I+1)$ values of m_I.

A nucleus with spin has associated with it a magnetic dipole moment (or simply magnetic moment) $\vec{\mu}$ that is proportional to the angular momentum $\vec{I}$ given by $[(I(I+1)]^{1/2}\hbar$. Thus,

$$\vec{\mu} = g_N \mu_N \vec{I} \qquad \ldots(1)$$

where g_N is called the nuclear g-factor and μ_N is the nuclear megneton defined as $\mu_N = e\hbar/2m_p$, where e is the electronic charge, m_p is the mass of the proton. Substituting the various values,

$$\mu_N = \frac{(1{\cdot}602 \times 10^{-19}\text{C}) \times (1{\cdot}055 \times 10^{-34}\text{Js})}{(2) \times 1{\cdot}673 \times 10^{-27}\text{kg}} = 5{\cdot}05 \times 10^{-27}\ \text{J T}^{-1}$$

The *magnitude* of the nuclear magnetic moment is thus given by

$$\mu = g_N \mu_N [I(I+1)]^{1/2} \qquad \ldots(2)$$

Also, since the magnetic moment and the angular momentum can be parallel or antiparallel vectors, g_N can have a positive or a negative value. It may be noted that whereas the value of the electron g-factor, g_e has been very accurately calculated to be equal to 2·0023, the value of the nuclear g-factor, g_N, can only be obtained from experiment and is different for different nuclei.

Example 1. Calculate the nuclear spin angular momentum and the magnetic moment for a proton, given that $I = \frac{1}{2}$, g_N for proton is 5·585 and $\mu_N = 5{\cdot}05 \times 10^{-27}$ J T^{-1}.

Solution : The nuclear spin angular momentum

$$= [I(I+1)]^{1/2}\hbar = \left[\tfrac{1}{2}\left(\tfrac{1}{2}+1\right)\right]^{1/2} \times (1{\cdot}054 \times 10^{-34}\ \text{Js})$$

$$= 0{\cdot}866 \times 1{\cdot}055 \times 10^{-34}\ \text{J s} = 0{\cdot}914 \times 10^{-34}\ \text{Js}$$

The nuclear magnetic moment is given by

$$\mu = g_N \mu_N [I(I+1)]^{1/2}$$

$$= (5{\cdot}585) \times (5{\cdot}05 \times 10^{-27}\ \text{J T}^{-1}) \left[\tfrac{1}{2}\left(\tfrac{1}{2}+1\right)\right]^{1/2} = 2{\cdot}44 \times 10^{-26}\ \text{J T}^{-1}$$

NMR of a 'bare' proton. A 'bare' nucleus is, of course, an ideality. Actually, nuclei are parts of atoms and molecules. However, it is useful to consider the NMR of a bare proton. From quantum mechanics it is known that the energy of interaction of nuclear magnetic moment μ with an external magnetic field B_z, applied in the z-direction, is given by

$$E = -\mu B_z \qquad \ldots(3)$$

Substituting the value of $\vec{\mu}$ from Eq. 1, we find that

$$E = -g_N \mu_N B_z \vec{I} \qquad \ldots(4)$$

As already mentioned, the nuclear spin I is quantized in the presence of the magnetic field and the energy of nuclear spin is defined only by its component m_I. We may thus write :

$$E_{m_I} = -g_N \mu_N B_z m_I \qquad \ldots(5)$$

Consider a bare proton ^{1}H with $I=1/2$ so that $m_I = \pm 1/2$. Thus, for $m_I = 1/2$, the energy

$$E_{1/2} = -\tfrac{1}{2} g_N \mu_N B_z \qquad \ldots(6)$$

and for $m_I = -1/2$, the energy

$$E_{-1/2} = \tfrac{1}{2} g_N \mu_N B_z \qquad \ldots(7)$$

It should be noted that in the absence of the external magnetic field, the two components of the proton spin have the same energy (*i.e.*, they are *degenerate*). However, in the presence of the magnetic field, the components have different energies given by Eqs. 6 and 7. This is expressed by saying that *the magnetic field lifts or removes the degeneracy of the spin components*. This is called ***Zeeman splitting of energy levels.*** The energy difference is given by

$$\Delta E = E_{-1/2} - E_{1/2} = g_N \mu_N B_z \qquad \ldots(8)$$

This is illustrated in Fig. 1.

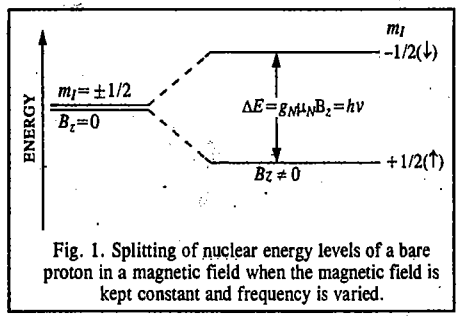

Fig. 1. Splitting of nuclear energy levels of a bare proton in a magnetic field when the magnetic field is kept constant and frequency is varied.

In order to induce transitions between the two energy levels $E_{-1/2}$ and $E_{1/2}$, *i.e.*, in order to let the nuclear spin 'flip' from the upward direction ($\uparrow$) to the downward direction ($\downarrow$), we must apply an oscillating radiofrequency field perpendicular to the direction of B_z. *The nuclear spin flips, provided the energy $h\nu$* of the radiofrequency photon of frequency ν is exactly equal to ΔE, *i.e.*,

$$\Delta E = g_N \mu_N B_z = h\nu \qquad \ldots(9)$$

This is called the **Bohr frequency condition.** Thus, the NMR frequency of a **bare proton** (or a bare nucleus with $I=1/2$) is given by

$$\nu = \frac{\Delta E}{h} = \frac{g_N \mu_N B_z}{h} \qquad \ldots(10)$$

It may be noted that g_N can be positive or negative but ν must be positive. Hence, only the absolute value of g_N should be used in calculating ν.

Eq. 10 shows that ν is directly proportional to B_z. We thus see that the NMR spectra can be recorded in two ways, *viz.*, *(i)* keeping the magnetic field B_z fixed and varying the frequency ν (Fig. 1)

or *(ii)* keeping ν fixed and varying B_z (Fig. 2). The latter mode is preferred in modern NMR spectrometers.

Example 2. Calculate the NMR frequency (in MHz) of the proton (^{1}H) in a magnetic field of intensity 1·4092 tesla, given that g_N = 5·585 and $\mu_N = 5{\cdot}05\times10^{-27}$ J T^{-1}.

Solution : From Eq. 10,

$$\nu = \frac{g_N\mu_N B_z}{h} = \frac{(5{\cdot}585)\times(5{\cdot}05\times10^{-27}\,\text{J T}^{-1})\times(1{\cdot}4092\,\text{T})}{6{\cdot}626\times10^{-34}\,\text{J s}}$$

$$= 60\times10^6\ \text{s}^{-1} = 60\times10^6\ \text{Hz} = \mathbf{60\ MHz}$$

This frequency lies in the radiofrequency region.

Example 3. Calculate the magnetic field strength required to observe the NMR frequency for fluorine (^{19}F) at 60 MHz. Given g_N for ^{19}F = 5·257 and $\mu_N = 5{\cdot}05\times10^{-27}$ J T^{-1}.

Solution. Since from Eq. 10, $\nu = g_N\mu_N B_z/\hbar$, we have

$$B_z = \frac{h\nu}{g_N\mu_N} = \frac{(6{\cdot}626\times10^{-34}\,\text{J s})(60\times10^6\ \text{s}^{-1})}{(5{\cdot}257)(5{\cdot}05\times10^{-27}\,\text{J T}^{-1})} = \mathbf{1{\cdot}4973\ T}$$

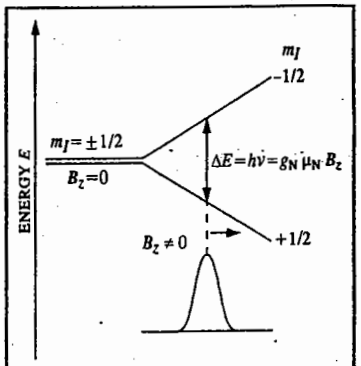

Fig. 2. Energy level diagram showing the splitting of nuclear energy levels of a bare proton in a magnetic field when the frequency is kept fixed and the magnetic field is varied.

It should be borne in mind that nuclei such as $^{12}_{6}$C and $^{14}_{6}$C have no spin (I=0) so that they have no magnetic moment ; they are called *non-magnetic* nuclei. Non-magnetic nuclei do not show NMR spectra because, their magnetic moment being zero, their energy levels do not exist. Thus, if an organic compound contains hydrogen, carbon and oxygen, only hydrogen nuclei (I=1/2) will show NMR spectra.

Some nuclear properties and NMR frequencies of a few nuclei in a magnetic field of intensity 1·4092 T are given in Table 1.

TABLE 1

Nuclear Magnetic Properties of Some Nuclei

Nucleus	% Abundance	Spin, I	g_N	NMR frequency ν in MHz at 1·4092 T
^{1}H	99·99	1/2	5·585	60·000
^{2}D	0·01	1	0·857	9·210
^{10}B	18·83	3	0·600	6·448
^{11}B	81·17	3/2	1·792	19·248
^{13}C	1·11	1/2	1·404	15·086
^{14}N	99·63	1	0·404	4·334
^{15}N	0·36	1/2	0·566	6·079
^{17}O	0·037	5/2	−0·757	8·134
^{19}F	100	1/2	5·255	56·444
^{29}Si	4·70	1/2	−1·110	11·919
^{31}P	100	1/2	2·261	24·286
^{35}Cl	75·41	3/2	0·547	5·879
^{37}Cl	24·60	3/2	0·455	4·893
^{127}I	100	5/2	1·118	12·005

Classically, the phenomenon of magnetic resonance can also be understood by invoking Larmor precession. A nucleus having a magnetic moment μ behaves as a bar magnet which spins on its axis. In the presence of the magnetic field B_z, the interaction of μ with B_z produces a torque. This torque causes μ to *precess* about B_z, as shown in Fig. 3. This phenomenon is called **Larmor precession** (in honour of the 19th century British mathematician, Joseph Larmor) and the angular frequency of precession is referred to as the **Larmor frequency,** ω_L (expressed in radians per second). Mathematically, Larmor frequency is given by

$$\omega_L = \gamma B_z \qquad \ldots(11)$$

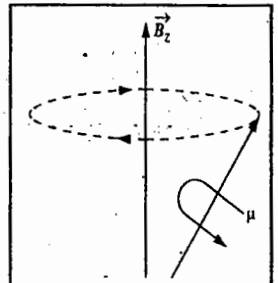

Fig. 3. Larmor precession of a nucleus in a magnetic field.

where γ is the **magnetogyric ratio** (formerly called gyromagnetic ratio) of the nucleus. It is defined as the ratio of the nuclear magnetic moment μ and the nuclear spin angular momentum $I\hbar$, *i.e.*,

$$\gamma = \frac{\mu}{I\hbar} \qquad \ldots(12)$$

It is expressed in terms of radians T^{-1} s^{-1} (or, simply as T^{-1} s^{-1}). Note that $\omega = 2\pi\nu$ where ν is the NMR frequency. It may be noted that $\gamma\hbar = g_N\mu_N$.

Positive values of g_N and μ_N denote a magnetic moment that is parallel to the spin; negative values indicate that the magnetic moment and spin are antiparallel.

Example 4. In a spectrometer operating at 1 T, the NMR frequency of ^{19}F is 40·06 MHz. Calculate the magnetogyric ratio of ^{19}F.

Solution : From Eq. 11,

$$\gamma = \frac{\omega_L}{B_z} = \frac{2\pi\nu}{B_z} = \frac{2\times(3{\cdot}1416)\times(40{\cdot}06\times10^6\,\text{s}^{-1})}{1\,\text{T}} = 2{\cdot}517\times10^8\ \text{T}^{-1}\,\text{s}^{-1}$$

Example 5. The magnetic moment of ^{31}P is equal to 1·1305 nuclear magnetons, *i.e.*, 1·1305 μ_N. Calculate its magnetogyric ratio and the *g*-factor. Given $\mu_N = 5{\cdot}05\times10^{-27}$ J T^{-1} and nuclear spin of ^{31}P is 1/2.

Solution : From Eq. 12,

$$\gamma = \frac{\mu}{I\hbar} = \frac{1{\cdot}1305\times(5{\cdot}05\times10^{-27}\,\text{J T}^{-1})\times(2\times3{\cdot}1416)}{(1/2)\times(6{\cdot}626\times10^{-34}\,\text{J s})} = 1{\cdot}083\times10^8\ \text{T}^{-1}\,\text{s}^{-1}$$

Now, from Eq. 1, $\mu = g_N\mu_N I$

For ^{31}P, $\mu = 1{\cdot}1305\,\mu_N$ and $I = \frac{1}{2}$ (given)

$\therefore$ $1{\cdot}1305\,\mu_N = \frac{1}{2}g_N\mu_N$, thus, $g_N = 2\times1{\cdot}1305 = \mathbf{2{\cdot}261}$

Experimental Technique of NMR Spectroscopy. A typical NMR spectrometer, shown in Fig. 4, consists of the following components : (1) a radiofrequency source of radiation (2) a receiver coil for the detection of the absorption of energy (3) a d.c.–magnetic field and (4) a receiver or an oscilloscope to display the NMR spectrum. The relation $\nu = g_N\mu_N B_z/h$ shows that the spectrum may be run at a fixed magnetic field by varying frequency or a fixed frequency by varying the magnetic field. In practice, it is preferable for most instruments to use a fixed frequency (which for protons is

of the order 60 MHz) supplied by a crystal-controlled radiofrequency oscillator and to vary the magnetic field applied to the sample by an electromagnet. When magnetic resonance condition is reached, the energy absorbed by the sample from the r.f. oscillator is measured electrically and displayed on the chart of a recorder or on an oscilloscope.

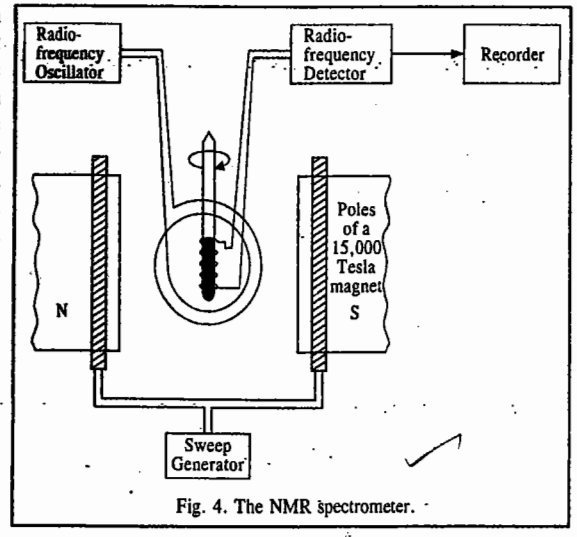

Fig. 4. The NMR spectrometer.

Chemical Shift. In practice, one does not investigate the NMR spectra of 'bare' nuclei. Nuclei are essential parts of molecules held together by the electrons of the chemical bonds. The magnetic field at which a free or 'bare' nucleus resonates is quite different from the field at which the same nucleus in a molecule resonates. It is thus clear that the electrons in a molecule affect the NMR frequency of a given nucleus in the molecule. The electrons are said to *shield* or *deshield* a nucleus from the applied magnetic field, depending upon whether the magnetic field generated by their motion opposes or reinforces the field. We shall discuss this aspect a little later in this chapter. Suffice it to mention here that the applied external magnetic field affects the motion of the electrons surrounding the nuclei thereby inducing local magnetic fields. The magnitude of the local magnetic field is determined by the electron distribution around a nucleus. The difference between the magnitudes of the magnetic field at which 'free' nuclei and molecular nuclei resonate is called **chemical shift.**

For measuring chemical shifts it is not possible to use a free nucleus as a reference. Instead, chemists use those compounds that exhibit only a *single sharp resonance line* as a reference for measuring chemical shifts. The most frequently employed reference compound is tetramethylsilane (TMS) having the formula, $Si(CH_3)_4$.

The local magnetic field B_{local} experienced by a nucleus in a molecule is related to the external magnetic field B_0 by

$$B_{local} = B_0 (1 - \sigma) \qquad ...(13)$$

where σ, a dimensionless quantity, is called the **screening constant** (or the **shielding constant**). For two nuclei A and B in a molecule, the local fields are

$$B_A = B_0 (1 - \sigma_A) \qquad ...(14)$$

$$B_B = B_0 (1 - \sigma_B) \qquad ...(15)$$

where σ_A and σ_B are the respective screening constants, Thus,

$$B_B - B_A = B_0 (1 - \sigma_B) - B_0 (1 - \sigma_A)$$

$$= B_0 (\sigma_A - \sigma_B) = B_0 \delta_{AB} \qquad ...(16)$$

where δ_{AB} (or, simply, δ) is the chemical shift of nucleus A with respect to nucleus B. In practice, we define chemical shift of a sample as

$$\delta = \frac{B_{sample} - B_{ref}}{B_0} \times 10^6 \text{ ppm} \qquad ...(17)$$

Since $B \propto \nu$, hence

$$\delta = \frac{\nu_{sample} - \nu_{TMS}}{\nu_0} \times 10^6 \text{ ppm} \qquad ...(18)$$

where the reference compound is tetramethylsilane (TMS). The chemical shift is expressed in parts per million (ppm).

The reasons for using TMS as the reference are as follows :

1. It has 12 equivalent protons ; this can be seen from its structure $Si(CH_3)_4$.

Since all the protons are in the same environment, TMS gives a single intense peak in its NMR spectrum.

2. It has a low boiling point (27°C) and thus can be easily recovered, if desired, after the spectrum is recorded.

3. It is chemically inert.

4. As will be discussed shortly in this chapter, the methyl groups in TMS are highly shielded by their electrons from the external magnetic field. Consequently, TMS shows NMR at a very high magnetic field strength compared to other protons.

It is pertinent to mention here that two chemical-shift scales, *viz.*, the δ-scale and the τ-scale are used in recording NMR signals. They are related by the expression

$$\delta + \tau = 10$$

i.e.,

$$(\tau = 10 - \delta) \qquad ...(19)$$

On the δ-scale, δ is set equal to zero at the reference peak (or signal) of TMS and it *increases downfield*. This scale has the disadvantage that a large value of δ implies that a proton undergoes a resonance at low field. Hence, it implies a low-shielding of the nucleus by the external magnetic field.

In the τ-scale, τ is set equal to 10 at the reference peak of TMS and it *decreases downfield.* Thus, a low value of τ implies that a proton undergoes a resonance at low field. Hence, it implies a low-shielding of the nucleus by the external magnetic field. It follows that a higher value of τ means a more shielded nucleus and hence a high-field resonance.

The τ-values for most organic compounds lie between 0 and 10. They are highly characteristic of the chemical environment of the magnetic nuclei. Thus, they can help in locating different kinds of protons in an organic molecule. The τ-values for some protons are given in Table 2.

TABLE 2

Typical Chemical Shifts For Protons in Different Environments

Compound	τ-Value (in ppm)	Compound	τ-Value (in ppm)
TMS	10·00	Dioxane	6·20
Cyclopropane	9·78	Water	4·80
Methane	9·77	Benzene	2·73
Tetramethylmethane	9·08	Ethylene	4·16
Ethanol :		Acetylene	7·81
methyl protons	8·83	Methyl fluoride	5·70
methylene protons	6·41	Methyl chloride	7·01
Cyclohexane	8·56	Methyl bromide	7·30
Acetone	7·91	Methyl iodide	7·81
Acetaldehyde :		Chloroform	2·30
methyl protons	7·85	Naphthalene	2·27
aldehydic protons	0·28		

Consider the proton-NMR spectrum of ethanol (Fig. 5). Each proton in the pure compound has its own electronic environment and hence a characteristic chemical shift. The liquid ethanol shows in its NMR spectrum three peaks at three values of the applied magnetic field corresponding to the **-OH** proton, the two equivalent $>CH_2$ protons and the three equivalent $-CH_3$ protons. The areas under the three absorption peaks are in the ratio of 1 : 2 : 3, respectively

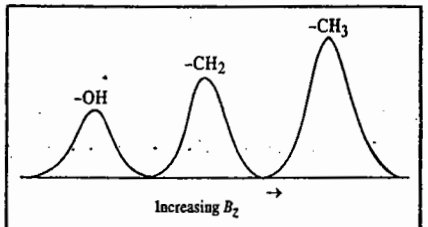

Fig. 5. Low-resolution NMR spectrum of ethanol.

Example 6. A compound shows a proton-NMR peak at 240 Hz down-field from the TMS peak in a spectrometer operating at 60 MHz. What are the values of the chemical shifts δ and τ in ppm relative to TMS ?

Solution : From Eq. 18, $\delta = \frac{\nu_{sample} - \nu_{TMS}}{\nu_0} \times 10^6$ (ppm) $= \frac{240\,s^{-1}}{60 \times 10^6\,s^{-1}} \times 10^6 = 4$ ppm ; $\tau = 10 - \delta = 6$ ppm

Shielding and Deshielding of Protons. The concept of chemical shift, introduced above, is closely linked with the shielding or deshielding of protons in a molecule. A *bare* proton, when exposed to a radiofrequency photon, 'flips' its spin from lower energy level to a higher energy level, *i.e.*, its spin changes its orientation from (↑) to (↓). However, all protons do not change or flip their spins at the same applied magnetic field because their energy depends upon the chemical environment of the protons. The magnetic field 'sensed' by a proton in a molecule is not the same as the applied magnetic field since the electrons in the bond close to the proton and the neighbouring electrons in other bonds *induce* their own magnetic field. This induced field may oppose or reinforce the applied magnetic field. The field experienced by the proton is thus the resultant of the applied and induced fields, as shown in Fig. 6. When the two fields reinforce, as in Fig. 6*(b)*, a smaller field must be applied to flip the proton. Such a proton is said to be *deshielded* and absorbs more *down-field* (*i.e.*, at lower magnetic field strength). On the other hand, when the fields oppose, as in Fig. 6*(c)*, a stronger field must be applied. The proton is now *shielded* and absorbs more *upfield* (*i.e.*, at higher magnetic field strength).

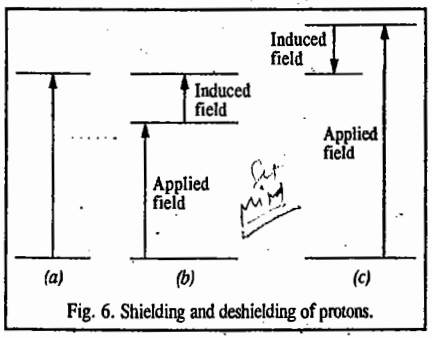

Fig. 6. Shielding and deshielding of protons.

Shielding Mechanism in NMR

The total contribution to shielding in NMR is customarily represented as

$$\sigma = \sigma(\text{local}) + \sigma(\text{molecule}) + \sigma(\text{solvent}) \quad ...(20)$$

where σ(local), the local contribution to shielding, is the sum of the positive diamagnetic contribution, σ_d and a negative paramagnetic contribution, σ_p, that is,

$$\sigma(\text{local}) = \sigma_d(\text{local}) + \sigma_p(\text{local}) \quad ...(21a)$$

The local contribution essentially comes from the electrons of the atom that contains the nucleus of interest. A magnetic field induces electronic circulation about a nucleus in a plane perpendicular to the applied magnetic field.

σ_d can be calculated from the **Lamb formula :**

$$\sigma_d = \frac{e^2\mu_0}{12\pi m_e}\left\langle\frac{1}{r}\right\rangle \quad ...(21b)$$

where μ_0 is the vacuum permeability, and r is the electron-nucleus distance.

In linear molecules such as acetylene, the total shielding which a proton experiences is a result of paramagnetic effect. Paramagnetic shielding arises from electronic circulations within molecules when they are specifically oriented with respect to the magnetic field. These electronic circulations about a nucleus produce a secondary magnetic field that is parallel to the applied magnetic field and frequently contributes to the shielding experienced by a neighbouring nucleus. *Local* paramagnetic circulations do not contribute to the shielding of protons but paramagnetic *electronic* circulations about atoms such as carbon, nitrogen and oxygen may contribute to the shielding of an adjacent or a neighbouring proton. Such is the case for acetylene molecule when it is oriented *parallel to the applied magnetic field.* The induced magnetic fields are paramagnetic at carbon but diamagnetic at the proton (Fig. 7*a*). This paramagnetic effect is important in shielding of other linear molecules. It may be noted that a proton may experience shielding effects caused by electronic circulations that originate in other parts of the molecule. Effects arising from electronic currents in other molecules will be averaged to zero by rapid thermal motion. Similarly, the currents in the same molecule will not cause shielding of a proton if such currents are averaged to zero by rapid rotation about single bonds. However, *in a relatively rigid molecule such currents can cause either shielding or deshielding of a proton.* These effects are called **anisotropic** effects since they depend on the *orientation* of the magnetic current.

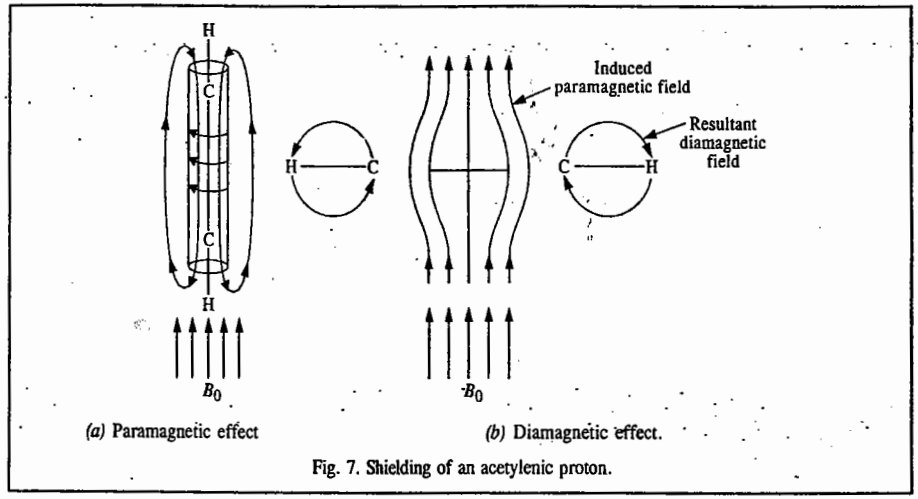

Fig. 7. Shielding of an acetylenic proton.

When acetylene molecule is oriented *perpendicular to the magnetic field* (Fig. 7*b*), a diamagnetic anisotropic effect occurs. The electronic circulations within the cylinderical pi-electron cloud induce a diamagnetic shielding at the acetylenic proton.

Let us next consider formaldehyde molecule, $CH_2=O$. When the carbonyl group is oriented such that the plane of the trigonal carbon atom is perpendicular to the field, diamagnetic circulations in the group produce anisotropic effect at the proton (Fig. 8.) that results in *deshielding*. It is probable that olefinic protons and, in fact, any group attached to the alkenic bond are *desheilded* because of diamagnetic anisotropic effects in the plane of the carbon-carbon double bond. Aromatic nuclei contain large closed loops of pi-electrons in which strong diamagnetic currents are induced by the magnetic field ; this is

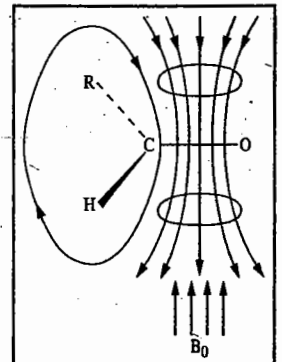

Fig. 8. Deshielding of an aldehydic proton by diamagnetic effect.

called the **ring current effect**. It causes *deshielding* of aromatic protons (Fig. 9).

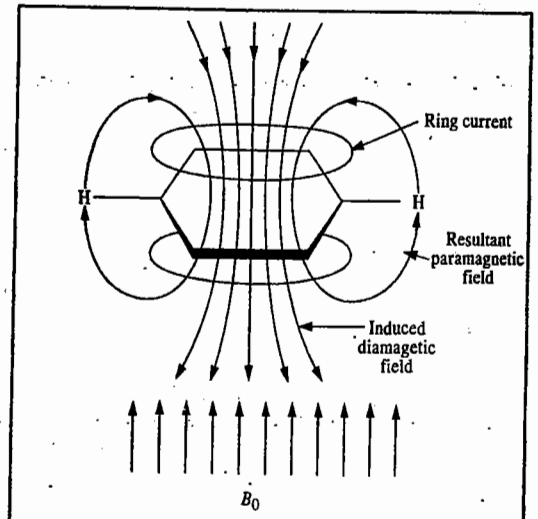

Fig. 9. Deshielding of aromatic protons due to ring current effect.

The shielding by the solvent can arise in a number of ways. Thus, the solvent polarity can affect the electron distribution near a magnetic nucleus. If a solvent is nonpolar, the polar solute can induce an electric dipole in the solvent molecules so that the polarized solvent molecules can distort the electron distribution of the solute molecule. The solute-solvent interactions such as hydrogen bonding, etc., can also lead to shielding or deshielding effects.

Nuclear Spin–Spin Interaction : Fine Structure in NMR

The NMR spectrum of ethanol, first observed in Bloch's laboratory in 1951, is of great historical importance because it demonstrated the application of NMR to structural elucidation in organic chemistry.

When the NMR spectrum of *acidified* ethanol is examined under high resolution, the peaks for CH_2 and CH_3 groups are seen to be split into multiplets, as shown in Fig. 10.

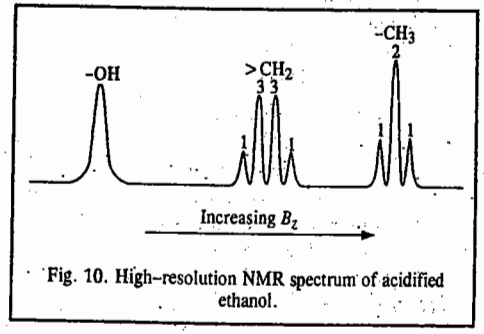

Fig. 10. High-resolution NMR spectrum of acidified ethanol.

This splitting of the lines arises as a result of **nuclear spin-spin interaction**, as illustrated below.

Relative to a given proton in the CH_3 group, the two protons of the CH_2 group can align themselves in four different ways, as shown below :

	(1)	(2)	(3)	(4)
Alignment of protons	↑↑	↑↓	↓↑	↓↓
Degeneracy	1	2		1
Σm_I	+1	0	0	-1

Since alignments (2) and (3) are energetically equivalent, the net spin combinations total *three*.

Relative to a proton in the CH_2 group, the three protons of the CH_3 group can align themselves in eight different ways, as shown below :

	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
Alignment of protons	↑↑↑	↑↑↓	↑↓↑	↓↑↑	↑↓↓	↓↑↓	↓↓↑	↓↓↓
Degeneracy	1	3			3			1
Σm_I	$+\frac{3}{2}$	$+\frac{1}{2}$	$+\frac{1}{2}$	$+\frac{1}{2}$	$-\frac{1}{2}$	$-\frac{1}{2}$	$-\frac{1}{2}$	$-\frac{3}{2}$

As can be easily seen, alignments (2), (3) and (4) are energetically equivalent and so are alignments (5), (6) and (7). The net spin combinations of protons in CH_3 group thus total *four*.

The three possible orientations of the CH_2 protons produce *three* different local fields at the CH_3 protons, thus splitting the CH_3 absorption peak into a *triplet, i.e.*, three lines of relative intensity ratio 1 : 2 : 1. Similarly, the *four* possible orientations of the CH_3 protons produce four different local fields at the CH_2 protons, thus splitting the CH_2 resonance into a *quartet, i.e.*, four lines of relative intensity ratio 1 : 3 : 3 : 1.

What about the influence of the OH proton on the CH_2 and the CH_3 protons of acidified ethanol? The answer is that H^+ ion of the acid catalyzes the exchange of protons between the OH groups of different molecules so that the life-time of an OH proton in any given conformation becomes too short to permit the observation of the effect of the OH proton on the CH_2 and CH_3 groups and vice versa. In other words, there is *no spin-spin interaction* between the OH proton and the other protons. Hence, the high resolution NMR spectrum of *acidified* ethanol consists of an OH singlet, a CH_2 quartet (1 : 3 : 3 : 1) and a CH_3 triplet (1 : 2 : 1), as shown in Fig. 10.

The proton NMR spectrum of *pure* ethanol is, however, different. Here because of the absence of the H^+ catalyst, the OH proton does not undergo any exchange between the OH groups of different ethanol molecules. The three different orientations of the CH_2 protons will split the OH peak into a *triplet* (1 : 2 : 1). Also, each of the lines of the CH_2 quartet would be split into a doublet as a result of two possible orientations of the OH proton which will produce two different local fields at the CH_2 protons. The NMR spectrum of pure ethanol thus consists of 3 lines for OH group, 8 lines for CH_2 group and 3 lines for CH_3 group. Since the CH_2 group in ethanol is flanked by OH and CH_3 groups, the magnitude of its splitting by the OH and CH_3 protons would be very much pronounced. However, the influence of the OH proton on the CH_3 protons will be negligible since these protons are not on adjacent carbon atoms.

The magnitude of the splitting between the lines of a given multiplet is given by the **spin-spin coupling constant** J (measured in units of Hz).

There are some general rules about spin-spin interactions which are helpful in calculating the number of lines expected in the NMR spectra. These are :

1. Protons of the same group do not interact among themselves to cause observable splitting (*e.g.*, the three protons in the CH_3 group do not interact with one another).

2. The multiplicity of the peak of a group of equivalent protons is determined by the *neighbouring* protons. In general, if n equivalent protons interact or couple with the protons on an adjacent carbon atom, the resonance peak is split into $n+1$ peaks or signals.

3. The intensities are symmetric about the mid-point of the group and the relative intensities of the $n+1$ peaks are given by the coefficients of the binomial expansion of order n, *i.e.*, $(1+x)^n$. These coefficients can be arranged in the so-called **Pascal's triangle**, as shown in Table 3.

TABLE 3

Pascal's Triangle giving Intensities of NMR Signals

Number of Protons, n	Number of NMR lines	Relative Intensities
0	1	1
1	2	1 1
2	3	1 2 1
3	4	1 3 3 1
4	5	1 4 6 4 1
5	6	1 5 10 10 5 1
6	7	1 6 15 20 15 6 1

It may be noted that the spin-spin interaction is *independent* of the applied magnetic field strength whereas the chemical shift depends on the field strength.

The proton-NMR spectrum of a molecule thus gives information about

(a) The *number of peaks* which enables us to know about the kinds of protons present in a molecule.

(b) *The positions of the peaks* which tell us about the electronic environment of each kind of proton.

(c) *The intensities of the peaks* which tell us about the number of protons of each kind that are present and

(d) *The splitting of a peak into several peaks* which tells us about the environment of a proton with respect to other nearby protons in the molecule.

Example 7. Predict the proton-NMR spectrum of ethyl acetate using the three rules mentioned earlier.

Solution : The molecule has the structure $CH_3—CO—O—CH_2—CH_3$

(a) From rule 1, there is no splitting due to spin-spin interaction of the protons in either of the two methyl groups or in the methylene group.

(b) From rule 2, the CH_2 protons split the CH_3 peak into three lines (*i.e.*, a triplet) and the CH_3 protons split the CH_2 peak into four lines (*i.e.*, a quartet).

(c) From rule 3, the intensities of the CH_3 triplet are given by the coefficients of the expansion $(1 + x)^2 = 1 + 2x + x^2$, *i.e.*, by the ratio of 1 : 2 : 1 and the intensities of the CH_3 quartet are given by the coefficients of the expansion $(1+x)^3 = 1 + 3x + 3x^2 + x^3$, *i.e.*, by the ratio of 1 : 3 : 3 : 1.

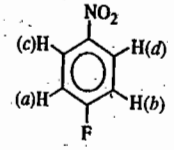
Example 8. Which of the following nuclei do not show nuclear magnetic resonance :

^1H, ^2H, ^{12}C, ^{13}C, ^{14}N, ^{15}N, ^{16}O, ^{19}F, ^{31}P, ^{32}S ?

Solution : Nuclei that contain odd number of protons and/or neutrons show NMR spectra, *i.e.*, are NMR-active since they have half-integral spin. Nuclei that have integral spin (in particular zero spin) are those which contain even numbers of protons and/or neutrons. These nuclei are NMR-inactive, *i.e.*, they do not show NMR. Thus, the NMR-inactive nuclei are ^{12}C (6p, 6n), ^{16}O (8p, 8n) and ^{32}S (16p, 16n).

Chemical Shift-Equivalent and Magnetically Equivalent Nuclei. If nuclei have exactly the same chemical shift, they are called **chemical shift-equivalent nuclei** and are designated by the same letter. Chemical shift-equivalent nuclei can be interchanged by one of the symmetry operations of a molecule. Thus, all the protons in benzene are chemical shift-equivalent since they can be interchanged by the six-fold symmetry axis of benzene.

If nuclei are coupled in exactly the same way to every other nucleus in the molecule, they are called **magnetically equivalent nuclei.** Thus, in parafluoronitrobenzene,



the protons *(a)* and *(b)* are chemical shift-equivalent since they are related by the mirror plane which bisects the molecule. The nuclear spin of F is $I = \frac{1}{2}$. Since F has identical bond distances and angles with respect to protons *(a)* and *(b)*, these protons are identically coupled to F. However, protons *(a)* and *(b)* are not identically coupled to protons *(c)* and *(d)*. Hence, they are not magnetically equivalent. Similarly, protons *(c)* and *(d)* are not magnetically equivalent.

Another way to decide the equivalence of two protons is by replacing each alternately by a group X. If the X derivatives are the same, the protons are equivalent. If the replacement of each H in a CH_2 gives 2 diastereomers, the protons are not equivalent.

Example 9. How many kinds of protons are there in

(i) CH_3CH_3 *(ii)* $CH_3CH_2CH_3$ *(iii)* $(CH_3)_2CHCH_2CH_3$ *(iv)* $C_6H_5CH_3$

(v) $C_6H_5NO_2$ *(vi)* $CH_2=CH_2$ *(vii)* $CH_3CH=CH_2$?

Solution : *(i)* One kind (all equivalent) : $CH_3^a\,CH_3^a$ *(ii)* 2 kinds : $CH_3^a\,CH_2^b\,CH_3^a$

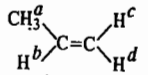
(iii) 4 kinds : $(CH_3^a)_2\,CH^b\,CH_2^c\,CH_3^d$

(iv) 2 kinds : $C_6H_5^a\,CH_3^b$

Theoretically there are three kinds of aromatic protons, *viz.*, ortho, meta and para. However, the ring protons are little affected by alkyl groups and are thus nearly equivalent.

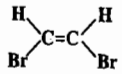
(v) 3 kinds : 2 ortho, 2 meta and one para. *(vi)* One kind (all equivalent)

(vii) 4 kinds :

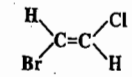


Example 10. Determine which of the following molecules will show spin-spin coupling in their NMR spectra. If the coupling or splitting is observed, give the multiplicity of each kind of proton, *i.e.*, give the number of lines arising from each proton :

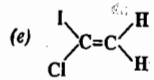
(a) $ClCH_2CH_2Cl$ *(b)* $ClCH_2CH_2I$ *(c)*



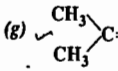
(d)



(e)



(f) $CH_3—CH=O$ *(g)*



(h) $CH_3—C(Cl_2)—CH_3$

Solution : Spin-spin splitting is not observed in *(a)*, *(c)*, *(g)* and *(h)* which have only equivalent protons. The protons of the CH_2 groups in *(b)* are non-equivalent each being split into a 1 : 2 : 1 triplet. In *(d)* the two protons are not equivalent and each is split into a doublet. The vinyl protons in *(e)* are not equivalent since one is *cis* to Cl and the other is *cis* to I so that each is split into a doublet. Notice that in this case the protons undergoing spin-spin interaction are on the same carbon. In *(f)* the protons of CH_3 and the proton of the —CH=O group are not equivalent ; the CH_3 resonance is split into a doublet and the —CH=O resonance is split into a 1 : 3 : 3 : 1 quartet.

Example 11. Predict the low-resolution NMR spectrum and the high-resolution NMR spectrum of acetone.

Solution : The low-resolution NMR spectrum shows only chemical shift of NMR lines of different protons whereas the high-resolution NMR spectrum shows both the chemical shift and the spin-spin coupling. However, in the case of acetone, $CH_3\diagdown\!\!\diagup C{=}O$, since all the protons are equivalent, only one line is observed in the low-resolution NMR as well as in the high-resolution NMR spectrum.

Example 12. An organic compound C_3H_6O contains a carbonyl group $\diagdown\!\!\diagup C{=}O$. How will its NMR spectrum decide whether it is an aldehyde or a ketone ?

Solution : The two possible structures are :

$CH_3^a\,CH_2^b\,CH^c{=}O$ and $CH_3^a\diagdown\!\!\diagup C{=}O$ (CH_3^a)

(I) (II)

For aldehyde (structure I), NMR spectrum will consist of a triplet for H^a, a complex multiplet (in fact, 8 lines) for H^b and a triplet for H^c. For ketone (structure II), since all the protons are equivalent, we will get only a singlet, *i.e.*, no spin–spin splitting occurs. Thus, the NMR spectrum would readily decide whether the compound is an aldehyde or a ketone.

Example 13. Predict the NMR spectrum of the compound $CH_3COCH_2C{\equiv}CCH_3$

Solution : Since in the compound $CH_3^a-CO-CH_2^b-C{\equiv}C-CH_3^c$, the three groups of protons (*a*, *b* and *c*) are far apart, no spin–spin coupling will be observed. Only the effects of chemical shifts of the three kinds of protons will be observed. H^a, H^b and H^c each will give rise to a singlet with relative intensities of 3 : 2 : 3, respectively.

Example 14. How do you account for the fact that nuclear spin–spin splitting is observed in 2–methyl propene but not in 1–chloro–2, 2–dimethyl propane ?

Solution : In 2-methyl propene,  although H^a and H^b are not on adjacent carbon atoms, they undergo spin–spin splitting because the coupling is transmitted through the π-electrons. In $(CH_3^a)_3C-CH_2^bCl$, H^a and H^b do not couple because they are not on adjacent carbon atoms : they are too far away from one another.

Example 15. How can the NMR spectrum distinguish between the isomers *p*–xylene and ethyl benzene ?

Solution : The isomers are

 *i.e.*, $p\text{-}CH_3^a\,C_6H_4^b\,CH_3^a$

 *i.e.*, $C_6H_5^a\,CH_2^b\,CH_3^c$

$p\text{-}CH_3^a\,C_6H_4^b\,CH_3^a$ has two kinds of protons and its NMR spectrum consists of two singlets. $C_6H_5^a\,CH_2^b\,CH_3^c$ has three kinds of protons and its NMR spectrum consists of a singlet for H^a, a quartet for H^b and a triplet for H^c.

Example 16. Predict the high–resolution proton–NMR spectra of CH_3CH_2Cl and CH_3CHDCl.

Solution : Deuterium(D) does not give a signal in the proton–NMR spectrum nor does it split the nearby protons. Thus, we can ignore its presence in the molecule. The NMR spectrum of $CH_3^a\,CH_2^bCl$ consists of 1 : 2 : 1 triplet for H^a and, more down–field, a 1 : 3 : 3 : 1 quartet for H^b. The NMR spectrum of $CH_3^a\,CH^bDCl$ has a doublet for H^a and, more downfield, 1 : 3 : 3 : 1 quartet for H^b.

Example 17. Predict the proton–NMR spectra of H_2, CH_4, C_2H_6 and C_6H_6.

Solution : All the four molecules contain equivalent protons which do not show spin–spin interaction. Hence, their proton–NMR spectra will consist of one signal only, *i.e.*, a *singlet*.

Example 18. Below are given the molecular formulae of some organic compounds that have only one NMR signal :

(*a*) C_5H_{12} (*b*) C_3H_6 (*c*) C_3H_4 (*d*) C_4H_6 (*e*) C_8H_{18} (*f*) C_2H_6O (*g*) $C_2H_4Br_2$

Draw structural formula for each of them.

Solution : Since there is only one NMR signal, all the protons must be equivalent.

(a) The compound is $(CH_3)_4C$ in which all 12 protons are present in 4 equivalent CH_3 groups.

(b) The compound is cyclopropane with structure,  which has 3 equivalent CH_2 groups.

(c) The compound has the structure, $H_2C{=}C{=}CH_2$ (allene) which has 2 equivalent CH_2 groups and a C atom with no protons.

(d) The compound has the structure, $CH_3C{\equiv}CCH_3$ which has 2 equivalent CH_3 groups and 2 carbons with no protons.

(e) The compound has the structure. $(CH_3)_3C-C(CH_3)_3$ which has 6 equivalent CH_3 groups and 2 other carbons with no protons

(f) The compound is dimethyl ether, CH_3-O-CH_3 which has 2 equivalent CH_3 groups.

(g) The compound has the structure, $BrCH_2-CH_2Br$ which has 2 equivalent CH_2 groups.

Example 19. Below are given the molecular formulae of some organic compounds that give 2 singlets in their proton–NMR spectra :

(*a*) $C_3H_6O_2$ (*b*) $C_3H_8O_2$ (*c*) C_2H_5OCl (*d*) $C_3H_5Cl_3$ (*e*) $C_5H_{10}Cl_2$.

Draw structural formula for each of them.

Solution : Since there is no spin–spin interaction, non–equivalent protons cannot be situated on adjacent carbons.

(a) The compound has the structure, $CH_3^aCO-O-CH_3^b$.

(b) The compound has the structure, $CH_3^a\,OCH_2^b\,OCH_3^a$

(c) The compound has the structure, $ClCH_2^a\,OCH_3^b$

(d) The compound has the structure, $CH_3^a\,CCl_2\,CH_2^b\,Cl$

(e) The compound has the structure, $ClCH_2^aC(CH_3^b)_2\,CH_2^a\,Cl$

Mechanism of Nuclear Spin–Spin Interaction. In 1951, N.F. Ramsey and E.M. Purcell proposed that in liquids and gases, the interaction between two nuclear spins is transmitted through the electrons of the chemical bonds that intervene between them. This is called *indirect electron–coupled nuclear spin–spin interaction.* Suppose two nuclear spins a and b are separated by a chemical bond formed between two electrons with spins 1 and 2, as follows :

If electron with spin 1 has a finite probability of being found at the nucleus with spin a, then the electron spin tends to be aligned antiparallel to the nuclear spin a. The electron spin 1 affects the alignment of spin 2 which, in turn, affects the alignment of nuclear spin b. Thus, as a result of the electron spin 1, the magnetic field at the other nucleus b is affected. In other words, the energy levels of nucleus b depend upon the spin orientation of nucleus a. It is thus evident that the nuclear spins a and b interact through the intervention of the electron spins 1 and 2. It may be remarked that this Ramsey–Purcell mechanism of nuclear spin–spin interaction is merely an extension of the so–called **Fermi contact interaction**, proposed by E. Fermi in 1930, according to which if an *s*–electron has a finite value of its wave function at the centre of a nucleus, then the electron spin can be 'felt' by the nuclear spin. N.F. Ramsey was the cowinner (with H.G. Dehmelt and W. Paul) of the 1989 Physics Nobel Prize.

One may well ask why there is no *direct nuclear* spin–spin interaction in liquids and gases. The reason is the following : According to electrodynamics, the energy of interaction through space between two nuclear dipole moments μ_1 and μ_2 (associated with the nuclear spins) is given by

$$E \propto \mu_1\mu_2\,(3\cos^2\theta - 1)/r^3 \qquad \ldots(22)$$

where r is the distance between μ_1 and μ_2 and θ is the angle between them. In a *solid*, this direct dipole–dipole interaction energy is found to be considerable. However, in fluids (*i.e.*, liquids and gases) due to the random *tumbling motion* of the molecules, the average value of $3\cos^2\theta = 1$ so that E vanishes. Thus, we find that while the direct dipole–dipole interaction is considerable in solids, it vanishes in liquids and gases.

The magnitude of nuclear spin–spin interaction falls off with increasing number of bonds intervening between the nuclei involved. This is expected because now the nuclei are too far to interact. A double bond, however, transmits spin–spin coupling more readily than a single bond, *i.e.*, the spin–spin coupling constant J between two atoms joined by a double bond is generally greater than

that joined by a single bond. The spin–spin coupling can also be transmitted through lone pair of electrons between nuclei that are sufficiently close together although not directly bonded.

The magnitude of the coupling constant J is also intimately related to the geometrical relationship of the bonds over which the coupling is transmitted. Thus, in the system H—C—C—H, the H—H coupling constant, known as the **vicinal coupling constant**, depends upon the dihedral angle ϕ between the C—H bonds. The angle ϕ is the angle between the projections of the two C—H bonds viewed along the C—C bond axis. It is found that

$$J_{vic} = 4{\cdot}22 - 0{\cdot}5 \cos \phi + 4{\cdot}5 \cos 2\phi \quad \ldots(23)$$

This is called the **Karplus relation**, proposed by the American chemical physicist, M. Karplus.

The variation of the vicinal coupling constant, J_{vic}, with the dihedral angle ϕ between the two vicinal C—H bonds, is shown in Fig. 11.

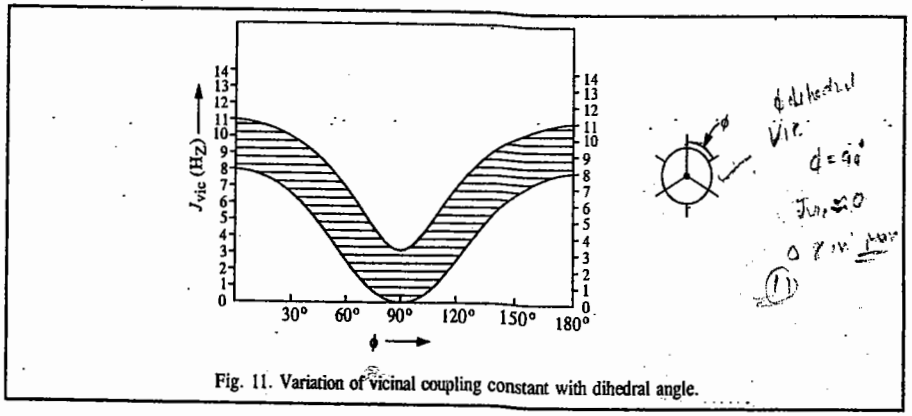


Fig. 11. Variation of vicinal coupling constant with dihedral angle.

Some typical J-values are given in Table 4.

TABLE 4

Spin–Spin Coupling Constants of Some Systems

System	J (Hz)	System	J (Hz)
H—H	276		7 to 10
H—F	521		
H—C	120 - 260		12 to 19
	- 20 to +6		
	5·5 to 7·5		ortho 6 to 9 meta 0·5 to 4 para 0 to 2·5

Largest vicinal couplings arise with the protons in the *trans* coplanar positions (ϕ=180°). Vicinal couplings for *cis* coplanar protons are almost as large (ϕ=0). Very small couplings arise between protons which are 90° to each other.

Complex NMR Spectra. The appearance of NMR spectra depends upon δ/J, *i.e.*, the ratio of the chemical shift to the spin–spin coupling constant. The spectra are called **first-order spectra** if δ/J is very large. The NMR spectrum of ethanol under high-resolution is a first-order spectrum. However, when the ratio δ/J is not large, several peaks appear resulting in a *complex* NMR spectrum.

NMR spectra are classified into AB system, AX system, ABC system, etc. If the chemical shift values of two nuclei are close together, the spin system is called an AB system. If, however, the chemical shift values of two nuclei are far apart (as in the case of hydrogen fluoride, HF) the spin system is called an AX system. Similarly, if the chemical shift values of three nuclei are close together, the system is called an ABC system. On the other hand, the spin system A_2BXY_2 has two A nuclei, one B nucleus with chemical shift close to that of the A nuclei and one X and two Y nuclei with chemical shift values close to one another but far removed from those of A and B.

Fig. 12 shows the NMR spectra of the AB spin system for J=10 Hz and δ/J values of *(a)* 5, *(b)* 4, *(c)* 3, *(d)* 2 and *(e)* 1. The inner pair of peaks has higher intensity than the outer pair. The coupling constant is obtained from the spacing between either pair of peaks. However, the differences in the values of the chemical shifts can be determined by an elaborate calculation involving the positions of all the peaks. The NMR spectra of complex nuclear systems are difficult to calculate quantum mechanically. They are *simulated* on high-speed computers.

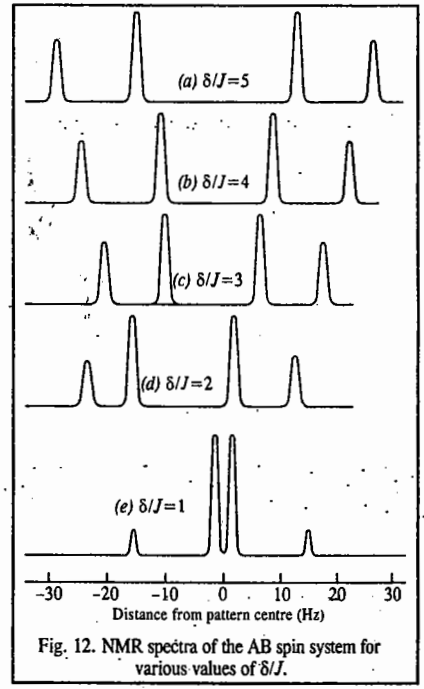

Fig. 12. NMR spectra of the AB spin system for various values of δ/J.

Complex NMR spectra can be simplified by methods which make chemical shift differences larger than spin–spin coupling constant. Since δ is *field-dependent* while J is *field-independent*, it is evident that a complex proton NMR spectrum, obtained at, say, 1·4 T (60 MHz), will be simplified if it is obtained at a higher field, say, 2·34 T (100 MHz). The NMR spectra run at 100 MHz yield chemical shifts almost twice as large as those run at 60 MHz. Spectral simplification can also be obtained by means of the so-called *shift reagents*, such as the complexes of the rare-earth metals, particularly those of europium and praseodymium. A small amount of the shift reagent added to the sample under study causes a marked increase in the chemical shift thereby reducing the distorted pattern of the spectrum.

NMR Spectra of Other Nuclei. Besides protons, other nuclei having nuclear spin $I=\frac{1}{2}$, such as ^{13}C, ^{19}F, ^{29}Si and ^{31}P, have also been investigated by NMR spectroscopy. The NMR spectra of ^{1}H and ^{19}F are most easily obtained because of their high natural abundance and large magnetogyric ratios. Spectra of other nuclei provide structural information about compounds the same way as the proton magnetic resonance spectra do. While ^{1}H-chemical shifts extend only over a small range of the order of 15 ppm, ^{31}P-chemical shifts have a span of about 400 ppm and ^{19}F-chemical shifts have a still wider span of 600 ppm. This wider range can be attributed to the greater number and mobility of extranuclear electrons which produce greater variation in diamagnetic shielding.

Nuclei such as ^{2}H, ^{10}B, ^{14}N, ^{35}Cl, etc., having nuclear spin $I > \frac{1}{2}$, do not have spherically symmetric charge distributions and, as a consequence, possess an electric quadrupole moment, eQ, where e is electric charge and Q is a measure of the deviation of the nuclear charge distribution

from spherical symmetry. Quadrupolar nuclei are quite "troublesome"; not only their own NMR lines are broadened but also those of the other nuclei in the molecule with which they undergo spin–spin interaction. Consider the two isotopically labelled ammonia molecules, $^{15}NH_3$ and $^{14}NH_3$. Whereas the NMR spectrum of the former (containing ^{15}N with $I=1/2$) is sharp, that of the latter (containing ^{14}N with $I=1$) is broad. The reason is that the electric qudrupole moment of the quadrupolar nucleus in question interacts with the fluctuating *EFG* (electric field gradient) which arises from the bonding and non-bonding electrons. This interaction effectively shortens the spin–lattice relaxation time, leading to broadening of NMR signal.

In recent years, the ^{13}C-NMR spectroscopy has emerged as a good structural tool although there is considerable difficulty in recording the ^{13}C-NMR spectra. This is due to the fact that ^{13}C has a very small natural abundance and a small value of the magnetogyric ratio.

Example 20. Predict the NMR spectrum of borohydride ion BH_4^-. The nuclear spin of ^{11}B is 3/2.

Solution : The four protons in BH_4^- are equivalent. Thus, the ^{11}B resonance splits into a quintet with the relative intensity ratio 1 : 4 : 6 : 4 : 1. Since the nuclear spin, I of ^{11}B is 3/2, in the presence of magnetic field its four components are +3/2, +1/2, –1/2 and –3/2. Thus, the proton resonance is split into a quartet by interaction with the ^{11}B nucleus, the four lines being equally intense.

Example 21. The ^{31}P-NMR spectrum of phosphonic acid gives a doublet whereas that of phosphinic acid gives a triplet. Write the structures of the two acids, justifying them.

Solution : Phosphonic acid,  Phosphinic acid, 
Both ^1H and ^{31}P have nuclear spin $I=1/2$. In phosphonic acid, the P atom is attached to one proton which causes its resonance to be split into a doublet. In phosphinic acid, the P atom is attached to two protons which cause its resonance to be split into a triplet in the intensity ratio 1 : 2 : 1.

Example 22. Describe the proton and deuteron-NMR spectra of HD.

Solution : For ^1H, $I=1/2$ and for ^2D, $I=1$. In the presence of magnetic field, the proton spin has two components, m_I = 1/2 and –1/2, whereas the deuteron spin has three components m_I = +1, 0 –1. Thus, the deuteron resonance is split by the proton into a doublet and the proton resonance is split by the deuteron into a triplet (1 : 2 : 1).

Example 23. Describe the proton-NMR and phosphorus-NMR spectra of phosphonium ion, PH_4^+.

Solution : Both ^1H and ^{31}P have $I=1/2$. Thus, the P atom splits the resonance of the four equivalent protons in PH_4^+ ion into a doublet and the protons split the phosphorus resonance into a quintet in the intensity ratio 1 : 4 : 6 : 4 : 1.

Example 24. Describe the proton-NMR and nitrogen-NMR spectra of the ammonium ion, NH_4^+.

Solution : ^1H has $I=1/2$ whereas ^{14}N has $I=1$. In the presence of the magnetic field, the ^{14}N-spin has three components : m_I = +1, 0, –1. Thus, the N-atom splits the resonance of the four equivalent protons in NH_4^+ ion into a 1 : 1 : 1 triplet. The protons split the nitrogen resonance into 1 : 4 : 6 : 4 : 1 quintet.

Example 25. Why is NMR spectrum of NH_3 broad whereas that of NH_4^+ ion is sharp ?

Solution : We know that ^{14}N ($I=1$) is a quadrupolar nucleus. The electric field gradient (*EFG*) at this nucleus due to the bonding electrons and the lone pair electrons on N atom interacts with the nuclear quadrupole moment of ^{14}N in NH_3, thereby broadening the NMR spectrum of ^{14}N which, in turn, broadens the spectrum of ^1H. However, in the case of NH_4^+ ion which is *spherically symmetrical*, the *EFG* vanishes (this is a result of quantum mechanics), so that there is *no* nuclear quadrupole interaction of *EFG* with the quadrupole moment of ^{14}N. Hence, the NMR spectrum of NH_4^+ ion is sharp.

FOURIER-TRANSFORM NMR SPECTROSCOPY

In 1966, R.R. Ernst and W.A. Anderson published a remarkable paper on the Fourier-Transform (FT) NMR spectroscopy. In this technique, spectra are presented in the *time-domain* as against the

conventional *continuous wave* (CW) NMR, where the spectra are presented in the *frequency domain*. In the frequency domain, the intensity of the radiation at the detector is a function of frequency, *i.e.*, $I(\nu)$, and in the time-domain, the intensity is a function of time, *i.e.*, $F(t)$. The $I(\nu)$ can be transformed by the mathematical technique known as **Fourier transform** into $F(t)$, as follows :

$$F(t) = \int_{-\infty}^{+\infty} e^{2\pi i\nu t} I(\nu)\, d\nu \qquad ...(24a)$$

Conversely, $F(t)$ can be transformed into $I(\nu)$ by the **inverse Fourier transform** :

$$I(\nu) = \int_{-\infty}^{+\infty} e^{-2\pi i\nu t} F(t)\, dt \qquad ...(24b)$$

These transforms are carried out by a computer attached to the NMR apparatus. $F(t)$ contains all the information about the NMR spectrum that $I(\nu)$ does. Now the question arises : Why do we need $F(t)$ if $I(\nu)$ can do the job ? The reason is that to measure the NMR spectrum in the frequency domain, one has to scan a very broad range of frequencies, which is time-consuming. On the other hand, to record the spectrum in the time-domain, *one can apply all the frequencies in a very short time*. Thus, a CW-NMR spectrum which takes, say, 25 minutes to scan, can be scanned in 25 seconds as FT-NMR spectrum. Clearly, FT-NMR is vastly faster than CW-NMR.

In order to excite FT-NMR, the band of frequencies required is obtained by applying a short, approximately square-wave pulse of radiofrequency power in the xy plane. Fig. 13 shows the Fourier synthesis of a square wave which is a superposition of several sinosoidal waves. Better approximation to square wave can be achieved by including more sine waves. Conversely, the analysis of $F(t)$ into its Fourier components yields a whole spectrum of different superimposed harmonic (sinosoidal) waves. In the pulsed FT-NMR spectrometer, the pulse B_1 is supplied by a radiofrequency field that has the Larmor (NMR) frequency ν_0 which is of the order of 100 MHz for ^1H-NMR. The Fourier components add to, or subtract from, this carrier frequency. Suppose the length of the pulse is t_p ($\approx$ 100 μs). The sample receives a range of frequencies of about $\nu_0 \pm 1/t_p$ which, in the present example, are 100 MHz ± 10 kHz.

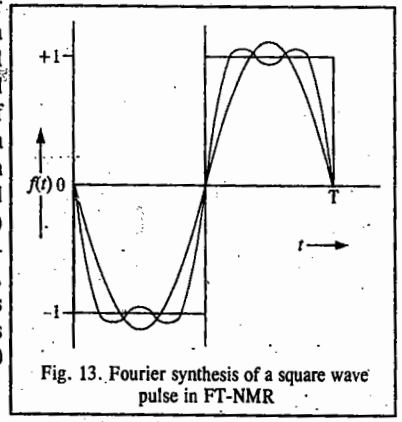

Fig. 13. Fourier synthesis of a square wave pulse in FT-NMR

As soon as the radiofrequency pulse B_1 terminates, the magnetization vector (of all the magnetic nuclei in the sample) in the xy-plane starts decaying. This important process is called **free induction decay** (FID) because the nuclei are freely precessing about the Zeeman field, B_0, in the absence of the radio frequency field B_1. Without going into details, we may remark that in order to improve the *signal-to-noise* (S/N) *ratio*, several consecutive pulses can be applied to the sample thereby considerably enhancing the intensity of the signal. The FIDs are collected in the computer and averaged before being Fourier-transformed to give the $I(\nu)$ spectrum. Most modern NMR spectrometers are based on the Fourier-transform technique. The Swiss scientist R.R. Ernst (1933 –) was awarded the 1991 Chemistry Nobel Prize for his contributions to the development of the methodology of high resolution NMR spectroscopy.

Thermal Equilibrium of Nuclear Spins and the Relaxation Processes in Magnetic Resonance

The Zeeman splitting of the nuclear or electron spins obtained by applying magnetic fields at room temperature, is very small. The relative Boltzmann population of the nuclear spins in the upper state and in the lower state is given by

$$n_{upper}/n_{lower} = \exp(-\Delta E/kT) = \exp(-g_N \mu_N B_0/kT) \qquad ...(25)$$

where n_{upper} and n_{lower} are the numbers of spins in the upper and lower energy states. At room temperature, $g_N \mu_N B_0 << kT$ so that the exponential can be approximated by a power series to give :

$$n_{upper}/n_{lower} \approx 1 - (g_N \mu_N B_0/kT) \quad ...(26)$$

The excess population in the lower state is then given by

$$\frac{n_{lower} - n_{upper}}{n_{lower} + n_{upper}} = \frac{g_N \mu_N B_0}{2kT} \quad ...(27)$$

which, for ordinary temperatures and magnetic field B_0, is very small. Now only the spins in the low energy state can absorb radiation which has to be of the right frequency to be absorbed. Since the excess population in the lower energy state is directly proportional to the magnetic flux density, B_0, the intensity of the NMR signal increases as B_0 increases. If the spin system is irradiated with too high a power, the excess spins at the lower energy will be used up so that the upper and lower energy states will become *equally populated*. No further energy can be absorbed from the field and the resonance absorption becomes *saturated*. As a result, no NMR measurement is possible. Fortunately, there is a mechanism whereby this situation is avoided. To record an NMR spectrum, there is a process known as **relaxation** *which removes the excitation energy from the upper state to restore the excess population in the ground state* so that the energy can be continuously absorbed from the radiofrequency field, B_1.

The transition from the lower to upper energy state corresponds to flipping of the nuclear magnetic moment vector from one allowed orientation to the other in the large Zeeman field B_0. In the ground state, the proton spins are aligned so that the z-components of the magnetic moment μ_z are in the direction of B_0. The radiofrequency field B_1 flips the nuclear moments to the opposite direction as the energy is absorbed. The relaxation process flips them back to the original orientation with the result that *the spin system returns to the ground state by transferring its energy of excitation to the random thermal motions in the surroundings.* In other words, the nuclear spin system becomes *cooler* and its surroundings become *warmer* as a result of the energy transfer.

If the excess number of nuclei in the lower energy level is represented by n and the initial number is n_0, the approach to the new equilibrium n_{eq} is described by

$$n - n_{eq} = (n_0 - n_{eq}) \exp(-t/T_1) \quad ...(28)$$

where t is the time and T_1 is called the **spin-lattice relaxation time**. The name *spin-lattice relaxation* originates from the fact that the first experiments were carried out on solid samples where the relaxation was brought about by the transfer of spin excitation energy to the lattice vibrations. The term spin-lattice relaxation has been retained but it refers to relaxation due to fluctuating magnetic fields arising from random motions in the surroundings of the spin system. This, in brief, is the basis of the so-called **Bloembergen-Purcell-Pound (BPP)** theory of relaxation processes in magnetic resonance, proposed in 1948. The detailed theory of the relaxation processes in magnetic resonance is very complicated, having been worked out by theorists such as Waller, van Vleck, Bloembergen, Purcell, Pound, Kubo and Tomita. It may be mentioned here that another quantity, the **transverse relaxation time**, T_2, also characterizes the relaxation process. The T_2-relaxation amounts to *loss of phase coherence of the precessing spins*. It can be considered as the characteristic time for the *transfer of entropy* from the surroundings to the spins. The most common cause of the T_1-relaxation is the magnetic dipole-dipole interaction. Paramagnetic substances, if present in the sample, *increase* the efficiency of the nuclear spin relaxation and thus *decrease* T_1. In liquids, T_1 and T_2 are almost equal. In solids, T_2 is of the order of microseconds. E.M. Purcell was the cowinner (with F. Bloch) of the 1952 Physics Nobel Prize and N. Bloembergen, the cowinner (with K. Siegbahn and A.L. Schawlow) of the 1981 Physics Nobel Prize.

Example 26. Calculate the relative Boltzmann population of the proton spins in the lower state to that in the upper state in a magnetic field of flux density 1T at room temperature. What is the excess population in the lower state ?

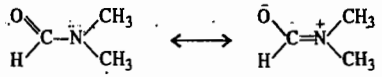
Solution :

$$\frac{n_{lower}}{n_{upper}} = 1 + \frac{g_N \mu_N B_0}{kT} = 1 + \frac{(5{\cdot}585)(5{\cdot}05 \times 10^{-27}\,JT^{-1})(1T)}{(1{\cdot}38 \times 10^{-23}\,JK^{-1})(298\,K)} = 1 + 6{\cdot}686 \times 10^{-6}$$

$$\frac{n_{lower} - n_{upper}}{n_{lower} + n_{upper}} = \frac{g_N \mu_N B_0}{2kT} = 3{\cdot}343 \times 10^{-6}$$

Study of Hindered Rotation by NMR Spectroscopy

When the NMR spectrum of N, N-dimethyl formamide (DMF), $HCON(CH_3)_2$, is recorded at room temperature, it consists of *two* signals, though one would expect the two CH_3 groups in magnetically equivalent environments. DMF is a resonance hybrid of the following forms which result from the conjugation between the carbonyl group and the nitrogen nonbonding pair, as a consequence of which the double-bond character of the C—N bond is increased sufficiently to cause hindered rotation at room temperature :



Similarly, the NMR spectrum of N,N-dimethylacetamide, consists of two NMR signals at room temperature as a result of hindered rotation about the C—N double bond :

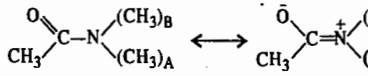


Fig. 14 shows the pmr (*i.e.*, proton-NMR) spectrum of N,N-dimethylacetamide when it is heated from 308 K to 368 K. At the lower temperature, two peaks are observed because the molecular skeleton is almost planar and the protons in the two methyl groups have different chemical shifts ν_A and ν_B. As the temperature is increased, the rate of the *cis-trans* isomerization increases so that at higher temperatures a single pmr signal is obtained since the rotation about the C—N bond is very rapid compared with the difference in the chemical shifts.

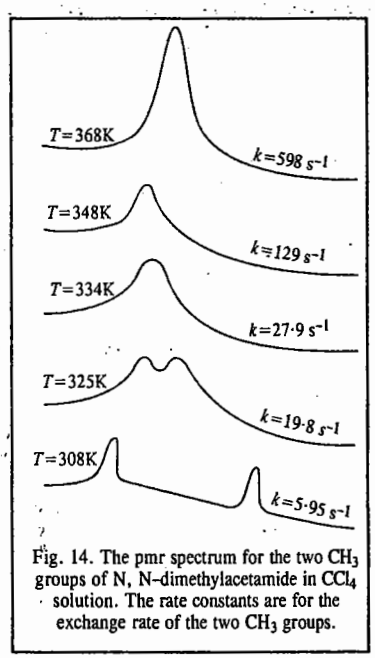

Fig. 14. The pmr spectrum for the two CH_3 groups of N, N-dimethylacetamide in CCl_4 solution. The rate constants are for the exchange rate of the two CH_3 groups.

Another example is that of 1, 2-dibromoethane ($BrCH_2CH_2Br$) whose four protons appear to be chemically indistinguishable and thus magnetically equivalent so that one would expect the NMR spectrum to show the same chemical shift for all the protons. However, the Newman projections shown in Fig. 15 show that the protons in different conformations are not in magnetically equivalent environments. Thus, the ringed proton is flanked by H and Br in the first conformer but by H and H in the second. The pmr spectrum, recorded at *low temperatures*, will enable these features to be distinguished since the molecular rotations about the C—C bond are sufficiently 'frozen'.

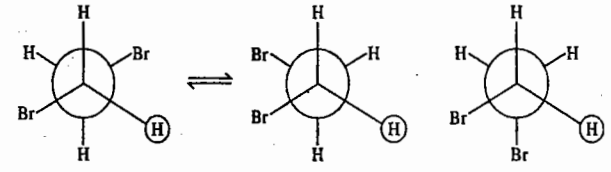

Fig. 15. Rotational isomers of 1, 2-dibromoethane.

However, at room temperature, the rotation is so rapid that each proton experiences the same time-averaged environment and only one sharp peak appears in the pmr spectrum.

Similar effects are found in *fluxional* molecules and in structures where steric effects can intervene as, for example, in the case of cyclohexane. (Fig. 16) :

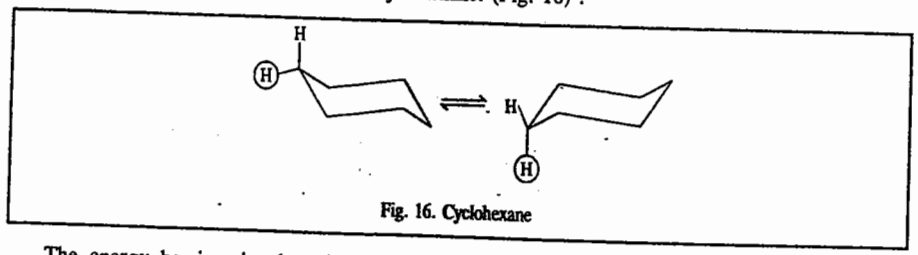

Fig. 16. Cyclohexane

The energy barriers involved in these rotational changes can be measured by NMR using a variable-temperature sample probe and noting the temperature at which the spectrum changes from that of the mixed conformers to that of a time-averaged situation. The basic theory of the exchange effects is outlined below.

For a reaction A $\rightleftarrows$ B, the mean life-time of the species A is $\tau = k_1^{-1}$ where k_1 is the first-order rate constant for the exchange. Thus, the width of the NMR peak (*i.e.*, signal) at half-height is $\delta\nu = k_1/\pi$. However, before we use this relation to calculate k_1, we must subtract the natural line width in the absence of exchange to obtain the residual broadening due only to exchange. In the other limit, at high exchange rates when the individual peaks have fused or coalesced, the line width is $\delta\nu = \pi(\nu_A - \nu_B)^2/k_1$, where ν_A and ν_B are the individual frequencies of the peaks for A and B, as determined by the measurements at low temperatures. At the temperature at which the NMR spectrum changes from that of two peaks to that of a single peak, *i.e.*, the flat-topped peak,

$$k_{1_c} = \pi\Delta\nu_0/\sqrt{2} \qquad \ldots(29)$$

where $\Delta\nu_0$ is the frequency separation between the two peaks.

Example 27. At the coalescence temperature 331 K, the frequency separation between the two NMR signals of N,N-dimethylacetamide is 10·85 Hz. Calculate the rate constant for the first-order chemical exchange of the two methyl groups.

Solution : $k_1 = \pi\,\Delta\nu_0/\sqrt{2} = \pi\,(10{\cdot}85\ s^{-1})/\sqrt{2} = 24{\cdot}1\ s^{-1}$

The Arrhenius-type plot of ln k_1 versus $1/T$ enables the evaluation of the activation energy which in this case is found to be 70 kJ mol^{-1}.

NUCLEAR MAGNETIC DOUBLE RESONANCE

Nuclear magnetic double resonance (NMDR), also called *double irradiation* or *spin decoupling*, is a technique very frequently used in the interpretation of complex NMR spectra. It is based on the principle that when one group of equivalent protons in a molecule is *irradiated* by applying very strong stationary radiofrequency field at the Larmor (resonance) frequency of the protons, it can no longer undergo spin-spin coupling with the neighbouring groups containing equivalent protons. As a result, the spectrum is simplified.

Fig. 17 shows the double resonance spectrum for pure ethanol. When protons of CH_3 group are irradiated (Fig. 17*b*), the resonance of the methylene protons collapses to a doublet because they are coupled only with the OH proton ; the coupling with CH_3 protons is destroyed. Similarly, when protons of the CH_2 group are irradiated (Fig. 17*c*), the resonances of the OH and methyl protons both collapse to singlets.

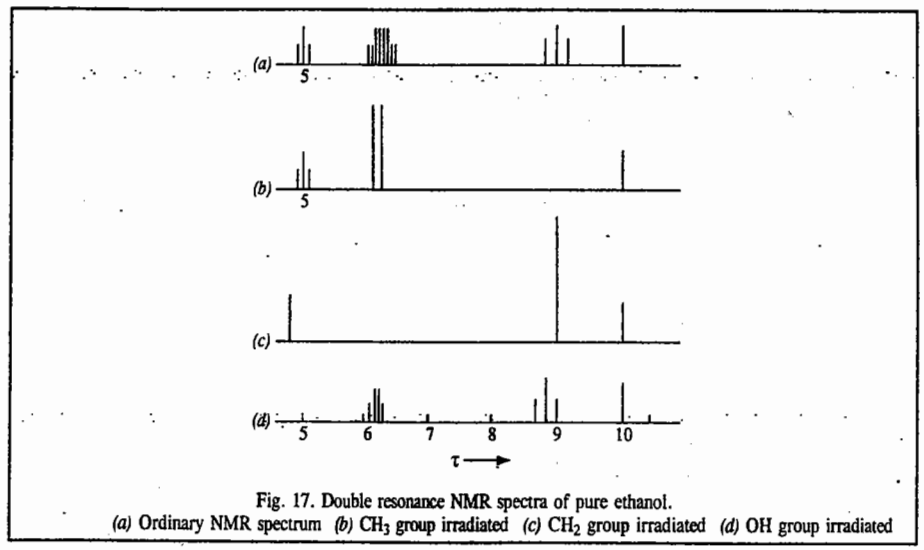

Fig. 17. Double resonance NMR spectra of pure ethanol.
(a) Ordinary NMR spectrum *(b)* CH_3 group irradiated *(c)* CH_2 group irradiated *(d)* OH group irradiated

Since an additional field is used, the experiment is called double resonance. Double irradiation always yields a simpler spectrum. For example, in an ABX spectrum, where it is difficult to extract coupling constants, irradiation of the X nucleus yields a simple AB system from which spin-spin coupling constants can be easily obtained.

SPECIAL TOPICS IN NUCLEAR MAGNETIC RESONANCE

1. Quantum Mechanical Description of the NMR Spectrum of an AB Spin System

The AB spin system is the simplest spin system. Consider a spin system of two nuclei A and B both having nuclear spin $I = 1/2$. In the presence of the Zeeman magnetic field, B_z, applied in the z-direction, the Hamiltonian for the various magnetic interactions is given by

$$\hat{H} = \hat{H}_{\text{Zeeman}} + \hat{H}_{sc} + \hat{H}_{\text{dip}} \qquad \ldots(30)$$

$\hat{H}_{\text{Zeeman}}$, which represents the interaction of the nuclei with B_z, is given by

$$\hat{H}_{\text{Zeeman}} = -g_N\mu_N I_z^A B_z(1-\sigma_A) - g_N\mu_N I_z^B B_z(1-\sigma_B) \qquad \ldots(31)$$

where I_z^A and I_z^B are the components of the nuclear spin quantum numbers of the nuclei A and B in the z-direction. $\hat{H}_{sc}$ (which represents the scalar coupling), is, in fact, the *indirect* spin-spin interaction, given by

$$\hat{H}_{sc} = J\,\boldsymbol{I}^A\cdot\boldsymbol{I}^B \qquad \ldots(32)$$

where J, the coupling constant, is a measure of the spin-spin interaction, and is given in Hz. The dipolar Hamiltonian, $\hat{H}_{\text{dip}}$, is given by

$$\hat{H}_{\text{dip}} = g_N^2\mu_N^2\left[\frac{\boldsymbol{I}^A\cdot\boldsymbol{I}^B}{r^3} - \frac{3(\boldsymbol{I}^A\cdot\boldsymbol{r})(\boldsymbol{I}^B\cdot\boldsymbol{r})}{r^5}\right] \qquad \ldots(33)$$

(Here r is the distance between the two nuclei). This Hamiltonian represents the *direct* interaction between the two nuclear spins in space. As a result of fast tumbling motion of molecules in the *liquid state*, it averages to zero. (It does not vanish in the solid state but we are here concerned with the NMR of the AB system in the liquid state.) It is convenient to work in frequency units, so Eq. 1 can be written as

$$\hat{H} = -\nu_0(1-\sigma_A)I_z^A - \nu_0(1-\sigma_B)I_z^B + JI^A \cdot I^B \quad ...(34)$$

where $$I^A \cdot I^B = I_x^A I_x^B + I_y^A I_y^B + I_z^A I_z^B \quad ...(35)$$

The Schrödinger wave equation is

$$\hat{H}\psi = E\psi \quad ...(36)$$

where ψ, the exact eigenfunction of $\hat{H}$, can be written as a linear combination of the basis set, *i.e.*, the basis spin functions ϕ_i :

$$\psi = \sum_i c_i \phi_i \quad ...(37)$$

For a two-nuclei AB system with $I = \frac{1}{2}$, there are four possible combinations of nuclear spins given by

$$\phi_1 = \alpha^A \alpha^B; \ \phi_2 = \alpha^A \beta^B \quad ...(38a)$$

$$\phi_3 = \beta^A \alpha^B; \ \phi_4 = \beta^A \beta^B \quad ...(39b)$$

Assuming that ψ is normalized, the energy E in Eq. 36 is given by

$$E = <\psi|\hat{H}|\psi> = \int \psi \hat{H} \psi \, d\tau \quad ...(39)$$

Using the variation method, the values of E are obtained by solving the secular determinant :

$$\begin{vmatrix} H_{11}-E & H_{12} & H_{13} & H_{14} \\ H_{21} & H_{22}-E & H_{23} & H_{24} \\ H_{31} & H_{32} & H_{33}-E & H_{34} \\ H_{41} & H_{42} & H_{43} & H_{44}-E \end{vmatrix} = 0 \quad ...(40)$$

We are now interested in evaluating the matrix elements H_{ij} occurring in Eq. 40. We can do this by employing the so-called *raising* and *lowering operators*, I^+ and I^-, defined by

$$I^+ = I_x + iI_y \quad ...(41a)$$

$$I^- = I_x - iI_y \quad ...(41b)$$

From the theory of angular momentum, these operators are known to have the following properties:

$$I^+|\alpha> = 0; \ I^+|\beta> = 1\alpha> \quad ...(42a)$$

$$I^-|\alpha> = \beta; \ I^-|\beta> = 0 \quad ...(42b)$$

Thus, we have $$I^{A+}I^{B-} = (I_x^A I_x^B + I_y^A I_y^B) + i(I_y^A I_x^B - I_x^A I_y^B) \quad ...(43a)$$

$$I^{A-}I^{B+} = (I_x^A I_x^B + I_y^A I_y^B) - i(I_y^A I_x^B - I_x^A I_y^B) \quad ...(43b)$$

Hence, Eq. 34 can be rewritten as

$$\hat{H} = \nu_0(1-\sigma_A)I_z^A - \nu_0(1-\sigma_B)I_z^B + J\left[I_z^A I_z^B + \tfrac{1}{2}(I^{A+}I^{B-} + I^{A-}I^{B+})\right] \quad ...(44)$$

It can be shown that if ϕ_i and ϕ_j have different values of m_I (the component of nuclear spin), then

$$\int \phi_i \hat{H} \phi_j \, d\tau = \int \phi_j \hat{H} \phi_i \, d\tau = 0 \quad ...(45)$$

The various matrix elements H_{ij} in Eq. 40 can be shown to be given by

$$H_{11} = -\frac{\nu_0}{2}(1-\sigma_A) - \frac{\nu_0}{2}(1-\sigma_B) + \frac{J}{4}$$

$$H_{22} = \frac{\nu_0}{2}(1-\sigma_A) - \frac{\nu_0}{2}(1-\sigma_B) - \frac{J}{4}$$

$$H_{33} = -\frac{\nu_0}{2}(1-\sigma_A) + \frac{\nu_0}{2}(1-\sigma_B) - \frac{J}{4}$$

$$H_{44} = \frac{\nu_0}{2}(1-\sigma_A) + \frac{\nu_0}{2}(1-\sigma_B) + \frac{J}{4}$$

$$H_{23} = H_{32} = \frac{J}{2}$$

The remaining matrix elements H_{12}, H_{21}, H_{13}, H_{31}, H_{14}, H_{41}, H_{24}, H_{42}, H_{34} and H_{43} are all zero. Eq. 40 now becomes

$$\begin{vmatrix} x_1 & 0 & 0 & 0 \\ 0 & x_2 & \frac{J}{2} & 0 \\ 0 & \frac{J}{2} & x_3 & 0 \\ 0 & 0 & 0 & x_4 \end{vmatrix} = 0 \quad ...(46)$$

where

$$x_1 = -\frac{\nu_0}{2}(1-\sigma_A) - \frac{\nu_0}{2}(1-\sigma_B) + \frac{J}{4} - E$$

$$x_2 = \frac{\nu_0}{2}(1-\sigma_A) - \frac{\nu_0}{2}(1-\sigma_B) - \frac{J}{4} - E$$

$$x_3 = -\frac{\nu_0}{2}(1-\sigma_A) + \frac{\nu_0}{2}(1-\sigma_B) - \frac{J}{4} - E$$

$$x_4 = \frac{\nu_0}{2}(1-\sigma_A) + \frac{\nu_0}{2}(1-\sigma_B) + \frac{J}{4} - E$$

The solution of the secular determinant (Eq. 46) yields

$$E_1 = \nu_0\left(-1 + \frac{\sigma_A}{2} + \frac{\sigma_B}{2}\right) + \frac{J}{4} \quad ...(47a)$$

$$E_4 = \nu_0\left(1 - \frac{\sigma_A}{2} - \frac{\sigma_B}{2}\right) + \frac{J}{4} \quad ...(47b)$$

Thus, $$E_1 = -M + \frac{J}{4}; \ E_4 = M + \frac{J}{4} \text{ where } M = \nu_0\left(1 - \frac{\sigma_A}{2} - \frac{\sigma_B}{2}\right)$$

For the other two energy values (E_2 and E_3) we have to evaluate the roots of the secular determinant

$$\begin{vmatrix} \frac{\nu_0}{2}(1-\sigma_A) - \frac{\nu_0}{2}(1-\sigma_B) - \frac{J}{4} - E & \frac{J}{2} \\ \frac{J}{2} & -\frac{\nu_0}{2}(1-\sigma_A) + \frac{\nu_0}{2}(1-\sigma_B) - \frac{J}{4} - E \end{vmatrix} = 0 \quad ...(48)$$

which yields $$E = -\frac{J}{4} \pm \left(\frac{\nu_0^2\delta^2}{4} + \frac{J^2}{4}\right)^{1/2} \quad \text{where } \delta = \sigma_A - \sigma_B$$

Thus, we have

$$E_2 = -\frac{J}{4} - \frac{1}{2}(\nu_0^2\delta^2 + J^2)^{1/2} = -\frac{J}{4} - \frac{1}{2}\nu_0\delta\left(1 + \frac{J^2}{2\nu_0^2\delta^2} + \ldots\ldots\right) \qquad \ldots(49a)$$

and $$E_3 = -\frac{J}{4} + \frac{1}{2}(\nu_0^2\delta^2 + J^2)^{1/2} = -\frac{J}{4} + \frac{1}{2}\nu_0\delta\left(1 + \frac{J^2}{2\nu_0^2\delta^2} + \ldots\ldots\right) \qquad \ldots(49b)$$

[In Eqs. (49*a*) and (49*b*), we have used the Taylor's series expansion, *viz.*,

$$(1+x)^{1/2} \approx 1 + x/2 + x^2/4 + \ldots\ldots]$$

Fig. 18 shows the energy level changes due to the various interactions.

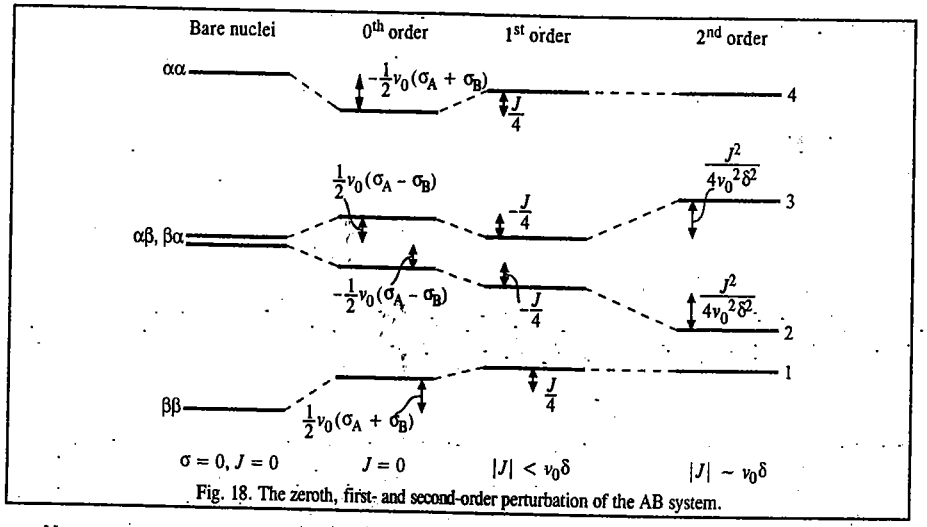

Fig. 18. The zeroth, first- and second-order perturbation of the AB system.

Next we are interested in the selection rules for the NMR transitions of the AB system. We apply the radio-field $\boldsymbol{B}_1$ to the sample to bring about transitions between nuclear sub- energy levels *m* and *n*. Experimentally $\boldsymbol{B}_1$ is applied in the *x*-direction; thus, $\boldsymbol{B}_1$ is perpendicular to the external Zeeman (magnetic) field $\boldsymbol{B}_z$. (If $\boldsymbol{B}_1$ and $\boldsymbol{B}_z$ are in the same z-direction, then the effect is merely the modulation of the Zeeman energy levels.) The interaction between $\boldsymbol{B}_1$ and the nuclear magnetic moment μ_x is given by the Hamiltonian , $\hat{H}'$:

$$\hat{H}' = \mu_x \boldsymbol{B}_1 \qquad \ldots(50)$$

where μ_x is the component of the nuclear magnetic moment in the *x*-direction. The transition probability is proportional to the square of the matrix element (or transition moment integral) $|< \psi_n |\hat{H}'| \psi_m >|^2$ or simply to $|< \psi_n |I_x| \psi_m >|^2$ since $\mu_x = I_x/\hbar\gamma$ where γ is the magnetogyric ratio of the nucleus. Omitting details, we can show that this last matrix element is zero (by substituting $I_x = (I^+ + I^-)/2$) unless the magnetic

spin quantum numbers for the two spin states *m* and *n* differ by ±1. Thus, the selection rule for the NMR transitions is $\Delta m_I = \pm 1$.

Using this selection rule, the allowed spectral transitions (in Hz) are :

$$E_2 - E_1 = -\frac{J}{2} + M - \frac{1}{2}\nu_0\delta\xi \qquad \ldots(51a)$$

$$E_3 - E_1 = -\frac{J}{2} + M + \frac{1}{2}\nu_0\delta\xi \qquad \ldots(51b)$$

$$E_4 - E_2 = \frac{J}{2} + M + \frac{1}{2}\nu_0\delta\xi \qquad \ldots(51c)$$

$$E_4 - E_3 = \frac{J}{2} + M - \frac{1}{2}\nu_0\delta\xi \qquad \ldots(51d)$$

where $$\xi = \left(1 + \frac{J^2}{2\nu_0^2\delta^2} + \ldots\ldots\right)$$

Fig. 19 shows the theoretical NMR spectra for the AB system for various values of *J* and $\nu_0\delta$.

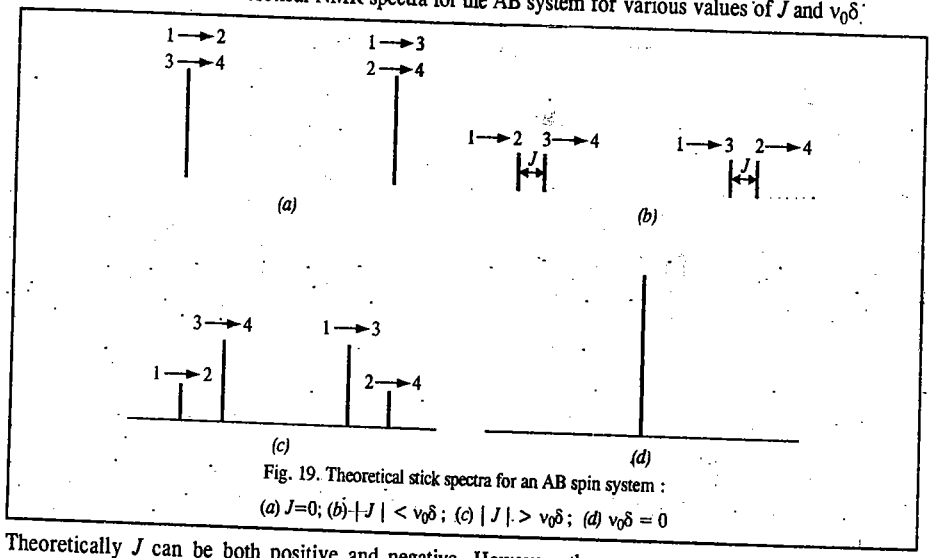

Fig. 19. Theoretical stick spectra for an AB spin system :
(*a*) *J*=0; (*b*) |*J*| < $\nu_0\delta$; (*c*) |*J*| > $\nu_0\delta$; (*d*) $\nu_0\delta$ = 0

Theoretically *J* can be both positive and negative. However, the appearance of the NMR spectrum depends only on the modulus of *J*, *i.e.*, | *J* |, the absolute magnitude.

With reference to Figs. 18 and 19, the following points may be noted :

1. In Fig. 18, the labelling of energy levels (| αα >, | αβ >, etc.) applies only to bare nuclei, zeroth- and first-order case. In the second-order perturbation case, the energy levels originally corresponding to |αβ > and |βα > are "mixed" ; they are thus really represented by linear combinations of the type (| αβ > ± | β α >).

2. In the first-order case where | *J* | < $\nu_0\delta$, the system is said to be *weakly coupled* and is usually called an AX system rather than AB system. The AB case applies only when there is a strong coupling between the nuclei, *i.e.*, | *J* | > $\nu_0\delta$.

3. Though the position and intensity of the spectral lines may change depending on the magnitude of the spin-spin interaction, the total area under the observed spectrum is the same for all cases.

4. When two nuclei have the same chemical shift, only one line is observed even though there is spin-spin interaction between them.

In practice, the analysis of an NMR spectrum is carried out by trial and error. This method consists in making intelligent guesses of Js and $\nu_0\delta s$ and constructing theoretical spectra to compare with the experimental spectrum.

2. Two-Dimensional NMR Spectroscopy

In Fig. 20, the rectangles denote radio frequency pulses applied to an NMR sample. Fig. 20(a) shows a single radio frequency pulse applied to the system followed by observation of the FID (free induction decay) as a function of time t. Fourier transformation of this function of t gives the NMR spectrum as a function of frequency ν.

This is a one-dimensional (1D) NMR spectrum. In Fig. 20(b) a pulse is applied, and after a time t_1, a second pulse is applied, and the FID is observed as a function of time t_2 upto a time $t_{2,max}$. Fourier transformation of this function of t_2 gives the NMR spectrum as a function of frequency. The spectrum's appearance will be influenced by the first pulse. We have obtained the spectrum as a function of a single variable; so this is still a 1D spectrum.

Now suppose we repeat the experiment in Fig. 20(b) except that we use a slightly longer time t_1 between the two pulses. We then repeat the experiment using successively larger values of the time interval t_1 between the two pulses. By collecting all the FIDs from the successive experiments, we get an FID that is now a function $f(t_1, t_2)$ of two variables t_1 and t_2. If we now do a Fourier transformation of $f(t_1, t_2)$ by integrating over both t_1 and t_2, we will get an NMR spectrum that will be a function of two frequencies : $f(\nu_1,\nu_2)$. This spectrum is called a **two-dimensional (2D) NMR spectrum.** The frequency ν_2 has the same meaning as the frequency in 1D NMR. The significance of the frequency ν_1 depends on the nature of the pulses used in the experiments. Over 100 different pulse patterns have been used in 2D NMR. Figs. 20(c) and 20(d) show two other pulse patterns. In Fig. 20(c), the time interval Δ remains fixed and t_1 is varied. In Fig. 20(d), the second pulse is twice as long as the first.

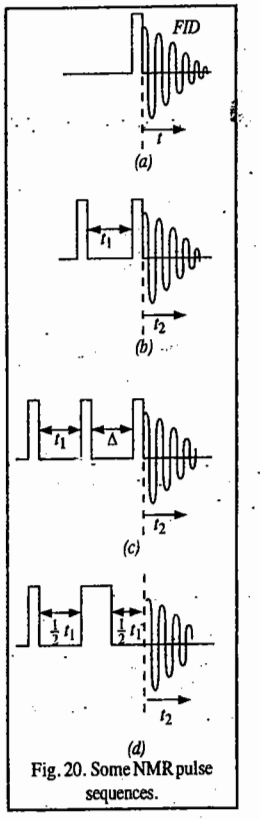

Fig. 20. Some NMR pulse sequences.

The proton NMR spectra of large molecules such as steroids, oligosaccharides, proteins, nucleic acids contain many overlapping lines and the lines that are extremely hard to assign to specific protons, even using very high field spectrometers. By using 2D NMR, we can resolve very complicated spectra and determine the structure and conformation of compounds for which the 1D spectrum is hopelessly complex. The development of 2D NMR in the 1980s has produced a revolutionary increase in the power of NMR to deduce the structures of large molecules. For further information refer to the following books :

Croasman, W.R., and R.M.K. Carlson (eds.), *Two-Dimensional NMR Spectroscopy*, VCH, 1987.

Schraml, J. and J.M. Bellama, *Two Dimensional NMR Spectroscopy*, Wiley, 1988.

3. NMR Spectra of Solids

The NMR spectra of solids, as ordinarily observed, are of little value. The first major difficulty is that dipolar couplings (the direct spin-spin interactions) which are averaged to zero by fast molecular tumblings in liquids, are not averaged to zero in solids. The long range couplings are also important. The combined effect of the many couplings in solids is to give very broad lines (resonances), often tens of kHz wide. (Changes in line widths can sometimes be used to give information about internal motions

in solids.) Secondly, the chemical shift of a nucleus depends on the orientation of the molecule with respect to the magnetic field, and in solids the effect of this chemical shift anisotropy is not averaged out by molecular tumbling and thus leads to line broadening, again of thousands of Hz. Study of this anisotropy may be helpful, but for our purposes we regard it only as something to overcome. Finally, again because of the immobility of the nuclei, the relaxation time T_1 is very long, which implies that multi-pulse methods are not very efficient. Hence, it is very difficult to get NMR spectra with good signal-to-noise ratio. Thus, solids give broad, featureless resonances with little information. However, by using special techniques, such as rapidly spinning the sample about an axis making angle θ to the magnetic field, the expression describing the line broadening due to chemical shift anisotropy includes a term $(3\cos^2\theta - 1)$. When $\theta = 54{\cdot}7°$ this term vanishes. The anisotropy effects can thus be eliminated. The spin-spin interactions are also eliminated. This technique is known as **magic angle spinning (MAS)** or **magic angle sample spinning (MASS).** We thus obtain high-resolution NMR spectra of solids. Such spectra of solids are used to study the structure and dynamics of solid polymers, biopolymers such as proteins, catalysts, molecules adsorbed on catalysts, coal, ceramics, glasses, etc. An example is of the use of ^{29}Si MAS-NMR spectra to infer the positions of Si atoms in natural and synthetic aluminosilicates.

4. Double Resonance

Though we have discussed double resonance (or double irradiation) already, we shall give further remarks on it. As we have said, in a double-resonance experiment, the sample is simultaneously exposed to rf radiation of two different frequencies, one frequency being used to observe radiation absorption and the second frequency to produce a perturbation that affects the spectrum. For instance, in observing natural-abundance ^{13}C spectra in organic compounds, in addition to applying a pulse of radio frequency radiation that covers the frequency range of ^{13}C absorptions, one also applies continuous strong rf radiation whose frequencies cover the range of proton absorption frequencies. This results in the removal of the spin-spin coupling between ^1H and ^{13}C nuclei (a process called **decoupling**). As a result, ^1H spins do not split the ^{13}C absorption lines. Since the probability that two C nuclei are both ^{13}C is very small, there is no $^{13}C - {}^{13}C$ spin-spin splitting in natural-abundance ^{13}C NMR. With no spin-spin coupling, the ^{13}C natural-abundance spectrum contains one line for each set of non equivalent carbons. In ^{13}C NMR, the reference compound is TMS and the ^{13}C chemical shifts in organic compounds usually lie in the range of δ from – 10 to 230 ppm. As with protons, the δ-value is characteristic of the kind of carbon being observed. For example, δ for C=O carbon in ketones usually between 200 and 220 ppm. The combination of proton and ^{13}C NMR is an extremely powerful method for structure determination. The convenient notation $^{13}C - \{^1H\}$ is used to identify **proton-decoupled carbon – 13 NMR spectra.** We usually double-irradiate *all* protons simultaneously while recording the ^{13}C spectrum. A decoupling signal is used that has all the ^1H frequencies spread around 80 MHz and is, therefore, a form of radio frequency noise. Spectra derived thus are ^1H-*decoupled* or *noise-decoupled.* Most ^{13}C spectra are recorded in this way.

5. The Nuclear Overhauser Effect (NOE)

Consider the following double-resonance experiment. The ^1H NMR spectrum of a molecule is recorded (using either a CW or FT spectrometer), while the sample is continuously irradiated with rf radiation of frequency ν_s, that is, the NMR absorption frequency of a specific set (which we call S) of chemically equivalent protons in the molecule. We then find that the intensities of all lines that are due to protons which are close to the set-S protons in the molecule are changed as compared with the spectrum taken without continuous radiation at ν_s. The radiation at ν_s changes the energy level population distribution of the set-S protons and the magnetic dipole-dipole interaction between the set-S protons and nearby protons changes the populations of the nearby protons, thereby changing the intensities of their NMR lines. This intensity change is the **Nuclear Overhauser Effect (NOE).** The magnitude of NOE is usually proportional to $1/r^6$ where r is the distance between the set-S protons and protons producing the line whose intensity is changed. The NOE is negligible for $r > 4$Å. The NOE can be used to help assign spectra and to find internuclear distances in a molecule.

The magnitude of NOE depends on the balance of relaxation mechanisms, and its value for an A – {X} experiment, occurring when dipole-dipole mechanisms predominate, is given by

$$NOE_{max} = 1 + \gamma_X/2\gamma_A \qquad \ldots(52)$$

where γs are the magnetogyric ratios.

Simply stated, in decoupling experiments the ratio of the total integrated double resonance intensity to single resonance intensity is called the NOE. The NOE enhancement can give a useful gain in signal-to-noise ratio. Dipolar relaxation is particularly important for spin 1/2 nuclei and as the rate is inversely proportional to the sixth power of the distance between the nuclei, it is most significant where the nucleus being irradiated is directly bonded to the one being observed. For $^{13}C - \{^1H\}$, the maximum effect is nearly 3 and enhancements close to this are normally seen for all carbons bound to hydrogen. It should also be noted that Eq. 52 leads to *negative* enhancements if γ_X or γ_A is negative. For $^{29}Si - \{^1H\}$, the maximum effect is $\sim -1{\cdot}5$ while for $^{15}N - \{^1H\}$, it is -4. But, as the minimum effect is $+1$, the actual effect may in practice be zero and expected resonances may be absent. Fig. 21 presents ^{29}Si spectra of $SiHPh_3$ showing the inversion of signals and the improvement in the signal-to-noise ratio obtained on proton decoupling.

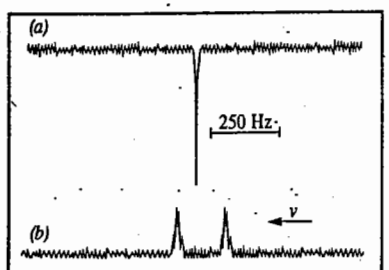

Fig. 21. Proton-decoupled (*a*) and coupled (*b*) ^{29}Si spectra of triphenylsilane.

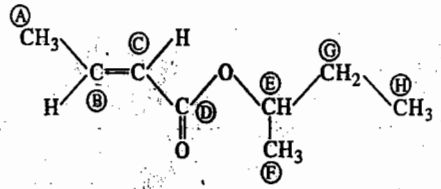
6. Off-Resonance Proton Decoupling

Fully proton-decoupled ^{13}C NMR spectra offer a distinct advantage over fully coupled spectra (sometimes called *non-decoupled* spectra) The advantage is that the removal of coupling multiplicity makes the spectrum simpler in appearance and ensures almost no confusing overlap in adjacent signals, but there is a sensitivity bonus in addition. Thus, for example, the methyl carbon in p-hydroxyacetophenone would appear in a non-decoupled spectrum as a 1 : 3 : 3 : 1 quartet because of the three attached and coupling protons and, when this is decoupled, the whole of the signal intensity appears as a single line (of intensity 8 relative to the outside lines of the quartet). The fact that the signal is a quartet proves that it arises from a methyl group and unfortunately this valuable piece of information is lost in the fully decoupled $^{13}C - \{^1H\}$ NMR spectrum. There are several techniques which allow this information to be retained ; the simplest consists in carrying out the proton decoupling by irradiation of the sample with radiofrequency which is not quite exactly that of the protons but a few hundred hertz displaced. The consequence of this off-resonance decoupling is an incomplete collapse of the multiplicity, and vestigial quartets remain from methyl carbons, with triplets from CH_2, doublets from CH and singlets from fully substituted carbons. It is convenient to annotate signals in $^{13}C - \{^1H\}$ spectra to indicate multiplicity, with the abbreviation *q*, *t*, *d* and *s* for quartet, triplet, doublet and singlet, respectively.

7. Application of 2D NMR

There are many forms of 2D spectra. Here we shall discuss a few of them by considering the example of *s*-butylcrotonate, $CH_3CH{=}CH{-}\overset{\overset{O}{\|}}{C}{-}O{-}\overset{\overset{CH_3}{|}}{CH}{-}CH_2{-}CH_3$:



The spectrum of this compound is fairly simple and can be easily interpreted.

Fig. 22. shows a 2D spectrum as an intensity contour map. Here the frequency across the page corresponds to the ^{13}C chemical shift, while the second frequency corresponds to ^{13}C–^1H spin-spin couplings. Thus, in one spectrum all the ^{13}C resonances can be seen and each one's coupling pattern can also be recognized. There are three quartets at the low frequency end, then a triplet, three doublets and a singlet all with smaller couplings as well. The information derived from this technique is called ***heteronuclear 2D J-resolved spectroscopy.***

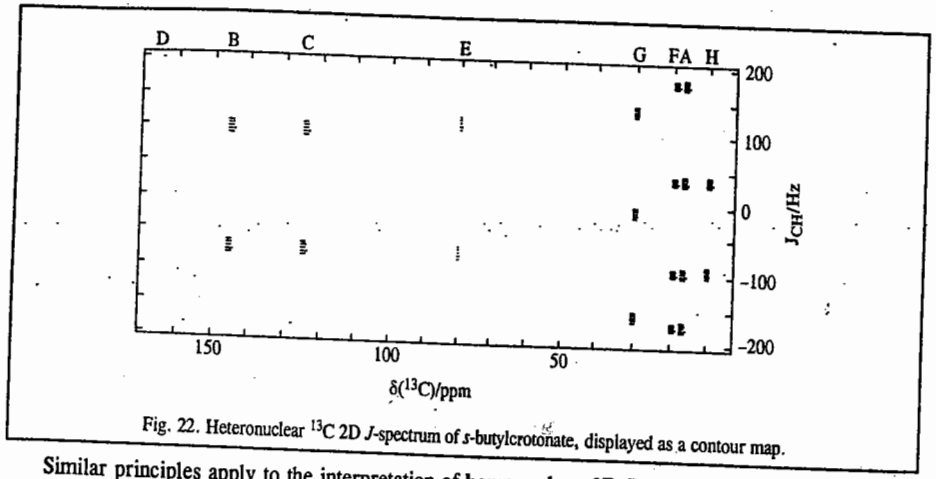


Fig. 22. Heteronuclear ^{13}C 2D *J*-spectrum of *s*-butylcrotonate, displayed as a contour map.

Similar principles apply to the interpretation of **homonuclear 2D J-resolved spectra,** although the method of obtaining them is different. Fig. 23. shows such a spectrum, again presented as an intensity contour plot. In this spectrum, one frequency scale covers ^1H chemical shifts and the other represents H—H couplings. The resonances for protons B, for instance, are clearly seen to be a doublet of quartets while those for protons A are (less clearly) a doublet of doublets. Thus, there is considerable spectral simplification, particularly for regions of the spectrum where multiplets overlap.

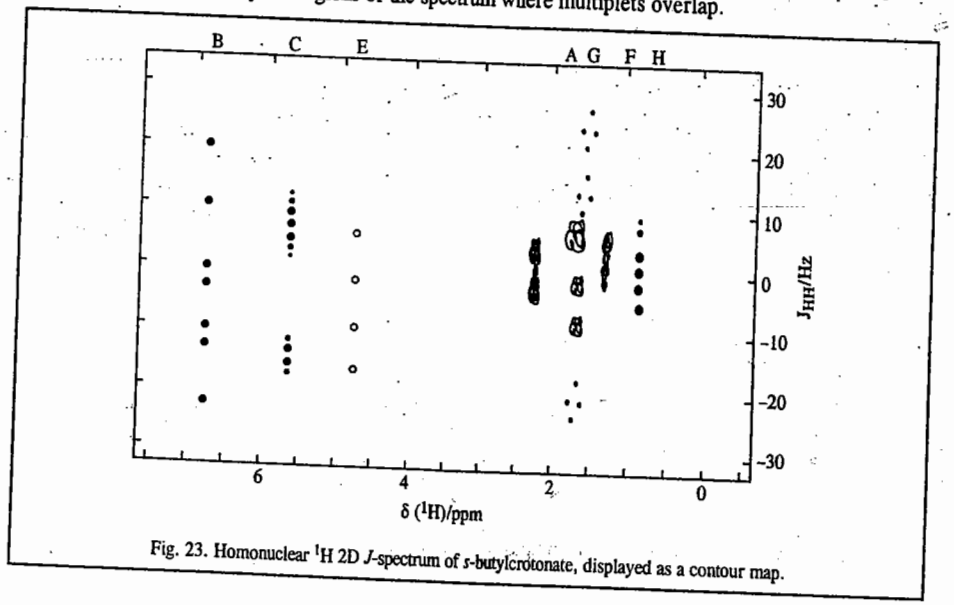

Fig. 23. Homonuclear ^1H 2D *J*-spectrum of *s*-butylcrotonate, displayed as a contour map.

Fig. 24 shows a $\delta(^{13}C) - \delta(^{1}H)$ chemical shift correlation spectrum. The correlation involves the shifts of the nuclei bonded to each other, and so in this case quaternary carbons do not appear.

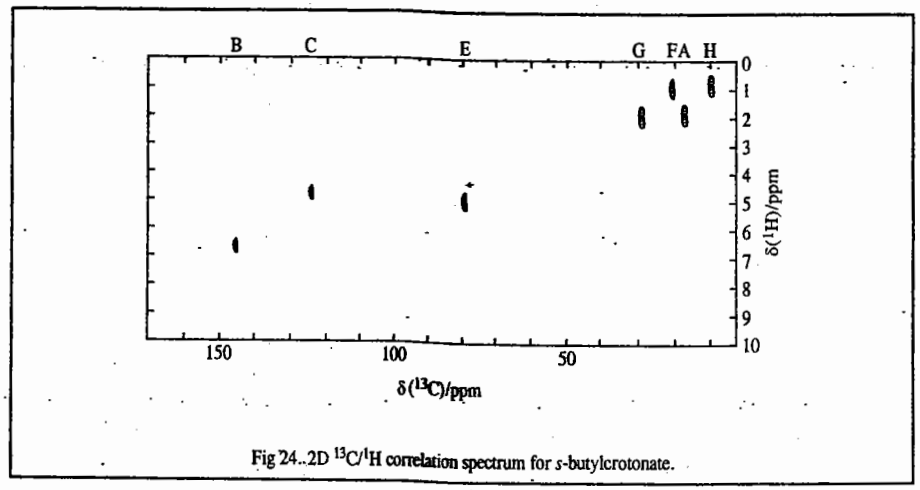

Fig 24..2D $^{13}C/^{1}H$ correlation spectrum for *s*-butylcrotonate.

It is necessary that all the one-bond coupling constants should be roughly equal. This type of spectrum offers an invaluable aid to assigning spectra. Thus, it is now clear that the higher frequency alkenic carbon resonance is associated with the higher frequency alkenic proton resonance (B), and we can also associate the methyl ^{13}C and ^{1}H resonances (A, F and H).

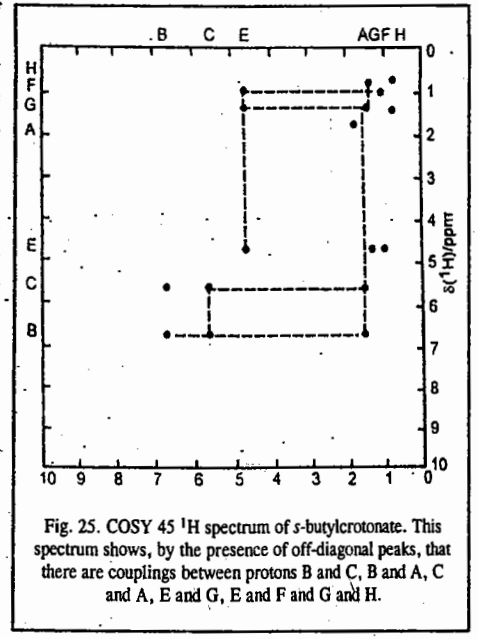

Fig. 25. COSY 45 ^{1}H spectrum of *s*-butylcrotonate. This spectrum shows, by the presence of off-diagonal peaks, that there are couplings between protons B and C, B and A, C and A, E and G, E and F and G and H.

Another 2D technique known as **correlation spectroscopy (COSY)** provides information about couplings between nuclei of a single isotope. In Fig. 25, representing COSY spectrum of *s*-butylcrotonate, both axes relate to proton chemical shifts and peaks appear on the diagonal at frequencies (the same frequency at each axis) corresponding to the resonances in the normal spectrum. The appearance of an off-diagonal peak at frequency (ν_1, ν_2) implies that there is a coupling between the nuclei resonating at ν_1 and at ν_2. Thus, it is easy to see that the two CH groups (marked as resonances B and C) couple with each other, and that one of them couples with the CH_2 group, marked A. Thus, the resonances of the crotonate group are clearly distinguished from those of the *s*-butyl group and other resonances can be made on the same basis. Other related pulse sequences include COSY 45 (actually used in Fig. 25) and NOESY (Nuclear Overhauser Effect Spectroscopy), discussed elsewhere, which depends on the local nuclear overhauser enhancements rather than couplings to give the off-diagonal peaks.

8. Internuclear Double Resonance (INDOR)

We shall now discuss INDOR, achieved through low power irradiation and Boltzmann population transfer. Consider the energy level diagram for an AX nuclear spin system (Fig. 26).

The nuclear spin wave function $|\alpha>$ refers to upwards (↑) spin orientation and the wave function $|\beta>$ refers to downward (↓) spin orientation ; they can also be called the spin quantum numbers of the A and X nuclei. At thermal equilibrium, the Boltzmann population differences are proportional to the energy differences, as these are small compared with the thermal energy k_BT. If the transition X_1 is saturated by an applied radio frequency field, the populations of the energy levels connected by this transition are equalized. As the intensities of lines A_1 and A_2 depend on the population differences of their associated energy levels, the intensity of A_2 is enhanced by irradiating X_1, while that of A_1 is diminished. In the same way, irradiation of X_2 increases the intensity of A_1 but decreases that of A_2. One way to present this information is as a plot of intensity of A_1 (or A_2) against irradiation (X) frequency, as shown in Fig. 27. This can easily be done with continuous wave NMR spectrometers simply by monitoring the chosen transition and scanning the irradiation frequency. The experiment, known as **internuclear double resonance (INDOR)**, thus provides information about the frequencies in the X-spectrum while observing only *A*. This technique, though not widely used these days, is still useful particularly if X is an insensitive nucleus for NMR or if only a proton NMR spectrometer is available. Thus, a $^{1}H - \{^{199}Hg\}$ INDOR spectrum of a compound containing SiH_3 derivatives of mercury showed a seven-line multiplet indicating that the compound had six equivalent protons, and was identified as $Hg(SiH_3)_2$ and not $HgCl(SiH_3)$.

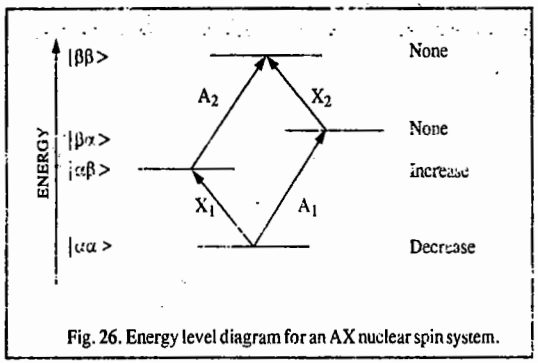

Fig. 26. Energy level diagram for an AX nuclear spin system.

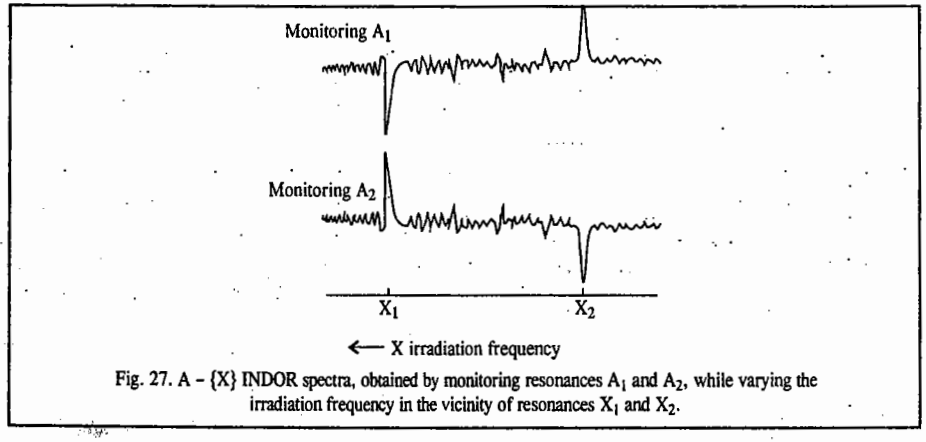

Fig. 27. A – {X} INDOR spectra, obtained by monitoring resonances A_1 and A_2, while varying the irradiation frequency in the vicinity of resonances X_1 and X_2.

9. Simplification of Complex NMR Spectra

For a non-first-order spectrum obtained at 60 MHz, three techniques are generally employed to simplify the complexity of the NMR spectrum. These are : (*a*) increased magnetic field strength, (*b*) spin decoupling (double resonance or double irradiation) and (*c*) use of chemical shift reagents.

a. Increased Field Strength. The chemical shift positions (when measured in Hz) are field-dependent whereas the spin-spin coupling constants are field-independent. Thus, a complex pmr spectrum obtained at, say, 60 MHz (1·4 T) will be simplified if it is obtained at a higher field 100 MHz (2·3T). For instance, methyl resonance in acetates appears at δ 2·0 or 2 ppm higher frequency than TMS. In a 60 MHz instrument (1·4 T), 2 ppm corresponds to 120 Hz while in a 100 MHz instrument (2·3 T), 2 ppm corresponds to 200 Hz. At 14·1T (600 MHz), 2 ppm corresponds to 1200 Hz. Thus, since the spin-spin coupling constants are field-independent, the ratio $\Delta\nu : J$ is effectively increased as the field strength is increased from 1·4 T to 14·1 T. If two coupling multiplets overlap at 1·4 T, we can pull the multiplets apart by increasing the magnetic field.

b. Double Resonance. Fig. 28 shows the double irradiation (spin decoupling) of an AX NMR spectrum of  . The proton A in this figure appears as a doublet because of the two spin orientations of X. If we irradiate X with the correct rf energy, we can stimulate rapid transitions (both upwards and downwards) between the two spin states of X so that the lifetime of a nucleus in any one spin state is too short to resolve the coupling with A. If proton A 'sees' only one time-averaged view of X, then A will come to resonance only once and not twice. By the same argument, if we irradiate proton A with the correct energy to cause it to undergo rapid transitions between its two spin states, proton X will only 'see' one time-averaged view of A and appear only as a singlet. Thus, the complex NMR spectrum is simplified. To perform this operation, we require, in addition to the basic NMR instrument, a *second* tunable rf source to irradiate the proton at the necessary precession frequency while recording the remainder of the spectrum as before. Since we are making simultaneous use of two rf sources, the technique is called **double irradiation.**

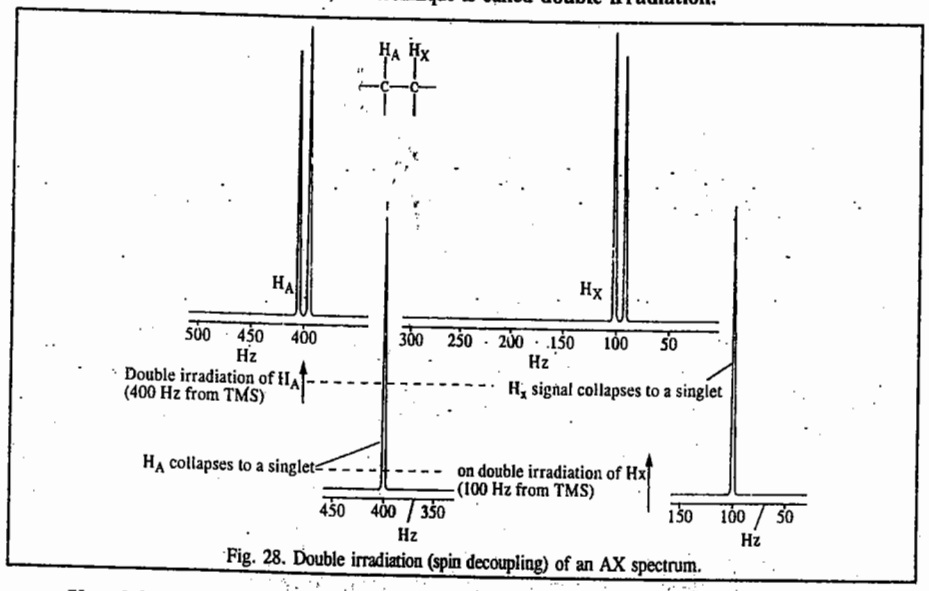

Fig. 28. Double irradiation (spin decoupling) of an AX spectrum.

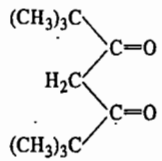
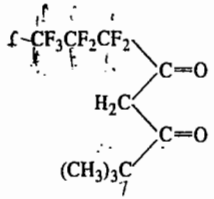
c. Use of Chemical Shift Reagents (Lanthanide Shift Reagents). The addition of the paramagnetic europium (III) ion complexes to the sample under study (say, 6-methyl quinoline)—whose NMR spectrum we want to obtain —induces enormous shifts to higher frequency in the quinoline resonance. Here the shift reagent modifies the magnetic field experienced by the protons (with the consequent simplification of the spectrum). The shift reagent coordinates with electronegative atoms in the substrate and thus modifies the magnetic field experienced by neighbouring protons. In fact, the

mechanism of the shift is two-fold. Unpaired electron spin in the paramagnetic ion (*e.g.*, Eu (III)) is partially transferred *through the intervening bonds* to the protons of the organic substrate; this is called **contact shift.** The spinning paramagnetic ion also generates magnetic vectors which operate *through space,* creating secondary magnetic fields around the protons; this is called **pseudo-contact shift** and predominates in the case of lanthanide ions.

The lanthanide complex should be soluble in common NMR solvents for wide applicability. The two most commonly used shift reagents are tris-chelates of lanthanide ions with the β-diketones, 2,2,6,6,-tetramethylheptane-3,5-dione (dipivanoylmethane, abbreviated as DPM and 1,1,1,2,2,3,3-heptafluoro-7,7-dimethyloctane-4,6-dione or simply heptafluorodimethyloctanedione (abbreviated as FOD) :

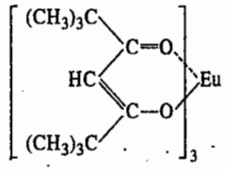


DPM

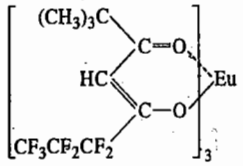


FOD

Typical lanthanide shift reagents are tris-(dipivanoylmethanato) europium and tris-1,1,1,2,2,3,3-heptafluoro-7,7-dimethyloctane-4,6-dionatoeuropium, the names of which are normally abbreviated to $Eu(dpm)_3$ and $Eu(fod)_3$, respectively :



$Eu(dpm)_3$



$Eu(fod)_3$

The extent of the lanthanide-induced shift is dependenent on the basicity of the functional group and on the nature, purity and concentration of the shift reagent. $Eu(fod)_3$ normally causes greater shifts as it is a stronger Lewis acid. It also has the advantage of a much higher solubility. The magnitude of the lanthanide-induced shift is considerably decreased by the presence of a small amount of water. Since many of the reagents are hygroscopic, care should be taken in their handling and storage.

10. NMR of Paramagnetic Compounds

Though paramagnetic compounds are troublesome to investigate by NMR (they are better studied by ESR), their NMR spectra do sometimes yield useful information. The two most obvious characteristics of the NMR spectra of paramagnetic materials are that the chemical shift scale is greatly expanded (for example, to more than 200 ppm for protons) and that the resonances may be broad. The signals from diamagnetic materials may also show these effects, in the presence of paramagnetic species, even in low concentrations. The broadening depends on the electronic spin-lattice relaxation time and/or the hyperfine electron-nuclear coupling.

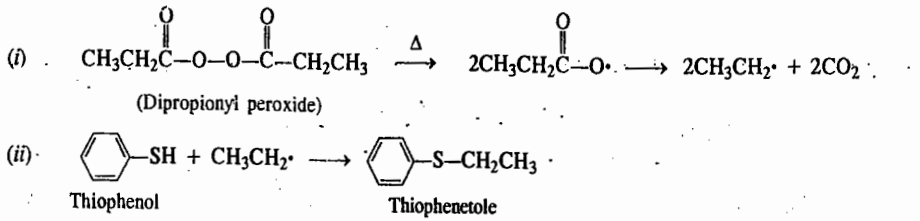
The observed paramagnetic shifts are made up of two components. First, there is a through-space dipolar interaction between the magnetic moments of the electron and the resonating nucleus, which gives a dipolar shift, known as a **pseudo-contact shift.** This contribution may be small and is rather

difficult to calculate theoretically so that the other component, known as the **contact shift,** may be identified. The origin of the contact shift may be understood if one considers the coupling between electron and nucleus which would give a doublet in the NMR spectrum under conditions of low spin-lattice relaxation but with a coupling constant of millions of Hz ! With such a large coupling, the intensities of the two resonances are not equal so that their weighted mean position is not midway between them. Under fast relaxation conditions, the collapsed singlet may fall some thousands of Hz away from the expected position—the contact shift.

Contact shifts give a measure of the unpaired spin density of the resonating nucleus and are thus particularly useful in studying the spin distribution in organic free radicals or in ligands in organometallic compounds. We have discussed earlier the use of the paramagnetic complexes of europium as shift reagents in simplifying complex pmr spectra.

11. Chemically Induced Dynamic Nuclear Polarization (CIDNP)

When dipropionyl peroxide is thermolyzed in an NMR tube in the presence of thiophenol, ethyl radicals are produced which react with the thiophenol to form thiophenetole :



If the pmr spectrum of thiophenetole is recorded *during* the course of the reaction, the ethyl signals appear as shown in Fig. 29 (*a*). The pmr spectrum of normal thiophenetole is shown in Fig.29(*b*) for comparison. We see that some of the lines in the spectrum (*a*) have increased intensity while other lines show increased emissions. This is interpreted by saying that the nuclear spins in the product of this radical reaction (that is, the nuclear spins of thiophenetole) are undergoing *dynamic polarization* because of the chemical reaction that is producing the molecule. This phenomenon is known as **chemically induced dynamic nuclear polarization (CIDNP).** Observation of CIDNP effects during a reaction is a good evidence that, at least in part, a radical mechanism is involved.

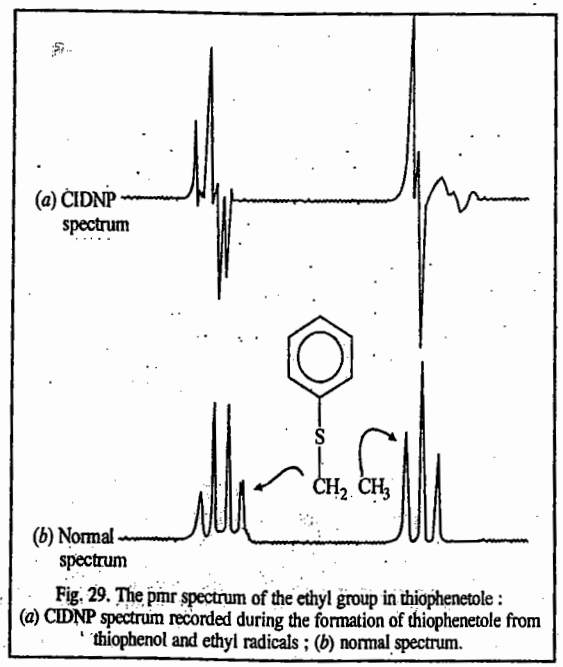


Fig. 29. The pmr spectrum of the ethyl group in thiophenetole : (*a*) CIDNP spectrum recorded during the formation of thiophenetole from thiophenol and ethyl radicals ; (*b*) normal spectrum.

The mechanism of CIDNP is complicated and the observed effect depends on the way in which particular nuclear spin states interact with the electron spins of the free radicals involved. Also, the free radicals from

a precursor molecule may follow several reaction paths, depending on whether the originally formed radical pair react together immediately or diffuse out from each other, to form other dimerization or transfer reactions. For a particular radical pair, the singlet and triplet electronic states undergo mixing processes under the influence of nearby nuclear spins ; if the resultant mixed electronic state is predominantly singlet in character, the associated nuclear spin states are enchanced in the product formed from the radical pair and the NMR of the product shows increased absorption for these spin states. If the mixed electronic state is predominantly triplet, emission will be shown for the corresponding nuclear spin states.

12. NMR of Liquid Crystals

In contrast to fluids, liquid crystals are compounds or mixtures which have one or more phases between liquid and solid, in which there is local alignment of molecules but no overall alignment. The material in these phases is thus fluid—*isotropic* in bulk but locally *anisotropic*. The liquid which is strongly anisotropic in many of its properties, produces on heating an *isotropic* liquid. These materials are referred to as **thermotropic liquid crystals** (*i.e.*, produced by melting of a solid). We have discussed in Chapter 12 the classification of liquid crystals into smectic, nematic and cholesteric crystals. In the presence of an electric or magnetic field, the fluid becomes anisotropic in bulk, as all the molecules tend to align in one particular direction, though they remain mobile. At the same time, the solute molecules also become oriented with respect to the applied field. Thus dipolar couplings are not lost by isotropic tumbling.

The NMR spectra of liquid crystals are affected dramatically because of major changes in coupling constants. Fig. 30 shows how all the couplings in $PF_2^{15}NH_2$ change and that some of the smaller ones become very large. Couplings of hundreds and thousands of Hz are normally observed. Whereas a first-order splitting J_{AX} is observed for an isotropic solution, it is replaced by

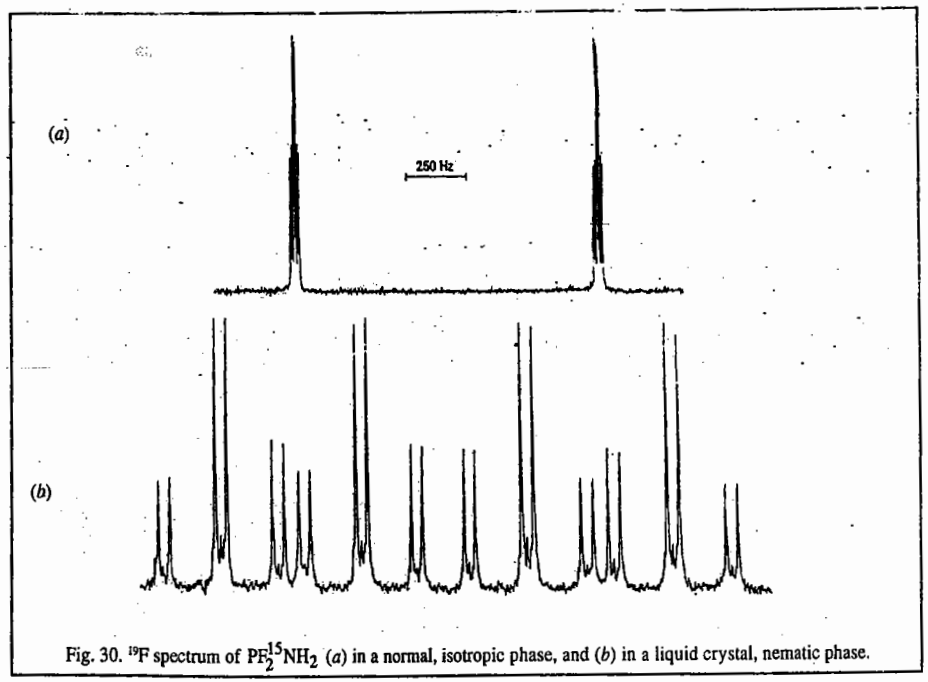

Fig. 30. ^{19}F spectrum of $PF_2^{15}NH_2$ (*a*) in a normal, isotropic phase, and (*b*) in a liquid crystal, nematic phase.

$J_{AX}+2D_{AX}$, in the case of a liquid crystal. In this way direct coupling may be determined. Also, coupling is now observed between nuclei which are chemically and magnetically equivalent. Thus, in Fig. 22 there is an extra doublet splitting corresponding to coupling between the two equivalent ^{19}F nuclei. Finally, a group of magnetically equivalent nuclei may not be fully equivalent, in that the couplings within the group (which are now observable) may not be all equal. Thus, for example, in benzene there are three different proton-proton dipolar couplings so that the ^1H spectrum is second-order. Such spectra must be analyzed in the normal way, using variants of analysis programs which take account of dipolar couplings.

Without going into details we may mention that the dipolar couplings which we assume to be measured or derived, are related to the molecular geometry and the so-called orientation parameters. These parameters describe the average orientation of the molecule with respect to the applied field. There is, of course, the problem of unknown orientation parameters, with the consequent need to make some structural assumptions. There is also a need to make allowance for the effects of vibrations on observed couplings. This involves a complete force field analysis of the molecule. There are also the problems arising from anisotropy in the indirect (J) couplings. Thus, there are many pitfalls for the unwary. However, the technique can provide useful structural data which otherwise are very difficult to obtain for molecules in solution.

MAGNETIC RESONANCE IMAGING (MRI)

The proton NMR spectroscopy can be used to form cross-sectional images of body parts in living subjects by displaying the intensity of a particular pmr transition (for example, proteins in water) as a function of the coordinates in the cross-sectional plane. This technique of **magnetic resonance imaging (MRI)** is widely used to diagnose diseases such as cancer from the signals generated from the soft tissues of the brain, eyes, spinal column, etc. The ability to scan soft tissues as, for example, of eyes, brain, spinal cord in a human skull, by MRI complements the information about the bone structure obtained from X-ray studies. This is an established medical diagnostic technique for soft tissue damage. The experimental technique has been sufficiently refined to produce not only very high resolution in detail but also a whole sequence of views of the head (see small inserts at the top of the figure) which can be presented in a sequence on a VDU (Video Display Unit) in the form of a moving picture so that the head can be "rotated" to allow all aspects to be examined.

From the basic principles of pmr we know that the protons in the head (in the water and the fat) undergo a sharp resonance at a given frequency only when the applied Zeeman magnetic field causes them to precess at their Larmor resonance frequency. At lower and higher values of the magnetic field, no pmr signal will be detected. Instead of applying a uniform magnetic field across the head, a *field gradient* is applied. At only one particular point along the field gradient (also called *phase gradient*) will the protons be in resonance and, therefore, this distance across the head can be correlated with the field gradient. The gradient is then altered and the resonance occurs at a different point, the distance of which along the gradient is again corrected. By scanning along several gradients applied across a network of axes through a slice of the head, an image of the protons present (that is, of the soft tissue present) is constructed. The complete reconstructed image is defined by repeating the process across several slices through the head.

The MRI technique is also used widely to detect physiological abnormalities and to observe metabolic processes. With **functional MRI**, blood flow in different regions of the brain can be studied and related to the mental activities of the subject. The special advantage of MRI is that it can image *soft* tissues whereas X-rays are largely used for imaging hard, bony structures and abnormally dense regions such as tumours. In fact, the invisibility of hard structures in MRI is an advantage as it allows the imaging of structures encased by bone, such as the brain and the spinal cord in the magnetic resonance imaging of human skull (Fig. 31). X-rays are known to be dangerous on account of the ionization they cause. The high magnetic fields used in MRI may also be

dangerous. However, there is no convincing evidence of their harmfulness and the technique is considered safe.

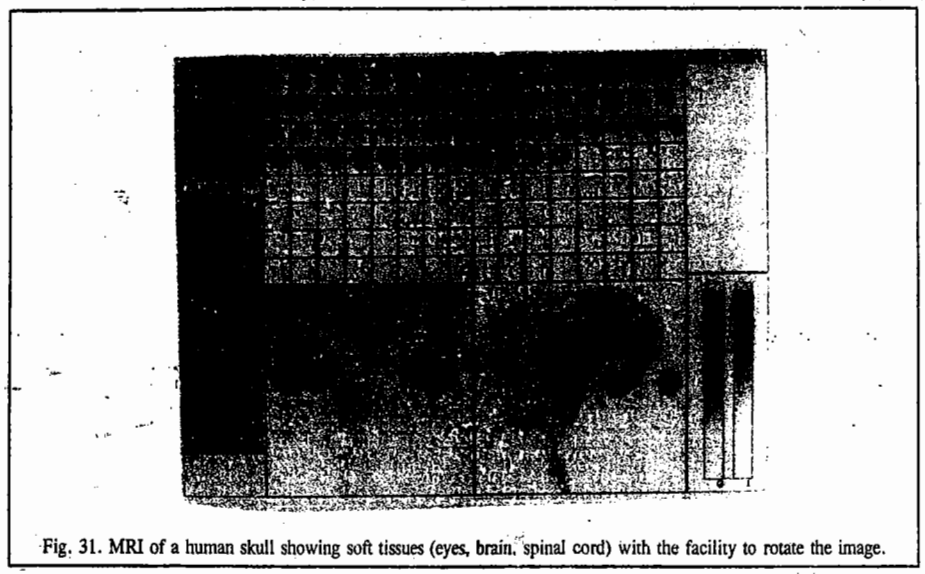

Fig. 31. MRI of a human skull showing soft tissues (eyes, brain, spinal cord) with the facility to rotate the image.

MRI is perhaps the most important non-invasive diagnostic tool in today's medicine. The 2003 Nobel Prize in Medicine/Physiology was awarded jointly to the American chemist Paul Lauterbur and the British scientist Peter Mansfield for discoveries that led to the use of "MRI for exact visualization of the various internal body structures". Lauterbur used field gradients in his investigations and Mansfield pioneered a technique in MRI, called echo planar imaging (EPI), which is an extremely rapid imaging technique using very fast gradients. MRI works by scanning essentially one line at a time. In order to make up an image, a series of such lines have to be scanned and assembled into a picture. EPI is basically a snapshot type of MRI that allows an image to be scanned all at once. This makes the process a lot quicker and renders 3D imaging feasible since a series of ten scans would generate ten 'slice' pictures. Unlike X-rays or computer-assisted tomography (CAT), MRI, as already remarked, does not use any ionizing radiation.

It must be emphasized again that MRI is particularly valuable for imaging the brain and the spinal cord. Nearly all brain disorders lead to changes in water content and even one percent difference can cause pathological change. MRI can pick up these changes. Multiple sclerosis arises from the local inflammation of the brain and the spinal cord. MRI can detect where the inflammation has occurred in the nervous system, how severe it is and the impact of treatment. Other examples are its use in treating movement disorders in Parkinson's disease and diagnosing prolonged lower back pain. Finally, it may be remarked that the 2003 Chemistry Nobel Prize awarded jointly to the U.S. medical scientists Peter Agre and Roderick McKinnon for research in the structure and chemistry of water channels and ion channels in cells, is related to MRI. While MRI is chiefly used to map the water content in cells and tissues, the work of Agre and McKinnon tells how water is transported through the cells and how signals from the cell propagate to enable the coordination of muscles and nerves. This is of utmost importance in the understanding of many diseases. A number of diseases can be attributed to the poor functioning of water and ion channels in the body. The knowledge of the structure and function of molecular channels now enables proper therapeutic intervention.

ELECTRON SPIN RESONANCE (ESR) SPECTRA

The phenomenon of **electron spin resonance (ESR)**, also called **electron paramagnetic resonance** (EPR), was discovered by the Soviet physicist Zavoisky in 1945, a year before the discovery of NMR by the American physicists Bloch and Purcell. Both NMR and ESR are collectively referred to as magnetic resonance phenomena. NMR and ESR are similar in their theoretical principles. However, while the former is observed in radiofrequency region, the latter is observed in microwave region of the electromagnetic spectrum. ESR has limited applications because it is observed primarily in systems containing unpaired electrons. Thus, the systems which can be investigated by ESR spectroscopy are organic or inorganic free radicals and ions of transition metals which contain unpaired *d* or *f* electrons. One of the most important uses of ESR technique lies in the detection of extremely short-lived (transient) free radical intermediates in chemical reactions.

ESR Spectrum of an Unpaired Electron. As is well known, an electon possesses a spin S whose value is $\frac{1}{2}$. The magnetic moment associated with this spin is given by

$$\vec{\mu} = -g_e \mu_B \vec{S} \qquad ...(53)$$

where g_e is the *Lande' g-factor* and μ_B is the Bohr magneton. The value of g_e is 2·0023. Bohr magneton, $\mu_B = e\hbar/2m_e$ where e is the electronic charge and m_e is the mass of the electron. Substituting various values, μ_B comes out to be equal to $9{\cdot}273\times10^{-24}$ J T^{-1}.

The energy associated with electron spin S in the magnetic field B_z, applied along the z-axis, is given by

$$E = -\vec{\mu}.\vec{B_z} \qquad ...(54)$$

The component of spin S along the field direction is m_s. Hence, from Eqs. 53 and 54,

$$E_{m_S} = g_e \mu_B B_z m_s \qquad ...(55)$$

Since $m_S = \pm\frac{1}{2}$, we have

$$E_{+1/2} = \frac{1}{2} g_e \mu_B B_z \qquad ...(56)$$

$$E_{-1/2} = -\frac{1}{2} g_e \mu_B B_z \qquad ...(57)$$

Here, too, as in the case of a bare proton, while in the absence of the applied magnetic field the two energy levels are degenerate, the degeneracy is removed in the presence of the magnetic field, as shown in Fig. 32

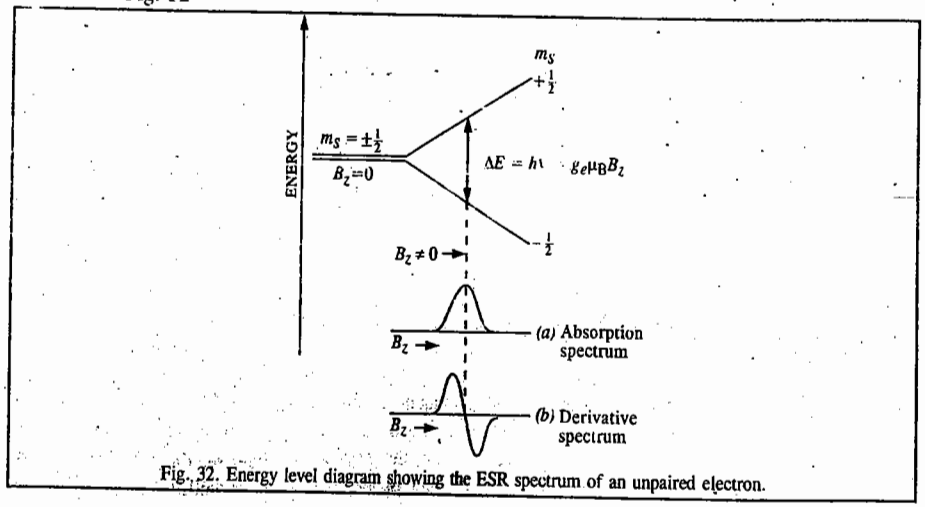

Fig. 32. Energy level diagram showing the ESR spectrum of an unpaired electron.

Application of an osciliating field perpendicular to the direction of B_z induces transitions between the two sub-energy levels provided the frequency of the oscillating field satisfies the Bohr-Einstein condition, *viz.*,

$$\Delta E = E_{1/2} - E_{-1/2} = g_e \mu_B B_z = h\nu \qquad ...(58)$$

Thus, the ESR frequency of the odd electron is given by

$$\nu = \Delta E/h = g_e \mu_B B_z/h \qquad ...(59)$$

Example 28. Calculate the ESR frequency of an unpaired electron in a magnetic field of 0·33 T, given that for the free electron, $g_e = 2$ and $\mu_B = 9{\cdot}273\times10^{-24}$ J T^{-1}.

Solution :
$$\nu = g_e \mu_B B_z/h = \frac{(2)(9{\cdot}273\times10^{-24}\text{ J T}^{-1})(0{\cdot}33\text{ T})}{6{\cdot}626\times10^{-34}\text{ J s}} \quad \text{[Eq. 59]}$$

$$= 9{,}000\times10^6\text{ s}^{-1} = 9{,}000\times10^6\text{ Hz} = 9{\cdot}00\text{ GHz}$$

Example 29. In an ESR spectrometer, the ESR frequency of the free electron is 9·5 GHz. Calculate the magnetic field at which the spectrometer is operating, $g_e = 2$ and $\mu_B = 9{\cdot}273\times10^{-24}$ J T^{-1}

Solution :
$$B_z = \frac{h\nu}{g_e\mu_B} = \frac{(6{\cdot}626\times10^{-34}\text{ J s})(9{\cdot}5\times10^9\text{ s}^{-1})}{(2)(9{\cdot}273\times10^{-24}\text{ J T}^{-1})} \quad \text{[Eq. 59]}$$

$$= 0{\cdot}339\text{ T} = 339{\cdot}0\text{ mT}$$ where mT means millitesla.

The ESR frequency falls in the microwave region. The reason why ν(ESR) falls in the microwave region whereas ν(NMR) falls in the radiofrequency region is that μ_B is about 2,000 times greater than μ_N which means that μ_e is about 660 times greater that μ_n, the nuclear magnetic moment.

In Fig. 24 is shown the ESR spectrum of the odd electron in two modes : *(a)* the absorption mode and *(b)* the derivative mode. Since the ESR spectra are generally broad (*i.e.*, not sharp), it is difficult to locate the peak in the absorption mode but it is quite easy to locate it in the derivative mode. Hence, the ESR spectra are generally recorded in the derivative mode.

Hyperfine Structure in ESR Spectra. Hyperfine structure (HFS) occurs as a result of the magnetic interaction between the electronic spin S and the nuclear spin I. The hyperfine interaction in ESR spectra is analogous to the fine structure, *i.e.*, nuclear spin-spin interaction in NMR spectra. As a result of this interaction, the ESR signals or peaks are split into several lines (HFS).

Let us consider the hyperfine interaction in the following seven cases : (1) hydrogen atom (2) methyl radical, $\cdot CH_3$ (3) the $(SO_3)_2NO^-$ radical anion (4) 1,4-benzosemiquinone radical anion (5) naphthalene negative ion (6) anthracene negative ion and (7) triphenylmethyl radical.

The selection rule for hyperfine transitions is

$$\Delta m_S = \pm 1\ ;\ \Delta m_I = 0 \qquad ...(60)$$

This selection rule may be interpreted by saying that the nuclear motion is much slower than the electronic motion so that during the time electron changes its spin orientation, the nucleus, being heavier, has no time to reorient its spin so that $\Delta m_I = 0$.

1. Hydrogen atom. It contains an unpaired electron with $S = \frac{1}{2}$ and a proton with nuclear spin $I = \frac{1}{2}$. Thus, $m_S = \pm\frac{1}{2}$ and $m_I = \pm\frac{1}{2}$. In the absence of magnetic field (B_z=0), the electron spin energy levels are degenerate, *i.e.*, have the same energy. Application of B_z removes the degeneracy between them, the $m_S = -\frac{1}{2}$ sublevel going down and the $m_s = +\frac{1}{2}$ sublevel going up (see Fig. 33). Each of these electron sublevels interacts with the nucleus giving four sublevels designated by the value of m_I. This is hyperfine interaction. Using the selection rule, two ESR lines, *i.e.*, a doublet, are observed, as shown in the experimental spectrum. They are equally intense, the spacing between them gives the **hyperfine coupling constant, *a***, expressed in units of tesla or millitesla.

2. Methyl radical, $\cdot CH_3$. It contains an unpaired electron with $S = \frac{1}{2}$ and three equivalent protons. Since for a proton, $I = \frac{1}{2}$, it is evident that for three equivalent protons, $m_I = +\frac{3}{2}, +\frac{1}{2}, -\frac{1}{2}, -\frac{3}{2}$. Also, $m_S = \pm\frac{1}{2}$. This interpretation of the ESR spectrum (Fig. 34) is similar to that of H atom given in Fig. 33. The ESR spectrum contains four equally spaced lines, *i.e.*, a quartet.

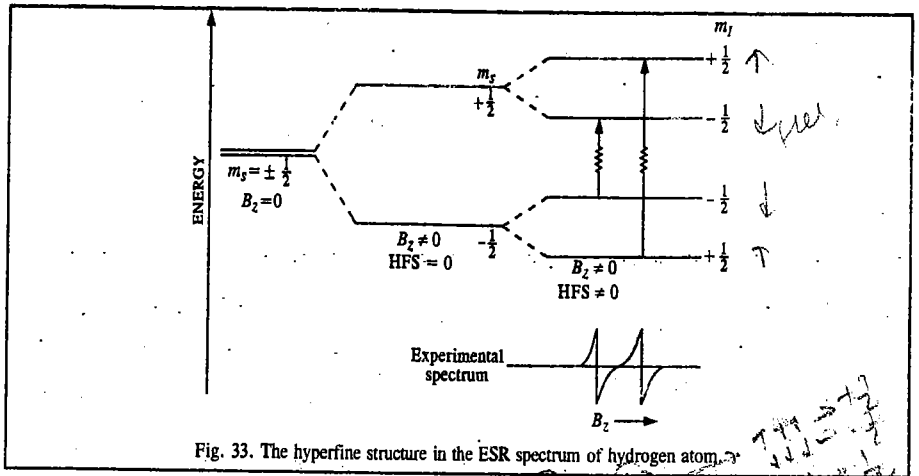

Fig. 33. The hyperfine structure in the ESR spectrum of hydrogen atom.

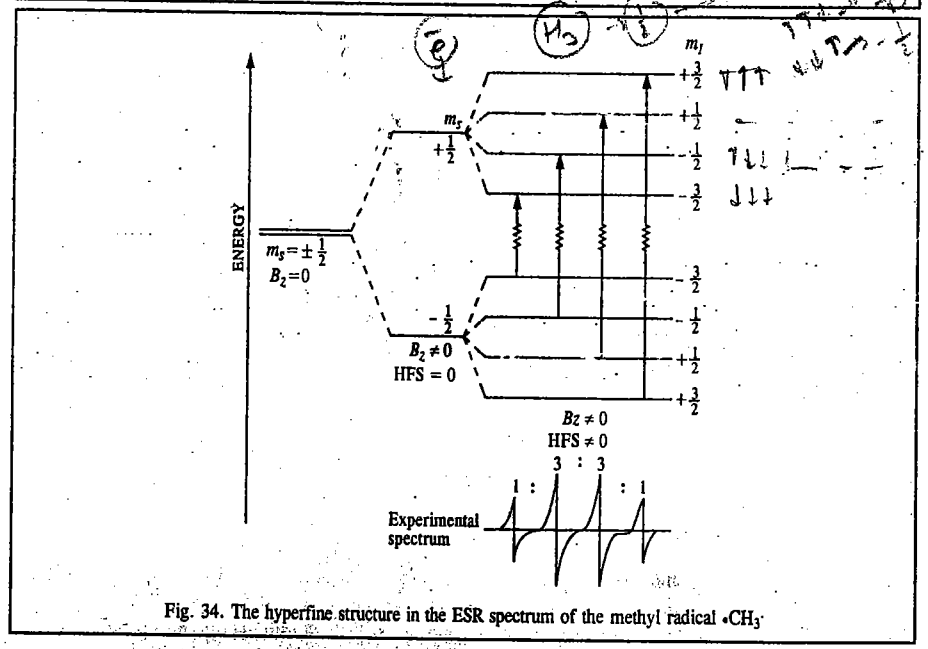

Fig. 34. The hyperfine structure in the ESR spectrum of the methyl radical $\cdot CH_3$

3. $(SO_3)_2NO^-$ anion. In this anion, the unpaired electron interacts with the nitrogen nucleus with $I=1$. Here, $m_S = \pm\frac{1}{2}$ and $m_I = +1, 0, -1$. The ESR spectrum (Fig. 35) contains three equally spaced lines, *i.e.*, a triplet.

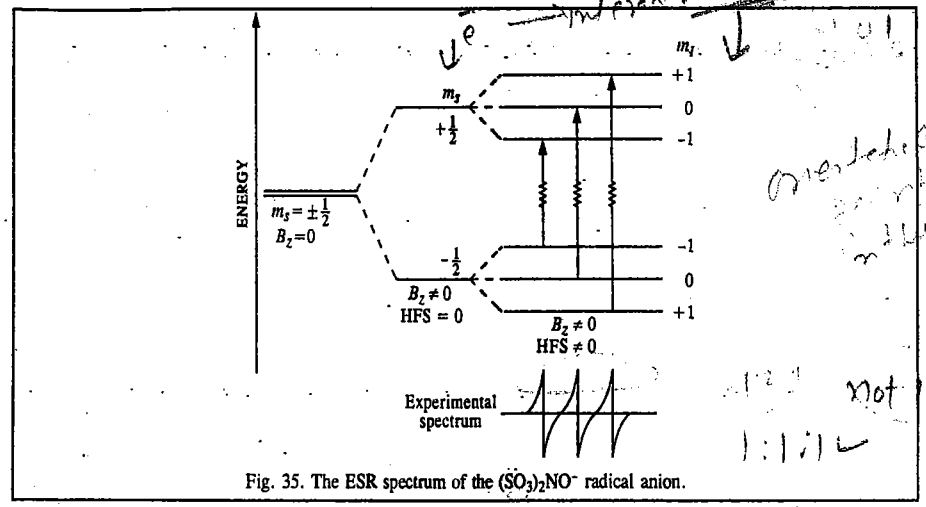

Fig. 35. The ESR spectrum of the $(SO_3)_2NO^-$ radical anion.

4. 1,4-Benzosemiquinone radical anion. This anion, having the structure  has one unpaired electron ($S = \frac{1}{2}$,) interacting with four equivalent protons. Since for a proton $I = \frac{1}{2}$, it is evident that for four equivalent protons, $m_I = +2, 1, 0, -1, -2$.

The ESR spectrum (Fig. 36) contains a quintet, *i.e.*, five equally spaced lines.

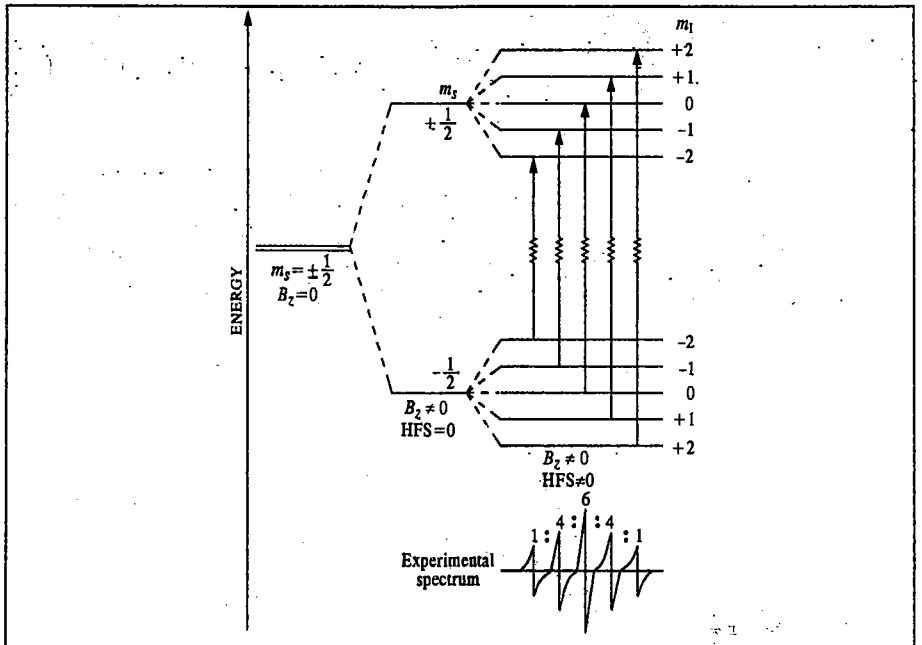

Fig. 36. The hyperfine structure in the ESR spectrum of *p*-benzosemiquinone radical anion.

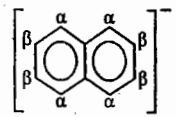
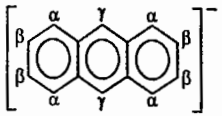
5. Naphthalene negative ion,



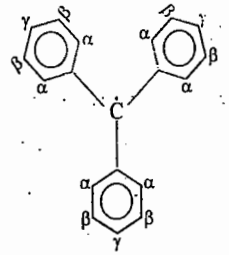
In this case, there are two sets (α and β) of four equivalent protons each. The ESR spectrum would thus show (4+1)×(4+1) = 25 lines.

6. Anthracene negative ion,



In this case, there are three sets of equivalent protons : sets α and β consist of four equivalent protons each and set γ consists of two equivalent protons. The ESR spectrum consists of (4+1) (4+1) (2+1) = 75 lines.

7. Triphenylmethyl radical, $\cdot C(C_6H_5)_3$, has the structure shown here.



It has also three sets of equivalent protons : sets α and β consist of six equivalent protons each and set γ consists of three equivalent protons. The ESR spectrum consists of (6+1)(6+1)(3+1)=196 lines. It is a triumph of theory that all the 196 lines have been observed. One can imagine the complexity of this spectrum !

The hyperfine structure in ESR spectra of complicated organic radical ions may consist of a very large number of lines all of which can be interpreted in a manner similar to the above.

In general, the ESR spectrum of a system where the unpaired electron interacts with n equivalent protons, contains $n+1$ lines and their relative intensities are given by Pascal's triangle, discussed earlier. Thus, we have for *(i)* H atom, 2 lines (*i.e.*, a doublet) of equal intensity *(ii)* for. $\cdot CH_3$ radical, 4 lines (*i.e.*, a quartet) in the intensity ratio 1 : 3 : 3 : 1, *(iii)* for the 1, 4-benzosemiquinone anion, 5 lines (*i.e.*, a quintet) in the intensity ratio 1 : 4 : 6 : 4 : 1 and for benzene radical anion, a septet in the relative intensity ratio 1 : 6 : 15 : 20 : 15 : 6 : 1 since here the unpaired electron interacts with six equivalent protons.

For nuclei with $I > 1/2$, other rules apply. Thus, the ^{14}N nucleus in $(SO_3)_2NO^-$ anion radical, with $I = 1$, gives a hyperfine pattern of 3 lines (triplet) of equal intensity. Similarly, a ^{63}Cu nucleus ($I = \frac{3}{2}$) interacting with an odd electron gives a hyperfine pattern of four lines (quartet) of equal intensity.

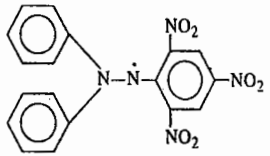
The hyperfine coupling constant a in hydrogen atom is 50·68 mT. This coupling is due entirely to the **Fermi contact interaction**, being propotional to the probability density of the 1*s* electron at the nucleus. In aromatic free radicals where the unpaired electron is delocalized over the molecular orbitals extending over the entire molecule, the probability of finding the electron on a given nucleus is evidently small ; hence, the hyperfine coupling constant is also small. Thus, the ESR spectrum of benzene radical anion, $C_6H_6^-$, containing six equivalent protons, is a septet with a = 0·375 mT. For $\cdot CH_3$ radical, consisting of a quartet, a=2·3 mT.

***g*-Factor.** The *g*-factor and the hyperfine coupling constant are the most important quantites determined from the ESR spectra of odd-electron systems. From the relation, $\nu = g_e\mu_B B_z/h$, we see that $g_e = h\nu/\mu_B B_z$. Thus, the *g*-factor is essentially a measure of the ratio between frequency and magnetic field. For the free electron, g_e = 2·0023. The organic radicals such as the methyl radical, have the *g*-value very close to the free-electron g_e value. Here only the spin of the electron contributes to g_e.

The deviation of g from g_e = 2·0023 depends on the ability of the applied magnetic flux density to induce local currents in the free radical and, therefore, its value gives some information about electronic structure.

However, in the case of the transition metal ions and their complexes, there is considerable interaction between the spin and the orbital motion of the electron which prevents complete *quenching of the orbital contribution*. Hence, for such systems, the *g*-value departs from the g_e-value. In transition metal complexes containing *d* shells less than half-filled, g is less than g_e while for shells more than half-filled, g is greater than g_e. Also, the *g*-value is **anisotropic**, *i.e.*, its magnitude depends upon the direction of measurement. The anisotropy in *g*-value is shown by systems in the solid state where conditions of restricted motion exist. In systems containing axial symmetry, the *g*-values along two dimensions, say, the x and y directions, are equal while the *g*-value along the z direction is different. Consider, for instance, an octahedral complex wherein two diametrically opposed ligands are pulled or pushed symmetrically while the remaining four ligands remain undisturbed. This is a case of axial symmetry. If the magnetic field is applied along the z direction, the *g*-value is designated as $g_\parallel$. If the field is applied perpendicular to the z-axis. (*i.e.*, if it is in the xy plane), the *g*-value is designated as $g_\perp$. In solutions, because of free rotating (or tumbling) motion, the *g*-factor is **isotropic**, *i.e.*, it is the average of the three *g*-values in the x, y and z directions.

Applications of ESR. The most important application of ESR is in the determination of the structure of organic and inorganic free radicals. These radicals may be produced chemically, photochemically or by using high-energy radiation. Since the free radicals are very short-lived, they are trapped in glasses, frozen rare-gas matrices or in crystals. In order to obtain a good spectrum, the free radical must be produced in a concentration of about 10^{-13} mol dm^{-3}. The intensity of an ESR signal is directly proportional to the number of the free radicals present. Hence, using ESR we can measure relative concentrations of free radicals produced under different conditions. Hyperfine interaction in ESR spectra can provide useful information about charge distribution within a molecule. Since hyperfine structure is a characteristic property of an ion or a radical, it may be used to identify unknown ions and radicals. Free radicals produced by irradiation of polymers by means of X-rays or gamma rays have also been investigated by ESR.



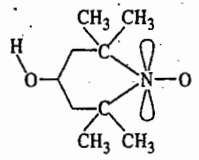
DDPH radical

One of the best known free radicals which is used for calibrating ESR spectra is DPPH (*i.e.*, α, α′-diphenylpicrylhydrazyl radical) :

It gives five extremely sharp peaks with intensity ratio 1 : 2 : 3 : 2 : 1 in the ESR spectrum.

Another application of ESR is in the investigation of molecules in the **triplet state.** A triplet state molecule has a total spin S = 1 so that its multiplicity, $2S + 1 = 3$. While a free radical with S=1/2 has an odd number of unpaired electrons, a triplet state molecule has an even number of electrons, two of them unpaired. We must carefully distinguish between a triplet state molecule and a diradical, for both contain two unpaired electrons. In a triplet state molecule, *the unpaired electrons must interact* whereas in a diradical the unpaired electrons do not interact since they are a great distance apart.

H.M. McConnell and his coworkers have found that groups with unpaired electrons can be attached to macromolecules such as proteins and membranes to obtain a great deal of information about their structure. The nitroxide molecules bound to macromolecules are called **spin labels.** These are stable molecules that possess an unpaired 2*p* electron. A commonly used nitroxide is 2,2,6, 6-tetramethyl piperidinol-N-oxyl, abbreviated TEMPOL, having the structure shown here.



(Tempol)

The unpaired electron interacts with the ^{14}N nucleus (with I=1) giving a hyperfine ESR spectrum with three lines. Spin labels give very useful information about the molecules to which they are bound. For instance, they can tell us about the rate of motion of a macromolecule to which they are bound, or the amount of thermal motion in a membrane in which they have been inserted. It is found that the bands of the ESR spectrum are narrow when the spin label is tumbling rapidly and broad when it is immobilized. The narrowing of the ESR bands arises from the more rapid relaxation of the spin when neighbouring groups are moving rapidly with respect to the spin label.

The spin label can also give information about the polarity of its environment. The extent to which the side bands are split from the central band depends upon the dielectric constant of the medium in which the spin label is dissolved. Solvents of high dielectric constant increase the splitting by augmenting the polarity of the N—O bond. Thus, a measurement of the splitting helps in estimating the polarity of the surroundings of the spin label. One can, for instance, determine if the spin label is bound near the polar head groups or near the non-polar hydrocarbon chains of a membrane.

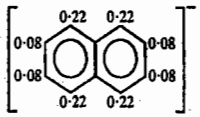
The hyperfine structure of an ESR spectrum is a kind of fingerprint that helps to identify the free radicals present in the sample. Again, since the magnitude of the splitting depends on the distribution of the unpaired electron near the magnetic nuclei present, the ESR spectrum can be used to map the molecular orbital occupied by the unpaired electron. This mapping is aided by the McConnell equation,

$$a = Q\rho, \text{ where } Q = 2{\cdot}25 \text{ mT} \qquad ...(61)$$

Here ρ is the unpaired electron spin density on a C atom and a is the hyperfine splitting constant observed for the H atom to which it is attached.

Example 30. The hyperfine constants in the ESR spectrum of (naphthalene)$^{-1}$ at the α and β positions are a=0·490 mT and a=0·183 mT, respectively. Map the unpaired electron spin density around the ring.

Solution : Using Eq. 61 and the given a values, we find the following mapping of the unpaired electron spin density at the α and β positions :



Notice that the unpaired electron spin density is greater at the α positions than at β positions because the hyperfine coupling constants at the α positions are greater than at the β positions.

Example 31. In an ESR spectrometer operating at 9·233 GHz, the centre of the spectrum of CH_3 radical occurred at 329·4 mT. Calculate the g-value of the free radical.

Solution : From Eq. 59,

$$g = \frac{h\nu}{\mu_B B} = \frac{(6{\cdot}626\times10^{-34}\text{ Js})(9{\cdot}233\times10^{9}\text{ s}^{-1})}{(9{\cdot}273\times10^{-24}\text{ JT}^{-1})(0{\cdot}3294\text{ T})} = 2{\cdot}0026$$

Example 32. The g-factor for the benzene radical anion, $C_6H_6^-$ is 2·0025. At what magnetic field intensity would you search for its ESR spectrum in a spectrometer operating at 9·302 GHz ?

Solution : Since from Eq. 59, $\nu = g\mu_B B/h$, hence, substituting various value,

$$B = \frac{h\nu}{g\mu_B} = \frac{(6{\cdot}626\times10^{-34}\text{ Js})(9{\cdot}302\times10^{9}\text{ s}^{-1})}{(2{\cdot}0025)(9{\cdot}273\times10^{-24}\text{ JT}^{-1})} = 0{\cdot}3319\text{ T} = 331{\cdot}9\text{ mT}$$

Example 33. In an ESR spectrometer operating at 9·302 GHz, the ESR spectrum of hydrogen atom gave two lines, one at 357·3 mT and the other at 306·6 mT. What is the hyperfine coupling constant of hydrogen atom ?

Solution : The spacing between the hyperfine lines in the ESR spectrum is called the *hyperfine coupling constant*; it is designated by the symbol, a. Thus,

$$a = (357{\cdot}3 - 306{\cdot}6)\text{ mT} = 50{\cdot}7\text{ mT}$$

Example 34. A free radical containing two equivalent protons gives a 1 : 2 : 1 triplet (*i.e.*, three lines) in the ESR spectrum. The lines occur at the magnetic field intensities of 330·2 mT, 332·5 mT and 334·8 mT. Calculate the hyperfine coupling constant for each proton.

Solution : Designating the ESR lines as 1, 2 and 3, and keeping in mind the fact that the protons are equivalent, we see that the hyperfine coupling constant a is given by

$$a = B(3) - B(2) = B(2) - B(1)$$
$$B(3) - B(2) = (334{\cdot}8 - 332{\cdot}5)\text{ mT} = 2{\cdot}3\text{ mT}$$
$$B(2) - B(1) = (332{\cdot}5 - 330{\cdot}2)\text{ mT} = 2{\cdot}3\text{ mT}$$
$$a = 2{\cdot}3\text{ mT}$$

Example 35. It is possible in commercial ESR spectrometers to detect the resonance from a sample containing 10^{10} spins per cm^3. Calculate the molar spin concentration corresponding to this detection limit.

Solution : Number of moles of electron spins $= \dfrac{10^{10}\text{ cm}^{-3}}{6{\cdot}022\times10^{23}\text{ mol}^{-1}} = 1{\cdot}66\times10^{-14}\text{ mol cm}^{-3}$

Thus, molar concentration (*i.e.*, the number of moles of spins per dm^3) is equal to $1{\cdot}66\times10^{-14}\text{ mol cm}^{-3}\times10^{3}\text{ cm}^{-3}/\text{dm}^3 = 1{\cdot}66\times10^{-11}\text{ mol dm}^{-3}$

The student will appreciate what an infinitesimally small molar concentration of free radical spins can be detected by ESR.

Example 36. Which valence state of copper, *i.e.*, Cu^+ ion or Cu^{2+} ion, will show an ESR spectrum and why ?

Solution : For Cu, the atomic number Z=29. Thus, Cu^+ ion contains 28 electrons and the Cu^{2+} ion 27 electrons. If we write the electronic structures of the two ions we find that Cu^+ ion is a d^{10} system containing no unpaired electron whereas Cu^{2+} ion is a d^9 system containing one unpaired d electron. Since systems containing unpaired electrons show ESR spectra, hence Cu^{2+} ion will give an ESR spectrum.

Example 37. Of the two molecules N_2 and O_2, which will show an ESR spectrum and why ?

Solution : The nitrogen molecule N_2 has fourteen electrons all of which are paired in the molecular orbitals of this molecule. However, the oxygen molecule O_2 has sixteen electrons of which there are two *unpaired* electrons in a degenerate pair of molecular orbitals. Thus, O_2 is paramagnetic and shows an ESR spectrum.

ESR OF ANISOTROPIC SYSTEMS

1. g-Factors and Hyperfine Splittings

In contrast to the ESR spectra of isotropic systems such as solutions, the chemical physicist is interested in the ESR spectra of anisotropic systems which include unstable species prepared by irradiation of crystalline materials or of substrates trapped in host matrices including frozen solutions. In such cases, the g-factors, hitherto regarded as simple scalar quantities, are treated as asymmetric tensors. A symmetric g-tensor can always be diagonalized to give the three principal g-factors, g_{xx}, g_{yy} and g_{zz}. In solution, these are averaged to give the single isotropic factor and for systems with spherical or cubic symmetry, they are equal. However, for a system with axial symmetry, one of these terms ($g_{\parallel}$) is different from the other two ($g_{\perp}$) and for lower symmetries, the three terms are all different.

Similarly, the hyperfine coupling (splitting) constants of isotropic systems must be replaced by tensors for anisotropic systems : here, too, there are two independent terms for symmetric tops and three terms for systems of lower symmetry. It is convenient to separate the hyperfine coupling constant tensor into an isotropic and an anisotropic part, as these components have different physical origins: the new anisotropic term is due to direct dipole—dipole and nucleus—electron interactions. These depend on the angle of the nucleus—electron vector to the magnetic field (that is why they are averaged to zero by tumbling) and are inversely proportional to the cube of the distance between the dipoles. Thus, the effects of anisotropy on g values and hypefine couplings in ESR spectroscopy are exactly analogous to the effects on chemical shifts and dipolar couplings in the NMR spectra of solids.

In an investigation of a single crystal by ESR, the spectra are found to depend on the orientation of the sample. Measurements taken at various angles enable us, in principle—and in several cases, in practice—to determine all the elements of the g-tensor and the hyperfine coupling tensor. Such a study yields valuable information about electron distribution. Frequently, spectral studies are made on anisotropic systems such as powders or frozen solutions which contain random mixtures aligned at all possible angles to the magnetic field. In the absence of hyperfine splitting, the resonance absorption has a distinctive envelope (Fig. 37). These envelopes have clear upper and lower cut-offs and for a system having no symmetry the envelope exhibit a well-defined maximum. Consequently,

the derivative curves have two or three peaks as shown from which the anisotropic g-values can be determined.

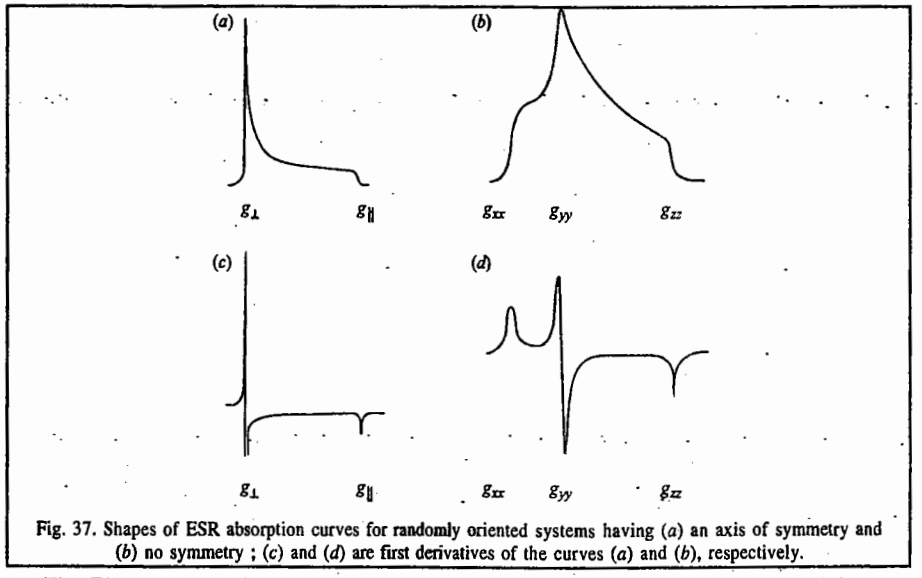


Fig. 37. Shapes of ESR absorption curves for randomly oriented systems having (a) an axis of symmetry and (b) no symmetry ; (c) and (d) are first derivatives of the curves (a) and (b), respectively.

The ESR spectra rapidly become very complex when the anisotropic hyperfine splittings are introduced. Fig. 38 shows a spectrum for the Li^+–CO_2^- ion pair, labelled with ^{13}C, in a CO_2 matrix. The patterns are basically similar to those of Fig. 29(c) with large ^{13}C and small ^7Li (I=3/2) hyperfine splittings. In this case, the spectrum is easy to analyze, though often computer fitting is necessary. In any spectral computer simulation, the spin Hamiltonian is set up ; this Hamiltonian includes terms such as quadrupolar nucleus–electron interactions, the details of which are found in standard books on the subject. In Fig. 30, parallel and perpendicular components can be seen, each showing splittings due to ^{13}C and ^7Li. The weak central lines are due to Li^+–$^{12}CO_2^-$.

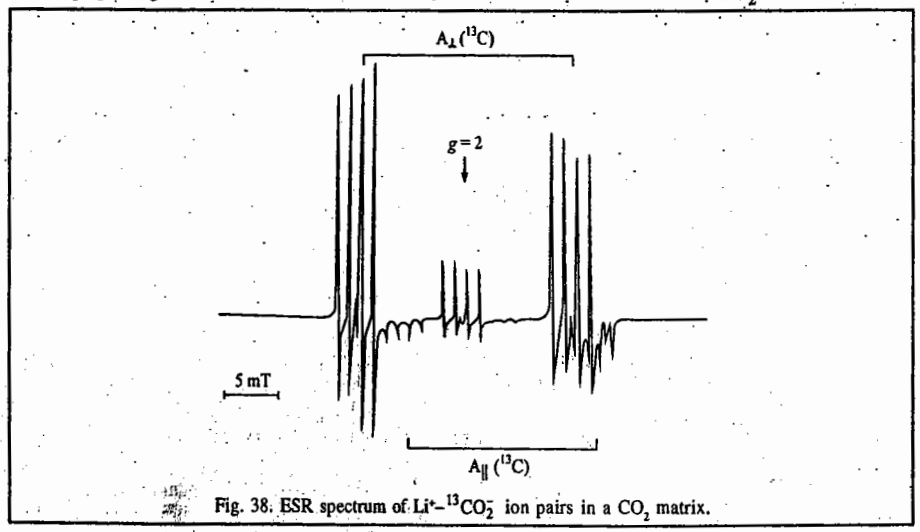

Fig. 38. ESR spectrum of Li^+–$^{13}CO_2^-$ ion pairs in a CO_2 matrix.

2. Kramers' Degeneracy and Zero-Field Splitting (ZFS)

We have so far considered ESR spectra of systems such as free radicals having just one unpaired electron. However, systems having many unpaired electrons (which involve *electron-electron interactions*) can also be investigated by ESR. There systems are, for instance, molecules having diamagnetic ground states but which possess excited triplet states (with two unpaired electrons) which have lifetimes long enough for their ESR spectra to be recorded. In the presence of a Zeeman (magnetic) field, a triplet state splits into its three components (Fig. 39), giving two possible transitions, $M_S = -1 \rightarrow 0$ and $M_S = 0 \rightarrow +1$, whose energies are identical.

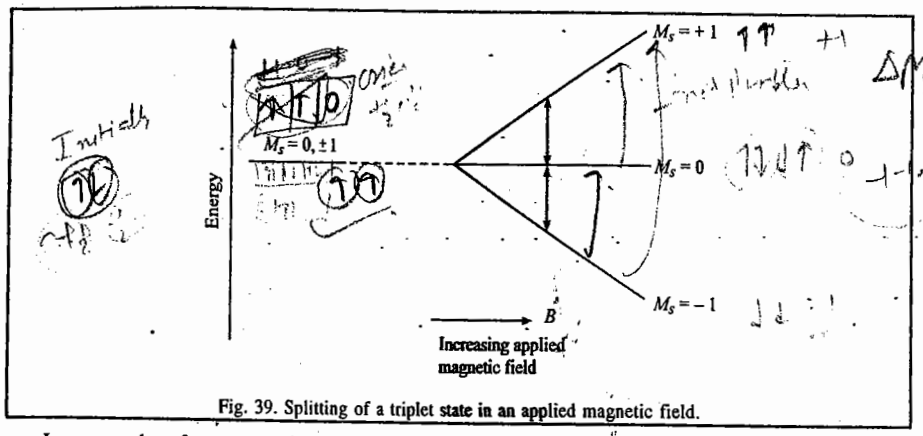

Fig. 39. Splitting of a triplet state in an applied magnetic field.

In a crystal or frozen sample, dipole-dipole interactions being anisotropic, the energy levels with $M_S = \pm1$ are shifted relative to that with $M_S = 0$ even in the absence of an applied magnetic field. Hence, when a magnetic field is applied, the two transitions no longer have the same energy (Fig. 40).

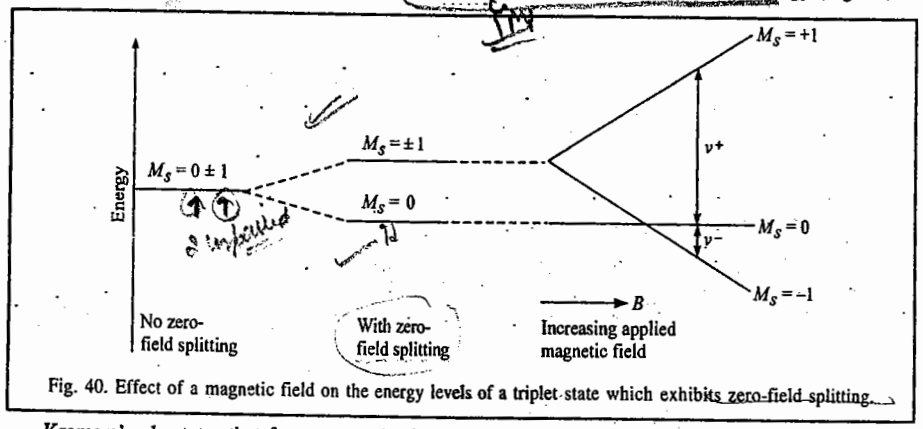

Fig. 40. Effect of a magnetic field on the energy levels of a triplet state which exhibits zero-field splitting.

Kramers' rule states that for a system having an *even* number of unpaired electron spins, the lowest energy state will be that with $M_S = 0$, as shown in Fig. 32 for a triplet state. All higher energy states in this case and *all* states for systems with an *odd* number of unpaired electron spins, will be doubly degenerate, corresponding to the two signs possible for $M_S \neq 0$. This degeneracy is known as **Kramers' degeneracy** ; it is removed by an applied magnetic (Zeeman) field, which shifts the two levels M_S=−1 and M_S=+1 in opposite directions (Fig. 40). As a consequence, the two allowed transitions (M_S=−1 → 0 and M_S=0 → +1), which are of equal energy in the absence of zero-field splitting (ZFS), are now of quite

different energy. Thus, *two* ESR signals are observed. If the ZFS is small compared with $g_{el}\mu_B B_0$, it will result in a pair of signals near $g=2{\cdot}0$, but if the splitting is large, as is often the case for transition metal ions, the apparent g-values may be very different from 2 and it may be impossible to observe the expected ESR transitions. For systems with very large splittings, the energy gap between the lowest energy level and higher ones may be so large that no crossings at all occur at magnetic fields normally used, as illustrated in Fig. 41, which shows the effect of a large ZFS on a quartet system ($S=3/2$, so that multiplicity $2S+1 = 4$). The separation induced between the $M_S = \pm 1/2$ and $M_S = \pm 3/2$ states is so large that only a single ESR signal, due to the $M_S = -1/2 \rightarrow M_S = +1/2$ transition, is observed near $g=2{\cdot}0$. The energies of the $M_S = -1/2 \rightarrow -3/2$ and $+1/2 \rightarrow +3/2$ transitions are outside the observable frequency range. In general, there is an *effective spin quantum number* which is equal to $|M_S|$ for the lowest state. This will be zero for an even number of unpaired electrons, giving no signal at all, and is often 1/2 for systems with an odd number of unpaired electrons, giving a simple spectrum in the normal frequency range.

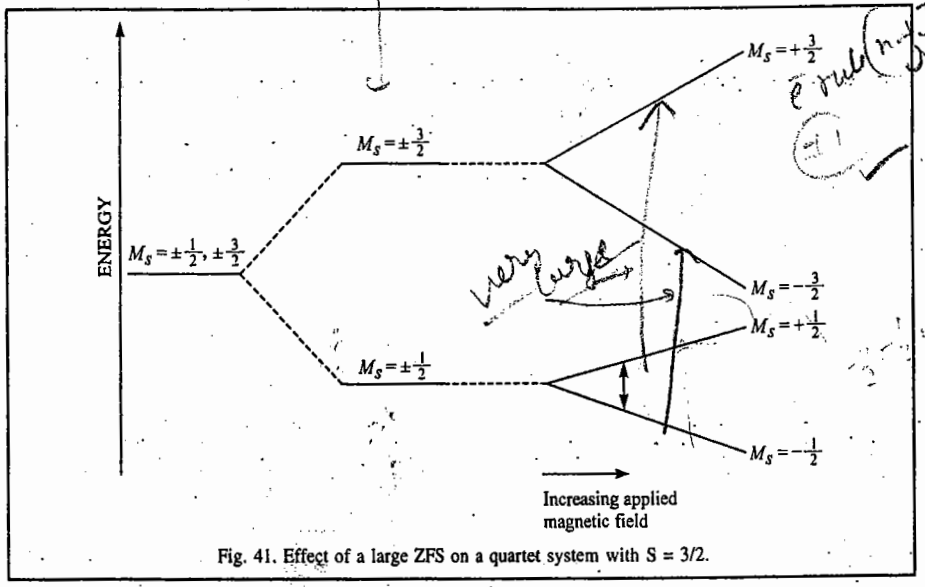

Fig. 41. Effect of a large ZFS on a quartet system with S = 3/2.

Another possible consequence of ZFS is that the $\Delta M_S = \pm 1$ selection rule for ESR transitions may break down, giving more observed transitions. Thus, the spectra, particularly for transition metal ions with several unpaired electrons, are very complicated. Also, the ZFS is anisotropic, which further complicates the ESR spectra of solids of less than cubic symmetry. No doubt, tumbling of molecules averages it to zero but in solution the spin-spin interactions cause rapid relaxation and the spectra are usually too broad to be observed. Intramolecular spin-spin interactions may similarly make spectra impossible to observe.

3. ESR Spectra of Transition Metal Complexes

The ESR spectra of transition metal ion complexes are complicated by the fact that they may have several approximately degenerate orbitals and several unpaired electrons. As a result, there may occur anisotropy in g-factors (due to orbital contribution to the magnetic moment) and also the zero-field effects, as discussed above. In an analysis of any system, we must ascertain the number of d electrons and also whether the complex is high or low spin. The consequences of Jahn-Teller distortion, which occurs to remove the degeneracy of any orbitally degenerate

ground state, and of ZFS and Kramers' degeneracy, must also be taken into consideration. Since ZFS arises primarily from spin–orbit coupling, it is much larger for heavier atoms than for lighter ones. Partly for this reason, the ESR spectra of Second and Third-row transition metal complexes are often harder to observe and interpret than those of First-row species. On the other hand, the rare-earth metal complexes for which spin-orbit coupling is small, often give clear, useful spectra. It must also be noted that if excited states lie close to the ground state, spin-lattice relaxation times will be short and spectral lines broad and the ESR spectra will be required to be observed at low temperatures.

Let us illustrate these principles by three examples :

1. d^3 system. In this system as found in Cr^{III}, the free ion ground state is ^4F and in an octahedral field, the electrons occupy the three lower (t_{2g}) orbitals giving a $^4A_2$ ground state (Fig 34). There is no Jahn-Teller distortion in this case but if there is tetragonal distortion, as in a complex with four ligands of one type and two (mutually *trans*) of another, the ground state becomes $^4B_1$. Then, there occurs ZFS and by Kramers' rule, the lowest state is degenerate and must give observable resonances. Other transitions, shown in Fig. 42 will also be observed so long as ZFS is not too large. Also, ground and excited states are well separated in energy, so spin–lattice relaxation times are long and the ESR spectral lines are narrow (sharp).

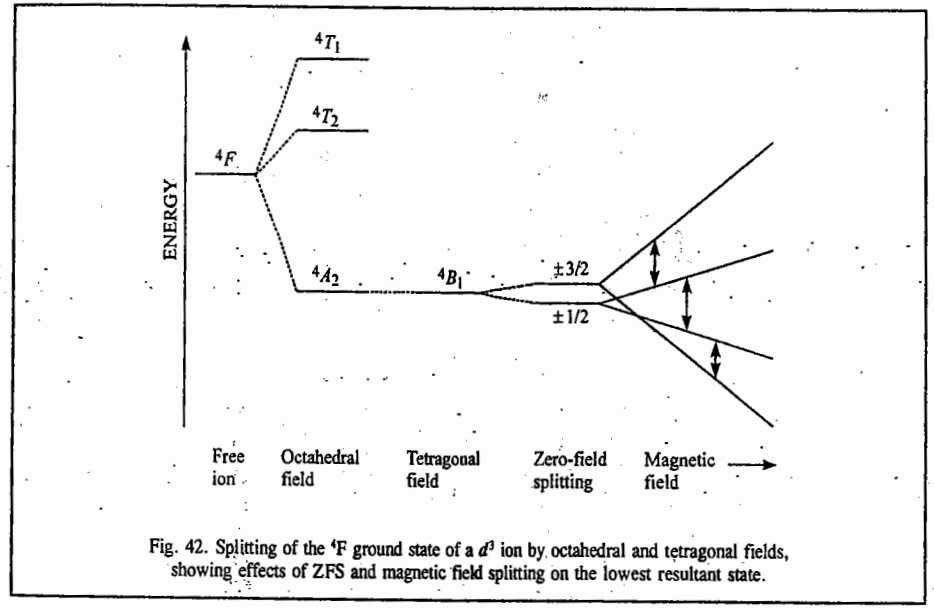

Fig. 42. Splitting of the ^4F ground state of a d^3 ion by octahedral and tetragonal fields, showing effects of ZFS and magnetic field splitting on the lowest resultant state.

2. d^6 system. Low-spin d^6 systems are diamagnetic and high-spin systems have ^5D ground states which split to give $^5T_2$ ground states in octahedral fields and $^5B_2$ states with tetragonal distortion. The ground states are connected to excited states by spin-orbit coupling giving short spin-lattice relaxation times and broad resonances and the spin-orbit coupling also gives large ZFS. The lowest level is not degenerate (Kramers' rule) and hence no resonances are observable.

3. d^9 system. For this system the ^2D ground state of the free ion becomes ^2E in an octahedral field and Jahn-Teller distortion yields a tetragonal structure whose ground state is ^2A (Fig. 35) A doublet

ground state gives ESR with no further problem. If, as is usually the case, the Jahn-Teller distortion is large, the spectral lines are narrow.

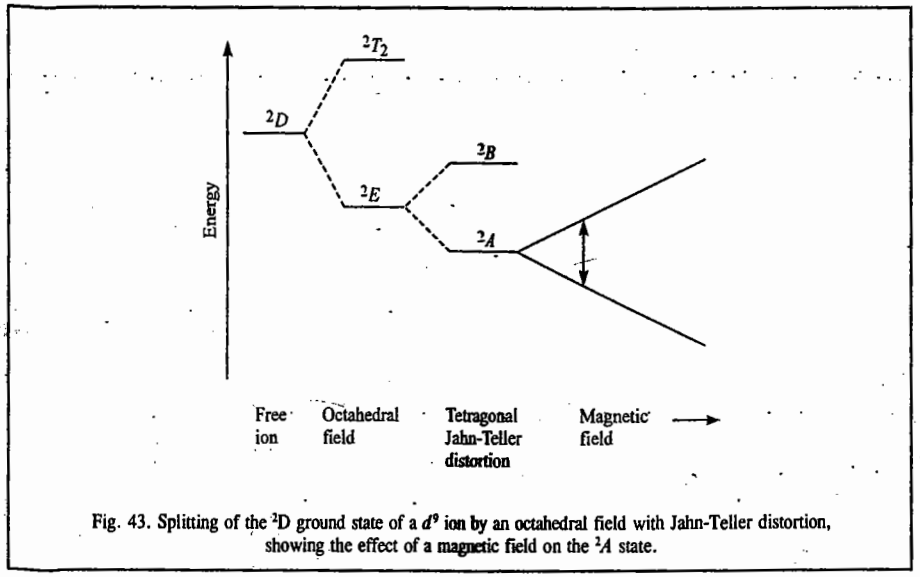

Fig. 43. Splitting of the ^2D ground state of a d^9 ion by an octahedral field with Jahn-Teller distortion, showing the effect of a magnetic field on the ^2A state.

Though the ESR spectra of transition metal ions are often very difficult to interpret, they serve as useful aids to identification, particularly using hyperfine splitting patterns ; they also serve as a means of studying the electron distribution. Values of $g_{\parallel}$ and $g_{\perp}$ can show which d orbitals are occupied and thus indicate the direction in which Jahn-Teller distortion has occurred, while hyperfine coupling constants can be used to determine the electron spin densities on various nuclei and to distinguish the components in s orbitals (isotropic) from those in p and d orbitals (anisotropic).

Example 47. *(a)*. Discuss briefly the fine structure and ZFS in ESR spectra. (*b*) Draw energy level diagrams for the values of total electron spin S = 1/2, 1, 3/2, 2, and 5/2 in the presence of applied magnetic field, showing the ESR transitions. (*c*) Draw energy level diagram for (*i*) $S = 1/2$, (*ii*) $S = 3/2$ for two different ZFS ; and (*iii*) $S = 1$ for three different ZFS.

Solution : *(a)* A species with spin S has a total of $2S+1$ energy states characterized by the quantum number M_S. In the absence of a magnetic field, all states with $M_S \neq 0$ are expected to remain doubly degenerate (*i.e.*, M_S and $-M_S$ correspond to the same energy). However, these doublets are usually separated from each other by electric fields produced by other atoms, which act *via* spin-orbit coupling. The extent of this **zero-field splitting (ZFS)** depends on the structure of the sample, the extent of spin-orbit coupling, etc. In principle, it is zero for strict cubic symmetry (Fig. 44) but, since such ideal behavior is rarely seen, ZFS is present in the vast majority of cases. The application of a magnetic field now removes the remaining degeneracy and transitions may be observed between adjacent states, following the selection rule $\Delta M_S = \pm 1$. In principle then, $2S$ transitions can occur, their separations representing the extent of ZFS (Fig. 45). The appearance of more than one line (when $S > 1/2$) is known as the **fine structure** in the spectrum. Whether or not all or any of the transitions can be observed, and what their g-values are, depends on the electron configuration and the ZFS, and, of course, on the magnetic field range of the spectrometer. We should also note that it is not entirely unknown for **forbidden lines** to appear, corresponding to $\Delta M_S = \pm 2$. It frequently happens that ZFS is very large. Under these circumstances, systems in which number n of unpaired electrons is even, may have no resonances within the observable range and those with odd n show only a single resonance corresponding to the $M_S = -\frac{1}{2}$ to $M_S = +\frac{1}{2}$ transition (Fig. 45).

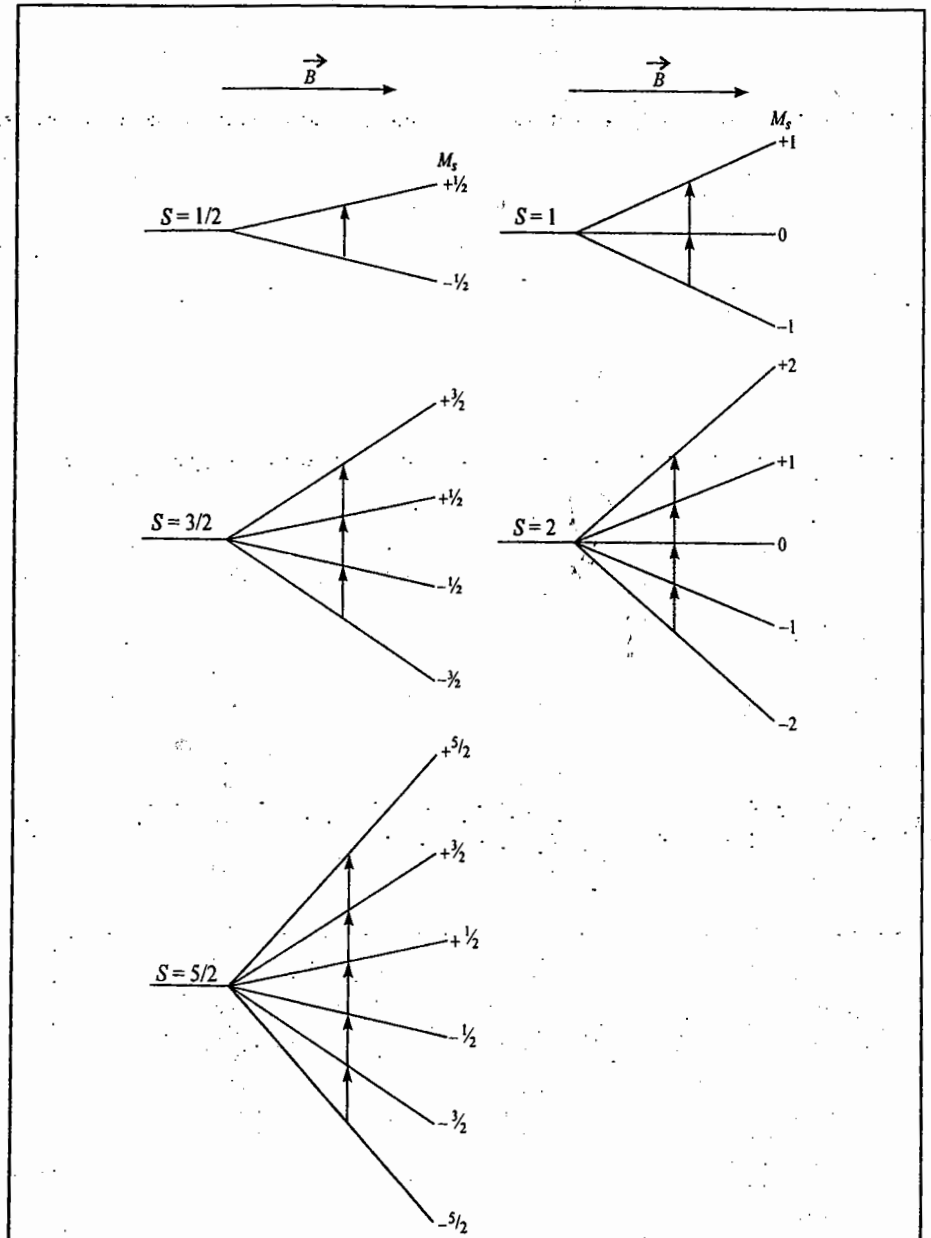

Fig. 44. Energy level diagrams for various values of S and no zero-field splitting. Note that the applied magnetic field increases from left to right and that all transitions for any one system occur at the same field-value.

(c) See Fig. 45

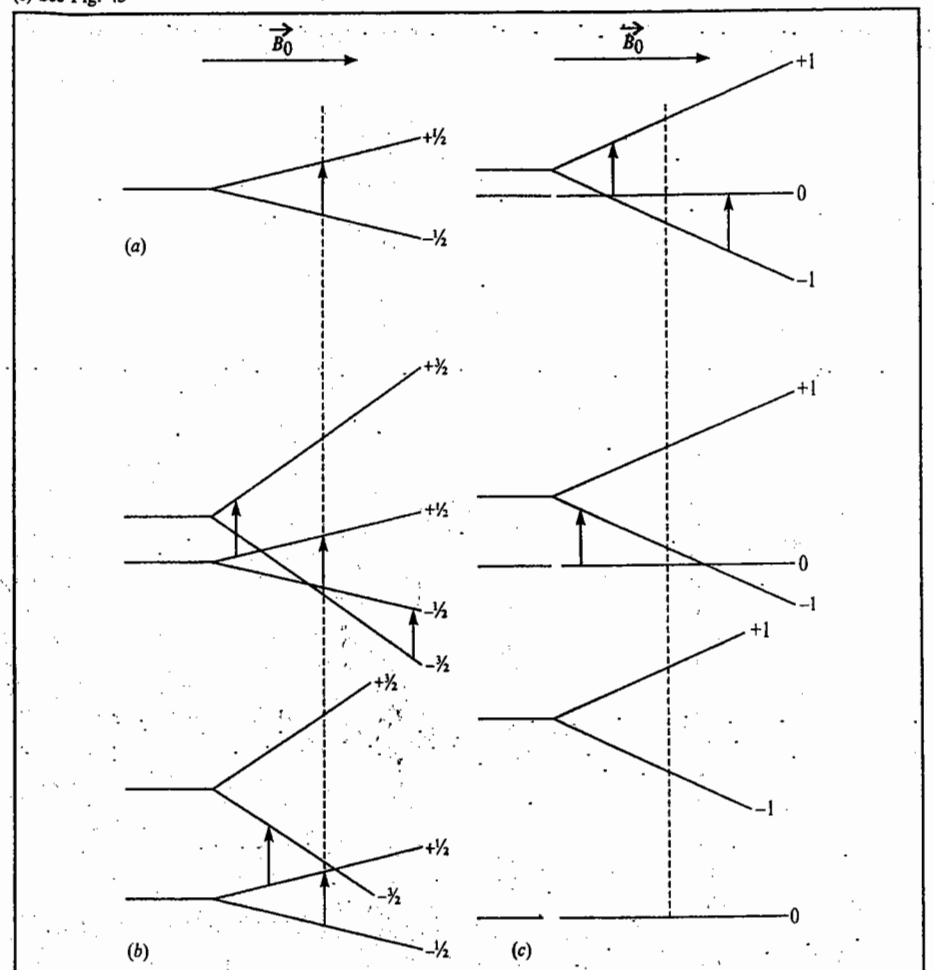

Fig. 45. Energy level diagrams : (*a*) $S=1/2$; (*b*) $S=3/2$ for two different zero-field splittings ; (*c*) $S=1$ for three different zero-field splittings. The dotted vertical lines mark the position of the (single) absorption line in the absence of zero-field splitting.

4. Multiple Resonance Techniques in ESR spectroscopy

Of the several multiple resonance techniques applied to ESR spectroscopy, two, *viz.*, **ENDOR** (electron–nuclear double resonance) and **ELDOR** (electron–electron double resonance) are of special interest. Fig. 46 shows an energy level diagram for a system which has a single electron spin and a nucleus with spin 1/2 .There are two allowed spin transitions, labelled E_1 and E_2, and the two transitions, labelled N_1 and N_2 involving the nuclear spins. These latter transitions would not normally be observed in an NMR spectrum since the resonances would be extremely broad. It may be noted that the electron–nucleus coupling constant may be comparable with or even greater than the resonance frequency of the nucleus in the absence of coupling and that the $|\alpha_e\alpha_n\rangle$ level may be lower in energy than $|\alpha_e\beta_n\rangle$.

In an ENDOR experiment, the ESR spectrum is observed while nuclear transitions are irradiated. The situation is similar to that in a nuclear INDOR experiment in that the populations of the various energy levels are perturbed and the ESR transitions change in intensity. Thus, for the system shown in Fig. 46, transition E_1 or E_2 monitored and the frequencies N_1 and N_2 are irradiated. Their frequencies depend on the magnetogyric ratio of the nucleus. One obvious application of ENDOR is in the identification of nuclei responsible for particular hyperfine splittings. Another major application is to systems for which the ESR spectrum is complex. A series of ENDOR spectra, each with as few as two lines, can greatly simplify the task of spectral assignment. Also, all double resonance methods are used for investigating relaxation processes.

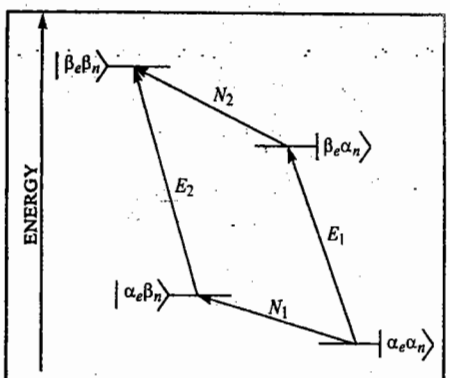

Fig. 46. Energy level diagram for a system with one unpaired electron and one nucleus with nuclear spin 1/2. The spin wave functions $|\alpha_e\ \beta_n\rangle$, etc., are designated by the spin quantum numbers of the electron and the nucleus.

An ELDOR experiment is rather different. Referring to Fig. 46, one electron spin transition is observed while the other is irradiated. As these transitions do not share energy levels, the effects of irradiation (also called *pumping*) are only seen as a result of spontaneous nuclear spin transitions. In an ELDOR spectrum, the intensity change in the monitored resonance is plotted against frequency difference, and in our example, a peak will occur at $|E_2 - E_1|$, which equals the hyperfine coupling constant. For a more complicated system, the spectrum may have several lines, each single line giving a direct measurement of a splitting constant. This is particularly useful for measuring very large splittings, or on occasion when a spectrum is complicated by numerous hyperfine splittings. ELDOR spectra also contain lines corresponding to pumping of the forbidden transitions (Fig. 46), that is $|\alpha_e\alpha_n\rangle$ to $|\beta_e\beta_n\rangle$ and $|\alpha_e\beta_n\rangle$ to $|\beta_e\alpha_n\rangle$ and these contain information about the mean nuclear frequency as well as the hyperfine coupling constant.

Example 48. Draw the energy level diagram (energy versus applied magnetic field) for a system with $S=3/2$ under the various circumstances listed below. Select a particular energy interval as corresponding to the spectrometer frequency, mark the possible ESR transition and note how their number changes [assume that the limit of applied field available is twice that corresponding to the transition in *(a)*].

***(a)* with no zero-field splitting (ZFS),**

***(b)* with small ZFS,**

***(c)* with ZFS comparable to the ESR spectrometer frequency and**

***(d)* with ZFS very much larger than the spectrometer frequency.**

Solution : See Fig. 47. Note that the $M_S = -1/2 \rightarrow +1/2$ transition is unaffected by ZFS and always appears, even though the other transitions may move out of the spectrometer range.

Example 49. Repeat the exercise of Example 48 for $S=2$.

Solution : See Fig. 48. Note the dependence of the line positions on the zero-field splitting (ZFS) and that it is possible for there to be no ESR lines at all in the spectrometer range.

Example 50. From the ESR spectrum shown in Fig. 49 estimate the *g*-value.

Solution : The centre of the line appears at about 326 mT and the reference signal at about 332 mT. Hence,

$$g = 2{\cdot}0028 \times 332/326 = 2{\cdot}04.$$

Example 51. From the ESR spectrum shown in Fig. 50, estimate the value of g and of A. Which type of spin system would give rise to this type of structure in the spectrum ?

Solution : The spectrum is a 1 : 2 : 1 triplet, centered at $B=3245$ G. The reference signal is at $B=3319$ G. Hence, $g = 2{\cdot}0028 \times 3319/3245 = 2{\cdot}048$. The hyperfine coupling constant A is the separation between the individual lines, 25 G. Such a spectrum would arise from coupling of the unpaired electron spin with two nuclei with $I=1/2$.

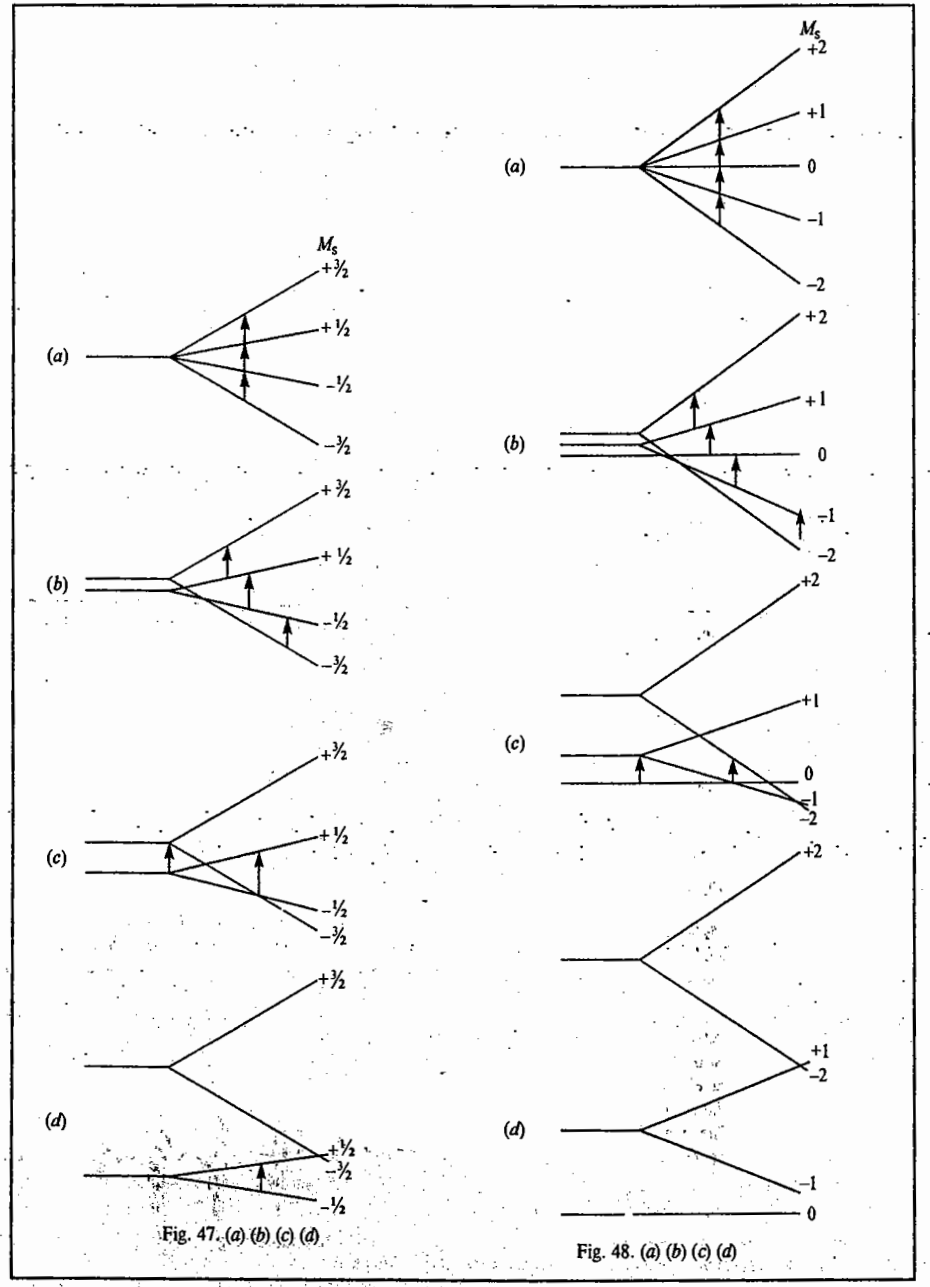

Fig. 47. (a) (b) (c) (d)

Fig. 48. (a) (b) (c) (d)

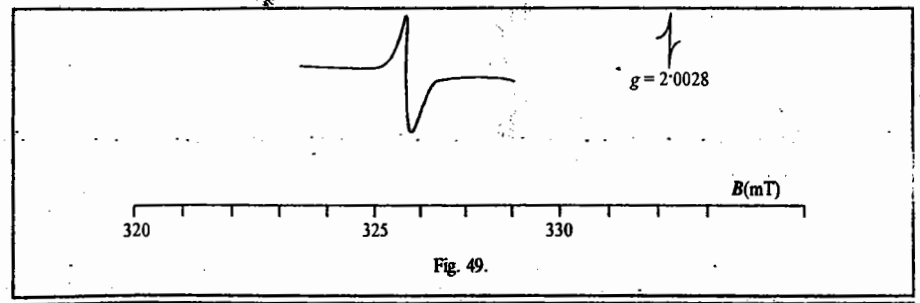

Fig. 49.

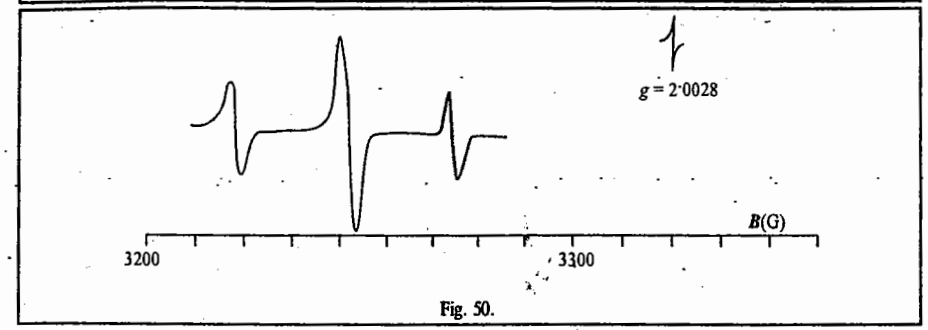

Fig. 50.

Example 52. Predict the ESR spectra expected for the following species in which M has *no* nuclear spin ($I = 0$) :

(a) $M^{\bullet}$ *(b)* $MH^{\bullet}$

(c) $MH_2^{\bullet}$ *(d)* $MH_3^{\bullet}$.

Solution : The spectra would have the following shapes :

(a) a singlet *(b)* a doublet

(c) a 1 : 2 :. 1 triplet *(d)* a 1: 3 : 3 : 1 quartet.

In *(c)* and *(d)*, the lines are equally spaced.

Example 53. The spectrum shown in Fig. 51 is for the radical anion $B_2H_6^+$, in which the boron atoms have been isotopically enriched to 98% in $^{11}B(I=3/2)$. What can be deduced about the numbers of boron and hydrogen nuclei with which the unpaired electron is interacting ? What implications does this have for the structure of the radical anion ?

Solution : The spectrum is a septet of septets. The large line-separation must be hyperfine splitting from ^{11}B. Therefore, the unpaired electron is interacting equally with both boron nuclei, *i.e.*, is delocalized equally between the two boron atoms. The small splitting must be due to the superhyperfine interaction with all six ^1H nuclei which must also be equivalent.

Diborane, B_2H_6, has an electron-deficient bridged structure containing four terminal and two bridging hydrogen atoms. The radical anion does not have this structure since the hydrogen atoms are now all equivalent. The simplest structure would be analogous to ethane, with only a single bonding electron holding the two BH_3 units together.

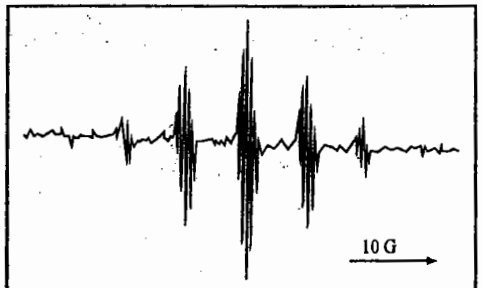

Fig. 51. The ESR spectrum of $B_2H_6^+$.

Example 54. Explain why minerals which contain iron only in oxidation state +2 do not give usually an ESR spectrum.

Solution : Most minerals contain high-spin iron (II) which has a d^6 configuration with four unpaired electrons ($S = 2$). Even-electron systems seldom give ESR spectra (see Example 49).

Example 55. Sketch the ESR spectra you would expect for

***(a)* a solution of Cu^{2+} in water and**

***(b)* The same solution after it has been frozen.**

Assume that only hyperfine coupling to Cu^{63} ($I = 3/2$) can be seen.

Solution : See Fig. 52.

(a) Solution spectra are isotropic even though the individual ions may have non-cubic symmetry. A simple quartet spectrum is, therefore, expected.

(b) When the solution is frozen, the ions are immobilized and have a random distribution of orientations. An anisotropic ESR spectrum showing $g_{\parallel}$ and $g_{\perp}$ is, therefore obtained. Since $A_{\parallel}$ is normally quite small for Cu^{2+}, A_{iso} is roughly equal to $A_{\perp}/3$, where A is the hyperfine coupling constant.

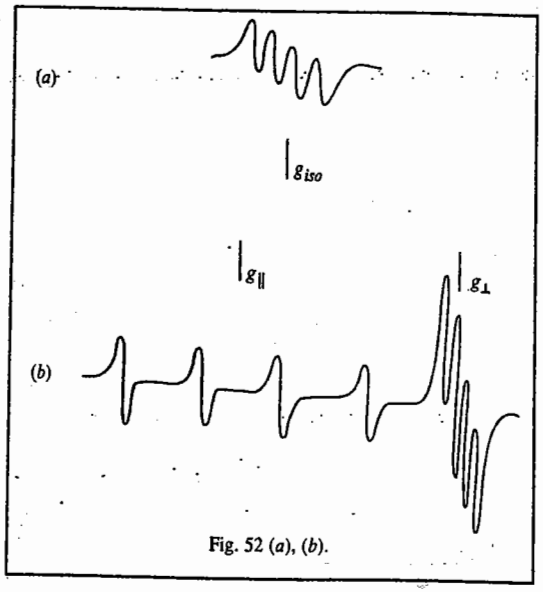

Fig. 52 (*a*), (*b*).

SPIN HAMILTONIAN

In gases and liquids, sharp magnetic resonance spectral lines occur as a result of rapid tumbling motion of molecules which average out the local fields. In solids, on the other hand, the electron finds itself in very complex environment of interacting fields. In the 1960s, Abragam and Price and later, Bleaney and Stevens, expressed the various interactions to which a paramagnetic ion is subjected, in the form of a spin Hamiltonian which is written as

$$\hat{H} = \hat{H}_{el} + \hat{H}_{cf} + \hat{H}_{L\text{-}S} + \hat{H}_{S\text{-}S} + \hat{H}_{Z} + \hat{H}_{hf} + \hat{H}_{Q} + \hat{H}_{N} + \hat{H}_{E} \qquad ...(62)$$

where the various terms, their energies given in parentheses, have the following significance :

$\hat{H}_{el}$ = Free ion or Coulomb energy (10^4 - 10^5 cm^{-1})

$\hat{H}_{cf}$ = Stark crystal field energy (10^3 - 10^4 cm^{-1})

$\hat{H}_{L\text{-}S}$ = Spin-orbit interaction (10^2 - 10^3 cm^{-1})

$\hat{H}_{S\text{-}S}$ = Electronic spin-spin interaction (0 - 1 cm^{-1})

$\hat{H}_{Z}$ = Zeeman interaction of electron with external magnetic field (0 - 1 cm^{-1})

$\hat{H}_{hf}$ = Hyperfine interaction between the electronic and magnetic moments (0 - 10^{-2} cm^{-1})

$\hat{H}_{Q}$ = Nuclear quadrupole interaction between electron and nucleus (10^{-3} cm^{-1})

$\hat{H}_{N}$ = Nuclear Zeeman interaction involving nuclear interaction with the magnetic field (10^{-4} cm^{-1})

$\hat{H}_{E}$ = Exchange interaction between two types of electrons ($< 10^{-4}$ cm^{-1}).

The energies of the nine terms in the spin Hamiltonian have been listed in the order of decreasing magnitude. The first Coulomb energy term involves the interaction of electrons with one another and with the nuclei. The second Stark term removes the $2L+1$ degeneracy of the salts of the metals of the First transition series. The Stark splittings are small in the salts of rare earths and actinides whose $4f$ and $5f$ shells, respectively, are shielded by closed electron shells.

The first three terms involve too much energy for excitation by ESR. The fourth, fifth and sixth terms are investigated in ESR since they lie in the microwave region. The last three terms are too small to be observed in the presence of $\hat{H}_Z$.

Consider Cu^{2+} ion, the $3d^9$ system with $^2D_{5/2}$ ground term. The total degeneracy of the ground electronic state is 10, being given by $(2L+1)(2S+1)$, *i.e.*, the product of the five-fold orbital degeneracy ($L=2$) and two-fold spin degeneracy $\left(S = \frac{1}{2}\right)$. In a tetragonal crystal field, the orbital degeneracy is partially removed (Fig. 53). Since the Cu^{2+} ion has an odd number of electrons, the spin degeneracy still remains, in accordance with Kramers' theorem. The spin-orbit interaction removes the orbital degeneracy completely. The Zeeman field removes the spin degeneracy. The ESR is observed between $m_s = -\frac{1}{2}$ and $m_s = +\frac{1}{2}$ levels. Since the copper nucleus has nuclear spin, $I = \frac{3}{2}$, hyperfine structure results, giving four transitions between the m_I sub-levels according to the selection rule $\Delta m_I = 0$.

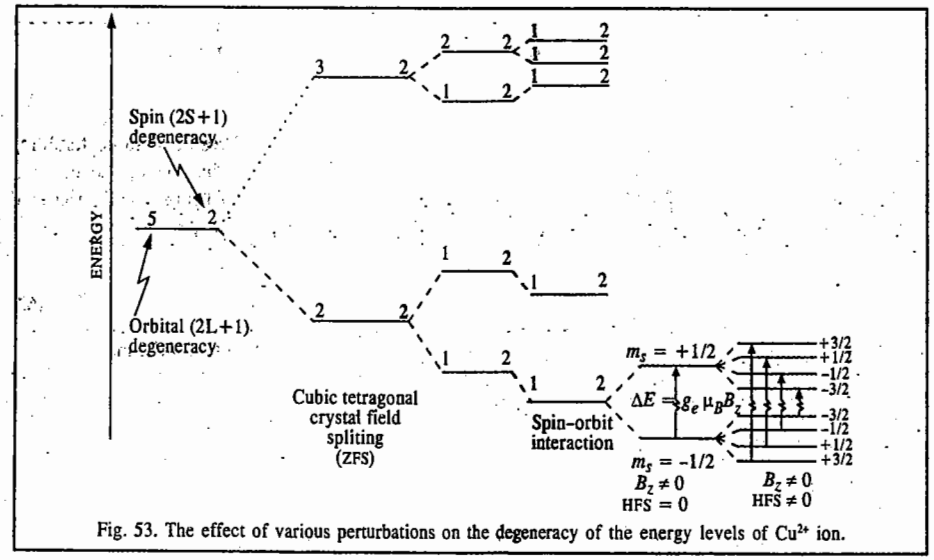

Fig. 53. The effect of various perturbations on the degeneracy of the energy levels of Cu^{2+} ion.

The spin Hamiltonian is formidable to use for computational purposes. It can, however, be used to describe the experimental results. For a trigonal or tetragonal crystal field where the magnetic field B is directed along the symmetry axis of the crystal, the spin Hamitonian can be written as

$$\hat{H} = \mu_B[g_{\perp} B_z S_z + g_{\perp}(B_x S_x + B_y S_y)] + D[S^2 - \tfrac{1}{3}S(S+1)] + E(S_x^2 - S_y^2)$$
$$+ A_z I_z S_z + A_x I_x S_x + A_y I_y S_y + Q[I_z^2 - \tfrac{1}{3}I(I+1)] - g_N \mu_N B I \qquad ...(63)$$

where the symbols have the following meaning :

S= effective electron spin; S_z = the z-component (along the magnetic field direction) of spin ;

S_x, S_y are the components along x and y-axes, respectively; I = nuclear spin and I_x, I_y, I_z are the Cartesian components ; D, E are the zero-field splitting constants, Q is the nuclear quadrupole moment and A is the hyperfine coupling constant.

The constants g, D, E, A and Q are determined empirically from experiment. The terms involving B and S denote the interaction of electronic magnetic moment with the Zeeman field; they are generally anisotropic. The terms involving D and E give rise to fine structure, resulting from the second-order effects of crystal field exerted via spin–orbit interaction. The terms involving I and S denoting hyperfine interaction are also anisotropic, resulting from dipole interactions between the nuclei and the electrons. The quadrupole interaction term (for nuclei with nuclear spin, $I \geq 1$) is also anisotropic. The last term represents the direct interaction between the nuclear magnetic moment and the Zeeman field. Though g is positive, the signs of other constants are very difficult to obtain since they have to be determined from second-order effects. Of course, not all the terms in Eq. 63 are of equal importance for a given metal ion. For instance, if an ion has no nuclear spin, the terms containing I vanish. For a free electron, on the other hand, D, E, I, A, Q are all zero so that the Hamiltonian assumes the form $H = g_e\mu_B B$, where g_e is now a scalar quantity.

By convention, S is assigned a value that makes the observed number of energy levels equal to $2S+1$. In those spin systems, where only the lower energy levels are occupied, the higher energy levels cannot be detected experimentally. Thus, the spin determined from the $2S+1$ observed levels corresponds to a fictitious state ; hence the effective spin is sometimes referred to as 'fictitious spin'.

MÖSSBAUER SPECTROSCOPY (MB SPECTROSCOPY)

The discovery of **Mössbauer effect** or Mössbauer spectroscopy (also known as the recoil-less nuclear gamma resonance fluorescence (NRF) spectroscopy) in 1958 by the German physicist Rudolf Mössbauer was hailed as a breakthrough in nuclear and solid state physics. Mössbauer shared the 1961 Physics Nobel Prize with the American nuclear physicist Robert Hofstadter (who was honoured for electron–nuclear scattering concerning the structure of the nucleons). Mössbauer spectroscopy has found wide application in elucidating the nature of the chemical bond in inorganic solid state chemistry and biological science, for instance, bonding in haemoglobin and oxyhaemoglobin.

Basic Principle of NRF Spectroscopy. Consider the original experiment performed by Mössbauer. Here ^{57}Co decays to the excited state of iron, $^{57}Fe^*$ by electron capture (EC), which further decays to the stable ^{57}Fe by the emission of delayed gamma ray (Fig. 54). This latter phenomenon is called **γ-ray fluorescence.** In the presence of a target nucleus ^{57}Fe, this gamma ray can be resonantly absorbed. Since the excited state $^{57}Fe^*$ has a finite life-time (τ), the uncertainty in the enegy of the emitted **γ-ray** is governed by the Heisenberg uncertainty principle, $\Delta E \Delta t \approx \hbar$, which can be rewritten in a slightly different notation as

$$\Gamma\tau \approx \hbar \qquad \ldots(64)$$

where Γ is the line width and τ is the life-time of the excited state. From Eq. 46 we see that since $10^{-11}\ s < \tau < 10^{-4}\ s$, $10^{-4} < \Gamma < 10^{-11}$ eV.

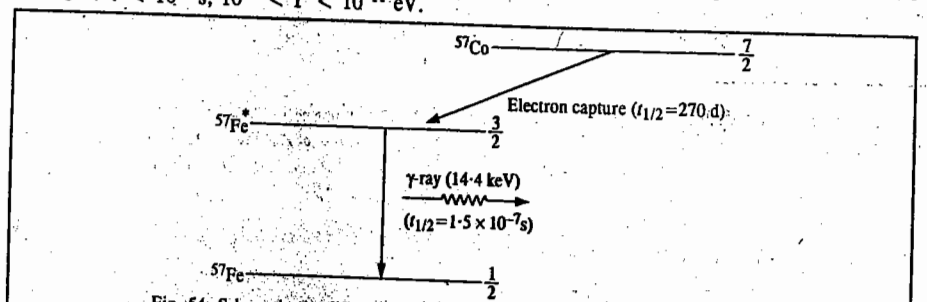

Fig. 54. Schematic simplified diagram showing the decay of the radioactive ^{57}Co to ^{57}Fe.

The momentum of the emitted γ-ray is given, according to the de Broglie relation, by

$$p = h/\lambda \qquad \ldots(65)$$

where λ is the γ-ray wave length. Since linear momentum must be conserved, the nucleus must recoil in the opposite direction, with the recoil energy R given by

$$R = p^2/2M \qquad \ldots(66)$$

where M is the mass of the recoiling nucleus. The target nucleus, too, must recoil with energy R on receiving the γ-ray, with the result that some of the energy of the γ-ray transition, E_γ, is converted into the recoil energy. Thus, for the emitting nucleus

$$E = E_\gamma - R \qquad \ldots(67)$$

and for the absorbing nucleus (absorber)

$$E = E_\gamma + R \qquad \ldots(68)$$

We see that the emission and absorption lines are centred $2R$ apart.

Since

$$E_\gamma = h\nu = hc/\lambda = pc \qquad \ldots(69)$$

we have, from Eqs. 66 and 69,

$$2R = E_\gamma^2/Mc^2 \qquad \ldots(70)$$

For the resonance absorption to occur, Γ must be greater than or equal to the loss in γ-ray energy due to recoil, *i.e.*,

$$\Gamma \approx 2R \qquad \ldots(71)$$

The plot of the number of the emitted γ-rays versus energy is given in Fig. 55.

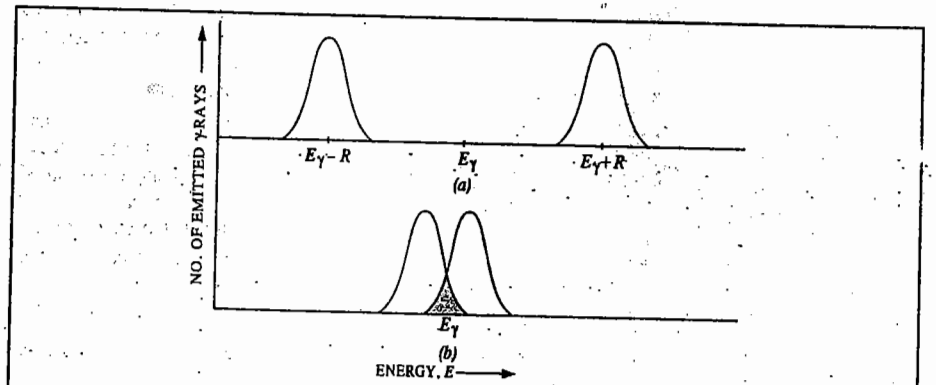

Fig. 55. *(a)* Resonance absorption and emission curves for $2R > \Gamma$.
(b) Resonance absorption and emission curves for $2R \approx \Gamma$.

Let us make an order-of-magnitude calculation. For the Mössbauer nuclide ^{57}Fe, it is found experimentally that E_γ = 14·4 keV; and $M = 1{\cdot}67 \times 10^{-27}$ kg. Hence, using Eq. 70, $R = 2 \times 10^{-3}$ eV. The life-time of the lowest excited state of ^{57}Fe is 10^{-7} s which, using Eq. 64, corresponds to Γ-value of about 5×10^{-9} eV. In other words, $R >> \Gamma$. Obviously, the resonance absorption condition, *viz.*, $\Gamma \approx 2R$ (Eq. 71) is not obtained. Mössbauer devised a very ingenious method to obtain the γ-ray resonance condition. He took the sample (containing the emitter nuclei) in the form of a solid at low temperatures. In the solid the nuclear recoil energy is dissipated among the lattice vibrations or the solid as a whole. Thus, the emitted γ-rays have the energy, E_γ. Likewise, no energy is lost to recoil

for the absorber nucleus. It should be noted that Mössbauer effect cannot be observed in liquids and gases because the recoil energy cannot be dissipated in these states of matter.

Mössbauer Experiment. The set-up that Mössbauer designed for his experiment is very simple (Fig. 56). The Doppler motion is given to the source, *i.e.*, the source is moved towards the absorber with velocity v by means of a velocity drive. The intersity of the emitted gamma rays is meausred as a function of the Doppler velocity, v. It must be remembered that the Doppler velocity given to the source relative to the absorber is necessary to bring the source and the absorber lines closer to meet the resonance absorption condition; it is *not* required to compensate the recoil energy because the recoil has already been eliminated by taking the sample in the form of a solid. When the source and the absorber move towards each other, the sign of Doppler velocity is taken to be positive. A typical Mössbauer spectrum is shown in Fig. 57.

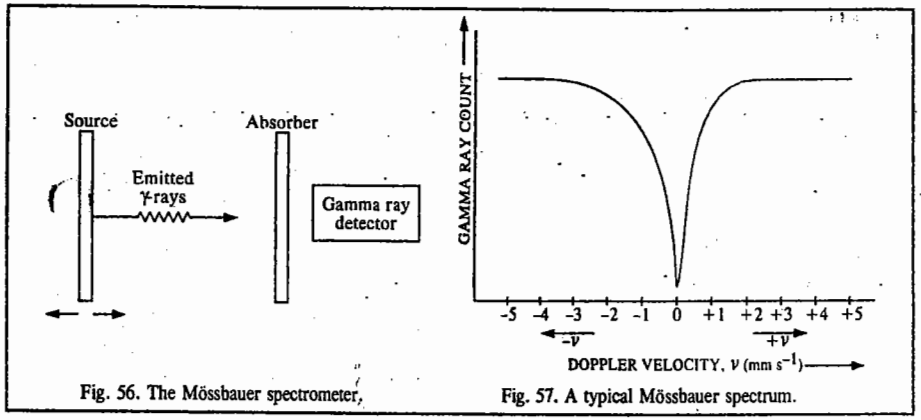

Fig. 56. The Mössbauer spectrometer.

Fig. 57. A typical Mössbauer spectrum.

More about Mössbauer Spectroscopy. Three quantities, called **hyperfine interactions**, are studied by Mössbauer spectroscopy. There are *chemical (isomer) shift* (δ); *nuclear electric quadrupole splitting* (ΔE_Q) and *nuclear Zeeman splitting*.

1. Chemical (Isomer) Shift. As a result of the electrostatic interaction between the nucleus and the electrons in a solid, the nuclear energy levels are shifted in both the source and the absorber. This shift, called the **isomer shift**, is given by

$$\delta = \frac{2\pi}{5} Ze^2 [|\psi_a(0)|^2 - |\psi_s(0)|^2](R_{ex}^2 - R_{gd}^2) \qquad ...(72)$$

where e is the electronic charge, Z the atomic number and R_{ex} and R_{gd} are the radii of the nucleus in the excited and the ground states, respectively. $|\psi_a(0)|^2$ is the electron density evaluated at the nucleus for the absorber and $|\psi_s(0)|^2$ is the corresponding quantity for the source. Since only s electrons have a finite wave function at the nucleus and the p and d electrons have vanishing wave functions at the nucleus, it is only the s electrons which are responsible for the isomer shift.

2. Nuclear Electric Quadrupole Splitting, ΔE_Q. Sometimes, as in the case of ^{57}Fe, the excited state has a nuclear spin > 1; here $I = 3/2$. If the quadrupole moment eQ of the ^{57}Fe nucleus in the absorber interacts with the *EFG* (electric field gradient) that is not spherically symmetric, the resulting interaction splits the excited state energy level into two lines, the splitting being called electric quadrupole splitting, ΔE_Q. The quantity e^2Qq is called nuclear electric quadrupole coupling constant. Fig. 58 illustrates the concepts of isomer shift and electric quadrupole splitting.

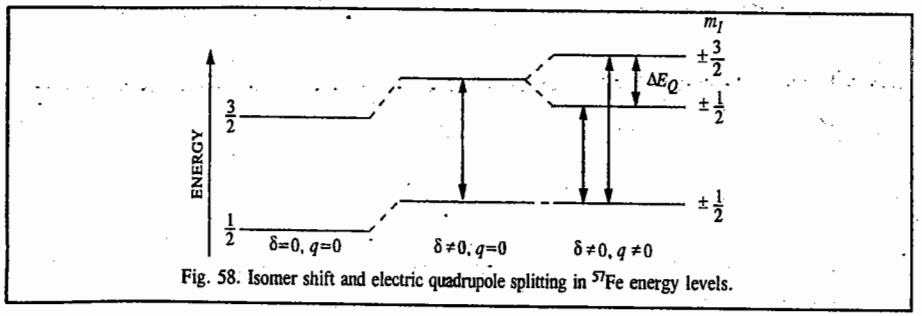

Fig. 58. Isomer shift and electric quadrupole splitting in ^{57}Fe energy levels.

Example 64. The Mössbauer spectrum of $K_4[Fe(CN)_6]$ consists of one line whereas that of $K_3[Fe(CN)_5NO]$ consists of two lines. Draw these spectra qualitatively and account for their appearance.

Solution : *(a)* $K_4[Fe(CN)_6]$. A single line Mössbauer spectrum shows only the effect of isomer shift because for the $[Fe(CN)_6]^{4-}$ anion, being spherically symmetric, $q=0$ (Fig. 59). Also, refer to Fig. 58.

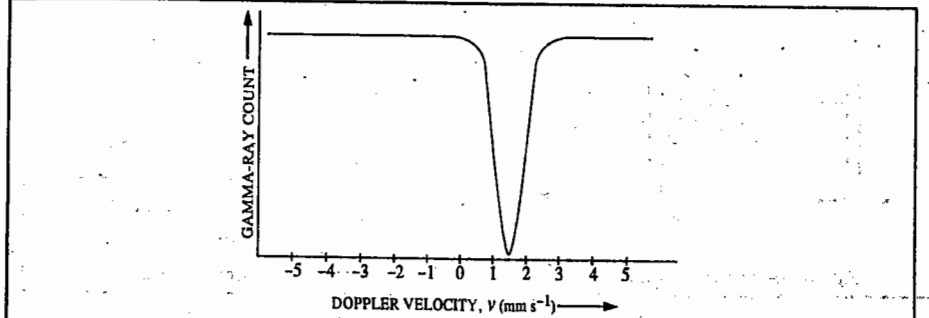

Fig. 59. The Mössbauer spectrum of $K_4[Fe(CN)_6]$. $\delta \neq 0$, $q = 0$

(b) $K_3[Fe(CN)_5NO]$. A two-line spectrum shows the effect of both the isomer shift and the quadrupole splitting because for the $[Fe(CN)_5NO]^{3-}$ anion, being not spherically symmetric, $q \neq 0$ (Fig. 60). Also, refer to Fig. 8.

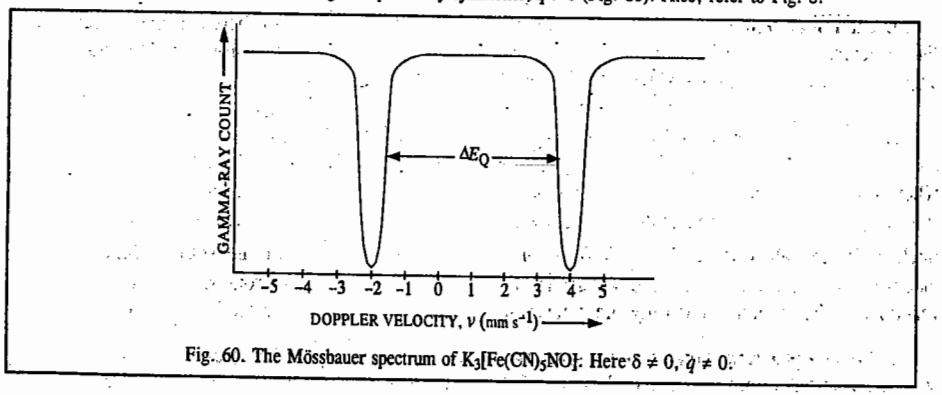

Fig. 60. The Mössbauer spectrum of $K_3[Fe(CN)_5NO]$: Here $\delta \neq 0$, $q \neq 0$.

3. Nuclear Zeeman Splitting (also called **magnetic hyperfine splitting**). The external nuclear Zeeman splitting is caused by the splitting of the nuclear energy levels by the magnetic field, B. In fact, in the metallic state of iron, very large internal magnetic field of the order of about 30 T, exists; this field, too, causes huge splitting. Fig. 61 shows the combined effect of isomer shift ($\delta \neq 0$)

and magnetic field ($\delta \neq 0$, $B \neq 0$) on the Mössbauer spectrum of ^{57}Fe. The selection rule $\Delta m_I = 0, \pm 1$ gives six lines in the spectrum.

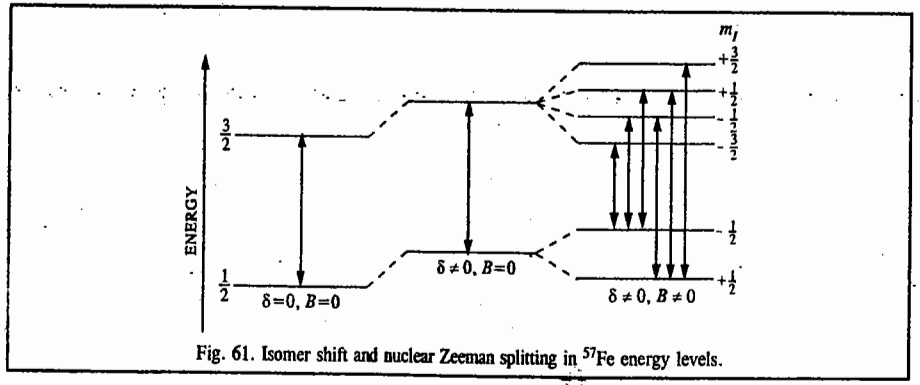

Fig. 61. Isomer shift and nuclear Zeeman splitting in ^{57}Fe energy levels.

PHOTOELECTRON SPECTROSCOPY (PES)

Photoelectron spectroscopy is a very important technique for determining the atomic and molecular energy levels and hence the ionization energies (or the binding energies) of atoms and molecules. Consider a few energy levels of an atom containing electrons with paired spins (Fig. 62). The ionization energy (IE), or preferably, the binding energy (BE) of the atom is defined as the *least* energy required to remove an electron from the highest occupied orbital. The electrons are classified as the ***valence electrons*** and the ***core electrons***. When the atom (or the molecule) is irradiated with ultraviolet (UV) radiation, photoionization occurs by the ejection of the valence electrons which carry away a certain kinetic energy (KE). On the other hand, irradiation by the highly energetic X-rays results in the ejection of the core electrons. The former technique is known as UV-PES or simply UPES and the latter as XPES. In each case, we have

$$h\nu = \text{BE} + \text{KE} \qquad \ldots(73)$$

where $h\nu$ is the photon energy. Thus,

$$\text{BE} = h\nu - \text{KE} \qquad \ldots(74)$$

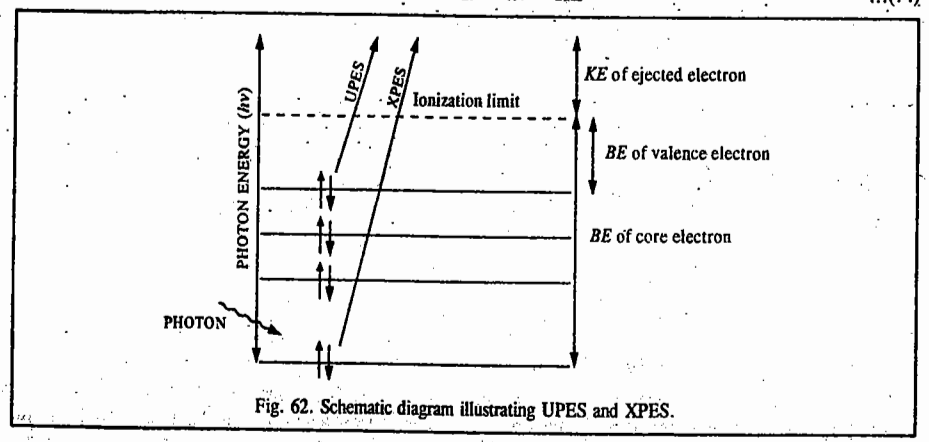

Fig. 62. Schematic diagram illustrating UPES and XPES.

It follows that knowing $h\nu$ and measuring KE, BE can be calculated. It may be mentioned that PES is the technique derived from Einstein's photoelectric effect where a beam of monochromatic

photons, incident on a metal, removes the electrons from the bulk of the metal (the metal is a "sea" of electrons), which carry away the excess kinetic energy. The work function of the metal, which is the energy required to remove the bulk electrons to the surface of the metal, is the analogue of the ionization energy of the atom (or the molecule) in PES. The Swedish physicist K. Siegbahn (1918-) pioneered the experimental and theoretical aspects of PES. He was the cowinner (with N. Bloembergen (1920-) and A.L. Schawlow (1921-)) of the 1981 Physics Nobel Prize.

In UPES, the most commonly used source of UV photons is a helium gas discharge tube; the most intense line has a wave length of 58·4 nm which corresponds to an energy of 21·22 eV. In XPES, we use an X-ray source of higher energy to ionize the inner core electrons. Here the X-ray beam is produced by electron bombardment of a metal target such as aluminium or magnesium. The K_α line for aluminium occurs at 1486·6 eV. Photoelectron spectra are interpreted in terms of **Koopmans' theorem** which states that the ionization energy, IE, is equal to the negative of the energy of the orbital (usually the HOMO) from which the electron is ejected, *i.e.*, $(\text{IE})_i = -E_i$. This very important theorem is, however, only an approximation since it ignores the fact that the remaining electrons adjust their distributions when ionization occurs.

Siegbahn's experimental technique of PES consists in measuring the kinetic energies of the photoelectrons using an electrostatic deflector which produces different deflections in the paths of the photoelectrons as they pass between charged plates. With the increase in field strength, electrons of different speeds and hence different kinetic energies, reach the detector. The photoelectron spectrum is recorded with intensity of electron flux as a function of the kinetic energy.

Atomic PES. The photoelectron spectra of inert gases argon, krypton and xenon, excited by the helium resonance radiation ($h\nu$ = 21·22 eV), are the simplest spectra. In each case, a two-line spectrum with roughly 2 : 1 intensity is obtained (Fig. 63). For argon, we have

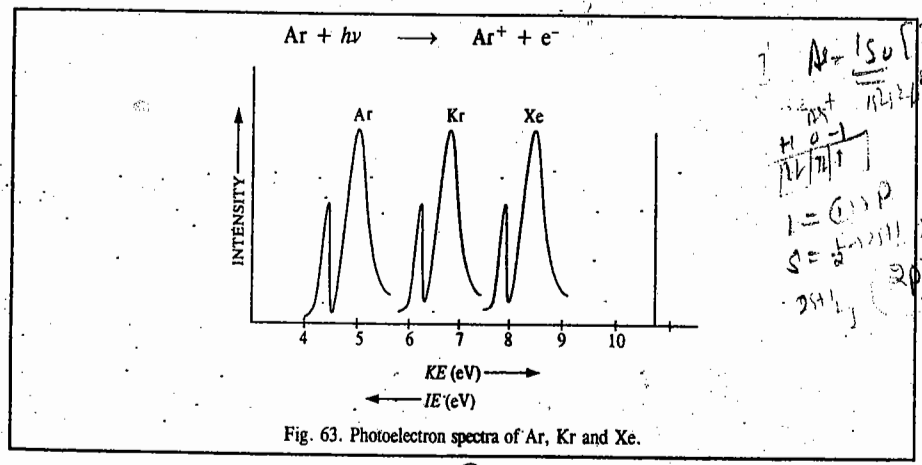

Fig. 63. Photoelectron spectra of Ar, Kr and Xe.

The term symbol of the ground state of Ar is $^1S_0$ while the term symbols of Ar^+ are $^2P_{1/2}$ and $^2P_{3/2}$. The two-line spectrum corresponds to the two transitions $^2P_{1/2} \leftarrow {}^1S_0$ and $^2P_{3/2} \leftarrow {}^1S_0$. For Argon, KE ≈ 5·40 eV (as shown in Fig. 63), so that IE = (21·22 - 5·40) eV ≈ 15·82 eV.

It may be mentioned that PES was earlier called electron spectroscopy for chemical analysis (ESCA) because it was used for research in analytical chemistry.

Applications of PES

1. Orbital Energies of Atoms. The simplest of all atoms, the hydrogen atom, using the 21·2 eV

energy photons from the helium atom, gives a kinetic energy spectrum which shows a single peak at 7·6 eV. The ion cannot have any internal energy because it has no electrons. Hence, the ionization potential of hydrogen atom is (21·2 – 7·6) = 13·6 eV, which is in agreement with values obtained by other methods.

We consider next the photoelectron spectra of the rare gas atoms, studied using the excitation energy $h\nu$ = 40·81 eV (Fig. 64).

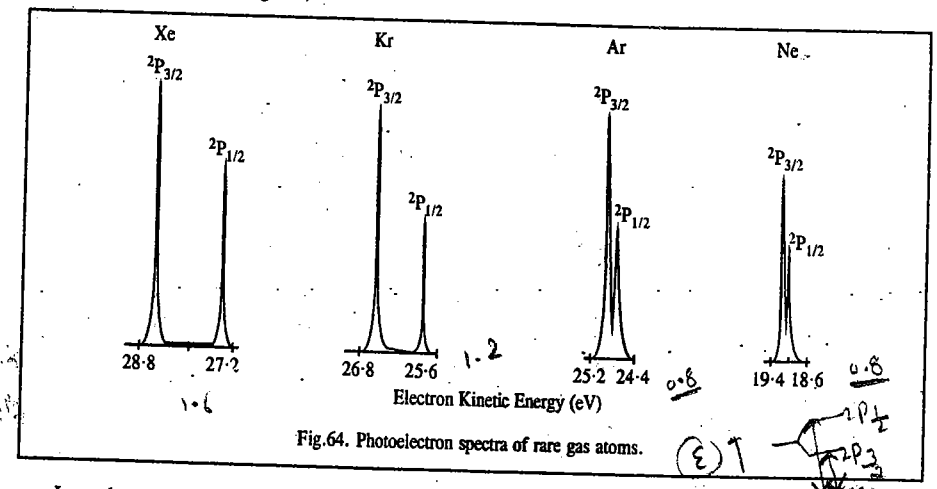

Fig.64. Photoelectron spectra of rare gas atoms.

In each case the spectrum consists of a doublet with the relative intensity in the ratio 2 : 1. The doublet is caused by the formation of two internal energy states of the ion. Argon, for instance, has the electronic configuration $1s^2\ 2s^2\ 2p^6\ 3s^2\ 3p^6$. The removal of the outermost electron gives an ion with the configuration $1s^2\ 2s^2\ 2p^6\ 3s^2\ 3p^5$ which is isoelectronic with chlorine atom. This configuration gives rise to two spin states $^2P_{3/2}$ and $^2P_{1/2}$. If the ionization leads to the lower state $^2P_{3/2}$, the ion has no internal energy and $h\nu = I + E_{el}$. If the ionization produces an upper level $^2P_{1/2}$, then $h\nu = I + E_{el} + E_{ion}$, where E_{ion} is equal to the separation between the two spin-orbit states $^2P_{3/2}$ and $^2P_{1/2}$. The relative intensities of the two peaks depend on the ratio of the degeneracies of the ionic states. Thus, we observe a doublet with the intensity ratio 2 : 1 for the photoelectron spectrum of Ar. If ionization is carried out by more energetic X-ray photons, more peaks are observed in the spectrum of Ar (Fig. 65). The

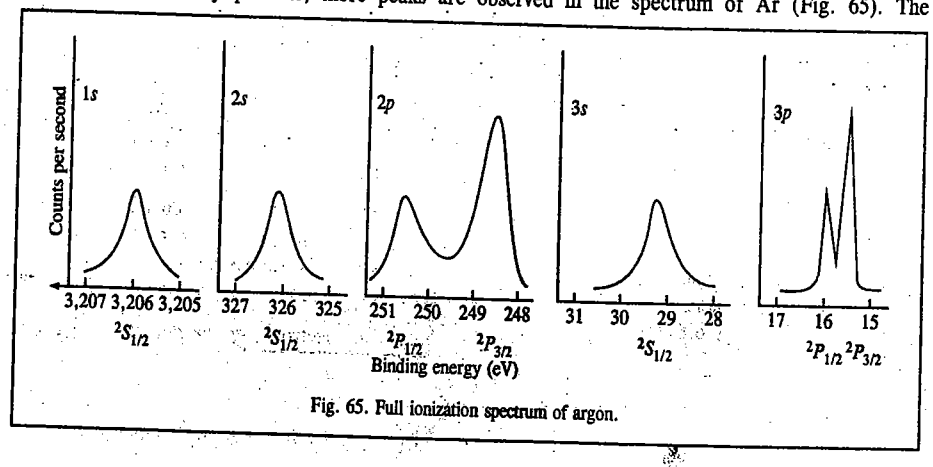

Fig. 65. Full ionization spectrum of argon.

horizontal scale gives the binding energy (BE) which is the energy required to remove the electron to form a particular state of the ion and is calculated by subtracting the photoelectron energy from the photon energy.

2. Orbital Energies of Molecules. In the case of molecules, the nature of the ionization bands produced by the emission of electrons from NBMOs, BMOs and ABMOs follows the following pattern which helps in the assignment of the ionization bands to MOs :

(*a*) If the ionized electron comes from an NBMO, the potential energy curve for the ion is almost the same as the one for the molecule, resulting in a single ionization line.

(*b*) If an electron is removed from a BMO, the bonding in the ion is expected to be weaker than that of the molecule. Hence, the potential energy curve of the ion will be shifted to the direction of longer equilibrium bonds. This gives rise to small vibrational spacing in the spectra, *i.e.*, vibrational fine structure is observed.

(*c*) If an electron is removed from a very strongly BMO or ABMO, the spectrum consists of a broad band, indicating dissociation or predissociation.

Thus, from the appearance of the spectrum and the value of the ionization potentials it is possible to deduce both the nature and the ordering of the MOs. In a high-resolution spectrum, the vibrational fine structure can often provide useful information regarding the nature of the MO involved. The most important applications of PES are in the checking of theoretical (quantum mechanical) calculations and the assignment of electronic spectra.

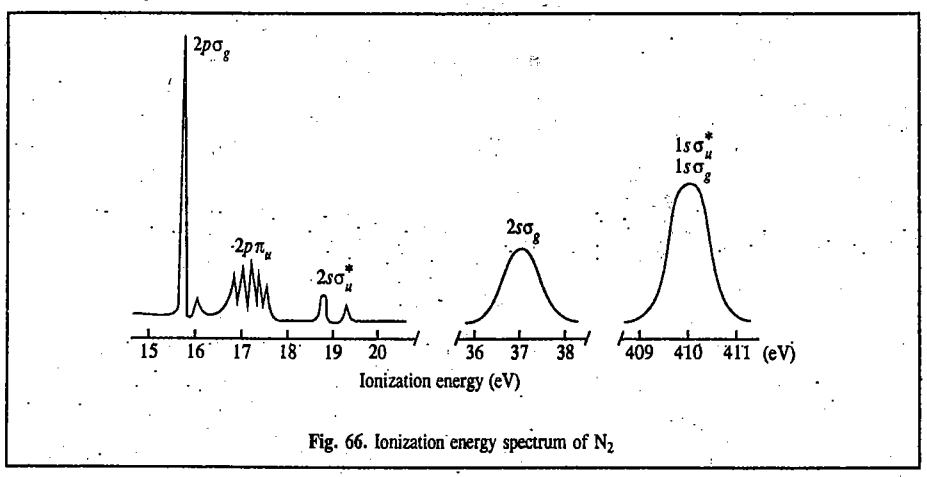

Fig. 66. Ionization energy spectrum of N_2

Fig. 66 gives the ionization energy spectrum of N_2. The molecular orbital pattern is also indicated. We may note that the $2p\sigma_g$ orbital has a lower ionization energy than the $2p\pi_u$ orbital.

3. Binding Energy of Core Electrons. The BE of core electrons varies depending on the electronic environment of the atom in the molecule. Consider the photoelectron spectrum of ethylchloroformate molecule (Fig. 67). In the molecule the electronic environment of each carbon atom is different and hence each one gives a different 1*s* ionization peak at slightly different energies. Binding energy difference of core electrons for non-equivalent atoms of the same kind in a molecule is called **chemical shift**. Chemical shifts can be obtained for the core electrons of all elements except hydrogen since the electron in a hydrogen atom is a valence electron. PES of core electrons has become a very powerful technique for structure determination.

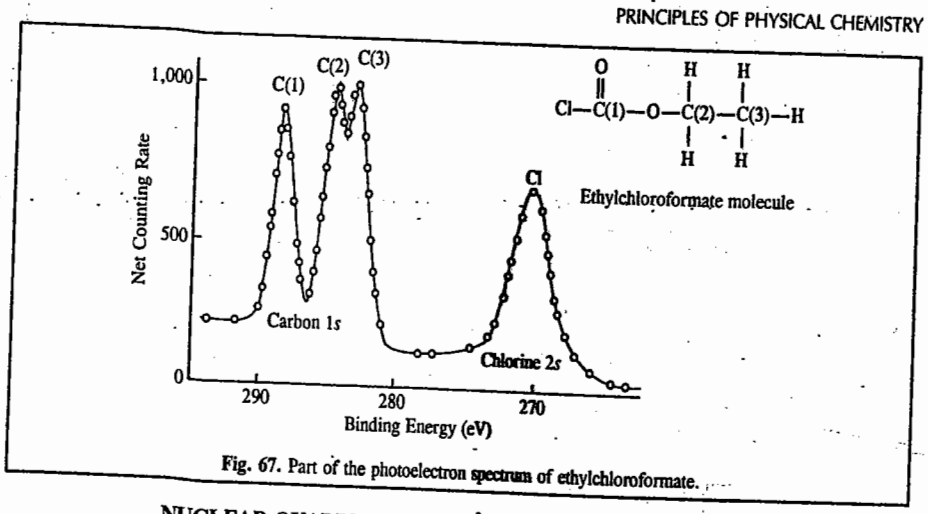

Fig. 67. Part of the photoelectron spectrum of ethylchloroformate.

NUCLEAR QUADRUPOLE RESONANCE (NQR) SPECTROSCOPY

Basic Theory. NQR spectroscopy was discovered in 1950 by physicist H.G. Dehmelt. NQR spectra, like Mössbauer spectra, are observed in the solid state. They are observed in the radiofrequency region. All nuclei having integral and half integral spins $\left(I = 1, \frac{3}{2}, 2, \frac{5}{2}, 3, \frac{7}{2}, \text{etc.}\right)$ possess nuclear electric quadrupole moments, designated as eQ (or simply as Q), where e is the electronic charge. Q is a measure of the deviation of nuclear charge from spherical symmetry. It is defined as

$$Q = \int \rho r^2 (3 \cos^2 \theta - 1)\, dr \qquad ...(75)$$

where ρ is the nuclear charge density, r is the distance from the origin to the element dr and θ is the angle between r and the spin axis. The quadrupole moment Q (or eQ) interacts with the electric field gradient (EFG), designated as q (or eq), created at the quadrupolar nucleus by the asymmetric charge distribution arising from the extranuclear electrons or the non-bonding electrons in the molecule of which the nucleus forms a part. The product of eQ and eq, *i.e.*, e^2Qq is called nuclear quadrupole coupling constant, also sometimes designated as QCC.

It is assumed that the nucleus is centred at the origin of an arbitrarily oriented coordinate system (X, Y, Z). The time-averaged electrostatic potential, V, is produced at the nucleus by all charges outside it. The electric field of all these charges is defined by

$$E = E_X \hat{i} + E_Y \hat{j} + E_Z \hat{k} \qquad ...(76)$$

where $\hat{i}$, $\hat{j}$, $\hat{k}$ are the unit vectors which specify the directions of the axes X, Y and Z, respectively. The components of the electric field are defined as

$$E_X = -(\partial V/\partial X); \quad E_Y = -(\partial V/\partial Y); \quad E_Z = -(\partial V/\partial Z)$$

The electric field gradient components are defined as

$$q_{XX} = -(\partial E_X/\partial X) = \partial^2 V/\partial X^2$$

$$q_{YY} = (\partial^2 V/\partial Y^2); \quad q_{ZZ} = (\partial^2 V/\partial Z^2)$$

Also,

$$q_{XY} = (\partial^2 V/\partial X \partial Y); \quad q_{YZ} = (\partial^2 V/\partial Y \partial Z); \text{ etc.}$$

The nine electric field gradient components may be written as a 3×3 **matrix** (or **tensor**) :

$$\begin{bmatrix} q_{XX} & q_{XY} & q_{XZ} \\ q_{YX} & q_{YY} & q_{YZ} \\ q_{ZX} & q_{ZY} & q_{ZZ} \end{bmatrix} \qquad ...(77)$$

They are found to be a *symmetric tensor* with $q_{ij} = q_{ji}$ so that

$$q_{XY} = q_{YX}; \quad q_{XZ} = q_{ZX}; \quad q_{YZ} = q_{ZY} \qquad ...(78)$$

Hence the EFG tensor given by Eq. 77 can be written as

$$\begin{bmatrix} q_{XX} & q_{XY} & q_{XZ} \\ q_{XY} & q_{YY} & q_{YZ} \\ q_{XZ} & q_{YZ} & q_{ZZ} \end{bmatrix} \qquad ...(79)$$

The diagonal components of this tensor are known to obey the **Laplace equation**

$$q_{XX} + q_{YY} + q_{ZZ} = 0 \qquad ...(80)$$

i.e., $\partial^2 V/\partial X^2 + \partial^2 V/\partial Y^2 + \partial^2 V/\partial Z^2 = 0$

or $$\nabla^2 V = 0 \qquad ...(81)$$

where $\nabla^2 = \partial^2/\partial X^2 + \partial^2/\partial Y^2 + \partial^2/\partial Z^2$ is the Laplacian operator. The four relations given by Eqs. 78 and 80 reduce the number of independent tensor components from nine to five. In general, it is convenient to choose a coordinate system (x, y, z) in which the *cross-components*, q_{ij} are zero. Such a coordinate system is called **principal axis system** and the EFG components in this system are designated as q_{xx}, q_{yy}, q_{zz}. In the principal axis system, we define

$$|q_{zz}| \geq |q_{yy}| \geq |q_{xx}| \qquad ...(82)$$

The modulus sign $|...|$ stands for the absolute value of the components. The largest EFG, q_{zz} is in the z-direction and the smallest EFG, q_{xx} is in the x-direction. From Eq. 80 the sum of the EFG components is zero. It follows, therefore, that only two parameters are needed to specify the EFG tensor. An important quantity, the **asymmetry parameter**, η, is defined as

$$\eta = (q_{xx} - q_{yy})/q_{zz} \qquad ...(83)$$

From Eqs. 80, 82 and 83, we see that the asymmetry parameter lies between 0 and 1, *i.e.*, $0 < \eta < 1$. When $\eta = 0$, we speak of a case of **axial symmetry** around the z-axis. In this case,

$$q_{xx} = q_{yy} = -\tfrac{1}{2} q_{zz} \qquad ...(84)$$

The EFG is said to be **spherical** if $q_{xx} = q_{yy} = q_{zz}$. In this case, there is no interaction of the nuclear quadrupole moment, Q, with the electronic charge distribution. The EFG is said to be nonsymmetric if $q_{xx} \neq q_{yy} \neq q_{zz}$. The following points should be borne in mind about NQR spectroscopy :

1. It is observed for nuclei with $I \geq 1$. When $I < 1$, the nuclei do not possess eQ so that there is no nuclear quadrupole interaction with eq.

2. NQR is observed in the solid state. In the gaseous and the liquid states, because of very fast molecular collisions resulting in a fast tumbling motion, the axis of rotation changes continuously so that EFG, q, averages to zero. Thus, there is no NQR interaction.

3. The quantities e^2Qq, q and η are three most important quantities in NQR spectroscopy. η is a measure of the nonsymmetry of the EFG.

With this digression on EFG, we are now ready to discuss the basic theory of NQR. The solution

of the Schrödinger wave equation for a quadrupolar nucleus having both the integral and half-integral spin ($I \geq 1$) gives the following expression for NQR energy levels :

$$E_{m_I} = \frac{e^2Qq}{4I(2I-1)}[3m_I^2 - I(I+1)]$$

$$= A(3m_I^2 - I(I+1)), \quad \text{where } A = \frac{e^2Qq}{4I(2I-1)} \qquad ...(85)$$

Here $m_I = -I, -I+1, \ldots, +I$; m_I is the component of the nuclear spin I along the axis of quantization, assumed to be the z-axis. The NQR energy level expression involves m_I^2 term; hence, the NQR energy levels are *doubly degenerate*. The selection rule for NQR transitions is $\Delta m_I = \pm 1$. Eq. 85 holds for an *axially symmetric* EFG, *i.e.*, $\eta = 0$.

We shall consider the NQR spectra of the following nuclei, assuming that $\eta = 0$: $^{14}_{7}N(I=1)$; $^{11}_{5}B\left(I=\frac{3}{2}\right)$; $^{35}_{17}Cl\left(I=\frac{3}{2}\right)$; the radioactive isotope $^{36}_{17}Cl^*(I=2)$; $^{27}_{13}Al\left(I=\frac{5}{2}\right)$; $^{132}_{55}Cs\left(I=\frac{7}{2}\right)$.

1. $^{14}_{7}\mathbf{N}$**:** ($I = 1$) so that $m_I = -1, 0, 1$. But, $m_I = -1$ and $m_I = +1$ levels are degenerate. Hence, $I \to 0, \pm 1$. Substituting these values of m_I in Eq. 85, we obtain

$E_0 = -\left(\frac{2}{4}\right)e^2Qq$, $E_{\pm 1} = \left(\frac{1}{4}\right)e^2Qq$. The selection rule $\Delta m_I = \pm 1$ gives only one NQR frequency (Fig. 68).

$$\nu\,(0 \to \pm 1) = (E_{\pm 1} - E_0)/h = \tfrac{3}{4}(e^2Qq/h) \qquad ...(86)$$

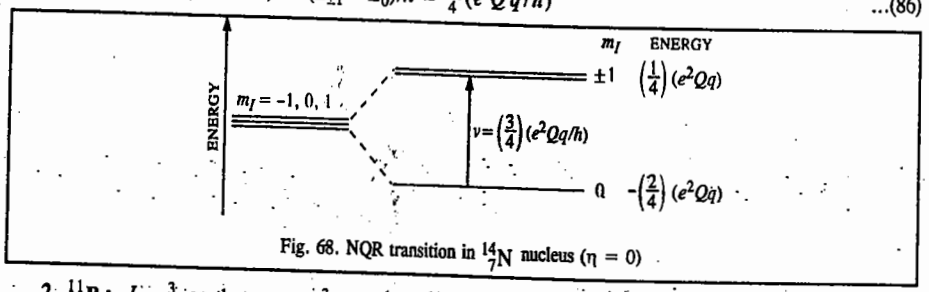

Fig. 68. NQR transition in $^{14}_{7}N$ nucleus ($\eta = 0$)

2. $^{11}_{5}\mathbf{B}$**:** $I = \frac{3}{2}$ so that $m_I = -\frac{3}{2}, -\frac{1}{2}, \frac{1}{2}, \frac{3}{2}$. Because of the m_I^2 term in the energy expression, the NQR interaction splits the $I = \frac{3}{2}$ level into two doubly-degenerate pairs of sublevels, $m_I = \pm\frac{1}{2}$ and $m_I = \pm\frac{3}{2}$. Thus, $I = \frac{3}{2} \to \pm\frac{1}{2}, \pm\frac{3}{2}$. Substituting these values of m_I in Eq. 85 we obtain $E_{\pm\frac{1}{2}} = -\left(\frac{1}{4}\right)(e^2Qq)$ and $E_{\pm\frac{3}{2}} = \left(\frac{1}{4}\right)(e^2Qq)$. The selection rule $\Delta m_I = \pm 1$ gives only one NQR frequency (Fig. 69), *viz.*,

$$\nu\left(\pm\tfrac{1}{2} \leftrightarrow \pm\tfrac{3}{2}\right) = (E_{\pm\,3/2} - E_{\pm\,1/2})/h = \left(\tfrac{1}{2}\right)(e^2Qq/h) \qquad ...(87)$$

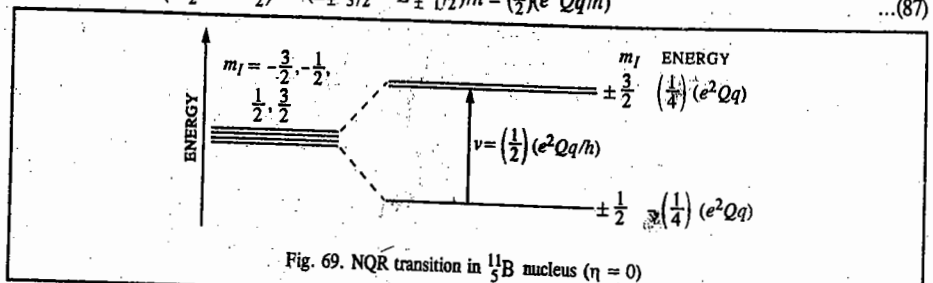

Fig. 69. NQR transition in $^{11}_{5}B$ nucleus ($\eta = 0$)

3. $^{35}_{17}\mathbf{Cl}$**:** $I = \frac{3}{2}$. The frequency is the same as in **(2)** above.

4. $^{36}_{17}\mathbf{Cl}^*$**:** $I = 2$. The NQR interaction gives the following pairs of energy sublevels : $m_I = 0$, ± 1, ± 2 (The $m_I = 0$ sublevel is non-degenerate).

$$E_0 = -\left(\tfrac{1}{4}\right)(e^2Qq); \quad E_{\pm 1} = -\left(\tfrac{1}{8}\right)(e^2Qq); \quad E_{\pm 2} = \left(\tfrac{1}{4}\right)(e^2Qq)$$

The selection rule $\Delta m_I = \pm 1$ gives two NQR frequencies (Fig. 70), *viz.*,

$$\left.\begin{aligned} \nu_1(0 \leftrightarrow \pm 1) &= (E_1 - E_0)/h = \left(\tfrac{1}{8}\right)(e^2Qq/h) \\ \nu_2(\pm 1 \leftrightarrow \pm 2) &= (E_{\pm 2} - E_{\pm 1})/h = \left(\tfrac{3}{8}\right)(e^2Qq/h) \end{aligned}\right\} \qquad ...(88)$$

We see that $\nu_1 : \nu_2 = 1 : 3$.

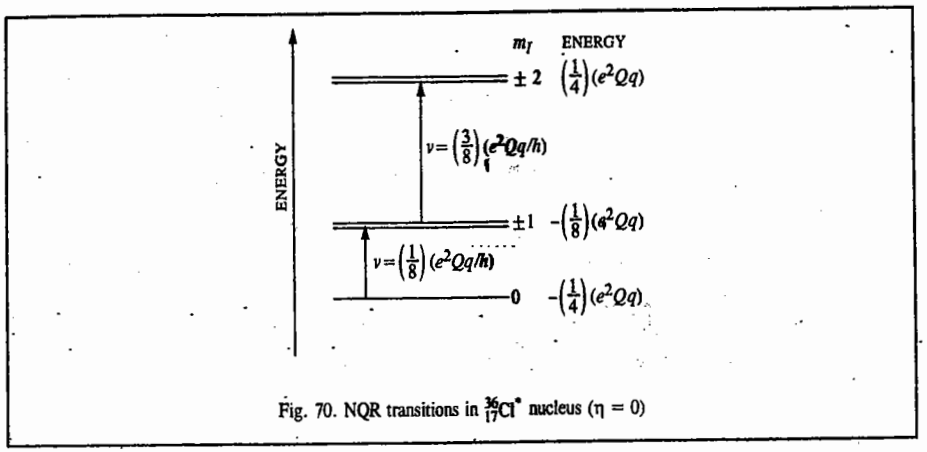

Fig. 70. NQR transitions in $^{36}_{17}Cl^*$ nucleus ($\eta = 0$)

5. $^{27}_{13}\mathbf{Al}$**:** $I = \frac{5}{2}$. The NQR interaction gives the following pairs of degenerate energy sublevels:

$$m_I = \pm\tfrac{5}{2}, \pm\tfrac{3}{2}, \pm\tfrac{1}{2}.$$

Substituting these values of m_I in Eq. 85 we obtain

$$E_{\pm\frac{1}{2}} = \left(-\tfrac{1}{5}\right)(e^2Qq); \quad E_{\pm\frac{3}{2}} = -\left(\tfrac{1}{20}\right)(e^2Qq); \quad E_{\pm\frac{5}{2}} = \left(\tfrac{1}{4}\right)(e^2Qq)$$

The selection rule $\Delta m_I = \pm 1$ gives two frequencies (Fig. 71), *viz.*,

$$\left.\begin{aligned} \nu_1\left(\pm\tfrac{1}{2} \leftrightarrow \pm\tfrac{3}{2}\right) &= \left(E_{\pm\frac{3}{2}} - E_{\pm\frac{1}{2}}\right)/h = \left(\tfrac{3}{20}\right)(e^2Qq/h) \\ \nu_2\left(\pm\tfrac{3}{2} \leftrightarrow \pm\tfrac{5}{2}\right) &= \left(E_{\pm\frac{5}{2}} - E_{\pm\frac{3}{2}}\right)/h = \left(\tfrac{6}{20}\right)(e^2Qq/h) \end{aligned}\right\} \qquad ...(89)$$

We see that $\nu_1 : \nu_2 = 1 : 2$.

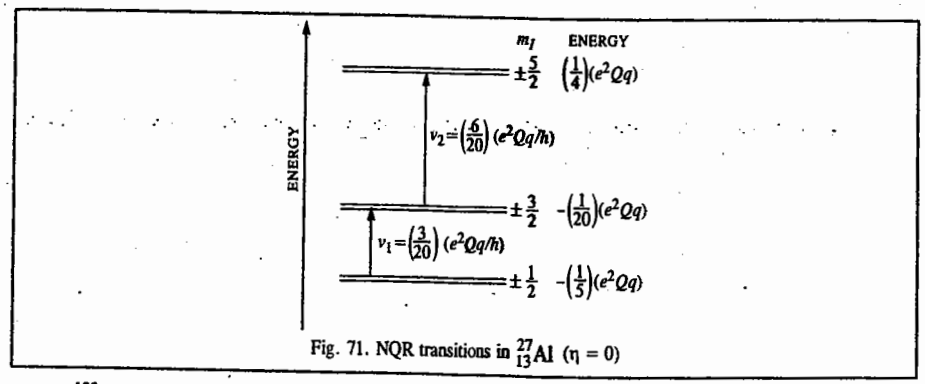

Fig. 71. NQR transitions in $^{27}_{13}Al$ ($\eta = 0$)

6. $^{133}_{55}Cs$: $I = \frac{7}{2}$. The NQR interaction gives the following pairs of degenerate energy sublevels:

$$m_I = \pm\tfrac{7}{2}, \pm\tfrac{5}{2}, \pm\tfrac{3}{2}, \pm\tfrac{1}{2}.$$

$$E_{\pm\frac{7}{2}} = \left(\tfrac{1}{4}\right)(e^2Qq) = \left(\tfrac{21}{84}\right)e^2Qq; \quad E_{\pm\frac{5}{2}} = \left(\tfrac{3}{84}\right)(e^2Qq)$$

$$E_{\pm\frac{3}{2}} = -\left(\tfrac{9}{84}\right)(e^2Qq); \quad E_{\pm\frac{1}{2}} = -\left(\tfrac{15}{84}\right)(e^2Qq)$$

The selection rule : $\Delta m_I = \pm 1$ gives three frequencies (Fig. 72), *viz.*,

$$\left.\begin{aligned}
\nu_1\left(\pm\tfrac{1}{2} \leftrightarrow \pm\tfrac{3}{2}\right) &= \left(E_{\pm\frac{3}{2}} - E_{\pm\frac{1}{2}}\right)/h = \left(\frac{6}{84}\right)(e^2Qq/h) \\
\nu_2\left(\pm\tfrac{3}{2} \leftrightarrow \pm\tfrac{5}{2}\right) &= \left(E_{\pm\frac{5}{2}} - E_{\pm\frac{3}{2}}\right)/h = \left(\frac{12}{84}\right)(e^2Qq/h) \\
\nu_3\left(\pm\tfrac{5}{2} \leftrightarrow \pm\tfrac{7}{2}\right) &= \left(E_{\pm\frac{7}{2}} - E_{\pm\frac{5}{2}}\right)/h = \left(\frac{18}{84}\right)(e^2Qq/h)
\end{aligned}\right\} \quad ...(90)$$

We see that $\nu_1 : \nu_2 : \nu_3 = 1 : 2 : 3$.

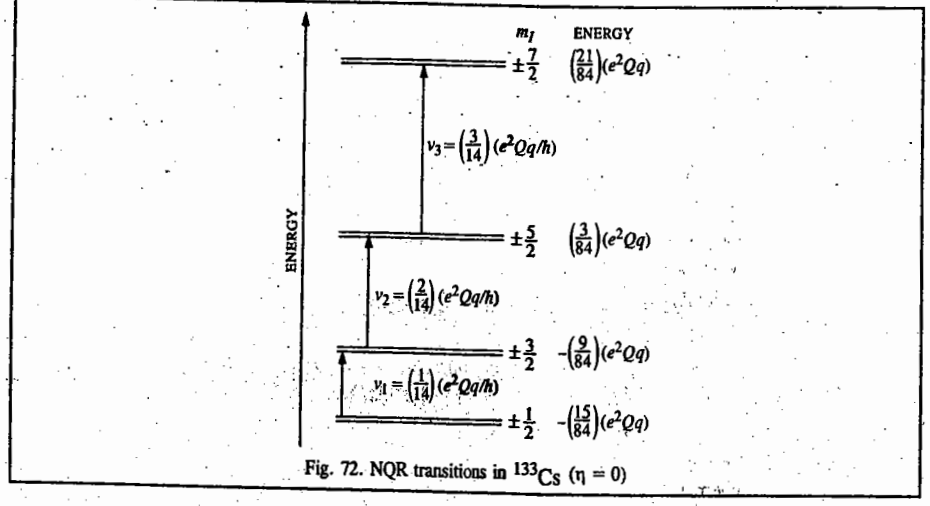

Fig. 72. NQR transitions in ^{133}Cs ($\eta = 0$)

NQR Spectra when EFG is not Axially Symmetric, *i.e.*, $\eta \neq 0$. The NQR spectra in the presence of non-axially symmetric EFG are very complex. The NQR energy level expression contains terms involving η and power of η. For instance, for $I=1$, the energy levels are given by

$$E_0 = -\tfrac{1}{2}(e^2Qq) \quad \text{and} \quad E_1 = \tfrac{1}{4}(e^2Qq)(1 \pm \eta)$$

The Bohr frequency condition and the selection rule $\Delta m_I = \pm 1$ gives the following two NQR frequencies (Fig. 73), *viz.*,

$$\left.\begin{aligned}
\nu_+(0 \rightarrow +1) &= \tfrac{3}{4}(e^2Qq/h)\left(1+\tfrac{1}{3}\eta\right) \\
\nu_-(0 \rightarrow -1) &= \tfrac{3}{4}(e^2Qq/h)\left(1-\tfrac{1}{3}\eta\right)
\end{aligned}\right\} \quad ...(91)$$

They are separated by an amount, $\Delta\nu$, given by $\Delta\nu = \frac{1}{2}(e^2Qq/h)\eta$. Thus, experimental measurement of the two frequencies yields the values of both e^2Qq and η.

For $I = \frac{3}{2}$, the two doubly degenerate energy levels are

$$E_{\pm\frac{1}{2}} = -\tfrac{1}{4}(e^2Qq)\left(1+\tfrac{1}{3}\eta^2\right)^{\frac{1}{2}}$$

$$E_{\pm\frac{3}{2}} = +\tfrac{1}{4}(e^2Qq)\left(1+\tfrac{1}{3}\eta^2\right)^{\frac{1}{2}}$$

The selection rule $\Delta m_I = \pm 1$ gives only one NQR frequency :

$$\nu\left(\pm\tfrac{1}{2} \leftrightarrow \pm\tfrac{3}{2}\right) = \tfrac{1}{2}(e^2Qq/h)\left(1+\tfrac{1}{3}\eta^2\right)^{\frac{1}{2}} \quad ...(92)$$

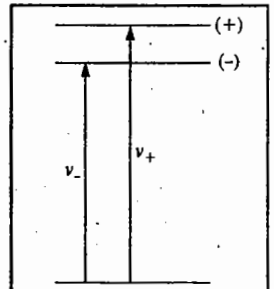

Fig. 73. NQR transitions for $I = 1$ ($\eta \neq 0$)

Since this equation contains two unknowns, e^2Qq and η, measurement of the NQR frequency does not permit them to be determined separately. If, however, from structural considerations η is known to be very small, it can be neglected and e^2Qq determined with sufficient accuracy. When $\eta > 0{\cdot}3$, the frequency expressions for $I = \frac{5}{2}, \frac{7}{2}, \frac{9}{2}$, etc., cannot be rigorously applied. Also, when $I \geq \frac{5}{2}$, we get two or more frequencies the measurement of which can yield both e^2Qq and η. When η is large, it is possible to observe some of the forbidden transitions ($\Delta m_I = \pm 2$), in addition to the strongly allowed transitions ($\Delta m_I = \pm 1$).

Zeeman Effect in NQR Spectra. The determination of both e^2Qq and η for the special case of $I = \frac{3}{2}$, which yields only one NQR frequency, can be done by using Zeeman effect. The applied magnetic (Zeeman) field removes the degeneracy of the $\pm\frac{1}{2}$ and $\pm\frac{3}{2}$ energy sublevels. It is theoretically found that whereas the $-\frac{3}{2}$ sublevel is raised in energy and the $+\frac{3}{2}$ sublevel is lowered, exactly similar splitting does not occur for the doubly degenerate sublevels $\pm\frac{1}{2}$. There occurs considerable *mixing of states* so that the $+\frac{1}{2}$ sublevel partakes some character of $-\frac{1}{2}$ sublevel and vice versa. The resulting sublevels are designated as + and –, respectively. The Zeeman splitting for the case $I = \frac{3}{2}$ is shown schematically in Fig. 74.

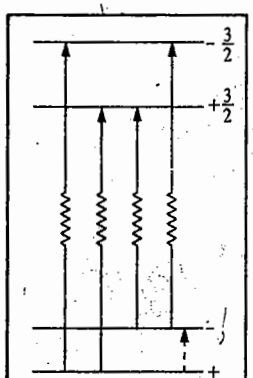

Fig. 74. Zeeman splitting for $I = \frac{3}{2}$ ($\eta \neq 0$)

The application of radiofrequency field brings about transitions between the different sublevels. The $+ \rightarrow -$ transition, shown by the dotted arrow, is of no interest since it involves a frequency much smaller than the NQR frequency. When the Zeeman field is of the order of 0·01 T, as is the case with several nuclei of chemical interest, this frequency is of the order of 0·1 MHz (or even less). This $+ \rightarrow -$ transition between the mixed states $\psi_{\pm}$ corresponds to the selection rule $\Delta|m_I| = 0$. The $\Delta|m_I| = 0$ transition, $+\frac{3}{2} \leftrightarrow -\frac{3}{2}$, not shown in Fig. 66, too, is of no interest. The $\Delta|m_I| = \pm 1$ transitions between the mixed states $\psi_{\pm}$ and the $\psi_{\pm 3/2}$ states give rise to the following four frequencies :

$$\left.\begin{aligned} \nu_\alpha \equiv \nu\left(+ \rightarrow +\tfrac{3}{2}\right);\ \nu_{\alpha'} \equiv \nu\left(- \rightarrow +\tfrac{3}{2}\right) \\ \nu_\beta \equiv \nu\left(+ \rightarrow -\tfrac{3}{2}\right);\ \nu_{\beta'} \equiv \nu\left(- \rightarrow -\tfrac{3}{2}\right) \end{aligned}\right\} \quad ...(93)$$

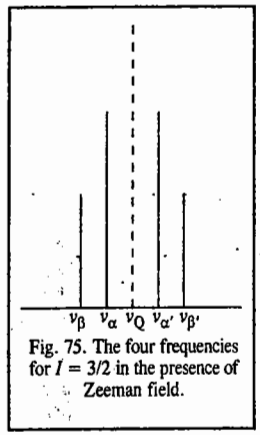

Fig. 75. The four frequencies for $I = 3/2$ in the presence of Zeeman field.

The four frequencies are symmetric about the pure NQR frequency, ν_Q. The inner pair of lines ν_α and $\nu_{\alpha'}$ has equal intensity. Likewise, the outer pair of lines ν_β and $\nu_{\beta'}$ has equal intensity. However, the α, α' pair is more intense than the β, β' pair (Fig. 75).

For a given orientation of the Zeeman field, both pairs of components α, α' and β, β' have maximum intensity when the *r.f.* field is perpendicular to the symmetry axis of the EFG tensor. Also, the intensity of the two pairs depends upon the orientation of the Zeeman field. Omitting the details of the intensity of the spectral lines, suffice it to say that from the Zeeman study, the two unknowns e^2Qq and η can be determined from the four *known* frequencies.

Townes-Dailey Theory of Nuclear Quadrupole Coupling

The nuclear quadrupole moment, Q, is known from theories of nuclear structure, but how do we calculate the EFG, q ? This problem was solved in the well, known Townes-Dailey theory proposed in 1949. These researchers suggested that in an atom, the EFG at the nucleus arises due to the electrons in various valence shells. Since closed shells, as well as the s orbitals have spherical symmetry, they do not contribute to the EFG. From the radial distribution functions in the theory of hydrogenic atoms we know that for small values of r (the distance of the electron from the nucleus), the p orbital wave function varies as r, the d orbital wave function varies as r^2, the f orbital wave function varies as r^3, etc. Thus, the probability of an electron being found at the nucleus decreases in the order $s > p > d > f$. Since quantum mechanically for an atom having one valence electron, the *EFG*, q_{atom}, is defined by

$$q_{atom} = -e\int \psi^* \left(\frac{3\cos^2\theta - 1}{r^3}\right)\psi d\tau \quad ...(94)$$

where ψ is the electronic wave function and θ is the angle between the fixed z-axis in space and the radius vector r (from the nucleus to the electron); r, θ, ϕ are the polar coordinates and the integration is over the whole range of coordinates. It follows, therefore, that contribution to q from various electrons (since it involves $<1/r^3>$ -dependence), decreases in the order $q_p >> q_d >> q_f$. As remarked above, q_s, the contribution to q from s electrons, is zero because of spherically symmetric charge distribution. Hence, we conclude that *only p electrons in an atom contribute significantly to* EFG. From Eq. 94 it can be shown theoretically that

$$q_{atom} = -\frac{2le}{2l+3} <1/r^3> \quad ...(95)$$

where l is the orbital angular momentum of the electron and $<1/r^3>$ is the expectation value (the average value) of the distance between the electron and the nucleus. The EFG gives an information about the electronic structure of an atom.

The above treatment can be extended to molecules. As in the case of atoms, in a molecule the EFG at a given nucleus due to valence electrons is given by

$$q_{mol} = -e\int \psi^* \left(\frac{3\cos^2\theta - 1}{r^3}\right)\psi d\tau \quad ...(96)$$

where ψ is now the *molecular* wave function of the electrons. Townes and Dailey used the LCAO-MO approximation for ψ :

$$\psi = \sum_i c_i \phi_i \quad ...(97)$$

where ϕ_is are the AOs and c_i the appropriate coefficients. The Townes-Dailey theory showed that the significant contribution to EFG at a nucleus in a molecule is due to the p type valence electrons involved in chemical bonding as well as the p type lone pair electrons. Contributions from the various polarization effects on the inner shells as well as other charges in the molecule are negligible.

The EFG can essentially arise from *asymmetry* in the electron distribution about the nucleus. Filled electron shells can, to a first approximation, be regarded as spherical. They can make a contribution to the EFG when they are polarized by the outer electrons or other charges (**Sternheimer effect**); this contribution can be substantial but is usually difficult to determine and is thus ignored. Non-bonding electrons in the valence shell of the atom being investigated make the biggest contribution. Thus, atoms with one, two or three lone pairs usually show very large values of the QCC. The next largest contribution arises from the electrons in the bonds to the ligands. Since these are shared with the ligand atoms, their average distance from the quadrupolar nucleus is greater than that of the non-bonding electrons. When the arrangement of bonds has symmetry less than cube, there will be a contribution to EFG. For instance, there is an EFG at the nucleus of the M atom in the molecule MAB_5 which depends upon the difference in the nature of the M–A and M–B bonds. Also, in a molecule, the electronic structure near a nucleus depends on the hybridization of the bonding orbital and the ionic character of the bond. The equation relating e^2Qq_{mol} of a halogen atom to e^2Qq is given by

$$e^2Qq_{mol} = [1 - s + d - i\,(1 - s - d)]\, e^2Qq \quad ...(98)$$

where s and d denote the amount of s and d character of the bonding orbital and i is the ionic character of the bond. If π bond is also present, then Eq. 98 is modified to

$$e^2Qq_{mol} = (1 - s + d - i - \pi)\, e^2Qq_{atom} \quad ...(99)$$

Applications of NQR Spectroscopy. As we see from Eqs. 98 and 99, a comparison of the QCCs in the atomic and the molecular state for the same nucleus gives information about the extent of hybridization and the ionic character (*i.e.*, **ionicity**) of the bond. The halogens have been extensively studied by NQR. The commonest isotopes investigated are those of chlorine and bromine, since the resonances occur in accessible regions and several halogen compounds are available. Both elements have two naturally occurring isotopes and all have I=3/2. Thus, even when all atoms occupy crystallographically identical sites, two resonances should be observed, one for each isotope. They may be recognized both from their relative intensities, 3 : 1 for ^{35}Cl : ^{37}Cl or 1 : 1 for ^{79}Br : ^{81}Br, and from their relative frequencies, 1·27 : 1 or 1·19 : 1, respectively (this is the ratio of the Qs since both must be in the same EFG). To calculate the ionicity of the interhalogen bond, for instance, we make the following reference points : (*i*) the free halogen molecule, in which the p_z-orbital of

each atom effectively contains a single electron (the p_x and p_y orbitals contain lone pairs of electrons), *(ii)* the halide ion, which is spherical and must have zero EFG. In these molecules the observed QCC is used to interpolate between the two reference values :

$$\text{Ionic character} = 1 - \frac{(e^2Qq/h)_0}{(e^2Qq/h)} \qquad \ldots(100)$$

in which $(e^2Qq/h)_0$ is the value corresponding to the halogen molecule (the halogen atom).

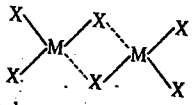
Table 10 gives the QCCs (quadrupole coupling constants, e^2Qq/h) of some halogen isotopes (^{35}Cl, ^{70}Br and ^{127}I) and some of their compounds.

TABLE 10

QCCs of Some Halogens and their Compounds

Molecule	e^2Qq/h (MHz)	Molecule	(e^2Qq/h) (MHz)
Cl (atomic)	109	CH_3Cl	75
Br (atomic)	769	NaBr	58
I (atomic)	2293	KBr	10·2
Br—Cl	104	CH_3Br	529
ICl	82·5	NaI	260
KCl	0·04	KI	60

NQR studies also confirm the dimeric nature of the Group III halides of the type MX_3 (which is also confirmed by X-ray diffraction). In the molecule $AlBr_3$, for instance, the basic halogen NQR spectrum consists of three resonance lines : two are closely spaced together and are far above the third. This indicates that the three halogen nuclei are not chemically equivalent. In the dimer molecule, therefore, there are two types of halogen atoms corresponding to the bridge and end positions :



The small difference of one set of halogen resonances is presumably due to a small difference in the crystalline field around the chemically equivalent set of atoms.

Example 47. Enumerate the NQR frequencies for a nucleus with $I = 9/2$ in an axially symmetric EFG ($\eta = 0$). How do they arise ?

Solution : For $I = \frac{9}{2}$, $m_I = \pm\frac{9}{2}, \pm\frac{7}{2}, \pm\frac{5}{2}, \pm\frac{3}{2}$ and $\pm\frac{1}{2}$ because of the presence of the m_I^2 term in the energy level expression. The selection rule $\Delta m_I = \pm 1$ gives four resonances as a result of NQR interaction :

$$\nu_1\left(\pm\tfrac{1}{2} \leftrightarrow \pm\tfrac{3}{2}\right);\quad \nu_2\left(\pm\tfrac{3}{2} \leftrightarrow \pm\tfrac{5}{2}\right);\quad \nu_3\left(\pm\tfrac{5}{2} \leftrightarrow \pm\tfrac{7}{2}\right);\quad \nu_4\left(\pm\tfrac{7}{2} \leftrightarrow \pm\tfrac{9}{2}\right)$$

Example 48. The NQR frequency for a nucleus with $I = \frac{3}{2}$ in an axially symmetric EFG ($\eta = 0$) is 100 MHz. Calculate e^2Qq/h.

Solution : $\nu = \frac{1}{2}(e^2Qq/h)$. Hence, $e^2Qq/h = 2\nu = 2\ (100\ \text{MHz}) = 200\ \text{MHz}$

Example 49. A quantity of interest in NQR spectroscopy is the fraction of the unbalanced p electrons, U_p, defined as $U_p = -\frac{(e^2Qq)_{\text{observed}}}{(e^2Qq)_{\text{for one electron}}}$. At 20 K, t-butylchloride shows two NQR frequencies

at 31·195 MHz and 24·586 MHz, the former being more intense. How do you account for these results ? Also, calculate U_p for ^{35}Cl and ^{37}Cl. Given (e^2Qq/h) for atomic chlorine is −109·6 MHz.

Solution : The more intense frequency is due to the more abundant isotope ^{35}Cl and the weaker frequency is due to the less abundant isotope ^{37}Cl. Since $I = 3/2$ for both the nuclei, hence

$\nu\left(\pm\frac{1}{2} \leftrightarrow \pm\frac{3}{2}\right) = \frac{1}{2}(e^2Qq/h)$ (assuming $\eta = 0$), so that

$(e^2Qq/h) = 2\nu = 62{\cdot}39$ MHz (for ^{35}Cl) and 49·17 MHz (for ^{37}Cl). The Cl atom, $1s^2\ 2s^2\ 2p^6\ 3s^2\ 3p_x^2\ 3p_y^2\ 3p_z^1$, contains one electron in the $3p_z$ orbital and is thus said to have $U_p = 1$. The (e^2Qq/h) value for atomic chlorine is −109·6 MHz. Hence, for ^{35}Cl,

$$U_p = \frac{-62{\cdot}39}{-109{\cdot}6} = 0{\cdot}573$$

Similarly, the U_p value for ^{37}Cl can be calculated.

For details, see T.P. Das and E.L. Hahn, *Nuclear Quadrupole Resonance Spectroscopy*, Academic Press, 1958.

I. Review Questions

1. Draw the NMR spectrum of a bare proton using an energy level diagram and the appropriate selection rule.
2. Why are NMR spectra observed in the rf region and the ESR spectra in the microwave region ?
3. What is the principle of Fourier-transform NMR ?
4. Discuss the relaxation processes in magnetic resonance spectroscopy.
5. Write short notes on nuclear magnetic double resonance and NOE.
6. Discuss the use of the lanthanide shift reagents in NMR.
7. How is NMR used in studying hindered rotation in molecules ?
8. Draw the ESR spectra of

   (i) an unpaired electron, *(ii)* hydrogen atom, *(iii)* methyl radical, *(iv)* triphenylmethyl radical. How do they arise ?
9. Illustrate, using energy level diagrams, Kramers' degeneracy and ZFS.
10. Discuss the ESR spectra of transition metal complexes.
11. Illustrate diagrammaticaly the combined effects of isomer shift, Zeeman effect and hyperfine splitting in Mössbauer spectra.
12. Write notes on : *(i)* Photoelectron spectroscopy (PES), *(ii)* Nuclear Quadrupole Resonance (NQR) spectroscopy.
13. Discuss the important applications of PES.

II. Problems

1. The low resolution pmr spectrum of a compound of molecular formula C_2H_4O consists of two peaks, the intensity of one being thrice that of the other. The high resolution pmr spectrum shows that the peak with low intensity is split into four components of relative intensity 1 : 3 : 3 : 1 and the peak with high intensity is split into a doublet with relative intensity 1 : 1. Identify the structure of the compound. **[Ans. $CH_3CH{=}O$]**
2. Describe the high resolution pmr spectrum of 1,1,2-trichloroethane.

[Ans. Triplet (1 : 2 : 1 intensities) and doublet (1 : 1 intensities.]

3. A compound with the empirical formula $C_4H_{10}O$ gave a pmr spectrum consisting of two groups of peaks with relative areas 3 and 2. Another substance with the same formula gave a pmr spectrum consisting of two peaks with relative areas 9 and 1. Identify the two compounds. **[Ans. diethyl ether, and *t*-butyl alcohol]**

4. A compound $C_{10}H_{14}$ shows two 2 pmr singlets : *A* at $\delta = 8{\cdot}0$ ppm and *B* at $\delta = 1{\cdot}0$ ppm. The ratio of their intensities is $A : B = 5 : 9$. What structure is consistent with these data ?

[Ans. *A* is caused by aromatic ring Hs and *B* by alkyl Hs. The structure is $C_6H_5C(CH_3)_3$.]

5. The nmr spectrum of a compound $C_3H_5ClF_2$ has 2 noncoupled triplets. Triplet *A* is 1·5 times the intensity of the more downfield triplet *B*. Suggest a structure. **[Ans. $ClC^BH_2CF_2C^AH_3$]**

6. The pmr spectrum of liquid diketene $C_4H_4O_2$ shows two peaks of equal intensity. What is the structure of the compound ?

7. Predict which of the following species will show ESR spectrum :

(i) $\dot{C}H_3$ *(ii)* $\ddot{C}H_2$ *(iii)* CH_4 *(iv)* H_2 *(v)* O_2 *(vi)* O_2^+ *(vii)* C_6H_6 *(viii)* $C_6H_6^-$ *(ix)* $CH_3CH_2\dot{C}H_2$ *(x)* $(CH_3)_2\dot{C}H$.

[Ans. *(i), (ii), (v), (vi), (viii), (ix) (x)*]

8. The ESR spectrum of a radical having the empirical formula C_3H_7 showed 14 lines with relative intensities of 1, 1, 6, 6, 15. 15, 6, 6, 1 and 1. Identify the radical. **[Ans. isopropyl radical]**

9. Predict the ESR spectrum of benzene radical anion, $C_6H_6^-$.

[Ans. 7 lines with relative intensities of 1 : 6 : 15 : 20 : 15 : 6 : 1]

10. Predict the number of ESR lines in the spectrum of *(a)* $CH_3\dot{C}H_2$ radical *(b)* $CH_3CH_2CH_2\cdot$ radical.

[Ans. *(a)* 12, *(b)* 36]

11. The ESR spectrum of an organic radical containing two carbon atoms consisted of 12 lines having relative intensities of 1, 2, 3, 1, 6, 3, 3, 6, 1, 3, 2 and 1. Identify the radical. **[Ans. $CH_3\dot{C}H_2$]**

12. The irradiation of a crystal of ammonium perchorate by γ-rays produced a free radical whose ESR spectrum consists of 12 lines. Identify the radical $I=(N) = 1$. **[Ans. NH_3]**

13. Predict the ESR spectrum of the hypothetical $\dot{N}H$ radical. **[Ans. 5 lines with relative intensity 1:1:2:1:1]**

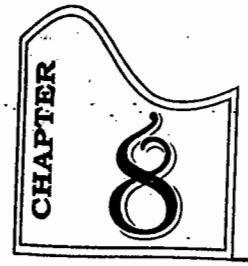
14. The line separations in ESR may be expressed in tesla (T) or MHz. Show how the conversion factor $1T = 2{\cdot}80 \times 10^4$ MHz is obtained.

15. An unpaired electron in the presence of two protons gives the following four-line ESR spectrum : $\Delta B/10^{-4}$ T = 0, 1, 3, 4. What are the two coupling constants in T and in MHz ?

[Ans. $a_1 = 3\times10^{-4}$ T or 8·40 MHz ; $a_2 = 1\times10^{-4}$ T or 2·80 MHz]

16. The UV spectrum of acetone shows two peaks at λ_{max}=280 nm, ε_{max}=15, and λ_{max}=190 n, ε_{max}= 100. *(a)* Identify the electronic transition for each *(b)* Which is more intense ?

[Ans. *(a)* The longer wavelength (280 nm) is associated with smaller energy ($\pi^* \leftarrow n$) transition, $\pi^* \leftarrow \pi$ transition occurs at 190 nm. *(b)* $\pi^* \leftarrow \pi$ has the larger ε_{max} and is more intense]



ELECTRIC AND MAGNETIC PROPERTIES OF MOLECULES

ELECTRIC PROPERTIES OF MOLECULES

Considerable structural information about a molecule can be obtained by placing it in an electrostatic field. When a molecule is placed in an electric field, the field distorts the electronic structure and changes the equilibrium positions of the nuclei giving rise to the separation of the centres of positive and negative charges. This is expressed by saying that the electric field induces a dipole moment in the molecule. The *induced dipole moment*, μ_{ind}, is directly proportional to the strength of the applied electrostatic field, *E*, *i.e.*,

$$\mu_{ind} \propto E \qquad ...(1)$$

$$= \alpha E \qquad ...(2)$$

where α, the constant of proportionality, is called the **polarizability** of the molecule. *It is a measure of the ease with which the molecule can be polarized.* From Eq. 2 we see that α is equal to the induced dipole moment generated by unit electric field strength.

The *permanent dipole moment*, μ, of a molecule having two equal charges $+q$ and $-q$, separated by a distance *r*, is defined as

$$\mu = qr \qquad ...(3)$$

The dipole moment has magnitude as well as direction. It is customary to regard it as being directed from the positively charged end towards the negatively charged end.

The dipole moment for a group of point charges q_i is given by

$$\mu = \sum_i q_i r_i \qquad ...(4)$$

where r_i is the vector distance from the origin to the charge q_i.

For a distribution of zero total charge, the dipole moment is equal to the product of the absolute charge of either the positive or the negative distribution and the vector distance *r* between the centres of the two distributions. Thus,

$$\mu = (+q)r = (-q)r \qquad ...(5)$$

Since the electronic charge $q = 1{\cdot}602\times10^{-19}$ C and $r = 10^{-10}$ m, hence,

$$\mu = (1{\cdot}602\times10^{-19}\text{ C})\times(10^{-10}\text{ m}) = 1{\cdot}602\times10^{-29}\text{ C m} = 4{\cdot}8\text{ D}$$

since 1 D (Debye) = $3{\cdot}336\times10^{-30}$ C m.

Polarization of a Molecule in an Electric Field. When a molecule is placed in an electric field, the field polarizes it in the following three ways :

1. Electronic polarization. The field distorts the electronic charge cloud of the molecule. This is called electronic polarization and the corresponding polarizability is termed electronic polarizability, α_e.

2. Atomic polarization. The nuclei, or the atoms, are distorted towards the negative end of the field. The corresponding polarizability is called **atomic polarizability**, α_a.

3. Orientation polarization. The electric field tends to align molecules having a permanent dipole moment along the direction of the field. The corresponding polarizability is called **orientation polarizability**, α_μ.

Thus, the total polarizability (α) of a molecule in an electric field is the sum of the three contributions, *i.e.*,

$$\alpha = \alpha_e + \alpha_a + \alpha_\mu \quad ...(6)$$

$$= \alpha_d + \alpha_\mu \quad ...(7)$$

where α_d ($= \alpha_e + \alpha_a$) is called the **distortion polarizability.**

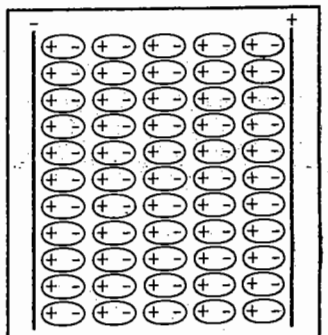


Fig. 1. Orientation of polar molecules in an electric field.

Clausius-Mosotti Equation. Suppose that several molecules of a substance in the solid, liquid or gaseous state are introduced into the space between the plates of a condenser which is charged by applying a constant electrostatic field. The substance is called a *dielectric* and is assumed to be an insulator. The charges on the condenser plates are partially compensated by the induced charges on the boundary of the dielectric (Fig. 1). The electric field strength in the dielectric is, therefore, reduced to a value E from its value E_0 in vacuum, the two quantities being related by the expression

$$E_0 = E + 4\pi P \quad ...(8)$$

where P, called the **dielectric polarization,** is the induced dipole moment per unit volume of the dielectric. Thus, $P = N\mu_{ind}$ where N is the number of molecules per unit volume of the dielectric.

From Eq. 8, $E_0/E = 1 + 4\pi(P/E) = 1 + 4\pi(N\mu_{ind}/E)$ ...(9)

or $\varepsilon_r = 1 + 4\pi N\alpha_d$ ...(10)

where the quantity ε_r ($= E_0/E$) is called the *dielectric constant* or *relative permittivity*. Here we have made use of the fact that $\alpha_d = \mu_{ind}/E$ where α_d, as already mentioned, is the distortion polarizability. The relative permittivity of the medium can be measured experimentally by using the relation.

$$\varepsilon_r = C/C_0 \quad ...(11)$$

where C and C_0 are the capacitances of the condenser with the medium and the vacuum, respectively, as the dielectric between the plates.

Suppose that one mole of a substance of molar volume V_m, density ρ and molar mass M is used as a dielectric. Then,

$$N = N_A/V_m = N_A\rho/M$$

where N_A is the Avogadro number. Hence, Eq. 10 can be written as

$$(\varepsilon_r - 1)M/\rho = 4\pi N_A\alpha_d \quad ...(12)$$

Evidently, the ratio $(\varepsilon_r - 1)/\rho$ is independent of ρ since α_d is a constant for a substance.

Eq. 12 holds for gases at very low pressures when the interaction of the dipole moments between the neighouring molecules is negligible since the molecules are far apart. However, at high pressures and for condensed phases (solids or liquids), this relation does not hold since now interactions between induced moments have to be taken into consideration. Clausius and Mosotti, taking into consideration these interactions for condensed phases, introduced the following relation :

$$P_m = \frac{\varepsilon_r - 1}{\varepsilon_r + 2} V_m = (4\pi/3)N_A\alpha_d \quad ...(13)$$

where the quantity P_m is called **molar polarization.** Eq. 13 is known as the **Clausius-Mosotti equation.**

Relative permittivity, ε_r, is also defined as $\varepsilon_r = \varepsilon/\varepsilon_0$ where ε is the permittivity of the medium and ε_0 is the permittivity of free space. In SI system, the Clausius-Mosotti equation is written as

$$P_m = \frac{\varepsilon_r - 1}{\varepsilon_r + 2} V_m = (N_A/3\varepsilon_0)\alpha_d \quad ...(14)$$

Since α_d (*viz.*, distortion polarizability) is a characteristic constant of a molecule, hence P_m, according to Eq.13, should be a constant, independent of density or temperature. This has been verified experimentally for non-polar molecules such as H_2, CO_2, CH_4, CCl_4, etc., which do not have a permanent dipole moment. The Clausius-Mosotti equation is not obeyed by polar molecules such as HCl, H_2O, NH_3, etc., which possess a permanent dipole moment.

Debye Equation. In 1912, Debye considered the behaviour of polar molecules placed between the plates of a condenser. In the absence of the electric field, as a result of thermal motion, the molecules are randomly oriented so that there is no *net* dipole moment in any direction (Fig. 2*a*). However, on the application of the electric field across the plates of the condenser, the molecules under the combined influence of the electric field and the thermal motion orient themselves as shown in Fig. 2*(b)*.

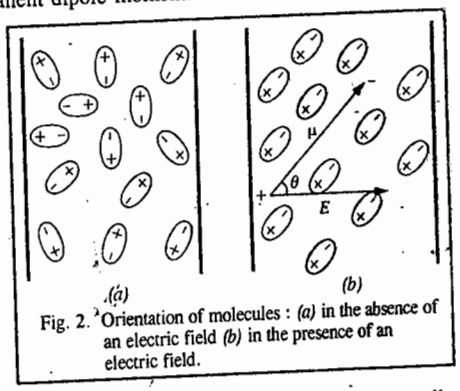

Fig. 2. Orientation of molecules : *(a)* in the absence of an electric field *(b)* in the presence of an electric field.

Debye calculated the average component of the permanent dipole moment μ of a molecule in the direction of the electric field as a function of temperature.

For a randomly oriented dipole in the absence of electric field, all orientations are equally probable. This means that the number of dipole moments directed within a solid angle $d\omega$ is $Ad\omega$, where A is a constant which depends on the number of molecules under observation.

The potential energy, U, of a polar molecule with molecular dipole moment μ oriented at an angle θ to the electric field of strength E is given by

$$U = -\mu E \cos\theta \quad ...(15)$$

According to the Boltzmann distribution, the number of molecules oriented within the solid angle $d\omega$ is given by

$$dN = A \exp(-U/kT)\, d\omega \quad ...(16)$$

$$= A \exp(\mu E \cos\theta/kT)\, d\omega \quad ...(17)$$

Hence, the average value of the dipole moment in the direction of the field is given by

$$\bar{\mu}_{ind} = \frac{\int A \exp(\mu E \cos\theta/kT)\mu\cos\theta\, d\omega}{\int A \exp(\mu E \cos\theta/kT)\, d\omega} \quad ...(18)$$

where the integrals are taken over all the possible orientations. Putting $\mu E/kT = x$ and $\cos\theta = y$ (so that $dy = \sin\theta\, d\theta$), we have

$$d\omega = 2\pi \sin\theta\, d\theta = 2\pi dy \quad ...(19)$$

Thus, Eq. 18 takes the form,

$$\frac{\bar{\mu}_{ind}}{\mu} = \frac{\int_{-1}^{+1} e^{xy} y\, dy}{\int_{-1}^{+1} e^{xy}\, dy} \quad ...(20)$$

Using the standard integrals,

$$\int_{-1}^{+1} e^{xy} dy = (e^x - e^{-x})/x \quad ...(21)$$

and $$\int_{-1}^{+1} e^{xy} y\,dy = (e^x - e^{-x})/x - (e^x - e^{-x})/x^2 \quad ...(22)$$

we find that $$\frac{\bar{\mu}_{ind}}{\mu} = \frac{e^x + e^{-x}}{e^x - e^{-x}} - \frac{1}{x} = \coth x - \frac{1}{x} \equiv L(x) \quad ...(23)$$

where $L(x)$ is called the **Langevin function.** The Langevin function is plotted in Fig. 3. At room temperature, $x << 1$ so that on expanding $L(x)$ as a power series, only the first term needs to be retained, giving $L(x) = x/3$ so that

$$\bar{\mu}_{ind} = (\mu^2/3kT)E \quad ...(24)$$

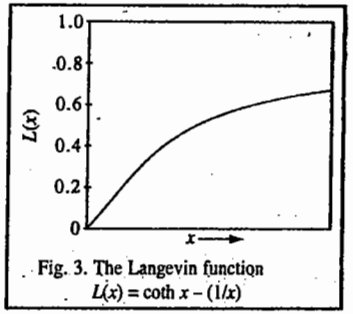

Fig. 3. The Langevin function $L(x) = \coth x - (1/x)$

Notice that $\bar{\mu}_{ind}$ decreases with increasing temperature ; also, $\bar{\mu}_{ind}$ is directly proportional to E. It must, however, be pointed out that the proportionality between $\bar{\mu}_{ind}$ and E cannot be maintained if E is large since in that case *saturation* occurs. Thus, if all the molecules are completely oriented, further increase in E will not increase $\bar{\mu}_{ind}$.

Defining the orientation polarizability α_μ as $\alpha_\mu = \bar{\mu}_{ind}/E$, we find from Eq. 24 that

$$\alpha_\mu = \mu^2/3kT \quad ...(25)$$

We see that α_μ depends upon the permanent dipole moment μ and the temperature. It decreases with increasing T. At higher temperatures, thermal motion reduces the dipole orientation in the field. Thus, from Eq. 7,

$$\alpha = \alpha_d + \mu^2/3kT \quad ...(26)$$

In Clausius-Mosotti equation, the term α_μ had been ignored. Debye, however, took into consideration both α_d and α_μ when Clausius-Mosotti equation takes the form

$$P_m = \frac{\varepsilon_r - 1}{\varepsilon_r + 2} V_m = \frac{4}{3}\pi N_A \left(\alpha_d + \frac{\mu^2}{3kT}\right) \quad ...(27)$$

In SI units, $$P_m = \frac{\varepsilon_r - 1}{\varepsilon_r + 2} V_m = \left(\frac{N_A}{3\varepsilon_0}\right)\left(\alpha_d + \frac{\mu^2}{3kT}\right) \quad ...(28)$$

Eq. 27 or 28 is called the **Debye equation.** According to this equation, P_m varies linearly with $1/T$. The slope and the intercept of the linear Debye plot are $(4/9)\pi N_A\mu^2/k$ or $(1/9\varepsilon_0)N_A\mu^2/k$ and $(4/3)\pi N_A\alpha_d$ or $(1/3\varepsilon_0)N_A\alpha_d$, respectively. From the slope and the intercept, μ and α_d of the molecule can be determined. The Dutch physicist, Peter Debye (1884–1966) was awarded the 1936 Chemistry Nobel Prize for contributions to molecular structure through his work on dipole moments.

Fig. 4 shows the linear plots for a gaseous non-polar molecule (such as CH_4 with $\mu=0$) and a gaseous polar molecule (such as HCl with $\mu \neq 0$). For a non-polar molecule, since $\mu=0$, the plot of P_m versus $1/T$ yields a straight line parallel to the $1/T$ axis.

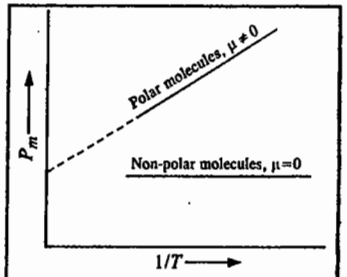

Fig. 4. Plots of P_m versus $1/T$ for gaseous polar and non-polar molecules.

Remarks on units. The units of polarizability can be deduced from Eq. 2 as follows. Since E is expressed as V m^{-1} (volt per metre) and μ_{ind} is expressed in C m, hence from dimensional analysis,

$$\alpha = \frac{\mu_{ind}}{E} = \frac{\text{C m}}{\text{V m}^{-1}} = \frac{\text{C m}}{\text{J C}^{-1}\,\text{m}^{-1}} = \text{J}^{-1}\,\text{C}^2\,\text{m}^2$$

It is customary to define **polarizaibility volume** (α') as $\alpha' = \alpha_d/4\pi\varepsilon_0$. Thus, α' has the units of volume :

$$\alpha' = \frac{\alpha_d}{4\pi\varepsilon_0} = \frac{\text{J}^{-1}\text{C}^2\,\text{m}^2}{\text{J}^{-1}\text{C}^2\,\text{m}^{-1}} = \text{m}^3$$ (The units of ε_0 are $J^{-1}\ C^2\ m^{-1}$).

The dipole moments, the polarizabilities and the polarizability volumes of some common molecules obtained from the Debye equation are given in Table 1.

TABLE 1

Dipole Moments, Polarizabilities and Polarizability Volumes of Some Common Molecules

Molecule	Dipole Moment		Polarizability	Polarizability volume
	$\mu/10^{-30}$ (C m)	μ (D)	$\alpha/10^{-40}$ ($J^{-1}\ C^2\ m^2$)	$\alpha'/10^{-30}$ (m^3)
H_2	0	0	0·91	0·82
N_2	0	0	1·97	1·77
CO_2	0	0	2·93	2·63
CO	0·39	0·12	2·20	1·98
HF	6·37	1·91	5·67	0·51
HCl	3·60	1·08	2·93	2·63
HBr	2·67	0·80	4·01	3·61
HI	1·40	0·42	6·06	5·45
H_2O	6·17	1·85	1·65	1·48
NH_3	4·90	1·47	2·47	2·22
CCl_4	0	0	11·70	10·50
$CHCl_3$	3·37	1·01	9·46	8·50
CH_2Cl_2	5·24	1·57	7·57	6·80
CH_3Cl	6·24	1·87	5·04	4·53
CH_4	0	0	2·89	2·60
C_6H_6	0	0	11·61	10·41
He	0	0	0·22	0·20
Ar	0	0	1·85	1·66

The value of α' for hydrogen atom is $0{\cdot}66\times10^{-30}$ m^3 whereas the values for alkali metals, in units of 10^{-30} m^3, are as follows : Li(12), Na(27), K(34). Notice the high polarizability volumes of the alkali metal atoms. This is due to easy distortion of valence electron density by the electric field.

Example 1. The dipole moment, μ, of HBr is 0·78 D and its dielectric constant (or relative permittivity, ε_r), at 20°C and 1 atm pressure is 1·00313. Calculate its distortion polarizability, α_d and polarizability volume, α'. Given $\varepsilon_0 = 8{\cdot}854\times10^{-12}$ $J^{-1}\ C^2\ m^{-1}$, $4\pi\varepsilon_0 = 1{\cdot}11265\times10^{-10}$ $J^{-1}\ C^2\ m^{-1}$.

Solution : From Eq. 28, $$P_m = \frac{\varepsilon_r - 1}{\varepsilon_r + 2} V_m = \frac{N_A}{3\varepsilon_0}\left(\alpha_d + \frac{\mu^2}{3kT}\right) \quad ...(i)$$

Under the given conditions of temperature and pressure, HBr behaves as an ideal gas with molar volume V_m given by $V_m = M/\rho = RT/P^0$, *i.e.*,

$$V_m = \frac{RT}{P^0} = \frac{8{\cdot}206\times10^{-5}\,\text{m}^3\,\text{atm}\,\text{mol}^{-1}\text{K}^{-1})(293\text{K})}{1\text{atm}} = 2{\cdot}40\times10^{-2}\ \text{m}^3\ \text{mol}^{-1}$$

$$\therefore \quad P_m = \frac{1{\cdot}00313 - 1}{1{\cdot}00313 + 2} \times (2{\cdot}40\times10^{-2}\ \text{m}^3\ \text{mol}^{-1}) = 0{\cdot}001\ \text{m}^3\ \text{mol}^{-1}$$

$\varepsilon_0 = 8{\cdot}854\times10^{-12}\ J^{-1}C^2m^{-1}$; $k = 1{\cdot}38\times10^{-23}\ JK^{-1}$

$$\mu = 0{\cdot}78 \text{ D} = (0{\cdot}78 \text{ D})\ (3{\cdot}336\times10^{-30} \text{ C m/D}) = 2{\cdot}60\times10^{-30} \text{ C m}$$

Substituting these values in Eq. *(i)*, we obtain

$$\alpha_d = 5{\cdot}5\times10^{-40} \text{ J}^{-1} \text{ C}^2 \text{ m}^2$$

The polarizability volume is given by

$$\alpha' = \frac{\alpha_d}{4\pi\varepsilon_0} = \frac{5{\cdot}5\times10^{-40} \text{ J}^{-1} \text{ C}^2 \text{ m}^2}{1{\cdot}11265\times10^{-10} \text{ J}^{-1} \text{ C}^2 \text{ m}^{-1}} = 4{\cdot}94\times10^{-30} \text{ m}^3$$

Dependence of Polarizability on Frequency. The treatment of polarisation discussed above is based on subjecting molecules to static electric field. When, however, the applied field is oscillating, the Debye equation is not applicable because when the frequency is very high, the permanent dipole moments of molecules cannot orient themselves sufficiently rapidly to align themselves with the ever-changing field direction. The result is that at such high frequencies the permanent dipole moment makes no contribution to the polarization of the molecules. Since a molecule requires about one pico-second (10^{-12} second) to rotate in a liquid, the dipolar contribution vanishes when the dielectric constant (or relative permittivity) is measured at frequencies above 10^{11} Hz (*i.e.*, in the microwave region). Accordingly, it is possible to measure the rate of molecular orientation in liquids by carrying out observations on the variation of polarization with frequency.

At microwave frequencies, the orientation polarization decreases with increase in frequency but thereafter the molecular distortion results in stretching and bending of the molecule by the electric field. This occurs in the infrared region (Fig. 5). When the frequency is so high that it changes more

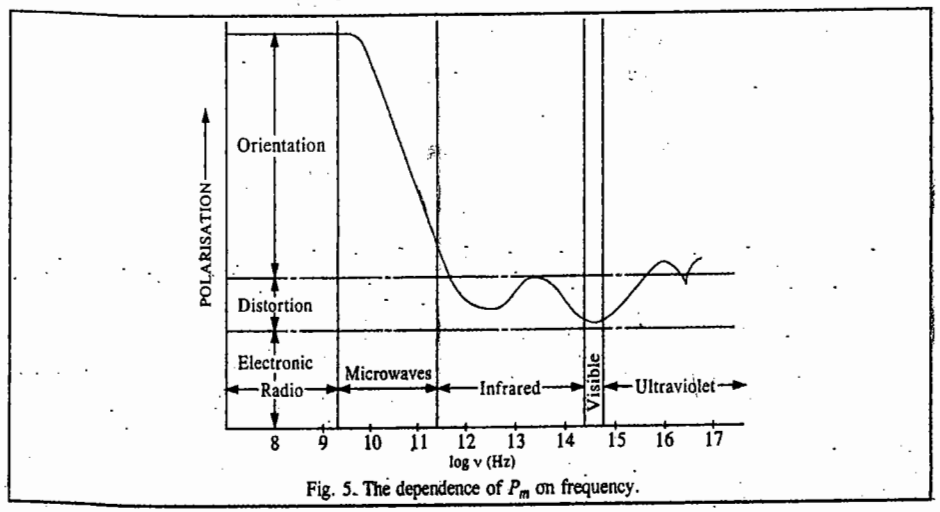

Fig. 5. The dependence of P_m on frequency.

quickly than the time required for the molecule to change its shape (which is the time required for a molecule to vibrate), *the distortion polarization makes no contribution to* P_m. Therefore, at higher frequencies falling in UV and visible regions only the *electronic contribution* to P_m remains. This is because electrons are light enough to respond to the rapidly changing direction of the applied electric field. Thus while in the infrared region, both the nuclei and the electrons follow the electric field, in UV and visible regions only electronic contribution remains.

A light wave is electromagnetic in nature, *i.e.*, it has rapidly changing electric and magnetic fields associated with it. The electric field of the light wave polarizes the medium through which it passes, pulling the electrons back and forth rapidly. Maxwell in his electromagnetic theory of light showed that at optical frequencies the dielectric constant (*i.e.*, relative permittivity) and the refractive index of the medium are related as follows :

$$\varepsilon_r \approx n_r^2 \qquad ...(29)$$

This relation, known as the **Maxwell relation,** holds only when the permanent dipole moment of a molecule does not contribute to ε_r and hence to P_m.

Thus, at optical frequencies, substitution of the Maxwell relation into the Clausius-Mosotti equation (Eq. 14) yields

$$P_m = R_m = \frac{n_r^2 - 1}{n_r^2 + 2} V_m = \frac{N_A \alpha_d}{3\varepsilon_0} \qquad ...(30)$$

where R_m is called **molar refraction.** Eq. 30 is known as the **Lorentz-Lorenz equation.** Using this equation, one can determine induced polarizations from the refractive index measurements. If these data are combined with dielectric data, the dipole moment can be determined from the Debye equation.

Eq. 30 can also be inverted to give an expression for the refractive index of a medium :

$$n_r = \left(\frac{V_m + 2R_m}{V_m - R_m}\right)^{1/2} \qquad ...(31)$$

Eq. 30 can be rearranged to yield an expression for distortion polarizability, α_d :

$$\alpha_d = 3\varepsilon_0 R_m / N_A \qquad ...(32)$$

so that the polarizability volume is given by

$$\alpha' = \alpha_d / 4\pi\varepsilon_0 = 3R_m / 4\pi N_A \qquad ...(33)$$

It may be mentioned that the Maxwell relation $\varepsilon_r \approx n_r^2$ holds only for non-polar molecules. For non-polar molecules ε_r and n_r need not be measured at the same frequency. Since in the case of non-polar molecules the orientation polarizability is absent and the nuclear distortion polarizability is negligible in comparison with the electronic distortion polarizability, it is immaterial whether ε_r and n_r are measured at the same frequency or at different frequencies. This means that the measurement of ε_r and n_r at different frequencies includes only the electronic polarization. Thus, for benzene, a non-polar molecule, $n_r = 1{\cdot}50$ and $\varepsilon_r = 2{\cdot}27$ so that $\varepsilon_r \approx n^2$. However, for water, a polar molecule, $n_r = 1{\cdot}33$ and $\varepsilon_r = 80$ so that $\varepsilon_r \neq n_r^2$. For polar molecules $\varepsilon_r \approx n_r^2$ only if both ε_r and n_r are measured *at the same frequency.*

For a molecule, R_m is additive, *i.e.*, it is equal to the sum of the molar refractions of individual atoms or of individual bonds. Table 2 lists the molar refractions of some common atoms, ions and bonds.

TABLE 2

Molar Refractions at 589 nm Wave Length

Bond	Molar Refraction R_m (cm^3 mol^{-1})	Atom or Ion	Molar Refraction R_m (cm^3 mol^{-1})
C–H	1·65	H	1·10
O–H	1·85	He	0·51
C–C	1·20	C	2·42
C=C	2·79	Li^+	0·07
C≡C	4·79	Na^+	0·46
C–O	1·41	K^+	2·12
C=O	3·34	Rb^+	3·57
C≡N	4·69	Be^{2+}	0·20
		Mg^{2+}	0·24
		Ca^{2+}	1·19

The molar refraction R_m can be calcuated from the measured value of the refractive index of the liquid or the solid. Eq. 30 can be combined with the Debye equation (Eq. 28) to obtain the following expression for the relative permittivity at low frequencies :

$$P_m = R_m + \frac{N_A \mu^2}{9\varepsilon_0 kT} \qquad ...(34)$$

i.e.,
$$\frac{\varepsilon_r - 1}{\varepsilon_r + 2} V_m = R_m + \frac{N_A \mu^2}{9\varepsilon_0 kT} \qquad ...(35)$$

In the c.g.s. system, Eq. 34 is written as

$$P_m = R_m + \frac{4\pi N_A \mu^2}{9kT} \qquad ...(36)$$

Example 2. Estimate the refractive index of water, given that the polarizability volume of water molecule at optical frequencies is $1{\cdot}5\times10^{-24}$ cm^3.

Solution : $V_m = M/\rho = 18{\cdot}02$ g mol^{-1}/1·00 g cm^{-3} = 18·02 cm^3 mol^{-1}

From Eq. 33, $R_m = \dfrac{4\pi\alpha' N_A}{3} = \dfrac{4\pi(1{\cdot}5\times10^{-24}\text{ cm}^3)\times(6{\cdot}022\times10^{23}\text{ mol}^{-1})}{3} = 3{\cdot}8$ cm^3 mol^{-1}

From Eq. 31, $n_r = \left(\dfrac{V_m + 2R_m}{V_m - R_m}\right)^{1/2} = \left\{\dfrac{(18{\cdot}02 + 2\times3{\cdot}8)\text{ cm}^3\text{ mol}^{-1}}{(18{\cdot}02 - 3{\cdot}8)\text{ cm}^3\text{ mol}^{-1}}\right\}^{1/2} = 1{\cdot}34$

Example 3. Calculate the polarizability and polarizability volume of water molecule at 20°C if at this temperature the refractive index of water is 1·3330 for a light of wave length 589 nm. Molar mass M for water = 18·015 g mol^{-1}, ρ = 0·9982 g cm^{-3} and $\varepsilon_0 = 8{\cdot}8542\times10^{-12}$ J^{-1} C^2 m^{-1}

Solution : From Eq. 32,

$$\alpha_d = \frac{3\varepsilon_0 R_m}{N_A} = \frac{3\varepsilon_0}{N_A}\left\{\frac{n_r^2 - 1}{n_r^2 + 1}\right\} V_m$$

$$= \frac{3\times(8{\cdot}8542\times10^{-12}\text{ J}^{-1}\text{C}^2\text{ m}^{-1})}{6{\cdot}022\times10^{23}\text{ mol}^{-1}} \times \left\{\frac{1{\cdot}3330^2 - 1}{1{\cdot}3330^2 + 2}\right\} \times \frac{18{\cdot}015\text{ g mol}^{-1}}{0{\cdot}9982\text{ g cm}^{-3}}$$

$$= 1{\cdot}6375\times10^{-40}\text{ J}^{-1}\text{ C}^2\text{ m}^2$$

$$\therefore \quad \alpha' = \frac{\alpha_d}{4\pi\varepsilon_0} = \frac{1{\cdot}6375\times10^{-40}\text{ J}^{-1}\text{C}^2\text{ m}^2}{4\pi\times(8{\cdot}8542\times10^{-12}\text{ J}^{-1}\text{C}^2\text{ m}^{-1}}$$

$$= 1{\cdot}4717\times10^{-24}\text{ cm}^3 = 1{\cdot}4717\times10^{-30}\text{ m}^3$$

Example 4. For a gaseous molecule AB_2 the refractive index is 1·00518 and the dielectric constant is 1·001. Determine if the molecule is linear or bent.

Solution : $n_r = 1{\cdot}00518$; $\varepsilon_r = 1{\cdot}001$. Thus, $\varepsilon_r \approx n_r^2$

Since the Maxwell relation holds for a non-polar molecule, hence the molecule AB_2 must be non-polar with dipole moment = 0. Thus, AB_2 is a linear molecule with the structure, B–A–B.

Example 5. For a gaseous hydrocarbon C_nH_{2n+2}, the refractive index at STP is 1·00138. Determine the formula of the hydrocarbon, given that the R_m values for H and C are 1·10 and 2·42 cm^3 mol^{-1}, respectively.

Solution : $R_m = \left(\dfrac{n_r^2 - 1}{n_r^2 + 2}\right)V_m = \left(\dfrac{(1{\cdot}00138)^2 - 1}{(1{\cdot}00138)^2 + 2}\right)$ (22,414 cm^3 mol^{-1}) = 20·75 cm^3 mol^{-1}

Also, since the atomic refractions are additive, hence

$R_m = nR_C + (2n+2)R_H$ so that

$20{\cdot}75$ cm^3 mol^{-1} = $[n(2{\cdot}42) + (2n+2)(1{\cdot}1)]$ cm^3 mol^{-1}

or $20{\cdot}75 = 4{\cdot}62n + 2{\cdot}2$, whence

$n = (20{\cdot}75 - 2{\cdot}2)/4{\cdot}62 = 18{\cdot}55/4{\cdot}62 = 4$

Hence, the formula of the hydrocarbon is C_4H_{10}.

Example 6. Estimate the refractive index of acetic acid for yellow sodium light (589 nm) given that at this wave length (or the corresponding frequency) the R_m values of the C—H, C—C, C—O, C=O and O—H bonds are 1·65, 1·20, 1·41, 3·34 and 1·85 cm^3 mol^{-1}, respectively. Also, for acetic acid, M = 60·05 g mol^{-1} and ρ = 1·046 g cm^{-3}.

Solution : Since the total R_m value of acetic acid molecule is the sum of the R_m values of the C—H, C—C, C—O, C=O and O—H bonds, hence

$$R_m = 3(\text{C—H}) + (\text{C—C}) + (\text{C=O}) + (\text{C—O}) + (\text{O—H})$$

$$= (3\times1{\cdot}65) + 1{\cdot}20 + 3{\cdot}34 + 1{\cdot}41 + 1{\cdot}85 = 12{\cdot}75\text{ cm}^3\text{ mol}^{-1}$$

$$V_m = M/\rho = (60{\cdot}05\text{ g mol}^{-1})/1{\cdot}046\text{ g cm}^{-3} = 57{\cdot}41\text{ cm}^3\text{ mol}^{-1}$$

Hence, from Eq. 3i,

$$n_r = \left[\frac{V_m + 2R_m}{V_m - R_m}\right]^{1/2} = \left(\frac{57{\cdot}41 + 2\times12{\cdot}75\text{cm}^3\text{ mol}^{-1}}{(57{\cdot}41 - 12{\cdot}75)\text{cm}^3\text{ mol}^{-1}}\right) = 1{\cdot}36$$

Example 7. Estimate the refractive index of steam at 100°C and 1 atm pressure, given that its polarizability volume is $1{\cdot}50\times10^{-24}$ cm^3.

Solution : As shown in the last example,

$$n_r = \left(\frac{1 + (8\pi\alpha' P/3kT}{1 - (4\pi\alpha' P/3kT}\right)^{1/2}$$

Now, $\alpha' = 1{\cdot}50\times10^{-24}\text{ cm}^3 = 1{\cdot}50\times10^{-30}\text{ m}^3$

$$4\pi\alpha' P/3kT = \frac{4\pi(1{\cdot}50\times10^{-30}\text{m}^3)(1{\cdot}01325\times10^5\text{ N m}^{-2})}{3\times[1{\cdot}38\times10^{-23}\text{ J K}^{-1})(373\text{ K})} = 1{\cdot}235\times10^{-4}$$

$$\therefore \quad n_r = \left(\frac{1 + 2{\cdot}470\times10^{-4}}{1 - 1{\cdot}235\times10^{-4}}\right)^{1/2} = 1{\cdot}00019$$

Example 8. If molar polarization of $NH_3(g)$ obeys the equation $P_m = a + b/T$ where the constants a and b have the values 5·6 and 12,000 cm^3 mol^{-1}, respectively, what is the relative permittivity of ammonia gas at S.T.P. ?

Solution : According to Eq. 27, $P_m = \left(\dfrac{\varepsilon_r - 1}{\varepsilon_r + 2}\right)V_m$,

where at STP, V_m = 22·414 dm^3 mol^{-1} = 22,414 cm^3 mol^{-1}

$$\frac{\varepsilon_r - 1}{\varepsilon_r + 2} = \frac{P_m}{V_m} = \frac{a + b/T}{V_m} = \frac{(5{\cdot}6 + 12{,}000/273)\text{ cm}^3\text{ mol}^{-1}}{22{,}414\text{ cm}^3\text{ mol}^{-1}}$$

$$= 49{\cdot}4/22{,}414 = 0{\cdot}00221$$

$$\frac{\varepsilon_r - 1}{\varepsilon_r + 2} = 0{\cdot}00221$$

$$\varepsilon_r - 1 = (\varepsilon_r + 2)(0{\cdot}00221) = 0{\cdot}00221\varepsilon_r + 0{\cdot}00442$$

$$\varepsilon_r(1 - 0{\cdot}00221) = 1{\cdot}00442$$

$$\therefore \quad \varepsilon_r = \frac{1{\cdot}00442}{0{\cdot}99779} = 1{\cdot}00664$$

Bond Moments. It is convenient to consider the permanent dipole moment of a molecule in terms of its *bond moments*. The bond moment is a vector quantity and can be associated with a chemical bond. The bond moments for some molecules are given in Table 3.

TABLE 3

Bond Moments of Some Chemical Bonds

Bond	Bond Moment (D)	Bond	Bond Moment (D)
C—H	0·4	H—I	0·4
C—F	1·4	O—H	1·6
C—Cl	1·5	N—H	1·3
C—Br	1·4	S—H	0·8
C—I	1·2	F—Cl	0·9
C—O	0·9	F—Br	1·3
C—N	0·2	Br—Cl	0·6
C=O	2·3	H—F	1·9
C—NO_2	3·5	H—Cl	1·0
		HBr	0·8

The bond moments for a given bond vary from molecule to molecule, though the variation is usually slight. For a molecule having only one bond, the bond moment is equal to the molecular dipole moment. However, for a polyatomic molecule, the molecular dipole moment is the resultant of the bond moments and can be obtained by vectorial addition of the bond moments. Thus, there is an intimate relationship between dipole moment and molecular geometry.

The molecular dipole moment can be resolved into bond moments. The *ionic character of a bond* can also be estimated from the knowledge of its bond moment. The bond moment is calculated assuming the bond to be completely ionic. This is illustrated in the following example.

Example 9. The bond angle in H_2O is 104·5° and the dipole moment is 1·85 D. Calculate the bond moment for the O—H bond. Also estimate the percent ionic character of the O—H bond, given that the O—H bond distance is 96 pm.

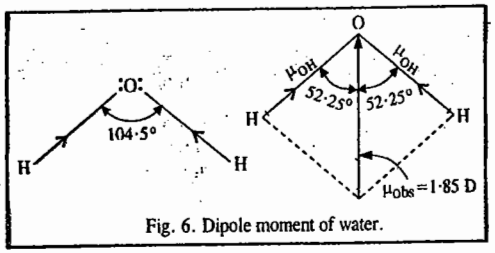

Fig. 6. Dipole moment of water.

Solution : As seen in Fig. 6, the angle between the O—H bonds in H_2O is 104·5° and the observed dipole moment is the vectorial sum of the two O—H bond moments.

Accordingly, $\mu_{observed} = 2\mu_{OH} \cos 52{\cdot}25°$

or $1{\cdot}85 \text{ D} = 2\mu_{OH} \times (0{\cdot}6129)$

$\therefore \quad \mu_{OH} = 1{\cdot}85 \text{ D}/(2 \times 0{\cdot}6129)$

$= 1{\cdot}51 \text{ D}$

$= 1{\cdot}51 \times 3{\cdot}336 \times 10^{-30} \text{ C m}$ $\quad (\because 1 \text{ D} = 3{\cdot}336 \times 10^{-30} \text{ C m})$

If the O—H bond is completely ionic, then the dipole moment

$$\mu_{ionic} = (1{\cdot}602 \times 10^{-19} \text{ C}) \times (96 \times 10^{-12} \text{ m}) = 1{\cdot}538 \times 10^{-29} \text{ C m}$$

Hence, % ionic character $= (\mu_{OH}/\mu_{ionic}) \times 100$

$$= \left(\frac{1{\cdot}51 \times 3{\cdot}336 \times 10^{-30} \text{ C m}}{1{\cdot}538 \times 10^{-29} \text{ C m}}\right) \times 100 = 24{\cdot}94$$

It should be noted that the resolution of a molecular dipole moment into bond moments is somewhat arbitrary. One could, for instance, assign a moment to the lone pair of electrons in H_2O or NH_3 as well as to the bonds.

Dipole Moments and Molecular Structure

The linear triatomic molecules of the type B—A—B (*e.g.*, CO_2) have no dipole moment, not because the individual C=O bonds are non-polar but because the two bond moments cancel being equal and opposite. Again, angular triatomic molecules (such as H_2O) and linear asymmetric molecules (such as N_2O) have dipole moments because their bond moments do not cancel. For polyatomic molecules, the

situation becomes increasingly complicated. For instance, in the case of the planar symmetrical molecule like AB_3, the three bond moments cancel to give a zero dipole moment. BF_3 belongs to this category.

On the other hand, the vector sum of bond moments of NH_3 does not cancel so that the molecule possesses a dipole moment. This indicates that the three hydrogen atoms do not lie symmetrically with respect to the nitrogen atom. The high value (1·40 D) of the dipole moment of NH_3 can be explained by assigning a triangular pyramidal structure to the molecule in which the nitrogen atom is situated at the apex of the pyramid and the three hydrogens lie at the three corners of the base.

Symmetrical polyatomic polar molecules do not show dipole moment if the vector sum of the bond moments cancels out. Examples are CH_4, CCl_4, SF_6, C_6H_6 and $[Ni(CN)_4]^{2-}$.

Dipole moments are helpful in distinguishing between the *cis* and *trans* isomers. Thus, the *cis* isomer of 1,2-dichloroethane has a dipole moment whereas the *trans* isomer does not. The zero dipole moment of the trans isomer is due to the fact that the vector sum of the bond moments of the two C—Cl bonds cancels out :

H—C—Cl ‖ H—C—Cl	H—C—Cl ‖ Cl—C—H
cis form	*trans* form
(μ = 1·86 D)	(μ = 0)

The dipole moment data can also help in the indentification of *cis* and *trans* isomers of square planar PtA_2B_2 complexes. The *trans* isomer should have a very small dipole moment whereas the *cis* isomer should possess a fairly large moment. This fact is corroborated experimentally.

It may also be noted that the experimental measurement can yield only the magnitude, not the direction, of the dipole moment. In most cases it is possible to have a fairly good idea of the direction of the dipole moment by considering the difference in electronegativities and by making comparison with similar molecules. However, in several cases, it is difficult to predict the direction of the dipole moment. A well known example is furnished by carbon monoxide, CO, which has a small value of μ=0·10 D.

Group Moments. When we want to evaluate dipole moments of benzene derivatives, we find that we need to know the *group moments* rather than the *bond moments*. For instance, the observed dipole moment of 1·68 D for chlorobenzene presumably arises from the dipole moment of the C—Cl group assuming that the C—H bonds in benzene have zero dipole moment. The group moments of some common groups are shown in Table 4.

TABLE 4

Group Moments of Some Common Groups

Group	NH_2	CH_3	H	Cl	OH	NO_2
Group moment (D)	+ 1·53	+ 0·41	0	−1·58	−1·60	−3·98

The sign of a group moment shows the direction in which the group moment operates. Thus, the negative sign implies that the group moment acts *towards* the ring whereas the positive sign implies that it acts *away* from the ring. By vectorial addition the dipole moment of a substituted benzene can be calculated.

Example 10. If in a substituted benzene, μ_1 and μ_2 are the bond moments inclined at an angle θ with respect to each other, then show that the dipole moment of the substituted benzene is given by the expression :

$$\mu = \left(\mu_1^2 + \mu_2^2 + 2\mu_1\mu_2 \cos\theta\right)^{1/2}$$

Solution : Let μ_x and μ_y be the x and y components of μ_1 and μ_2. Then,

$$\mu = \left(\mu_x^2 + \mu_y^2\right)^{1/2} \qquad \ldots(i)$$

If θ_1 and θ_2 are the angles which μ_1 and μ_2, respectively, make with the x-axis, then

$$\mu_x = \mu_{1,x} + \mu_{2,x} = \mu_1 \cos\theta_1 + \mu_2 \cos\theta_2 \quad ...(ii)$$

Similarly, $$\mu_y = \mu_{1,y} + \mu_{2,y} = \mu_1 \sin\theta_1 + \mu_2 \sin\theta_2 \quad ...(iii)$$

Substituting Eqs. *(ii)* and *(iii)* into Eq. *(i)*, we have

$$\mu = \{(\mu_1 \cos\theta_1 + \mu_2 \cos\theta_2)^2 + (\mu_1 \sin\theta_1 + \mu_2 \sin\theta_2)^2\}^{1/2}$$

$$= \{(\mu_1^2 \cos^2\theta_1 + \mu_2^2 \cos^2\theta_2 + 2\mu_1\mu_2 \cos\theta_1 \cos\theta_2) + (\mu_1^2 \sin^2\theta_1 + \mu_2^2 \sin^2\theta_2 + 2\mu_1\mu_2 \sin\theta_1 \sin\theta_2)\}^{1/2}$$

which can be rearranged to give

$$\mu = \{\mu_1^2 + \mu_2^2 + 2\mu_1\mu_2(\cos\theta_1 \cos\theta_2 + \sin\theta_1 \sin\theta_2)\}^{1/2}$$

$$= \{\mu_1^2 + \mu_2^2 + 2\mu_1\mu_2 \cos(\theta_1 - \theta_2)\}^{1/2}$$

$$= \{\mu_1^2 + \mu_2^2 + 2\mu_1\mu_2 \cos\theta\}^{1/2} \quad \text{where } \theta_1 - \theta_2 = \theta.$$

Example 11. If μ is the dipole moment of the monosubstituted benzene C_6H_5X, derive expressions for the dipole moments of 1,2-disubstituted benzene, $C_6H_4X_2$ and 1,3-disubstituted benzene, $C_6H_4X_2$.

Solution : As shown in the last example,

$$\mu = \{\mu_1^2 + \mu_2^2 + 2\mu_1\mu_2 \cos\theta\}^{1/2}$$

Now, for 1,2-$C_6H_4X_2$, $\theta = 60°$ whereas for 1,3-$C_6H_4X_2$, $\theta = 120°$

Thus, for 1,2-$C_6H_4X_2$, we have, $\mu_{total} = \{\mu_1^2 + \mu_2^2 + 2\mu_1\mu_2 \cos 60\}^{1/2}$

$$= (2\mu^2 + 2\mu^2 \cos 60)^{1/2} = (3\mu^2)^{1/2} = \sqrt{3}\mu$$

where we have made use of the fact that $\mu_1 = \mu_2 = \mu$

Similarly, for 1,3-$C_6H_4X_2$, we have,

$$\mu_{(total} = \{\mu_1^2 + \mu_2^2 + 2\mu_1\mu_2 \cos 120\}^{1/2}$$

$$= (2\mu^2 - 2\mu^2 \sin 30)^{1/2} = (2\mu^2 - \mu^2)^{1/2} = \mu$$

Example 12. The molecular dipole moment of chlorobenzene is 1·69 D. Calculate the dipole moments of *ortho*, *meta* and *para* dichlorobenzenes.

Solution : Using the expression derived in the last example, we have

for the ortho compound, $\mu = \sqrt{3}$ (1·69 D) = (1·732) (1·69 D) = 2·93 D

for the meta compound, μ = 1·69 D

and for the para compound, $\mu = 0$ since the two dipoles are directed to each other at an angle of 180°. The results agree excellently with the experimental values of 1·68 D and 0, respectively, of the meta and para disubstituted benzenes. However, there is disagreement with the experimental value (2·52 D) of the ortho compound. This is presumably due to the fact that in the ortho $C_6H_4Cl_2$, the two Cl atoms being close, there may be *repulsion* between them so that θ is greater than 60°. Also, the proximity of the two Cl atoms may alter the C–Cl bond moments.

MAGNETIC PROPERTIES OF MOLECULES

The magnetic properties of atoms and molecules are, in general, of less interest than the electrical properties dealt with above. Nevertheless, since the theory of magnetic properties is analogous in several ways to the theory of electric properties, important information about the molecular structure can be obtained by studying the magnetic behaviour of matter.

The force F acting between two magnetic dipoles of pole strengths m_1 and m_2 separated by a distance r, is given by

$$F = m_1 m_2 / \mu r^2 \quad ...(37)$$

where μ is a constant characteristic of the medium and is called **magnetic permeability** of the medium. Magnetic permeability is the magnetic counterpart of electric permittivity. Magnetic permeability

measures the tendency of the magnetic lines of force to pass through the medium, compared with their tendency to pass through vacuum for which $\mu = 1$. A substance is said to be diamagnetic when $\mu < 1$ and paramagnetic when $\mu > 1$. Thus, a diamagnetic substance is less permeable to the magnetic lines of force than a vaccum. The magnetic lines of force deflect away from a diamagnetic sample whereas they deflect towards a paramagnetic sample (Fig. 7).

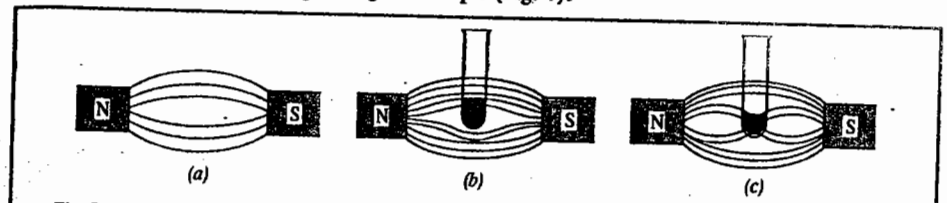

Fig. 7. Magnetic lines of force showing the effect of diamagnetic and paramagnetic substance on the magnetic field. *(a)* Vacuum *(b)* Diamagnetic *(c)* Paramagnetic.

The magnetic properties of matter are discussed in terms of the magnetic field intensity vector, H and the magnetic induction (or magnetic flux density) B. When a substance is placed in a magnetic field, the magnetization M, *i.e.*, the magnetic moment per unit volume, is related to B and H by the relation

$$B = \mu_0 (H + M) \quad ...(38)$$

where μ_0 is the permeability of vacuum.

Also, $$B = \mu H \quad ...(39)$$

From Eqs. 38 and 39, $$M = H[(\mu/\mu_0) - 1] = H(\mu_r - 1) \quad ...(40)$$

where $\mu_r = \mu/\mu_0$ is the *relative permeability* of the medium ($\mu_0 = 4\pi \times 10^{-7}$ J C^{-2} m^{-1} s^2).

A very important quantity, **magnetic susceptibility, is defined as**

$$\chi = M/H = \mu_r - 1 \quad ...(41)$$

The magnetic susceptibility is a dimensionless quantity. The *molar magnetic susceptibility* is defined as

$$\chi_m = V_m \chi \quad ...(42)$$

where V_m is the molar volume.

Magnetic susceptibility is related to magnetic permeability as follows :

$$\chi = (\mu - 1)/4\pi\rho \quad ...(43)$$

where ρ is the density in g cm^{-3}.

For *diamagnetic* solids, the relative permeability $\mu_r < 1$ so that χ is negative. Such substances are copper, graphite, antimony, bismuth, etc. For *paramagnetic* solids (such as Al, Pt, etc.,) $\mu_r > 1$ so that χ is positive. For *ferromagnetic* solids (such as Fe, Co, Ni, etc.,) μ_r and χ are very high, their values ranging between 200 and 100,000. It should be noted that for a diamagnetic substance, χ is small, negative, independent of magnetic field intensity and also independent of temperature. For a paramagnetic substance, χ is large, positive, independent of magnetic field intensity and decreases with increase in temperature. For a ferromagnetic substance, χ is very large, positive and depends upon the magnetic field intensity, the temperature and the previous history of the sample. Then, there are the so-called antiferromagnetic substances for which χ is small and positive. These substances show hysteresis effects and possess transition temperature, called the **Neel point.** The French physicist Louis Neel (1904–1999) was the cowinner (with the Swedish physicist H. Alfven (1908–1995) of the 1970 Phyiscs Nobel Prize. Neel was honoured for contributions to antiferromagnetism and ferromagnetism and Alfven was honoured for work on magnetohydrodynamics and plasma physics.

Table 5 summarizes the magnitudes, signs and origins of the various forms of magnetic behaviour.

TABLE 5

Types of Magnetic Behaviour and Their Characteristics

Type of magnetic susceptibility	Sign	Approximate magnitude	Dependence on magnetic field intensity	Origin
Diamagnetism	Negative	1×10^{-6}	Independent	Electronic charge
Paramagnetism	Positive	$0 - 10^{-4}$	Independent	Angular momentum (electron spin)
Ferromagnetism	Positive	$10^{-2} - 10^{-4}$	Dependent	↑↑ dipole exchange
Antiferromagnetism	Positive	$0 - 10^{-4}$	May depend	↑↓ dipole exchange

Molecular Interpretation of Diamagnetism and Paramagnetism

Diamagnetism. The classical theory of diamagnetism and paramagnetism was developed by P. Langevin in 1905 and the quantum theory was formulated by J.H. van Vleck in 1932. Langevin explained diamagnetism as resulting from the orbital motion of electrons of atoms or molecules. Qualitatively, it can be understood by involving Lenz's law which states that when a current flows in a coil of wire in a magnetic field, the field induces a current in the coil in a manner as to oppose the applied field. Similarly, the applied magnetic field perturbs the orbital motion of electrons, inducing a magnetic field which opposes its own direction. In atoms having more than one electron, the orbits are partially oriented at random relative to the field. The molar diamagnetic susceptibility is given by

$$\chi^d_{m,\,\text{atom}} = -\frac{ZN_A e^2}{6m_e^2}\sum_i \langle r_i^2 \rangle = -2{\cdot}832\times10^{16} \langle r_i^2 \rangle \qquad \ldots(44)$$

where $\langle r_i^2 \rangle$ is the mean square distance of ith orbit from the nucleus ; Z is the atomic number and e and m_e are, respectively, the charge and mass of electron. Notice that χ^d_m is negative and *temperature-independent*. The negative sign in Eq. 44 indicates that diamagnetic susceptibility decreases the magnetic induction through the sample and produces repulsion of the material by the magnetic field. Diamagnetism is a fundamental property of all matter irrespective of whether it possesses a permanent magnetic moment or not.

P. Pascal has shown that diamagnetism in a molecule can be estimated from contributions of atoms and bonds within the molecule. Such diamagnetic contributions of atoms and bonds in a molecule are called **Pascal's constants**. Pascal's constants for some atoms and bonds are given in Table 6.

TABLE 6

Pascal's Constants for Atoms and Bonds

Atom or Bond	Pascal's constant	Atom or Bond	Pascal's constant
H	$-2{\cdot}9\times10^{-6}$	I	−44·6
C	−6·0	Si	−13·0
N (open chain)	−5·5	S	−15·1
N (ring)	−4·6	B	−7·0
N (amines)	−1·5	C=C	5·5
O (alcohol, ether)	−4·6	C=C − C=C	10·6
O (ketones)	−1·7	N=N	1·85
O (carboxyl)	−3·3	C=N	8·2
F	−6·3	C≡N	0·8
Cl	$-20{\cdot}1\times10^{-6}$	C≡C	0·8
Br	−30·6	Benzene ring	−1·4

The results obtained with the help of Eq. 44, however, do not agree well with the experimental data. It is, therefore, necessary to treat diamagnetic susceptibilities of atoms and molecules on an empirical basis. The diamagnetic susceptibility of a molecule may be written as

$$\chi^d_{m,\,\text{molecule}} = \sum_i \chi^{d,i}_{m,\,\text{atom}} + \sum \chi_{B,j} \qquad \ldots(45)$$

where $\chi^{d,i}_{m,\text{atom}}$ is the molar atomic diamagnetic susceptibility associated with atom i and $\chi_{B,j}$ is that associated with jth bond in the molecule.

Paramagnetism. Paramagnetism can be considered as arising from the magnetic behaviour of an electron moving around the nucleus of an atom. The orbital motion of an electron corresponds to the passage of current through a coil of wire. This current produces a magnetic field perpendicular to the coil. The magnetic moment of the current loop is given by $\mu_m = iA$, where A is the area of the loop and i is the current. If the current is due to electron of mass m_e and charge e, moving with a velocity v, then $i = -ev/2\pi r$ so that

$$\mu_m = -(ev/2\pi r)\,\pi r^2 = -evr/2 \qquad \ldots(46)$$

where r is the radius of the loop.

The classical theory of paramagnetism developed by Langevin assumes that each atom or molecule is a small bar magnet having a magnetic moment μ and undergoing thermal agitation proportional to the absolute temperature. The magnetic moment may be due to either the orbital motion of an electron or to an unpaired electron spin. Assuming that the thermal agitation of the system creates a disorder in the system, the molar paramagnetic susceptibility due to the permanent magnetic moment was found to be given by

$$\chi^p_m = \frac{N_A\mu_m^2}{3kT} = \frac{C}{T} \qquad \ldots(47)$$

where C is a constant. The inverse variation of χ^p_m with temperature had been established experimentally by P. Curie prior to the development of the theory and is known as **Curie's law.** Eq. 47 holds over a limited range. Since all substances show diamagnetic behaviour, the total molar susceptibility of a substance is given by the sum of Eqs. 45 and 47. In practice, however, the diamagnetic contribution is only a small fraction of the paramagnetic contribution when the latter is present. Hence, except for accurate measurements or for large molecules it is often neglected. Eq. 47 has been derived on the assumption that the system is rigid and remains unchanged by the external field. However, the external field *does* distort (or polarize) the system so that χ^p_m is more correctly given by

$$\chi^p_m = \frac{N_A\mu_m^2}{3kT} + N_A\alpha_m \qquad \ldots(48)$$

$$= N_A\mu_0\left(\alpha_m + \frac{\mu_m^2}{3kT}\right) \qquad \ldots(49)$$

where α_m is the **magnetic polarizability** (or **magnetizability**) of the system. The magnetic moment due to electron spin is given by

$$\mu_s = g_e\mu_B\,[s\,(s+1)]^{1/2} \qquad \ldots(50)$$

where $\mu_B = e\hbar/2m_e$ is called the Bohr magneton, B.M. The value of μ_B is $9{\cdot}273\times10^{-24}$ J T^{-1} (joule per tesla). If more than one electron is present, the individual electron spins add vectorially giving

$$\mu_S = g_e\,\mu_B\,[S(S+1)]^{1/2} \qquad \ldots(51)$$

where the total spin S is given by

$$S = \sum_i s_i \qquad \ldots(52)$$

the summation being carried over the individual spins of the electrons. For an electron, $g_e = 2$.

The magnetic moment due to the orbital motion of the electrons having quantum number L is given by

$$\mu_L = \mu_B [L(L+1)]^{1/2} \qquad ...(53)$$

If μ_{eff} is the *effective magnetic moment* of an atom or a system, *i.e.*, If $\mu = \mu_{eff} = \mu_B$, then, neglecting the last term in Eq. 48, we have

$$\mu_{eff} = \left[3kT\chi_m^p / \left(N_A \mu_B^2\right)\right]^{1/2} = 2 \cdot 828 \left(\chi_m^p T\right)^{1/2} \qquad ...(54)$$

Notice that μ_{eff} can be found without neglecting $N_A\alpha_m$ if we measure χ_m^p as a function of temperature and use the slope of the resulting curve.

The orbital motions of the electrons are tied to the nuclear configuration of the atom so that they cannot orient themselves with the magnetic field. Therefore, the orbital contribution to magnetic moment given by Eq. 53 is quite small and can be neglected. According to van Vleck, this phenomenon which occurs in the ions of the metals of the First transition metal series, is called the **quenching of orbital angular momentum.** Hence,

$$\chi_m^p = \frac{N_A \mu_0 g_e^2 \mu_B^2 S(S+1)}{3kT} = \frac{6 \cdot 3001 \times S(S+1)}{T} \text{ cm}^3 \text{ mol}^{-1} \qquad ...(55)$$

From the measured value of χ_m^p, we can determine S and hence the number of unpaired electrons present. The American physicist van Vleck (1899-1980) was the cowinner {with his student P.W. Anderson and the British physicist N.F. Mott (1905–1996)} of the 1977 Physics Nobel Prize for their fundamental theoretical investigations of the electronic structure of magnetic and disordered systems.

Example 13. At 25°C, the molar magnetic susceptibility of water is $-13 \cdot 0 \times 10^{-6}$ cm^3 mol^{-1} and its density is 0·9970 g cm^{-3}. Calculate *(a)* the specific magnetic susceptibility and *(b)* the magnetic permeability of water at this temperature.

Solution : *(a)* The specific magnetic susceptibility is defined as $\chi_{sp} = \chi_m/M$.

$$\chi_{sp} = \frac{-13 \cdot 0 \times 10^{-6} \text{ cm}^3 \text{ mol}^{-1}}{18 \cdot 0 \text{ g mol}^{-1}} = -0 \cdot 722 \times 10^{-6} \text{ cm}^3 \text{ g}^{-1}$$

(b) From Eq. 43, $\chi = (\mu - 1)/4\pi\rho$; hence,

$$\mu = 4\pi\rho\chi + 1 = (4\pi)\,(0 \cdot 9970 \text{ g cm}^{-3})\,(-0 \cdot 722 \times 10^{-6} \text{ cm}^3 \text{ g}^{-1}) + 1$$
$$= -9 \cdot 0 \times 10^{-6} + 1 = 0 \cdot 99999$$

Notice that $\mu < 1$, as it should be because water is diamagnetic.

Example 14. The experimental value of molar magnetic susceptibility for benzene is $-54 \cdot 8 \times 10^{-6}$ cm^3 mol^{-1}. Compare it with the calculated value using the data given in Table 6 and comment on your result.

Solution : For benzene, we have

$$6\,C = 6\,(-6 \cdot 0 \times 10^{-6}) = -36 \cdot 0 \times 10^{-6}$$
$$6\,H = 6\,(-2 \cdot 9 \times 10^{-6}) = -17 \cdot 4 \times 10^{-6}$$
$$3\,(C=C) = 3\,(5 \cdot 5 \times 10^{-6}) = 16 \cdot 5 \times 10^{-6}$$
$$1 \text{ benzene ring} = 1\,(-1 \cdot 4 \times 10^{-6}) = -1 \cdot 40 \times 10^{-6}$$
$$\therefore \quad \chi_m = -38 \cdot 3 \times 10^{-6} \text{ cm}^3 \text{ mol}^{-1}$$

The calculated value of χ_m does not agree with the experimental value. The agreement would exist if the C=C contribution were neglected. This shows that there is no true C=C bond in the benzene molecule as is actually the case since the molecule is a resonance hybrid.

Example 15. At 25°C, a coordinate compound (M=200 g mol^{-1}) has density equal to 3·24 g cm^{-3}. If it contains three unpaired electrons, calculate the molar magnetic susceptibility and the magnetic susceptibility.

Solution : $\chi_m^p = \frac{N_A \mu_0 g_e^2 \mu_B^2 S(S+1)}{3kT} = 6 \cdot 3001 \times \frac{S(S+1)}{T}$ (Eq. 55)

For an electron, $g_e = 2$. Since the number of unpaired electrons = 3, the total spin $S = 3/2$

Hence, at 298 K,

$$\chi_m^p = \frac{(6 \cdot 3001)(3/2)(5/2)}{298} \text{ cm}^3 \text{ mol}^{-1} = 7 \cdot 9 \times 10^{-2} \text{ cm}^3 \text{ mol}^{-1}$$

The magnetic susceptibility is defined as

$$\chi = \chi_m^p / V_m = \chi_m^p \rho / M \qquad (\because V_m = M/\rho)$$

Introducing the various values, we have

$$\chi = \frac{(7 \cdot 9 \times 10^{-2} \text{ cm}^3 \text{ mol}^{-1})(3 \cdot 24 \text{ g cm}^{-3})}{200 \text{ g mol}^{-1}} = 1 \cdot 3 \times 10^{-3}$$

Measurement of Magnetic Susceptibility. The magnetic susceptibility of a substance is measured by means of the **Gouy balance** designed by the French physicist L.G. Gouy. The substance is taken in a vertical tube which is suspended vertically by means of a wire from one arm of the balance such that its lower part which contains the substance lies in the middle of the two poles of an electromagnet (Fig. 8).

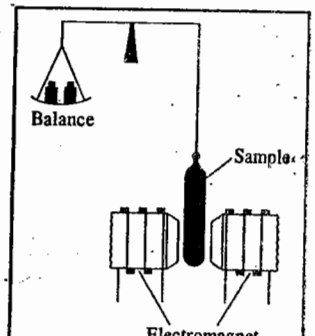

Fig. 8. Gouy's method for measurement of magnetic susceptibilities.

When the electromagnet is turned on, the sample may be attracted towards the magnetic field if it is paramagnetic or repelled by the magnetic field if it is diamagnetic. For a paramagnetic substance, the attraction is due to the alignments of the tiny magnets generated by the magnetic field. These alignments lower the potential energy of the system. For a diamagnetic substance, the potential energy is lower *outside* the magnetic field.

The modern version of the Gouy balance for the determination of magnetic susceptibility makes use of a **superconducting quantum interference device** (SQUID). A SQUID takes advantage of the quantization of magnetic flux and the property of current loops in superconductors that, as part of the circuit, include a weakly conducting link through which electrons must tunnel. The current that flows in the loop in a magnetic field depends on the value of the magnetic flux, and a SQUID can be exploited as a very sensitive magnetometer.

We are interested in calculating the force experienced by the sample as it moves in a non-homogeneous magnetic field whose value is minimum outside and maximum at the centre.

The magnetic moment of the sample within a small segment of the tube of area A and length dy (and hence the volume Ady) is given by

$$\mu_m = \chi (B/\mu_0) Ady \qquad ...(56)$$

where χ is volume magnetic susceptibility which is related to χ_m as $\chi_m = V_m\chi$, B is the strength of the magnetic field and μ_0 is the magnetic permeability of air or vacuum.

This magnetic moment acts in the direction of the magnetic field. If dB is the change in the magnetic induction over the length dy, then change in the potential energy of the sample is given by

$$dV = -\chi(B/\mu_0)(Ady)dB \qquad ...(57)$$

Since the force, dF, experienced by the sample is the negative gradient of this potential, we have

$$dF = -(dV/dy) = \frac{\chi}{\mu_0} ABdB \qquad ...(58)$$

Integration of Eq. 58 gives the total force experienced by the sample as it moves from outside the magnetic field (where the field is equal to zero) to the centre of the field (where its value is maximum).

$$F = \int_0^F dF = \int_{B=0}^{B=B_{max}} \frac{\chi}{\mu_0} ABdB \qquad ...(59)$$

$$= \frac{1}{2}\left(\frac{\chi}{\mu_0}\right) AB_{max}^2 \qquad ...(60)$$

Including the buoyancy correction, Eq. 60 can be written as

$$F = \left(\frac{1}{2}\chi_B - \chi_0\right) A(B_{max}2/\mu_0) \qquad ...(61)$$

where χ_0 is the volume magnetic susceptibility of air. In order to keep the position of the sample unshifted, the force is measured in terms of the masses that are added to or removed from the balance pan. Thus, we have

$$F = (\Delta m)g \qquad ...(62)$$

where Δm is the change in apparent mass and g is the acceleration due to gravity.

Example 16. The Gouy balance results showed that a sample of a complex ion in a tube of $1{\cdot}75\times10^{-5}$ m^2 cross-section that was partly in a magnetic flux density of 0·4 T was pushed into the field by a force equal to $2{\cdot}50\times10^{-4}$ N. Calculate the magnetic susceptibility χ. (Given $\mu_0 = 4\pi\times10^{-7}$ J C^{-2} m^{-1} s^2)

Solution : Since the sample is pushed into the field, it is *paramagnetic*, From Eq. 60,

$$\chi = 2F\mu_0/AB_{max}^2$$

$$= \frac{2(2{\cdot}50\times10^{-4}\text{ N})(4\pi\times10^{-7}\text{ J C}^{-2}\text{ m}^{-1}\text{ s}^2)}{(1{\cdot}75\times10^{-5}\text{ m}^2)(0{\cdot}4\text{ J C}^{-1}\text{ s m}^{-2})^2} = 89{\cdot}76\times10^{-6}$$

Example 17. The Gouy-balance results showed that a sample of water in a tube of 0·1 cm^2 cross-section that was partly in a magnetic flux density of 1 T was pushed out of the field by a force equal to the weight of 36 mg. Calculate the magnetic susceptibility χ and the molar magnetic susceptibility of the sample. ($\mu_0 = 4\pi\times10^{-7}$ J C^{-2} m^{-1} s^2)

Solution : $\chi = -\dfrac{2F\mu_0}{AB_{max}^2}$

$$= -\frac{2(36\times10^{-6}\text{ kg})(9{\cdot}80\text{ N kg}^{-1})(4\pi\times10^{-7}\text{ J C}^{-2}\text{ m}^{-1}\text{ s}^2)}{(0{\cdot}1\times10^{-4}\text{ m}^2)(1\text{ J C}^{-1}\text{ s m}^{-2})} \qquad (\because 1\text{ T} = \text{J C}^{-1}\text{ s m}^{-2})$$

$$= -89\times10^{-6}$$

(We have taken negative sign because the sample is *pushed out* of the field implying that it is diamagnetic.)

$$\therefore \quad \chi_m = \chi V_m = (-89\times10^{-6})\left(\frac{18\text{ g mol}^{-1}}{1{\cdot}00\text{ g cm}^{-3}}\right)$$

$$= -1{\cdot}60\times10^{-3}\text{ cm}^3\text{ mol}^{-1}$$

Ferromagnetism and Antiferromagnetism

Some paramagnetic solids at low temperatures undergo a transition to a state in which large domains of spins are aligned parallel to each other (↑↑↑↑↑↑↑↑). This cooperative alignment gives rise to very strong magnetization. The ferromagnetic transition occurs at the **Curie temperature** (in honour of P. Curie) and results in *ferromagnetism*. On the other hand, in some other solids, the cooperative effect leads to alternating spin orientations (↑↓↑↓↑↓↑↓↑↓), giving rise to low magnetization. The antiferromagnetic transition occurs at the Neel temperature and results in *antiferromagnetism*. P. Curie (1859-1906) shared the 1903 Physics Nobel Prize with his wife M. Curie (1867-1934) and H. Becquerel (1852-1908) for the discovery of spontaneous radioactivity.

I. Review Questions

1. What is meant by polarizability of a molecule ? Derive the Clausius-Mosotti equation.
2. Explain the terms : total molar polarization, induced molar polarization, orientation polarization and distortion polarization.
3. Explain how the dipole moment of a gaseous molecule can be determined the Debye equation.
4. What information regarding the structure of molecules can be obtained from the knowledge of their dipole moments ? What is meant by bond moment and group moment ?
5. Write a short note on diamagnetism, paramagnetism, ferromagnetism and antiferromagnetism.
6. What are the factors which contribute to paramagnetism in a substance ?

II. Problems

1. For $SO_2(g)$ at 0°C and 1 atm pressure, the relative permittivity is 1·00993 and the dipole moment is 1·63 D. Assuming that the gas behaves ideally, calculate *(a)* the total molar polarization *(b)* the induced molar polarization *(c)* the orientation polarization and *(d)* the distortion polarizability.
   [Ans. *(a)* $73{\cdot}95\times10^{-6}$ m^3 mol^{-1} *(b)* $14{\cdot}67\times10^{-6}$ m^3 mol^{-1} *(c)* $59{\cdot}28\times10^{-6}$ m^3 mol^{-1} *(d)* $6{\cdot}456\times10^{-40}$ J^{-1} C^2 m^2]
2. For $NH_3(g)$ at STP the dipole moment is 1·44 D and the distortion polarization is 6·0 cm^3. Calculate the relative permittivity (*i.e.*, dielectric constant) of NH_3, assuming ideality. [Ans. 1·007]
3. The refractive index of a gaseous alkane C_nH_{2n+2} is 1·38 and the density is 0·66 g cm^{-3}. If the atomic refractions of H and C are 1·1 cm^3 mol^{-1} and 2·42 cm^3 mol^{-1}, respectively, what is the molecular formula of the compound ? [Ans. C_5H_{12}]
4. The molar refractions R_m (in cm^3 mol^{-1}) of *n*-butanol, ethanol and methanol are 20·6, 12·3 and 8·3, respectively. Calculate R_m for *n*-butanol. [Ans. 22·1 cm^3 mol^{-1}]
5. The dipole moment of $NH_3(g)$ is 1·46 D. If the angle HNH is 108°, calculate the bond moment of N—H bond. [Ans. 1·458 D]
6. The bond moments of the C—H and C—Cl bonds are 0·4 D and 1·5D, respectively. Calculate the dipole moments of CH_3Cl, CH_2Cl_2 and $CHCl_3$ molecules. [Ans. 1·9D, 1·266 D, 1·902 D, respectively]
7. In a magnetic susceptibility determination experiment carried out on $[CoF_6]^{3-}$ (which contains 4 unpaired electrons). 0·1 M solution of the salt of this ion in a 1-cm diameter test tube was suspended in the Gouy balance. Calculate the change in apparent mass of the salt when the magnetic field strength was 0·5 T. [Ans. $1{\cdot}01\times10^{-5}$ kg]
8. The dipole moment of $NH_3(g)$ is 1·46 D. If the angle HNH is 108°, calculate the bond moment of N—H bond. [Ans. 1·458 D]
9. The temperature-dependence of molar polarization of water vapour is given below :

T(K)	384·3	420·1	444·7	484·1	522·0
P_m (cm^3 mol^{-1})	57·4	53·6	53·5	46·8	43·4

Using the Debye equation, calculate the dipole moment of water molecule. Assuming that the bond angle is 105°, also calculate the OH bond moment. [Ans. 1·85 D, 1·52 D]

CHAPTER 9

THE GASEOUS STATE–I IDEAL GASES

Amongst the three common states of matter, the gaseous state is the simplest. The laws of gaseous behaviour are more uniform and are better understood. The well known laws of gaseous behaviour are Boyle's law, Charles' law, Graham's law, Dalton's law and Avogadro's law. At the time of their enunciation, these laws were only empirical generalisations based on experimental observations. There was no theoretical background to justify them. In the nineteenth century, however, Kronig, Clausius, Maxwell and Boltzmann developed a theory, known as Kinetic Molecular Theory of Gases, which provided sound theoretical basis for the various gas laws. The eighteenth century Swiss mathematician, D. Bernoulli, too, had developed his ideas about the kinetic theory of gases.

Kinetic Molecular Theory of Gases. It is based on the following postulates :

1. A gas consists of a large number of minute particles, called molecules. The molecules are so small that their actual volume is a negligible fraction of the total volume (space) occupied by the gas.

2. The molecules are in a state of constant rapid motion in all possible directions, colliding in a random manner with one another and with the walls of the vessel.

3. The molecular collisions are perfectly elastic so that there is no net loss of energy when gas molecules collide with one another or against the walls of the vessel. The kinetic energy may be transferred from one molecule to another but it is not converted into any other form of energy such as heat.

4. There are no attractive forces between molecules or between molecules and the walls of the vessel in which the gas is contained. The molecules move completely independent of one another.

5. The pressure of a gas is due to the bombardment of the molecules on the walls of the containing vessel.

6. The laws of classical mechanics (in particular the Newton's second law of motion) are applicable to the motion of gaseous molecules.

It may be emphasised that the above postulates are meant for an *ideal gas only*. These are only approximately valid for a real gas.

Pressure of an Ideal Gas. From the above postulates, it is possible, by applying the laws of classical mechanics, to derive an expression for the pressure of a gas.

Let us consider N molecules of a gas, each having a mass m, enclosed in a cubical vessel of volume V, each side of the cube being l. The motion of molecules in the container, at any instant, is totally random.

Consider one molecule of the gas having a velocity c. This velocity can be resolved into three components u, v and w, along the three axes, x, y and z. The velocity components are, evidently, perpendicular to the walls of the container. It can be easily shown that

$$c^2 = u^2 + v^2 + w^2 \qquad ...(1)$$

Consider the motion of one molecule along the x-axis, striking the wall which is perpendicular to its motion. Since the collision is elastic and the wall remains stationary, on rebounding, only the sign of the velocity component changes. The resulting change of momentum in the x-direction (Δp_x) is,

therefore, given by

$$\Delta p_x = m\{u - (-u)\} = 2mu \qquad ...(2)$$

Immediately after the collision, the molecule takes time equal to l/u to collide with the opposite wall (and time equal to $2l/u$ to strike against the same wall again). Hence, the frequency of collisions on the two opposite walls is given by u/l and the change in momentum per unit time is given by

$$\Delta p_x/\Delta t = 2mu \times u/l = 2mu^2/l \qquad ...(3)$$

The total change in momentum of the single molecule per unit time arising from collisions on all the six walls is given by

$$\Delta p/\Delta t = 2mu^2/l + 2mv^2/l + 2mw^2/l = (2m/l)(u^2 + v^2 + w^2) = 2mc^2/l \qquad ...(4)$$

The total change in momentum per unit time for all the N molecules in the container is obtained by summing the contributions of all the molecules. Thus,

$$\frac{\Delta p_{\text{total}}}{\Delta t} = \sum_{i=1}^{N} \frac{2mc_i^2}{l} = \frac{2m}{l} \sum_{i=1}^{N} c_i^2 \qquad ...(5)$$

Defining mean square velocity as

$$\langle c^2 \rangle = \Sigma c_i^2/N \qquad ...(6)$$

we get,

$$\Delta p_{\text{total}}/\Delta t = \frac{2mN}{l} \langle c^2 \rangle \qquad ...(7)$$

According to Newton's second law of motion, the rate of change of momentum ($\Delta p_{\text{total}}/\Delta t$) is force ($f$) and force per unit area is pressure (P). Since the face area (A) of the cubical vessel is $6l^2$ and its volume is V, the pressure exerted by N molecules of the gas on the walls of the vessel is given by

$$P = \frac{f}{A} = \frac{2mN\langle c^2 \rangle}{l(6l^2)} = \frac{1}{3V} mN \langle c^2 \rangle \qquad ...(8)$$

Evidently, $\langle c^2 \rangle^{1/2}$ would be the **root mean square velocity** of the gaseous molecules, given by $(\Sigma c_i^2/N)^{1/2}$.

For the sake of convenience, the root mean square velocity is denoted by c. Therefore, Eq. 8, giving the pressure of the gas, is written as

$$P = (1/3V)mNc^2 \qquad ...(9)$$

Eq. 9 is generally expressed as

$$PV = (1/3)mNc^2 \qquad ...(10)$$

This is known as the **kinetic gas equation.**

Derivation of Gas Laws. All the gas laws can be easily derived from the kinetic gas equation, as shown below.

1. Boyle's Law. We know that molecular velocities increase with rise in temperature. Since kinetic energy varies as square of velocity, it is possible to define temperature in terms of kinetic energy. Thus, according to kinetic theory, the absolute temperature T of a gas is proportional to the mean kinetic energy, $\frac{1}{2}mc^2$, per molecule. It is, thus, evident that, at a constant temperature, the mean kinetic energy per molecule ($\frac{1}{2}mc^2$) of any gas remains constant.

The kinetic gas equation may be written as

$$PV = \tfrac{2}{3} \times \tfrac{1}{2} mNc^2 \qquad ...(11)$$

If a definite mass of a gas is under consideration, then the number of molecules N of the gas must also be constant. It follows, therefore, that for a given mass of a gas, at constant temperature, the quantity on the right hand side of Eq. 11 must remain constant. Hence,

$$PV = \text{constant}$$

Thus, PV is constant at constant temperature. This is **Boyle's law.**

2. Charles' Law. For a definite quantity of a gas (*i.e.*, N = constant), Eq. 11 at constant pressure may be written as

$$V \propto \tfrac{1}{2}mc^2 \qquad \ldots(12)$$

The quantity $\frac{1}{2}mc^2$, being the mean kinetic energy **per molecule**, varies as the temperature T, as discussed above. Hence,

$$V \propto T \quad \text{(at constant pressure)}$$

Thus, at constant pressure, the volume of a given **mass** of a gas varies directly as the absolute temperature. This is **Charles' law.**

3. Avogadro's Law. For any two gases, the kinetic gas **equation** may be written as

$$P_1V_1 = \tfrac{2}{3} \times \tfrac{1}{2} m_1N_1c_1^2 \quad \text{and} \quad P_2V_2 = \tfrac{2}{3} \times \tfrac{1}{2} m_2N_2c_2^2$$

When pressures and volumes of the two gases are the **same**, that is, when $P_1 = P_2$ and $V_1 = V_2$, it follows that

$$(1/2)m_1N_1c_1^2 = (1/2)m_2N_2c_2^2 \qquad \ldots(13)$$

If the two gases are also at the same temperature, **the mean** molecular kinetic energy of each gas is the same, that is,

$$(1/2)m_1c_1^2 = (1/2)m_2c_2^2 \qquad \ldots(14)$$

Dividing Eq. 13 by Eq. 14, we get

$$N_1 = N_2$$

Thus, equal volumes of all gases under the same **conditions** of temperature and pressure contain equal number of molecules. This is **Avogadro's law.**

It follows from Avogadro's law that **molar volume, *i.e.*, the** volume occupied by one mole of each substance in the gaseous state (which is numerically **equal** to 22·414 dm^3 at N.T.P.) would contain the same number of molecules. This number **is called** the **Avogadro's number**, N_A. Its numerical value is $6{\cdot}022 \times 10^{23}$ mol^{-1}. Obviously, the **quantity** n/N_A would give the number of moles, n, of the gaseous substance.

4. Ideal Gas Equation. Combining Boyle's law, **Charles' law** and Avogadro's law, we find that the volume of a gas depends on the pressure, temperature **and number** of moles, as follows :

$V \propto 1/P$ (at constant T and n) (Boyle's law)

$V \propto T$ (at constant P and n) (Charles' law)

$V \propto n$ (at constant T and P) (Avogadro's law)

Thus, V should be proportional to the product of these **three** terms, *i.e.*,

$$V \propto nT/P = R(nT/P)$$

or
$$PV = nRT \qquad \ldots(15)$$

where R, the proportionality constant, is called the **gas constant. Eq.** 15 is called the **ideal gas equation.**

Since one mole of an ideal gas occupies a volume of **22·414** dm^3 at N.T.P., we find from Eq. 15 that the ideal gas constant

$$R = \frac{PV}{nT} = \frac{(1\,\text{atm})(22{\cdot}414\,\text{dm}^3)}{(1\,\text{mol})(273{\cdot}15\,\text{K})} = 0{\cdot}08206\ \text{dm}^3\ \text{atm}\ \text{K}^{-1}\ \text{mol}^{-1}$$

In SI units, 1 atm = $1{\cdot}01325 \times 10^5$ N m^{-2} so that

$$R = \frac{PV}{nT} = \frac{(1{\cdot}03125 \times 10^5\ \text{N m}^{-2})(22{\cdot}414 \times 10^{-3}\ \text{m}^3)}{(1\,\text{mol})(273{\cdot}15\,\text{K})}$$

$$= 8{\cdot}314\ \text{N m K}^{-1}\ \text{mol}^{-1} = 8{\cdot}314\ \text{J K}^{-1}\ \text{mol}^{-1} \qquad (\text{J} = \text{N m})$$

5. Graham's Law of Diffusion. Since

$$PV = \tfrac{1}{3}mNc^2 \qquad \text{(Eq. 10)}$$

$$\therefore \quad c = \sqrt{3PV/mN} = \sqrt{3P/\rho} \qquad \ldots(16)$$

$\{\because mN/V$ = total mass of gas/volume = density of the gas $(\rho)\}$

The rate of diffusion (r) of a gas will, evidently, depend upon the mean velocity of its molecules, that is,

$$r \propto c \propto (3P/\rho)^{1/2} \propto (1/\rho)^{1/2} \quad \text{(at constant pressure)}$$

Thus, *the rate of diffusion of a gas is inversely proportional to the square root of the density of the gas at constant pressure. This is* **Graham's law of diffusion.**

6. Dalton's Law of Partial Pressures. Suppose, N_1 molecules, each of mass m_1, of a gas A, are contained in a vessel of volume V. Then, according to Eq. 9, the pressure p_a of the gas will be given by

$$p_a = m_1N_1c_1^2/3V \qquad \ldots(17)$$

where c_1 is the root mean square velocity of the molecules of the gas A.

Now, suppose, N_2 molecules, each of mass m_2, of another gas B, are contained in the same vessel at the same temperature and there is no other gas present at that time. The pressure p_b of this gas will be given by

$$p_b = m_2N_2c_2^2/3V \qquad \ldots(18)$$

where c_2 is the root mean square velocity of the molecules of the gas B.

If both the gases are present in the same vessel at the same time, the total pressure P will be given by

$$P = m_1N_1c_1^2/3V + m_2N_2c_2^2/3V = p_a + p_b$$

Similarly, if three, four or more gases are present, the total pressure will be given by

$$P = p_a + p_b + p_c + p_d + \cdots\cdots \qquad \ldots(19)$$

This is **Dalton's law** of partial pressures.

Kinetic Energy and Temperature. Suppose one mole of a gas is under consideration. The number of molecules involved will then be N_A (the Avogadro's number). The kinetic gas equation may then be written as

$$PV = \tfrac{1}{3}mN_A c^2 = \tfrac{2}{3} \times \tfrac{1}{2}mN_A c^2 = \tfrac{2}{3} \times E \qquad \ldots(20)$$

where E is the translational kinetic energy of one mole of the gas.

Since for one mole of an ideal gas, $PV = RT$,

$$\therefore \quad E = \tfrac{3}{2}RT \qquad \ldots(21)$$

Thus, *the translational kinetic energy of an ideal (perfect) gas is directly proportional to the absolute temperature.*

Further, since translational kinetic energy $\propto c^2$, it follows that

$$c^2 \propto T \quad \text{or} \quad c \propto \sqrt{T}$$

Thus, the molecular velocity of any gas is proportional to the square root of the absolute temperature. The molecular motion is, therefore, often termed as **thermal motion** of the molecules. At absolute zero (*i.e.*, T=0), kinetic energy is zero. In other words, thermal motion ceases completely at absolute zero.

It readily follows from Eq. 21 that the translational kinetic energy of a gas is independent of the volume (or pressure), the molar mass or the nature of the gas. It depends only on temperature (T). Thus, a hydrogen molecule has the same average translational kinetic energy as a molecule of nitrogen, ammonia or methane. The molecular velocity, of course, would be different in each gas.

The average translational kinetic energy of *one molecule of* an ideal gas will be given by

$$\varepsilon = E/N_A = (3/2)RT/N_A = \tfrac{3}{2}kT$$

where k ($= R/N_A$) is the **Boltzmann constant** whose numerical value = $1{\cdot}38 \times 10^{-23}$ J K^{-1}.

Example 1. Calculate the average translational kinetic energy of an ideal gas per molecule (ε) and per mole (E) at 25°C.

Solution : $\varepsilon = \frac{3}{2} kT = 3/2\ (1{\cdot}38\times10^{-23}\ \text{J K}^{-1})\ (298\ \text{K}) = 6{\cdot}17\times10^{-21}\ \text{J per molecule}$

$E = \frac{3}{2} RT = 3/2\ (8{\cdot}314\ \text{J K}^{-1}\ \text{mol}^{-1})\ (298\ \text{K}) = 3{\cdot}716\times10^{3}\ \text{J mol}^{-1}$

Maxwell Distribution of Molecular Velocities

As a result of random collisions of gaseous molecules, the molecular velocities keep on changing. Consider a gas molecule of mass m having a velocity component u. Then, the kinetic energy, ε, associated with this velocity component is $\frac{1}{2}mu^2$. The probability that this molecule has its velocity component between u and $u+du$ is given by $p(u)$. In the 19th century, Boltzmann had shown that the probability for a molecule to have an energy ε was proportional to $e^{-\varepsilon/kT}$. It is apparent that

$$p(u) \propto e^{-\varepsilon/kT} \propto e^{-mu^2/2kT} \qquad (\because\ \varepsilon = 1/2\ mu^2)$$

or
$$p(u)du = Ae^{-mu^2/2kT}du \qquad ...(22)$$

where A is the constant of proportionality. This constant can be evaluated by requiring that the total probability must be unity. Thus,

$$\int_{-\infty}^{+\infty} p(u)du = A\int_{-\infty}^{+\infty} e^{-mu^2/2kT}\,du = 1 \qquad ...(23)$$

The range of integration of velocity component u is $-\infty$ to $+\infty$ since velocity has both magnitude and direction. The integral in Eq. 23 can be easily evaluated. Setting $m/2kT=a$, it is found from calculus that

$$\int_{-\infty}^{+\infty} e^{-au^2}du = (\pi/a)^{1/2} = \left(\frac{2\pi kT}{m}\right)^{1/2} \qquad ...(24)$$

From Eqs. 23 and 24, $A(2\pi kT/m)^{1/2} = 1$ so that $A = (m/2\pi kT)^{1/2}$ ...(25)

Substituting for A in Eq. 22, we have

$$p(u)du = \left(\frac{m}{2\pi kT}\right)^{1/2} e^{-mu^2/2kT}du \qquad ...(26)$$

Eq. 26 is called the Maxwell distribution of molecular velocities in one dimension. It is easy to derive the Maxwell's distribution of molecular velocities in three dimensions by multiplying the three one-dimension distributions with one another. Thus,

$$p(u,v,w) = p(u)\,p(v)\,p(w) \qquad ...(27)$$

where v and w are the velocity components in the other two dimensions.

$$\therefore \quad p(u,v,w)du\,dv\,dw = p(u)du \times p(v)dv \times p(w)dw$$

$$= \left(\frac{m}{2\pi kT}\right)^{3/2} \exp\left[-\frac{m(u^2+v^2+w^2)}{2kT}\right]du\,dv\,dw \qquad ...(28)$$

We are, however, interested in an expression which gives the *fraction of molecules with a velocity between c and $c+dc$* ($c^2=u^2+v^2+w^2$) regardless of the direction. These are molecules whose velocity points lie within a spherical shell of thickness dc at a distance c. This shell has the volume $4\pi c^2dc$, which is the integral of $dudvdw$ in Eq. 28 over the spherical shell. Hence, we find that

$$p(c)dc = 4\pi\left(\frac{m}{2\pi kT}\right)^{3/2} c^2 \exp(-mc^2/2kT)dc \qquad ...(29)$$

This result was obtained by Maxwell in 1860 and is called the **Maxwell distribution of molecular velocities.** It is customary to write $p(c)dc$ as dN/N, where N is the total number of gas molecules. The quantity dN/N (or $p(c)dc$) gives the fraction of molecules with velocity between c and $c+dc$. The

molecular mass $m = M/N_A$ where M is the molar mass and N_A is the Avogadro's number. Accordingly, Eq. 29 may also be written as

$$p(c)dc = \frac{dN}{N} = 4\pi\left(\frac{M}{2\pi RT}\right)^{3/2} c^2 \exp\left(-\frac{Mc^2}{2RT}\right)dc \qquad ...(30)$$

The Maxwell distribution of molecular velocities is plotted in Fig. 1.

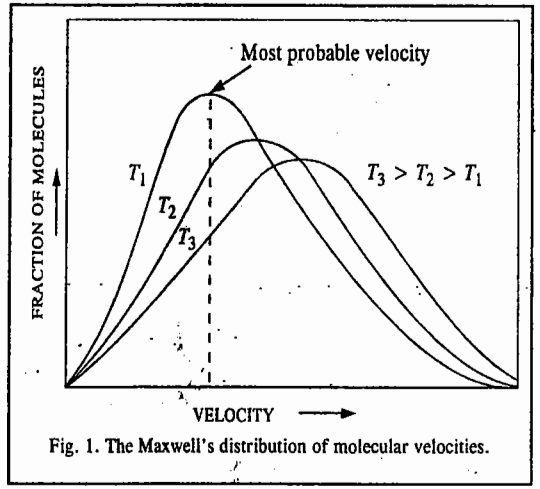

Fig. 1. The Maxwell's distribution of molecular velocities.

We see that the fraction of molecules having velocities greater than zero increases with an increase in velocity, reaches a maximum and then falls off towards zero again at higher velocities.

The important features of the curves are as follows :

1. The fraction of molecules with too low or too high velocities is very small.

2. There is a certain velocity for which the fraction of molecules is maximum. This is called the most probable velocity.

The **most probable velocity** of a gas is the velocity possessed by maximum number of molecules of the gas at a given temperature. It corresponds to the peak of the curve. Its value, at a given temperature, depends upon the volume of the gas.

Effect of Temperature on Distribution of Molecular Velocities. The most probable velocity increases with rise in temperature, as shown in Fig. 1. The entire distribution curve, in fact, shifts to the right with rise in temperature, as shown. The rise in temperature, therefore, increases the fraction of the molecules having high velocities considerably. This can readily be understood from the presence of the factor, $\exp(-mc^2/2kT)$, in Eq. 29. The exponent has a negative sign and the temperature T is in the denominator. The factor, therefore, increases markedly with increases in temperature. This factor is known as the **Boltzmann factor.**

Further, knowing that $\frac{1}{2}mc^2$ is the kinetic energy of one molecule of the gas having velocity c, the factor

$$\exp(-mc^2/2kT) = \exp(-\varepsilon/kT) \qquad ...(31)$$

where ε ($=\frac{1}{2}mc^2$) gives the kinetic energy per molecule of the gas. The greater the temperature, the greater is the value of ε. Hence, there is rapid increase of the Boltzmann factor with increase in temperature. This conclusion finds application in the theory of reaction rates also.

Maxwell Distribution of Molecular Kinetic Energies. With the help of Eq. 29 it is possible to know how the kinetic energies of translation of molecules are distributed amongst the various molecules. The fraction of molecules having kinetic energies in the range of ε and $\varepsilon+d\varepsilon$, *viz.*, dN_ε/N, can be determined as follows :

$$\varepsilon = \tfrac{1}{2}mc^2 \quad \text{or} \quad c^2 = (2\varepsilon/m)$$

$$\therefore \quad 2cdc = (2/m)(d\varepsilon) \quad \text{or} \quad cdc = d\varepsilon/m \qquad ...(32)$$

Thus,
$$c^2dc = c\frac{d\varepsilon}{m} = \left(\frac{2\varepsilon}{m}\right)^{1/2}\left(\frac{d\varepsilon}{m}\right) = \frac{\sqrt{2\varepsilon}}{(m)^{3/2}}d\varepsilon \qquad ...(33)$$

Substituting the above value of c^2dc in Eq. 29, we have

$$p(c)\,dc = \frac{dN_\varepsilon}{N} = 4\pi\left(\frac{m}{2\pi kT}\right)^{3/2}\left(\frac{\sqrt{2\varepsilon}}{m^{3/2}}\right)d\varepsilon \exp\left(-\frac{\varepsilon}{kT}\right) \quad ...(34)$$

$$= \frac{2\sqrt{\varepsilon}}{\sqrt{\pi}\,(kT)^{3/2}} \exp\left(-\frac{\varepsilon}{kT}\right)d\varepsilon \quad ...(35)$$

This is the **Maxwell distribution of molecular kinetic energies.**

Example 2. Calculate the fraction of oxygen molecules at 1 atm and 27°C whose kinetic energies lie in the range of $(\varepsilon - 0{\cdot}005\varepsilon)$ and $(\varepsilon + 0{\cdot}005\varepsilon)$.

Solution : According to the Maxwell's distribution of molecular kinetic energies,

$$\frac{dN_\varepsilon}{N} = \frac{2\sqrt{\varepsilon}}{\sqrt{\pi}\,(kT)^{3/2}} \exp\left(-\frac{\varepsilon}{kT}\right)d\varepsilon \quad \text{(Eq. 35)}$$

At 27°C, kinetic energy of the gas is given by

$$\varepsilon = 3/2\ (1{\cdot}38\times10^{-23}\ \text{J K}^{-1})\ (300\ \text{K}) = 6{\cdot}21\times10^{-21}\ \text{J}$$

$$d\varepsilon = (\varepsilon + 0{\cdot}005\varepsilon) - (\varepsilon - 0{\cdot}005\varepsilon) = 0{\cdot}01\varepsilon = 6{\cdot}21\times10^{-23}\ \text{J}$$

Substituting these values in Maxwell's equation (35), we have

$$\frac{dN_\varepsilon}{N} = \left\{\frac{2(6{\cdot}21\times10^{-21}\,\text{J})^{1/2}}{1{\cdot}77[(1{\cdot}38\times10^{-23}\,\text{JK}^{-1})(300\text{K})]^{3/2}}\right\} \times \left\{\exp\left(-\frac{6{\cdot}21\times10^{-21}\,\text{J}}{1{\cdot}38\times10^{-23}\,\text{JK}^{-1}\times300\,\text{K}}\right)(6{\cdot}21\times10^{-23}\,\text{J})\right\}$$

$$= \frac{2\times0{\cdot}788\times10^{-10}\,\text{J}^{-1}}{1{\cdot}77\times0{\cdot}266\times10^{-30}} \exp(-1{\cdot}5)\times6{\cdot}21\times10^{-23}\,\text{J}$$

$$= 4{\cdot}647\times10^{-3}$$

The Maxwell distribution of kinetic energies at two different temperatures is shown in Fig. 2 in which the factor $(1/N)\ (dN_\varepsilon/d\varepsilon)$ is plotted against ε. As can be seen, the most probable kinetic energy increases with increase in temperature as expected. The maximum in the probability function corresponds to *the most probable kinetic energy.*

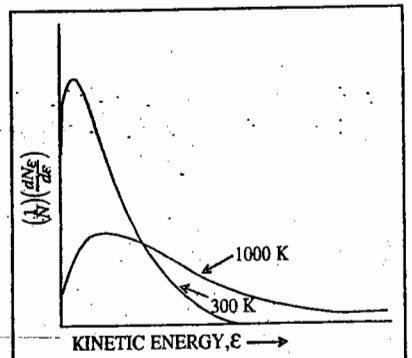

Fig. 2. Maxwell's distribution of kinetic energies at two different temperatures.

It can be easily shown with the help of Eq. 35 that *(i)* the most probable kinetic energy is given by $kT/2$ per molecule or $RT/2$ per mole of the gas and *(ii)* the average kinetic energy per mole is given by $(3/2)N_Akt=(3/2)RT$. This result is, evidently, in agreement with that obtained from the kinetic theory (Eq. 21).

Types of Molecular Velocities. Three types of molecular velocities are reckoned with in the study of gases. These are : *(i)* the most probable velocity, c_p *(ii)* the average velocity, $<c>$ and *(iii)* the root mean square velocity $<c^2>^{1/2}$.

The **most probable velocity** is defined as the velocity possessed by maximum number of molecules of a gas at a given temperature.

The **average velocity** is given by the arithmetic mean of different velocities possessed by the molecules of the gas at a given temperature. If $c_1, c_2, c_3 \ldots\ldots c_n$ are the individual velocities of the gas molecules and n is their total number, then, average velocity is given by

$$\frac{c_1 + c_2 + c_3 + \cdots\cdots c_n}{\quad} \quad (36)$$

If, however, $c_1, c_2, c_3 \ldots\ldots$ are the velocities possessed by *groups* of $n_1, n_2, n_3 \ldots\ldots$ molecules of the gas, respectively, then, average velocity is given by

$$<c> = \frac{n_1c_1 + n_2c_2 + n_3c_3 + \cdots\cdots}{n_1 + n_2 + n_3 + \cdots\cdots} \quad ...(37)$$

The root mean square velocity is defined as the square root of the mean of the squares of different velocities possessed by molecules of a gas at a given temperature. Evidently, the root mean square velocity would be given by

$$<c^2>^{1/2} = \left[\frac{c_1^2 + c_2^2 + c_3^2 + \cdots\cdots c_n^2}{n}\right]^{1/2} \quad ...(38)$$

where $c_1, c_2, c_3 \ldots\ldots c_n$ are the individual velocities of n molecules of the gas. Alternatively,

$$<c^2>^{1/2} = \left[\frac{n_1c_1^2 + n_2c_2^2 + n_3c_3^2 + \cdots\cdots}{n_1 + n_2 + n_3 + \cdots\cdots}\right]^{1/2} \quad ...(39)$$

where $c_1, c_2, c_3, \ldots\ldots$ are velocities possessed by groups of $n_1, n_2, n_3 \ldots\ldots$ molecules, respectively.

With the help of the Maxwell equation (Eq. 29), it is possible to derive mathematical expressions for the three types of velocities, *viz.*, the most probable velocity, c_p ; the average velocity, $<c>$ and the root mean square velocity, $<c^2>^{1/2}$. These expressions are as follows :

$$c_p = (2kT/m)^{1/2} = (2RT/M)^{1/2} \quad ...(40)$$

$$<c> = (8kT/\pi m)^{1/2} = (8RT/\pi M)^{1/2} \quad ...(41)$$

$$<c^2>^{1/2} = (3kT/m)^{1/2} = (3RT/M)^{1/2} \quad ...(42)$$

It is found that

$$<c^2>^{1/2} : <c> : c_p = 1{\cdot}00 : 0{\cdot}92 : 0{\cdot}82$$

Derivation of Expressions for c_p, $<c>$ and $<c^2>^{1/2}$

1. Expression for c_p. Differentiating Eq. 29 with respect to c (using dN/N for $p(c)dc$) and setting the result equal to zero, as required for a maximum, we have

$$\frac{d}{dc}\left(\frac{dN}{N}\right) = \left(\frac{m}{2\pi kT}\right)^{3/2} \exp(-mc^2/2kT)\left[8\pi c + 4\pi c^2\left(-\frac{mc}{kT}\right)\right] = 0 \quad ...(43)$$

The factor $(m/2\pi kT)^{3/2}$ is a constant, different from zero. Also, the factor $\exp(-mc^2/2kT)$ is not equal to zero. Hence, the third factor, *viz.*,

$$8\pi c + 4\pi\varepsilon^2\ (-mc/kT) = 0 \quad ...(44)$$

$$\therefore \quad c \equiv c_p = (2kT/m)^{1/2} = (2RT/M)^{1/2} \quad ...(45)$$

2. Expression for $<c>$. The average velocity is given by the expression

$$<c> = \int_0^\infty cp(c)dc \quad ...(46)$$

Substituting the value of $p(c)dc$ from Eq. 29, we have

$$<c> = 4\pi\left(\frac{m}{2\pi kT}\right)^{3/2}\int_0^\infty c^3 \exp\left(-\frac{mc^2}{2kT}\right)dc \quad ...(47)$$

Let $\quad mc^2/2kT = x^2$ so that $c^2 = 2kTx^2/m$ ...(48)

Differentiating both sides, we have

$$dc = 2kT\,xdx/mc \quad ...(49)$$

Also from Eq. 48, $\quad c = (2kTx^2/m)^{1/2} = (2kT/m)^{1/2}\,x$ ...(50)

Substituting the above value of c in Eq. 49, we have

$$dc = \frac{2kTx\,dx}{m(2kT/m)^{1/2}x} = \left(\frac{2kT}{m}\right)^{1/2} dx \qquad ...(51)$$

From Eq. 50, $\quad c^3 = (2kT/m)^{3/2}x^3 \qquad ...(52)$

Hence, the expression

$$\int_0^\infty c^3 \exp\left(-\frac{mc^2}{2kT}\right) dc = \int_0^\infty \left(\frac{2kT}{m}\right)^{3/2} x^3 e^{-x^2} \left(\frac{2kT}{m}\right)^{1/2} dx \qquad ...(53)$$

$$= \left(\frac{2kT}{m}\right)^2 \int_0^\infty x^3 e^{-x^2} dx = \left(\frac{2kT}{m}\right)^2 \left(\frac{1}{2}\right) \quad \left(\int_0^\infty x^3 e^{-x^2} dx = \frac{1}{2}\right) \qquad ...(54)$$

Thus, from Eqs. 47 and 54,

$$<c> = 4\pi\left(\frac{m}{2\pi kT}\right)^{3/2}\left(\frac{2kT}{m}\right)^2\left(\frac{1}{2}\right) = (8kT/\pi m)^{1/2} = (8RT/\pi M)^{1/2} \qquad ...(55)$$

3. Expression for $<c^2>^{1/2}$. The root mean square velocity is defined as

$$<c^2>^{1/2} = \left\{\int_0^\infty c^2 p(c)dx\right\}^{1/2} \qquad ...(56)$$

From Eq. 29, the expression

$$\int_0^\infty c^2 p(c)dc = 4\pi\left(\frac{m}{2\pi kT}\right)^{3/2} \int_0^\infty c^4 \exp\left(-\frac{mc^2}{2kT}\right) dc \qquad ...(57)$$

Let $\quad mc^2/(2kT) = x^2$ so that $c^4 = \left(\frac{2kT}{m}\right)^2 x^4 \qquad ...(58)$

From Eq. 58, $\quad c = \left(\frac{2kT}{m}\right)^{1/2} x$ so that $dc = \left(\frac{2kT}{m}\right)^{1/2} dx \qquad ...(59)$

From Eqs. 57, 58 and 59, it follows that

$$\int_0^\infty c^2 p(c)dc = 4\pi\left(\frac{m}{2\pi kT}\right)^{3/2}\left(\frac{2kT}{m}\right)^2\left(\frac{2kT}{m}\right)^{1/2}\int_0^\infty x^4 e^{-x^2} dx \qquad ...(60)$$

From the tables of definite integrals, we know that

$$\int_0^\infty x^4 e^{-x^2} dx = (3/8)\pi^{1/2} \qquad ...(61)$$

From the above equations, we have

$$\left\{\int_0^\infty c^2 p(c)dc\right\}^{1/2} = <c^2>^{1/2} = \left(\frac{3kT}{m}\right)^{1/2}$$

$$= \left(\frac{3RT}{M}\right)^{1/2} \qquad ...(62)$$

The molecular distribution of the three types of velocities is shown in Fig. 3

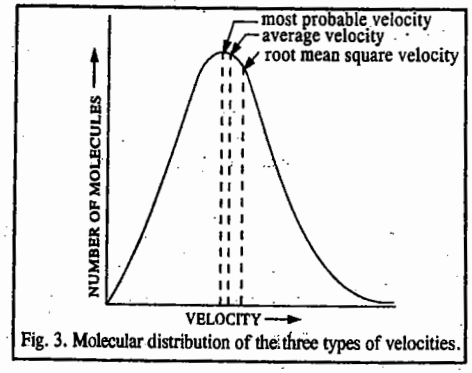

Fig. 3. Molecular distribution of the three types of velocities.

Example 3. For hydrogen gas, calculate *(a)* the root mean square velocity $<c^2>^{1/2}$ *(b)* the average velocity $<c>$ and *(c)* the most probable velocity c_p, at 0°C.

Solution : The molar mass M of H_2 = 2·016 g mol^{-1} = 2·016×10^{-3} kg mol^{-1}

(a) From Eq. 42,

$$<c^2>^{1/2} = \left(\frac{3RT}{M}\right)^{1/2} = \left(\frac{(3)(8\cdot314\ \text{J K}^{-1}\ \text{mol}^{-1})(273\cdot15\ \text{K})}{2\cdot016\times10^{-3}\ \text{kg mol}^{-1}}\right)^{1/2}$$

Recalling that J = kg m^2 s^{-2}, we find that $<c>^{1/2}$ = **1·84×10^3 m s^{-1}**

(b) From Eq. 41, $<c> = \left(\frac{8RT}{\pi M}\right)^{1/2} = \left(\frac{(8)(8\cdot314\ \text{J K}^{-1}\ \text{mol}^{-1})(273\cdot15\ \text{K})}{(3\cdot1416)(2\cdot016\times10^{-3}\ \text{kg mol}^{-1})}\right)^{1/2}$

= **1·69×10^3 m s^{-1}**

(c) From Eq. 40, $c_p = \left(\frac{2RT}{M}\right)^{1/2} = \left(\frac{(2)(8\cdot314\ \text{J K}^{-1}\ \text{mol}^{-1})(273\cdot15\ \text{K})}{2\cdot016\times10^{-3}\ \text{kg mol}^{-1}}\right)^{1/2}$

= **1·50×10^3 m s^{-1}**

The average velocities of some common gaseous molecules are given in Table 1.

TABLE 1

Average Velocities (m s^{-1}) of Some Common Gaseous Molecules at 0°C

Gas	$<c>$	Gas	$<c>$	Gas	$<c>$
Hydrogen	1692·0	Oxygen	425·2	Methane	600·6
Deuterium	1196·0	Chlorine	285·6	Ammonia	582·7
Helium	1204·0	Mercury vapour	170·0	Carbon dioxide	362·5
Nitrogen	454·2	Argon	380·8	Carbon monoxide	454·5

Example 4. Calculate the temperatures at which the root mean square velocity, the average velocity and the most probable velocity of oxygen gas are all equal to 1,500 m s^{-1}.

Solution : Let the respective temperatures be T_1, T_2 and T_3.

$$<c^2>^{1/2} = (3RT_1/M)^{1/2} = 1\cdot5\times10^3\ \text{m s}^{-1}$$

$$\therefore \quad T_1 = \frac{(1\cdot5\times10^3\ \text{m s}^{-1})^2(32\times10^3\ \text{kg mol}^{-1})}{3\times8\cdot314\ \text{J K}^{-1}\ \text{mol}^{-1}} = 2886\ \text{K} \qquad [M = 32\ \text{g mol}^{-1}]$$

$$<c> = (8RT_2/\pi M)^{1/2} = 1\cdot5\times10^3\ \text{m s}^{-1}$$

$$\therefore \quad T_2 = \frac{(1\cdot5\times10^{-3}\ \text{m s}^{-1})^2(32\times10^{-3}\ \text{kg mol}^{-1})(3\cdot1416)}{8\times8\cdot314\ \text{J K}^{-1}\ \text{mol}^{-1}} = 3399\ \text{K}$$

(iii) $\quad c_p = (2RT_3/M)^{1/2} = 1\cdot5\times10^3\ \text{m s}^{-1}$

$$\therefore \quad T_3 = \frac{(1\cdot5\times10^3\ \text{m s}^{-1})^2(32\times10^{-3}\ \text{kg mol}^{-1})}{2\times8\cdot314\ \text{J K}^{-1}\ \text{mol}^{-1}} = 4330\ \text{K}$$

Example 5. Calculate the temperature at which the average velocity of oxygen equals that of hydrogen at 20 K

Solution : $\quad <c> = (8RT/\pi M)^{1/2}$, *i.e.*, $<c> \propto (T/M)^{1/2}$

Let $<c>_1$ and $<c>_2$ be the average velocities of O_2 and H_2, respectively.

$$\frac{<c>_1}{<c>_2} = \left(\frac{T_1/M_1}{T_2/M_2}\right)^{1/2} = 1 \quad \text{so that} \quad T_1/M_1 = T_2/M_2$$

or $\quad T_1/32\ \text{g mol}^{-1} = T_2/2\ \text{g mol}^{-1}$

$$\therefore \quad T_1 = (32/2)T_2 = 16\times20\ \text{K} = 320\ \text{K}$$

Example 6. Calculate the root mean square velocity of nitrogen at 27°C and 70 cm pressure. Density of Hg=13·6 g cm^{-3}.

Solution : Volume V_2 at 27°C and 70 cm pressure is given by the relation $P_2V_2/T_2 = P_1V_1/T_1$:

$$\frac{70\text{ cm} \times V_2}{300\text{ K}} = \frac{76\text{ cm} \times 0{\cdot}0224\text{ m}^3\text{ mol}^{-1}}{273\text{ K}}$$

$$\therefore \quad V_2 = 0{\cdot}026725\text{ m}^3\text{ mol}^{-1}$$

Pressure, $P = (70/76) \times 101{,}325\text{ N m}^{-2}$

$$< c^2 >^{1/2} = \left(\frac{3RT}{M}\right)^{1/2} = \left(\frac{3PV}{M}\right)^{1/2} \qquad \text{(Eq. 42)}$$

$$= \left(\frac{(3)\,(70/76) \times 101{,}325\text{ N m}^{-2})\,(0{\cdot}026725\text{ m}^3\text{ mol}^{-1})}{28 \times 10^{-3}\text{ kg mol}^{-1}}\right)^{1/2}$$

$$= \mathbf{517\text{ m s}^{-1}}$$

(Newton, N = kg m s^{-2})

Expansivity and Compressibility. Gases expand on heating and are compressed on applying pressure. The variation of volume V with temperature T, keeping pressure P constant, is called the **coefficient of thermal expansion** or simply **expansivity**, α, of the gas. Thus,

$$\alpha = \frac{1}{V}\left(\frac{\partial V}{\partial T}\right)_P \qquad \ldots(63)$$

The variation of V with P, keeping T constant, is called the **coefficient of isothermal compressibility** or simply **compressibility**, β, of the gas. Thus,

$$\beta = -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_T \qquad \ldots(64)$$

The volume of a gas decreases as pressure increases so that the quantity $(\partial V/\partial P)_T$ is negative. Hence, a minus sign is included in the definition so as to make β positive. Note that α has the dimensions of T^{-1} and β those of P^{-1}.

Example 7. Show that for an ideal gas, $\alpha = 1/T$ and $\beta = 1/P$.

Solution : For n moles of an ideal gas, $PV = nRT$

or $$V = nRT/P \qquad \ldots(i)$$

Differentiating Eq. *(i)* with respect to T at constant P, we have

$$(\partial V/\partial P)_P = -nR/P = V/T$$

$$\therefore \quad \alpha = 1/V\,(\partial V/\partial T)_P = (1/V)(V/T) = 1/T$$

Again, differentiating Eq. *(i)* with respect to P at constant T, we have

$$(\partial V/\partial P)_T = -nRT/P^2 = (nRT/P)\,(-1/P) = -(V/P)$$

$$\therefore \quad \beta = -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_T = \left(-\frac{1}{V}\right)\left(-\frac{V}{P}\right) = \frac{1}{P}$$

Thus, $$\alpha = 1/T \quad \text{and} \quad \beta = 1/P$$

Example 8. Writing $V = f(P, T, n)$, taking its differential and using Boyle's law, Charles' law and other relations, derive the ideal gas equation.

Solution : $$V = f(P, T, n) \qquad \ldots(i)$$

i.e., volume of a gas is a function of its pressure, temperature and number of moles. As we shall see in thermodynamics, the volume is a state function so that its total differential can be written as

$$dV = (\partial V/\partial P)_{T,n}\,dP + (\partial V/\partial T)_{P,n}\,dT + (\partial V/\partial n)_{T,P}\,dn \qquad \ldots(ii)$$

From Boyle's law, at constant T and n,

$$PV = K \text{ so that } V = K/P$$

Differentiating with respect to P, at constant T and n, we have

$$(\partial V/\partial P)_{T,n} = -K/P^2 = -PV/P^2 = -V/P \qquad \ldots(iii)$$

Similarly, from Charles' law, at constant P and n, $V = KT$ so that

$$(\partial V/\partial T)_{P,n} = K' = V/T \qquad \ldots(iv)$$

Again, since at constant P and T, $V \propto n$, we can write

$$V = K''n$$

$$\therefore \quad (\partial V/\partial n)_{P,T} = K'' = V/n \qquad \ldots(v)$$

Substituting Eqs. *(iii)*, *(iv)* and *(v)* in Eq. *(ii)*, we have

$$dV = -V\,dP/P + V\,dT/T + V\,dn/n$$

or $$dV/V = -dP/P + dT/T + dn/n \qquad \ldots(vi)$$

Integrating, we get $\int \frac{dV}{V} = -\int \frac{dP}{P} + \int \frac{dT}{T} + \int \frac{dn}{n}$

Setting the constant of integration $= \ln R$, where R is the gas constant, we have

$$\ln V = -\ln P + \ln T + \ln n + \ln R$$

$$\ln V + \ln P = \ln n + \ln R + \ln T$$

$$\ln (PV) = \ln (nRT)$$

or $$PV = nRT \text{ which is the ideal gas equation.}$$

Collision Parameters

Collision Diameter. The kinetic theory of gases treats molecules as point masses. When two such molecules approach each other, a point is reached at which the mutual repulsion between the molecules (resulting from electronic and nuclear replusions) becomes so strong that it causes reversal of the direction of their motion. *The distance between the centres of the two molecules at the point of their closest approach is known as* **collision diameter.** It is denoted by d, as shown in Fig. 4. Evidently, a gaseous molecule can be regarded as a rigid (or hard) sphere of radius d. The volume $(4/3)\pi d^3$ is known as the effective volume of the molecule.

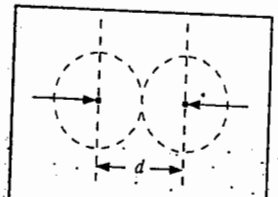

Fig. 4. Collision of two molecules. Concept of collision diameter.

It can be easily seen that if the distance between the centres of two molecules is less than d, there would be a collision between them. Thus, collision is an event in which the centres of two identical molecules come within a distance d from each other.

Collision Cross-section. The model of gaseous molecules as hard, non-interacting spheres of diameter d can satisfactorily account for various gaseous properties such as the transport properties (viscosity, diffusion and thermal conductivity), the mean free path and the number of collisions the molecules undergo. It can be easily visualised that when two molecules collide, the effective area of the target is πd^2. The quantity πd^2 is called the **collision cross-section** σ of the molecule because it is the cross-sectional area of an imaginary sphere surrounding the molecule into which the centre of another molecule cannot penetrate.

Collision Number. It can be shown on kinetic considerations that in a gas, the number of molecules with which a *single molecule* will collide per unit time is given by $\sqrt{2}\pi d^2 < c > \rho$ where $< c >$ is the average velocity of the molecules and ρ is the number density, *i.e.*, the number of molecules per unit volume of the gas. This expression, evidently, gives the number of collisions suffered by a single molecule per unit time per unit volume of the gas. This is known as the **collision number**. Thus,

$$Z_1 = \sqrt{2}\,\pi d^2 < c > \rho \qquad \ldots(65)$$

The total number of molecules colliding per unit time per unit volume of the gas is, therefore, given by $\sqrt{2}\pi d^2 < c > \rho^2$. Since each collision involves two molecules, the number of collisions of

like molecules occurring per unit time per unit volume of the gas is given by

$$Z_{11} = \tfrac{1}{2}(\sqrt{2}\,\pi d^2 < c > \rho^2) = \frac{1}{\sqrt{2}}(\pi d^2 < c > \rho^2) \qquad ...(66)$$

Collision Frequency. The number Z_{11} in Eq. 66 gives the collision frequency of the gas. Thus, **collision frequency** is the number of molecular collisions occurring per unit time per unit volume of the gas.

It readily follows that the number of collisions of molecules of type 1 with those of type 2, would be given by

$$Z_{12} = \frac{1}{\sqrt{2}}(\pi d_{av}^2 < c > \rho_1\rho_2) \quad (d_{av} = (d_1+d_2)/2) \qquad ...(67)$$

where ρ_1 and ρ_2 are the *number densities* of molecules of type 1 and 2, respectively. The number density ρ is equal to P/kT, as shown below :

For an ideal gas, $PV = nRT = nN_Ak$

$$\therefore \qquad P = nN_Ak T/V = NkT/V \qquad ...(68)$$

where $N(=nN_A)$ is the total number of molecules in n moles of the gas. Since ρ is the number of molecules per unit volume, hence $\rho = N/V$. Thus, $P = \rho kT$.

$$\therefore \qquad \rho = P/kT \qquad ...(69)$$

Eqs. 65 and 66 may thus be written as

$$Z_1 = \sqrt{2}\pi d^2 < c > P/kT \qquad ...(70)$$

and

$$Z_{11} = \frac{\pi d^2 < c > P^2}{\sqrt{2}(kT)^2} \qquad ...(71)$$

It may be noted that while units of Z_1 are s^{-1}, those of Z_{11} are $s^{-1}\ m^{-3}$.

Mean Free Path. A very important quantity in kinetic theory of gases is the **mean free path**, λ, defined as the mean distance travelled by a gas molecule between two successive collisions. Evidently,

$$\lambda = \frac{<c>}{Z_1} = \frac{<c>}{\sqrt{2}\pi d^2 <c> P/kT} = \frac{kT}{\sqrt{2}\pi d^2 P} \qquad ...(72)$$

From Eq. 72, we see that $\lambda \propto 1/P$, *i.e., the mean free path of a gas molecule is inversely proportional to pressure.* This fact is of tremendous importance in vacuum systems. It should be borne in mind that at 1 atm pressure, λ is very small compared with the macroscopic dimensions (such as 1 cm) of the container which implies that the molecules collide with one another far more frequently than they collide with the walls of the container and that a molecule moves a distance of several molecular diameters before colliding with another molecule.

In a good vacuum where the pressure is of the order of 10^{-3} atm, a simple calculation shows that λ is very large compared with the dimensions of the container. Thus, in a good vacuum the gas molecules collide far more frequently with the walls of the container than with one another. Under such conditions, the gas is called a **Knudsen gas.**

Example 9. For oxygen gas at 25°C, calculate *(a)* the mean free path at 1 atm pressure *(b)* the mean free path at 10^{-3} mm Hg pressure *(c)* the number of collisions per second per molecule *(d)* the number of collisions per cubic metre per second and *(e)* the number of moles of collisions per dm^3 per second. In parts *(c)*, *(d)* and *(e)*, the pressure is 1 atm. The collision diameter of oxygen molecule is 361 picometre.

Solution : *(a)* 1 atm $= 1{\cdot}01325\times10^5\ N\ m^{-2}$ $\qquad T = 25°C = 298\ K$

$$d = 361\ pm = 361\times10^{-12}\ m = 3{\cdot}61\times10^{-10}\ m$$

From Eq. 72, $$\lambda = \frac{kT}{\sqrt{2}\pi d^2 P} = \frac{(1{\cdot}38\times10^{-23}\,J\,K^{-1})(298\,K)}{(1{\cdot}4142)(3{\cdot}1416)(3{\cdot}61\times10^{-10}\,m)^2(1{\cdot}01325\times10^5\,N\,m^{-2})}$$

$$= 7{\cdot}02\times10^{-8}\ m = 70{\cdot}2\ nm \qquad [J = kg\ m^2\ s^{-2} = N\ m]$$

(b) $$P = 10^{-3}\ mm\ Hg = \frac{(10^{-3}\,mm\,Hg)(1{\cdot}01325\times10^5\,N\,m^{-2}\,atm^{-1})}{760\,mm\,Hg\,atm^{-1}} = 0{\cdot}1333\ N\ m^{-2}$$

$$\therefore \qquad \lambda = \frac{(1{\cdot}38\times10^{-23}\,J\,K^{-1})(298\,K)}{(1{\cdot}4142)(3{\cdot}1416)(3{\cdot}61\times10^{-10}\,m)^2(0{\cdot}1333\,N\,m^{-2})} = 5{\cdot}3\times10^{-2}\ m$$

(c) From Eq. 41, $$<c> = \left(\frac{8RT}{\pi M}\right)^{1/2} = \left[\frac{(8)(8{\cdot}314\,J\,K^{-1}\,mol^{-1})(298\,K)}{(3{\cdot}1416)(32\times10^{-3}\,kg\,mol^{-1})}\right]^{1/2} = 444{\cdot}0\ m\ s^{-1}$$

From Eq. 70, $$Z_1 = \sqrt{2}\pi d^2 <c> P/kT$$

$$= \frac{(1{\cdot}4142)(3{\cdot}1416)(3{\cdot}61\times10^{-10}\,m)^2(444{\cdot}0\,m\,s^{-1})(1{\cdot}01325\times10^5\,N\,m^{-2})}{(1{\cdot}38\times10^{-23}\,J\,K^{-1})(298\,K)}$$

$$= 6{\cdot}32\times10^9\ s^{-1}$$

(d) From Eq. 71, $$Z_{11} = \frac{\pi d^2 <c> P^2}{\sqrt{2}\,(kT)^2} \qquad [\because \rho = P/kT]$$

$$= \frac{(3{\cdot}1416)(3{\cdot}61\times10^{-10}\,m)^2(444{\cdot}0\,m\,s^{-1})(1{\cdot}01325\times10^5\,N\,m^{-2})^2}{(1{\cdot}4142)(1{\cdot}38\times10^{-23}\,J\,K^{-1})^2(298\,K)^2}$$

$$= 7{\cdot}77\times10^{34}\ m^{-3}\ s^{-1}$$

(e) $N_A = 6{\cdot}022\times10^{23}\ mol^{-1}$ and $1\ dm^3 = 10^{-3}\ m^3$

$$\therefore \qquad Z_{11} = \frac{(7{\cdot}77\times10^{34}\,m^{-3}\,s^{-1})(10^{-3}\,m^3\,dm^{-3})}{6{\cdot}022\times10^{23}\,mol^{-1}} = 1{\cdot}29\times10^8\ mol\ dm^{-3}\ s^{-1}$$

Some properties of gas molecules derived from the kinetic theory of gases are given in Table 2.

TABLE 2

Gas Properties at 25°C and 1 atm Pressure

Gas	Collision Diameter d (m)	Mean Free Path λ (m)	Collision Frequency Z_1 (s^{-1})	Collision Frequency Z_{11} ($m^{-3}\ s^{-1}$)
He	$2{\cdot}18\times10^{-10}$	$19{\cdot}0\times10^{-8}$	$6{\cdot}6\times10^9$	$8{\cdot}1\times10^{34}$

N_2	3·74	6·5	7·3	9·0
O_2	3·57	7·1	6·1	7·5
CO_2	4·56	4·4	8·6	10·6

TRANSPORT PROPERTIES

There is a particularly simple group of processes, called the **transport processes**, in which some physical quantity such as mass or energy or momentum or electrical charge is transported from one region of a system to another. Consider a metal bar connecting two heat reservoirs at different temperatures. Heat flows through the bar from the high-temperature reservoir to the low-temperature reservoir; the heat flow is the manifestation of the transport of energy through the bar. The energy flow is easily measurable. Another example is the transport of electrical charge through a conductor by the application of an electrical potential difference between the ends of the conductor. Mass is transported in the flow of a fluid through a pipe as a result of the pressure difference between the ends of the pipe. Diffusion is the mass transport that occurs in a mixture if a concentration gradient is present. The viscosity of a fluid, its resistance to flow, is determined by the transport of momentum in a direction perpendicular to the direction of the flow.

In all cases, the **flow**, *viz.*, the amount of physical **quantity** transported in unit time through a unit area perpendicular to the direction of flow, is *proportional to the negative gradient* of some other physical property such as temperature, pressure or electrical potential. Choosing the z-axis as the direction of flow, the general flow or transport is given by

$$J_z = L\left(-\frac{\partial Y}{\partial z}\right) \qquad ...(73)$$

where J_z is the flow (also called **flux**), *i.e.*, the amount of quantity transported per square meter per second, L is the proportionality constant (called the **phenomenological coefficient**) and $(-\partial Y/\partial z)$ is the negative gradient of Y in the direction of flow (also called the **generalized force**). Y may be any of the quantities such as temperature, electrical potential, pressure and so on. Since flow occurs in a particular direction, it is a vector quantity; Eq. 73 describes the z-component of the vector. For the cases mentioned above, we have the following equations for flow in the z-direction :

Heat flow	$J_z = -\kappa_T \frac{\partial T}{\partial z}$	(Fourier's law)	...(74)
Electrical current	$J_z = -\kappa \frac{\partial \phi}{\partial z}$	(Ohm's law) (ϕ is potential difference)	...(75)
Fluid flow	$J_z = -f \frac{\partial P}{\partial z}$	(Poiseuille's law)	...(76)
Diffusion	$J_z = -D \frac{\partial \rho}{\partial z}$	(Fick's law)	...(77)

In the above equations, κ_T is the thermal conductivity coefficient, κ is the electrical conductivity, f is a frictional coefficient related to viscosity, D is the diffusion coefficient and ρ is the *number density, i.e.*, the number of molecules per m^3.

Consider the flow of heat from one end of a metal bar to the other. If the hot end is at $z=0$ and the cold end at Z, then in the steady state, the temperature as a function of z appears as shown in Fig. 5. The value of $\partial T/\partial z$ is negative so that $(-\partial T/\partial z)$ is positive. The heat flow is in the positive direction (from the hot to the cold end).

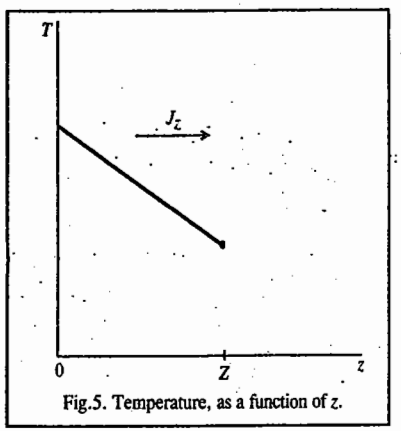

Fig.5. Temperature, as a function of z.

If we define $(X_T)_z = -\partial T/\partial z$ ...(78)

as the 'generalized force' that is driving the heat flow, we can write Eq. 74 as

$$J_z = \kappa_T (X_T)_z \text{ (Fourier's law)} \qquad ...(79)$$

and can say that the flow has the same sign as the force. Thus, any of the transport laws, given by Eqs. 74, 75, 76 and 77 can be written in the form

$$J = LX \qquad ...(80)$$

Eq. 80 shows that the flux of any quantity is proportional to the force that drives the flux. This proportionality between the flux (the flow) and the force is called a linear law. The force is always the *negative gradient* of an intensive quantity. Fundamental contributions to these laws, which have been experimentally verified though they were initially proposed as empirical laws, have been made by L. Onsager.

It can be shown that for any transport

$$j = \rho \bar{c} q \qquad ...(81)$$

where j is the rate of flow, ρ is the number density, $\bar{c}$ is the mean speed of the molecules of the

physical quantity and q is the amount of the physical quantity possessed by each carrier. Eq. 81 is the **general equation for transport phenomena.**

We shall now discuss the three important transport phenomena, *viz.*, thermal conductivity, viscosity and diffusion in gases.

1. Thermal Conductivity of a Gas. Consider a vessel containing a gas. Let us consider two large metal plates parallel to the xy-plane and separated by a distance Z, at temperatures T_1 and T_2, the hotter plate (T_2) being the upper one. After some time a steady state will be established in which there is a downward flow of heat at constant rate. This flow of heat results from the fact that the molecules at the upper levels have a greater thermal energy than those at the lower levels; the molecules moving downwards carry more energy than those moving upwards.

In order to calculate the energy flow in unit time through 1 m^2 parallel to the xy-plane, we imagine a large number of horizontal layers in the gas, each successive layer at a slightly higher temperature than the one below it. The change in temperature with height is given by

$$\frac{\partial T}{\partial z} = \frac{\Delta T}{\Delta z} = \frac{T_2 - T_1}{Z - 0} \qquad ...(82)$$

if the lower plate lies at the position $z = 0$ and the upper one at $z = Z$. The temperature gradient, $\partial T/\partial z$, is constant so that at any height z the temperature is given by

$$T = T_1 + \left(\frac{\partial T}{\partial z}\right) z \qquad ...(83)$$

If the gas is monoatomic with an average thermal energy $\bar{\varepsilon} = 3/2\ kT$, then the average energy of the molecules at the height z is given by

$$\bar{\varepsilon} = \frac{3}{2}kT = \frac{3}{2}k\left[T_1 + \left(\frac{\partial T}{\partial z}\right)z\right] \qquad ...(84)$$

To calculate the heat flow, we consider an area 1 m^2 in a horizontal plane at the height z (Fig. 6).

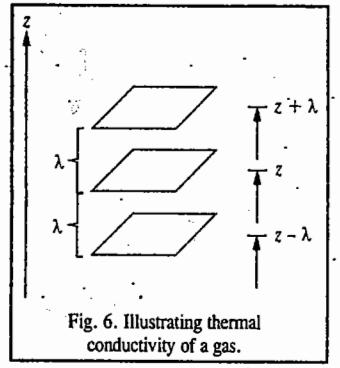

Fig. 6. Illustrating thermal conductivity of a gas.

The energy carried by a molecule as it passes through the plane depends on the temperature of the layer of gas at which the molecule had its last opportunity to adjust its energy. This last adjustment occurred during the last collision with another molecule. Suppose that, on an average, the molecules have travelled a distance λ (the mean free path) since their last collision. If the surface of interest lies at a height z, the molecules going down made their last collision at a height $z+\lambda$, while those going up made their last collision at a height $z - \lambda$ (Fig. 6). The molecules carry an amount of energy appropriate to the height where the last collision occurred. The downward flow of energy is given by Eqs. 81 and 84, as

$$\varepsilon\downarrow = \frac{1}{6}\rho(\bar{c})_{z+\lambda}\frac{3}{2}k\left[T_1 + \left(\frac{\partial T}{\partial z}\right)(z+\lambda)\right] \qquad ...(85)$$

while the upward flow is given by

$$\varepsilon\uparrow = \frac{1}{6}\rho(\bar{c})_{z-\lambda}\frac{3}{2}k\left[T_1 + \left(\frac{\partial T}{\partial z}\right)(z-\lambda)\right] \qquad ...(86)$$

The factor 1/6 appears since, on an average, only 1/6 of the molecules are going down and only 1/6 going up. The net flow upward is denoted by J_ε and is given by

$$J_\varepsilon = \varepsilon\uparrow - \varepsilon\downarrow \qquad ...(87)$$

Now if the gas is not to have net motion through the surface we require that the number of molecules

going up in unit time must equal the number going down, so that

$$\frac{1}{6}\rho(\bar{c})_{z+\lambda} = \frac{1}{6}\rho(\bar{c})_{z-\lambda} \qquad ...(88)$$

which means that $\rho\bar{c}$ has the same value at every height. Substituting for $\varepsilon\downarrow$ and $\varepsilon\uparrow$ from Eqs. 85 and 86 into Eq. 87 and using Eq. 88, we obtain

$$J_\varepsilon = \frac{1}{6}\rho\bar{c}\frac{3}{2}k\left(\frac{\partial T}{\partial z}\right)[(z-\lambda)-(z+\lambda)] = -\frac{1}{2}\rho\bar{c}k\lambda\left(\frac{\partial T}{\partial z}\right) \qquad ...(89)$$

Comparing this equation with the empirical Fourier's law (Eq. 74), we find that

$$\kappa_T = \frac{1}{2}\rho\bar{c}k\lambda$$

$$= \frac{1}{3}\left(\frac{\rho}{N_A}\right)C_{v,m}\bar{c}\lambda \qquad ...(90)$$

since the molar heat capacity $C_{v,m}=(3/2)R=(3/2)kN_A$ or $k=2C_{v,m}/3N_A$. The factor (ρ/N_A) is the concentration in mol m^{-3}. From the kinetic theory of gases, we know that $\bar{c} = (8kT/\pi m)^{1/2}$. The mean free path, λ, is given by

$$\lambda = \frac{1}{\sqrt{2}\sigma\rho} \qquad ...(91)$$

where σ is the collision cross-section ($\sigma=\pi d^2$, where d is the collision diameter of the gaseous molecules, assumed as hard spheres). Hence, from Eqs. 90 and 91, the thermal conductivity of a gas is given by

$$\kappa_T = \frac{\bar{c}C_{v,m}}{3\sqrt{2}\sigma N_A} \qquad ...(92)$$

We see from Eq. 92 that the thermal conductivity is *independent of pressure*. This has been confirmed experimentally. Again, if $C_{v,m}$ is independent of temperature, then everything on the right of Eq. 92 is constant except $\bar{c}$, which is proportional to $T^{1/2}$. Therefore, κ_T should increase as $T^{1/2}$. This, too, has been confirmed experimentally.

Note that Eq. 90 can also be rewritten as

$$\kappa_T = \left(\frac{1}{3}\right)\lambda\bar{c}C_{v,m}[A] \qquad ...(93)$$

because $\rho = N/V$ so that $\rho/N_A = n/V$ where the number of moles $n = N/N_A$ and n/V can be considered as the molar concentration [A] of the gas A.

Example 10. Calculate the thermal conductivity of air at room temperature. Assume that the molar mass of air is 29 g mol^{-1} and the collision cross-section of $O_2(g)$ and $N_2(g)$, which air consists of, is 0·42 nm^2. Since air is a mixture of diatomic gases, its constant volume molar heat capacity is (5/2)R.

Solution : $\kappa_T = (1/3)\lambda\bar{c}C_{v,m}[A]$ [Eq. 93]

It can be easily shown that $[A]=P/RT$. Also, $\lambda = kT/\sqrt{2}\,\sigma P$; $\bar{c} = (8kT/\pi m)^{1/2} = (8RT/\pi M)^{1/2}$, $C_{v,m}=(5/2)R$. Substituting these expressions, we have

$$\kappa_T = \frac{1}{3}\times\frac{kT}{\sqrt{2}\sigma P}\times\left(\frac{8RT}{\pi M}\right)^{1/2}\times\frac{5}{2}R\times\frac{P}{RT} = \frac{5}{3\sqrt{\pi}\sigma}\frac{k}{}\left(\frac{RT}{M}\right)^{1/2}$$

Substituting the given data, we get

$$\kappa_T = \frac{5}{3\sqrt{\pi}}\times\frac{1{\cdot}38\times10^{-23}\,JK^{-1}}{0{\cdot}42\times10^{-18}\,m^2}\times\left(\frac{(8{\cdot}314\,JK^{-1}mol^{-1})(298\,K)}{29\times10^{-3}\,kg\,mol^{-1}}\right)^{1/2}$$

$$= 9{\cdot}0\times10^{-3}\ J\ K^{-1}\ m^{-1}\ s^{-1}$$

Example 11. For hard sphere polyatomic gaseous molecules of water, the thermal conductivity is given by

$$\kappa_T = \frac{5}{16}\left(\frac{kT}{\pi m}\right)^{1/2}\frac{C_{v,m}+(9/4)R}{N_A d^2}$$

Predict κ_T for water vapour at 298 K, assuming that $C_{v,m}$ = 25·26 JK^{-1} mol^{-1} and the collision diameter, d = 0·50 nm.

Solution : Note that here m is the mass of one molecule given by M/N_A, where M is the molar mass.

Substituting the given data,

$$\kappa_T = \frac{5}{16}\left(\frac{(1{\cdot}38\times10^{-23}\,JK^{-1})(298K)[1kg\,m^2s^{-2})(1J)]}{\pi(18{\cdot}02\times10^{-3}\,kg\,mol^{-1})/(6{\cdot}022\times10^{23}\,mol^{-1})}\right)^{1/2}$$

$$\times\frac{\left(25{\cdot}26\,JK^{-1}mol^{-1}+\frac{9}{4}(8{\cdot}314\,JK^{-1}mol^{-1}\right)}{(6{\cdot}022\times10^{23}\,mol^{-1})(5{\cdot}0\times10^{-10}\,m)^2} \qquad (J = kg\ m^2\ s^{-2})$$

$$= 0{\cdot}019\ J\ K^{-1}\ m^{-1}\ s^{-1}$$

This value agrees favourably with the experimental value of 0·018 J K^{-1} m^{-1} s^{-1}.

2. Viscosity. The formula for the coefficient of viscosity of a gas can be derived in a way similar to that used for heat conduction. We imagine two very large parallel flat plates, one lying in the xy-plane, the other at a distance Z above the xy-plane. We keep the lower plate stationary and pull the upper plate in $+x$ direction with a velocity U. The viscosity of the gas exerts a drag on the moving plate. To keep the plate in uniform motion, a force must be applied to balance the viscous drag. If we look at the situation in another way, we find that if the upper plate moves with a velocity U, the viscous force will tend to set the lower plate in motion. A force must be applied to the lower plate to keep it in place.

Again we suppose that the gas between the plates is made up of a series of horizontal layers. The layer next to the lower plate is immobile. As we move upwards, each successive layer has a slightly larger component of velocity in the x-direction, the topmost layer at the height Z having the velocity U. This type of flow, in which there is a regular gradation of velocity in passing from one layer to the next, is called **laminar flow.** The layer at the height z has a velocity in the x-direction given by u_z :

$$u_z = \frac{\partial u}{\partial z}z \qquad ...(94)$$

At $z=Z$, $u=U$ so that

$$\frac{\partial u}{\partial z} = \frac{U}{Z} \qquad ...(95)$$

If we observe a layer at height z, we see that molecules enter this layer from the neighbouring layers. The molecules from the upper layers will bring extra momentum x to this layer while those which come from below are deficient in momentum. There is, therefore, a net downward flow of momentum x through the layer. Now we shall calculate the rate of this flow through 1 m^2 of the layer at height z (Fig. 7).

The number of molecules passing downwards through 1 m^2 s^{-1} is (1/6) $\rho\bar{c}$ and as many come upwards as come downwards. The molecules that pass downwards through the layer at z carry momentum x appropriate to

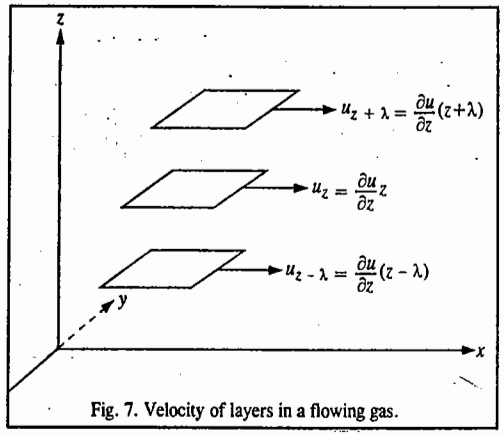

Fig. 7. Velocity of layers in a flowing gas.

the layer in which they made their last collision *viz*,, the layer at height $z + \lambda$. The momentum x is given by

$$mu_{z+\lambda} = m\left(\frac{\partial u}{\partial z}\right)(z+\lambda) \qquad ...(96)$$

Hence, the momentum coming down through 1 m^2 s^{-1} is given by

$$(mu)\downarrow = \frac{1}{6}\rho\bar{c}m\left(\frac{\partial u}{\partial z}\right)(z+\lambda) \qquad ...(97)$$

Similarly, the momentum coming up is given by

$$(mu)\uparrow = \frac{1}{6}\rho\bar{c}m\left(\frac{\partial u}{\partial z}\right)(z-\lambda) \qquad ...(98)$$

since the molecules coming up adjust their momentum in the layer at $z-\lambda$. The net downward flow of momentum x is given by

$$(mu)\downarrow - (mu)\uparrow = \frac{1}{3}\rho\bar{c}m\lambda\left(\frac{\partial u}{\partial z}\right) \qquad ...(99)$$

Since this quantity is independent of z, it must also be equal to the net momentum x transferred in one second to 1 m^2 of the lower plate. Since the momentum transfered per unit time is the force, the force acting in the x-direction on 1 m^2 of the lower plate is given by

$$f_x = \frac{1}{3}\rho\bar{c}m\lambda\left(\frac{\partial u}{\partial z}\right) \qquad ...(100)$$

To hold this plate stationary, we must apply an equal and opposite force f_{-x} such that $f_x + f_{-x} = 0$. The coefficient of viscosity, η, is defined as

$$f_{-x} = -\eta\left(\frac{\partial u}{\partial z}\right) \qquad ...(101)$$

The coefficient of viscosity is the force that must be applied to hold the lower plate stationary if the velocity gradient $\partial u/\partial z$ is unity and the plate has unit area. Comparing Eqs. 99 and 100, we have

$$\eta = \frac{1}{3}\rho\bar{c}m\lambda, \qquad ...(102)$$

If the mass density of the gas is ρ_{mass}, then $\rho_{mass} = \rho m$ and

$$\eta = \frac{1}{3}\rho_{masss}\bar{c}\lambda \qquad ...(103)$$

The numerical factor 1/3 is not quite correct since the flow of gas produces a non-equilibrium situation. For elastic spheres, the factor should be 1/2. The unit of the viscosity coefficient is N s m^{-2} = 1 Pascal second (Pa s) = 1 kg m^{-1} s^{-1}.

Eq. 102 can be further simplified as

$$\eta = \frac{1}{3}\lambda\bar{c}\rho m = \frac{1}{3}\lambda\bar{c}\left(\frac{N}{V}\right)m = \frac{1}{3}\lambda\bar{c}\left(\frac{nN_A}{V}\right)\left(\frac{M}{N_A}\right)$$

[$\because$ number of moles $n = N/N_A$ and $m = M/N_A$ where M is the molar mass]

Thus,

$$\eta = \frac{1}{3}\lambda\bar{c}M[A] \qquad ...(104)$$

where [A] (the molar concentration of the gas A) = n/V.

Note that Eq. 104 is only approximate.

Like thermal conductivity, the viscosity of a gas is also independent of pressure. The physical reason is the same : At higher pressure, more molecules are available to transport momentum but they carry it less far on account of the shorter mean free path. The pressure-independence of both η

and κ_T was one of the great initial triumphs of the kinetic theory of gases. Again, an unexpected result is that, because $\bar{c} \propto T^{1/2}$, η is proportional to $T^{1/2}$. That is, the viscosity of a gas *increases* with increase in temperature (unlike the viscosity of a liquid which *decreases* with increase in temperature). This conclusion can be easily explained when we remember that at high temperatures the molecules travel more quickly, so the flux of momentum is greater.

Comparison of Eqs. 102 and 90 shows that since $M = N_A m$,

$$\frac{\kappa_T}{\eta} = \frac{C_{v,m}}{M} \qquad ...(105)$$

This ratio is heat capacity per unit mass. More accurate theory, as well as experiment, show that for monoatomic gases (such as He, Ne, Ar, etc.),

$$\frac{\kappa_T}{\eta} = 2{\cdot}5\frac{C_{v,m}}{M} \qquad ...(106)$$

Determination of collision diameter from the measurement of the coefficient of viscosity. Since $\bar{c} = (8kT/\pi m)^{1/2}$ and $\lambda = 1/\sqrt{2}\sigma\rho$ where σ is the collision cross-section ($\sigma = \pi d^2$, where d is the collision diameter), we see that when these values are substituted in Eq. 104, we find that

$$\eta = \frac{2(mkT)^{1/2}}{3\pi^{3/2}d^2} = \frac{2(MRT)^{1/2}}{3\pi^{3/2}N_A d^2} \qquad ...(107)$$

which expresses η in terms of M, T and the quantity $N_A d^2$. Knowing N_A, then the collision diameter, can be calculated from the measured values of η.

Alternatively, if another expression involving N_A and d is available, the values of both N_A and d can be calculated. For instance, for a gas obeying the van der Waals equation of state, we know that the van der Waals constant b is given by

$$b = \frac{2}{3}\pi N_A d^2 \qquad ...(108)$$

Eliminating N_A from Eqs. 107 and 108 and solving for d, we get

$$d = \frac{9}{4}\eta b\left(\frac{\pi}{MRT}\right)^{1/2} \qquad ...(109)$$

Using this result in Eq. 107, we obtain

$$N_A = \left(\frac{32}{243\pi b^2}\right)\left(\frac{MRT}{\pi\eta^2}\right)^{3/2} \qquad ...(110)$$

It was from Eqs. 109 and 110 that the first concrete estimates of Avogadro's number (N_A) and the collision diameter (d) were obtained. Table 3 shows the values of d, calculated from η.

TABLE 3

Collision Diameter from η Measurements at 20°C

Gas	η(μPa s)	d(pm)
Ar	22·17	297
NH_3	9·82	361
CH_4	10·87	338
CO_2	14·80	373
C_2H_4	10·08	404

Example 12. The coefficient of viscosity of CO_2 is 14·80 μPa s at 20°C. Calculate its collision diameter.

Solution : From Eq. 107, $\eta = \dfrac{2(MRT)^{1/2}}{3\pi^{3/2}N_A d^2}$ so that $d^2 = \dfrac{2(MRT)^{1/2}}{3\pi^{3/2}N_A\eta}$

Thus,
$$d^2 = \frac{2[(44{\cdot}01\times10^{-3}\,\text{kg mol}^{-1})(8{\cdot}314\,\text{J K}^{-1}\text{mol}^{-1})(293{\cdot}15\,\text{K})]^{1/2}}{3(3{\cdot}1416)^{3/2}(6{\cdot}022\times10^{23}\,\text{mol}^{-1})(14{\cdot}80\times10^{-6}\,\text{Pa s})}$$

Since Pa s = kg m^{-1} s^{-1}, hence

$$d^2 = 13{\cdot}91\times10^{-20}\ \text{m}^2 \qquad [\text{J} = \text{kg m}^2\,\text{s}^{-2}]$$

Hence,
$$d = 3{\cdot}730\times10^{-10}\ \text{m} = \mathbf{373{\cdot}0\ pm} \qquad [\text{pm} = 10^{-12}\ \text{m}]$$

Example 13. For gaseous molecules that can be considered to be rigid hard spheres, the coefficient of viscosity is given by the equation

$$\eta = \frac{5\bar{c}\,m}{32\sqrt{2}d^2}$$

Using the value of the collision diameter, $d = 0{\cdot}353$ nm for O_2 at 1·0 bar and 25°C, calculate η. Repeat the calculation at a pressure of 10·0 bar.

Solution : (Note that the given equation for η is slightly different from Eq. 107).

$$d = 0{\cdot}353 \text{ nm} = 0{\cdot}353\times10^{-9} \text{ m} = 3{\cdot}53\times10^{-10} \text{ m}$$

$$\bar{c} = (8\ kT/\pi m)^{1/2} = (8\ RT/\pi M)^{1/2}$$

$$= \left(\frac{8(8{\cdot}314\,\text{J K}^{-1}\text{mol}^{-1})(298\,\text{K})[\text{kg m}^2\,\text{s}^{-2}/(\text{J})]}{\pi(32{\cdot}00\times10^{-3}\,\text{kg mol}^{-1})}\right)^{12} \qquad [\text{J} = \text{kg m}^2\,\text{s}^{-2}]$$

$$= 444 \text{ m s}^{-1}$$

Hence, substituting in the given equation,

$$\eta = \frac{5(444\,\text{m s}^{-1})(32{\cdot}00\times10^{-3}\,\text{kg mol}^{-1})/(6{\cdot}022\times10^{23}\,\text{mol}^{-1})}{32(\sqrt{2})(3{\cdot}53\times10^{-10}\text{m})^2}$$

$$= 2{\cdot}09\times10^{-5} \text{ kg m}^{-1}\,\text{s}^{-1} = 2{\cdot}09\times10^{-5} \text{ Pa s} \qquad [\text{Pa s} = \text{kg m}^{-1}\,\text{s}^{-1}]$$

$$= 20{\cdot}9 \text{ μPa s}$$

Since η of a gas is independent of pressure, $\eta = 2{\cdot}09\times10^{-5}$ Pas at both 1·0 bar and 10·0 bar.

Example 14. The coefficient of viscosity of gaseous argon at 25°C is $2{\cdot}10\times10^{-5}$ Pa s. Express the value in units of N s m^{-2}, kg m^{-1} s^{-1} and poise, P ($P=10^{-1}$ kg m^{-1} s^{-1}).

Solution : Recall that Pa = N m^{-2} and N = kg m s^{-2}. Hence, making the necessary conversions,

$$\eta = (2{\cdot}10\times10^{-5} \text{ Pa s})\ (\text{N m}^{-2})/\text{Pa} = 2{\cdot}10\times10^{-5} \text{ N s m}^{-2}$$

Again,
$$(2{\cdot}10\times10^{-5} \text{ N s m}^{-2})\ \text{kg m s}^{-2}/\text{N} = 2{\cdot}10\times10^{-5} \text{ kg m}^{-1}\,\text{s}^{-1}$$

and
$$(2{\cdot}10\times10^{-5} \text{ kg m}^{-1}\,\text{s}^{-1})/(10^{-1} \text{ kg m}^{-1}\,\text{s}^{-1}/\text{P}) = 2{\cdot}10\times10^{-4} \text{ P}$$

3. Diffusion. If the concentration is not uniform in a mixture of gases, the gases diffuse into one another until the composition is uniform. The derivation of the diffusion coefficient in such a situation is lengthy and rather complicated since each gas has a different value for mean speed, $\bar{c}$ and mean free path, λ. To simplify matters we treat the case of a single gas so that there is only one value of $\bar{c}$ and λ. The result obtained is very nearly correct for the diffusion of one isotope into another. Let us suppose that some of the molecules of the gas are painted red; the gas is confined in a vertical tube and the number density (*i.e.*, number of molecules per m^3), ρ_r, of red molecules is greater at one end than at the other. Then, the number density, ρ, of unpainted molecules must also vary from one end to the other if the total pressure is to be uniform throughout the tube. For each species we write for the number density at height z, as

$$\rho = \rho_0 + \frac{\partial\rho}{\partial z}z\,;\quad \rho_r = \rho_{r_0} + \frac{\partial\rho_r}{\partial z}z$$

where ρ_0 and ρ_{r_0} are the number densities at $z = 0$.

Consider a horizontal area of 1 m^2 at height z. The number of red molecules passing downwards through this area per second is given by

$$\rho_r\downarrow = \tfrac{1}{6}\bar{c}(\rho_r)_{z+\lambda} = \tfrac{1}{6}\bar{c}\left[\rho_{r_0} + \frac{\partial\rho_r}{\partial z}(z+\lambda)\right] \qquad ...(111)$$

since the molecules originate in the layer at $z+\lambda$. Similarly, the number coming up from below is given by

$$\rho_r\uparrow = \tfrac{1}{6}\bar{c}(\rho_r)_{z-\lambda} = \tfrac{1}{6}\bar{c}\left[\rho_{r_0} + \frac{\partial\rho_r}{\partial z}(z-\lambda)\right] \qquad ...(112)$$

The net flow upwards is thus given by

$$\rho_r\uparrow - \rho_r\downarrow = -(1/3)\bar{c}\lambda\frac{\partial\rho_r}{\partial z} \qquad ...(113)$$

By the law of diffusion (Eq. 77), the upward flow is given by $-D_r(\partial\rho_r/\rho z)$. D_r is the diffusion coefficient for the red molecules.

Thus, we have from Eqs. 77 and 113,

$$D_r = (1/3)\bar{c}\lambda \qquad ...(114)$$

However, the red molecules differ from the others only by a coat of paint so that

$$D = (1/3)\bar{c}\lambda \qquad ...(115)$$

Since $\bar{c}$ is inversely proportional to $M^{1/2}$, we can understand **Graham's law** which states that the rate of diffusion of a gas is inversely proportional to the square root of the molar mass.

Since the mean free path, λ, is inversely proportional to the pressure ($\lambda = kT/\sqrt{2}\,\sigma P$), the diffusion coefficient decreases with increase in pressure. The molecules have to fight their way through the swarm of other molecules by making collisions. At high pressures, they make many more collisions and their progress in any given direction is slowed.

Summary of Transport Properties in a Gas. Kinetic theory interprets the phenomenological laws of transport on the basis of a single mechanism and expresses the values of κ_T, η and D in terms of the mean free path (λ), number density (ρ) and the mean speed ($\bar{c}$) of the gas molecules. The equations are :

$$\kappa_T = (1/3)\lambda\bar{c}\,(\rho/N_A)\,C_{v,m} \qquad \text{(Eq. 90)}$$

$$\eta = (1/3)\lambda\bar{c}\rho m \qquad \text{(Eq. 102)}$$

$$D = (1/3)\lambda\bar{c} \qquad \text{(Eq. 115)}$$

Since all of these depend on λ, they are sometimes called **free path phenomena.**

Example 15. How does the mean free path in a sample of a gas vary with temperature in a constant volume container ?

Solution : $$\lambda = \frac{kT}{\sqrt{2}\sigma P} = \frac{kTV}{n(\sqrt{2})\sigma RT} = \frac{V}{n(\sqrt{2})\sigma N_A} \qquad [P = nRT/V;\ k = R/N_A]$$

Thus, at constant V, λ is independent of T.

Example 16. At what pressure does the mean free path of argon (g) at 25°C become comparable to the size of a 1·0 litre vessel that contains it ? Assume that $\sigma = 0{\cdot}36$ nm^2

Solution : $\lambda = \frac{kT}{\sqrt{2}\sigma\text{H}}$. Thus, $P = \frac{kT}{\sqrt{2}\sigma\lambda}$

Now, $$\lambda \approx (1000 \text{ cm}^3)^{1/3} = 10 \text{ cm} = 0{\cdot}10 \text{ m}$$

$$\therefore\quad P = \frac{(1{\cdot}38\times10^{-23}\,\text{J K}^{-1})(298\,\text{K})}{\sqrt{2}\,(0{\cdot}36\times10^{-18}\,\text{m}^2)(0{\cdot}10\,\text{m})} = 0{\cdot}081 \text{ N m}^{-2} = 0{\cdot}081 \text{ Pa}$$

$$= \frac{0{\cdot}081 \text{ Pa}}{1{\cdot}01325\times10^5 \text{ Pa / atm}} = 8{\cdot}0\times10^{-7} \text{ atm} = 6{\cdot}1\times10^{-4} \text{ Torr} \qquad (1 \text{ atm} = 760 \text{ Torr})$$

Example 17. At what pressure does the mean free path of argon at 25°C become comparable to the diameter of the atoms themselves ? Given $\sigma = 0{\cdot}36$ nm^2.

Solution. $$\lambda = \frac{kT}{\sqrt{2}\sigma P}\text{; thus, } P = \frac{kT}{\sqrt{2}\sigma\lambda}$$

$$\sigma = \pi d^2,\quad d = (\sigma/\pi)^{1/2} = \left(\frac{0{\cdot}36\text{nm}^2}{\pi}\right)^{1/2} = 0{\cdot}34\text{nm}$$

$$\therefore\quad \lambda \approx d = 0{\cdot}34 \text{ nm}$$

$$P = \frac{(1{\cdot}38\times10^{-23}\,\text{J K}^{-1})(298\,\text{K})}{\sqrt{2}\,(0{\cdot}36\times10^{-18}\,\text{m}^2)(0{\cdot}34\times10^{-9}\,\text{m})} = 2{\cdot}4\times10^7 \text{ N m}^{-2}$$

$$= 2{\cdot}4\times10^7 \text{ Pa} = \frac{2{\cdot}4\times10^7 \text{ Pa}}{1{\cdot}01325\times10^5 \text{ Pa / atm}} \approx 240 \text{ atm} \qquad [\text{J} = \text{N m};\ \text{Pa} = \text{N m}^{-2}]$$

This pressure is comparable to the pressure in a compressed gas cylinder in which argon gas is normally stored.

Role of argon in an incandescent lamps. Langmuir made an important application of the concept of the mean free path and diffusion in the construction of an incandescent lamp. When electric current is passed through an ordinary lamp, it heats the tungsten filament white hot. The filament gets oxidized and there occurs an immediate burn out. This can be prevented by evacuating the bulb. However, if the pressure becomes too low, the mean free path of the tungsten atoms becomes large compared with the size of the bulb, with the result that the tungsten atoms which 'boil off' from the filament directly hit the glass wall without colliding with a gas molecule. The tungsten atoms condense on the glass wall thereby blackening the bulb. The un-interrupted loss of tungsten atoms from the filament weakens the filament which soon breaks. Langmuir suggested the introduction of argon gas into the bulb under a pressure of a few centimetres. This reduces λ to a value less than the diameter of the filament. Thus, a tungsten atom that has 'boiled off' travels only a short distance before hitting a gas molecule. As a result of this collision, the tungsten atom is reflected back on to the filament. The tungsten atoms leave the region of the filament by slow diffusion through the argon gas. Thus, we see how the presence of argon in the bulbs lengthens considerably the life of the bulb.

Degrees of Freedom of a Gaseous Molecule

The motion of atoms and molecules is generally described in terms of the degrees of freedom they possess. The **degrees of freedom** *of a molecule are defined as the independent number of parameters required to describe the state of the molecule completely.* When a gaseous molecule is heated, the energy supplied to it may bring about three kinds of motion in it. These are : the translationl motion, the rotational motion and the vibrational motion. This is expressed by saying that the molecule possesses translational, rotational and vibrational degrees of freedom.

Translation Degrees of Freedom. Atoms possess only translational degrees of freedom. If we consider an atom as a *mass point*, then the mass point requires three coordinates (such as x, y, z in the Cartesian coordinates system) to specify its position. The atom has thus *three translational degrees of freedom* in the x, y and z directions. If the atom is moving with a velocity c, then

$$c^2 = c_x^2 + c_y^2 + c_z^2 \qquad ...(116)$$

where c_x, c_y and c_z are the components of velocity c in the three directions. Multiplying Eq. 116 by $m/2$, where m is the mass of the atom, we have

$$\tfrac{1}{2}mc^2 = \tfrac{1}{2}mc_x^2 + \tfrac{1}{2}mc_y^2 + \tfrac{1}{2}mc_z^2 \qquad ...(117)$$

or Kinetic energy, $\varepsilon_k = \varepsilon_{k,x} + \varepsilon_{k,y} + \varepsilon_{k,z}$ ...(118)

Thus, the kinetic energy ε_k, too, can be resolved into three components along the three Cartesian axes.

It may be noted that the rotational motion of an atom about an axis perpendicular to it and passing through its centre contributes negligible energy compared with its translational motion.

As in the case of atoms, three coordinates are needed to specify the centre of gravity of a molecule. Thus, the centre of gravity of any molecule has three translational degrees of freedom.

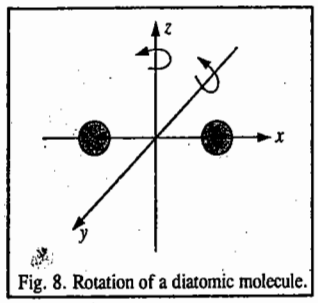

Fig. 8. Rotation of a diatomic molecule.

Rotational Degrees of Freedom. A diatomic molecule lying along the X-axis can undergo rotation about the mutually perpendicular Y-axis and Z-axis passing through its centre of gravity, as shown in Fig. 8. This is expressed by saying that a diatomic molecule has *two rotational degrees of freedom.*

If I is the moment of inertia of the molecule and ω is its angular velocity, then the rotational energy is given by

$$E_{rot} = I\omega^2 \qquad ...(119)$$

It may be noted that the moment of inertia of the molecule and hence its rotational energy along the x-axis is negligible.

All *linear* molecules, such as CO_2 and C_2H_2, have two rotational degrees of freedom because their rotational motion is similar to that of a diatomic molecule.

However, *non-linear* molecules, such as H_2O, H_2S, CH_4, C_6H_6, etc., can undergo rotation about the three Cartesian axes so that they have *three rotational degrees of freedom.* The rotational motion of H_2O molecule is shown in Fig. 9.

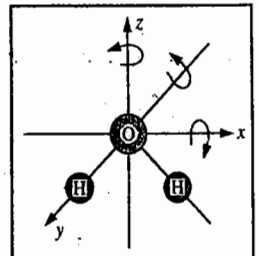

Fig. 9. Rotation of triatomic non-linear H_2O molecule.

Vibrational Degrees of Freedom. As already mentioned, atoms possess only translational degrees of freedom.

In a diatomic molecule, the masses m_1 and m_2 vibrate back and forth relative to their centre of mass in opposite directions, as shown in Fig. 10. The two masses reach the extremes of their respective motions at the same time. The diatomic molecule has only *one vibrational degree of freedom, i.e.,* it has only one frequency, called the fundamental vibrational frequency. During vibrational motion, the bond of the molecule behaves like a spring and the molecule exhibits a simple harmonic motion provided the displacement of the nuclei from the equilibrium configuration is not too much. At the two extremes of motion which correspond to extension and compression of the chemical bond between the two atoms, the potential energy is maximum. On the other hand, when the atoms are in their equilibrium position, the kinetic energy is maximum. Thus, during vibration, there is a constant interchange of kinetic and potential energy.

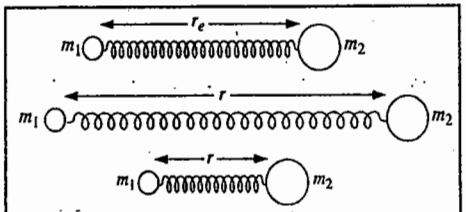

Fig. 10. Vibration of a diatomic molecule.

A polyatomic molecule containing n atoms or nuclei, has $3n$ degrees of freedom since each atom requires 3 degrees of freedom in the x, y and z directions to specify its position. If we subtract the translational and rotational degrees of freedom from the total $3n$ degrees of freedom, we find that we are left with $3n - 6$ *internal degrees of freedom* for a non-linear molecule and $3n - 5$ *internal degrees of freedom* for a linear molecule. The $3n - 6$ internal degrees of freedom of a non-linear molecule correspond to its $3n - 6$ *normal modes of vibration.* Similarly, the $3n - 5$ normal degrees of freedom of a linear molecule correspond to its $3n - 5$ normal modes of vibration. A **normal mode of vibration** *is defined as the molecular motion in which all the atoms in the molecule vibrate with the same frequency and all the atoms pass through their equilibrium positions simultaneously.* The relative vibrational amplitudes of individual atoms may be different in magnitude and direction but the centre of gravity of the molecule does not change.

Modes of vibration may result in the stretching and bending of the molecular bonds. The stretching may be *symmetric* or *asymmetric* while the bending may be *in plane* or *out of plane*. These modes are observed in the infrared region (6500–4,000 cm^{-1}) of the electromagnetic spectrum.

The various modes of vibration of H_2O and CO_2 molecules are shown in Fig. 11

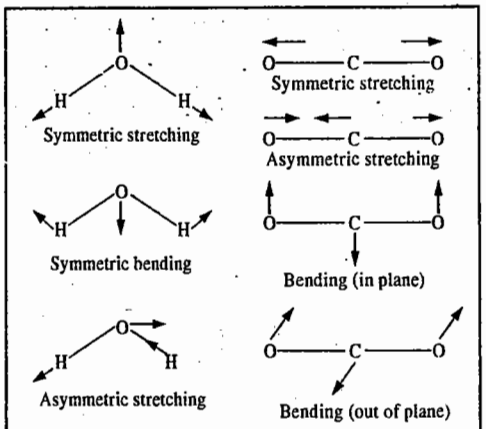

Fig. 11. Various modes of vibration of H_2O and CO_2 molecules.

Example 18. Calculate the various degrees of freedom of the following molecules :

(a) He (b) H_2 (c) HCl (d) H_2O (e) CO_2 (f) C_2H_2 (g) C_6H_6 and (h) a protein molecule containing 44,700 atoms.

Solution : Let N be the number of degrees of freedom and n, the number of atoms in a molecule. Then,

(a) He : $n = 1$; $N_{tr} = 3$ $N_{rot} = 0$ $N_{vib} = 0$

(b) H_2 : $n = 2$; $N_{tr} = 3$ $N_{rot} = 2$ $N_{vib} = 3\times2 - 5 = 1$

(c) HCl : $n = 2$; $N_{tr} = 3$ $N_{rot} = 2$ $N_{vib} = 3\times2 - 5 = 1$

(d) H_2O : It is a non-linear molecule.

$n = 3$; $N_{tr} = 3$ $N_{rot} = 3$ $N_{vib} = 3\times3 - 6 = 3$

(e) CO_2 : It is a linear molecule.

$n = 3$; $N_{tr} = 3$ $N_{rot} = 2$ $N_{vib} = 3\times3 - 5 = 4$

(f) HC≡CH : It is a linear molecule.

$n = 4$; $N_{tr} = 3$ $N_{rot} = 2$ $N_{vib} = 3\times4 - 5 = 7$

(g) C_6H_6 : It is non-linear molecule.

$n = 12$; $N_{tr} = 3$ $N_{rot} = 3$ $N_{vib} = 3\times12 - 6 = 30$

(h) Protein molecule : It is a macromolecule.

$n = 44700$; $N_{tr} = 3$ $N_{rot} = 31$ $N_{vib} = 3\times44700 - 6 = 134,100$

(We can neglet 6 in comparison with 134,100)

The translational, rotational and vibrational degrees of freedom can be written in the shortened notation as follows :

(a) He : (3,0,0) (b) H_2 : (3,2,1) (c) HCl : (3,2,1) (d) H_2O : (3,3,3)

(e) CO_2 : (3,2,4) (f) C_2H_2 : (3,2,7) (g) C_6H_6 : (3,3,30), etc.

It should be remembered that the rotational degrees of freedom are associated with substances in both the gaseous and liquid states. However, in the *solid state*, the molecules possess only *vibrational degrees of freedom*. The translational and rotational motions in solids are converted into vibrational motion where the atoms in the lattice vibrate to and fro about their equilibrium positions.

Principle of Equipartition of Energy

From the kinetic theory of gases we know that the average translational kinetic energy of a molecule of an ideal gas is given by

$$\varepsilon = \tfrac{3}{2}kT \qquad ...(120)$$

According to the **law of equipartition of energy**, *the total energy of a molecule is divided equally amongst the various degrees of freedom of the molecule.*

The distribution of kinetic energy along the x, y and z directions is given by

$$\varepsilon = \varepsilon_x + \varepsilon_y + \varepsilon_z \qquad ...(121)$$

Since the motion of gas molecules is random and the motion along the three Cartesian axes is equally probable, hence from Eqs. 120 and 121,

$$\varepsilon_x = \varepsilon_y = \varepsilon_z = 1/3\text{rd of } \varepsilon = \tfrac{1}{2}kT \qquad ...(122)$$

Eq. 122 shows that each component of kinetic motion contributes equally to the total kinetic energy and that *the kinetic energy for each degree of freedom* is $\frac{1}{2}kT$ *per molecule* or $\frac{1}{2}RT$ *per mole.*

Following similar lines of arguments, it can be shown that *each rotational degree of freedom* also contributes $\frac{1}{2}kT$ per molecule or $\frac{1}{2}RT$ per mole to the total energy.

As regards the *vibrational motion,* the two atoms oscillate against each other, as shown in Fig. 10. The molecule, therefore, possesses *both* potential and kinetic energy, as already discussed. This means that the energy of vibration involves *two degrees of freedom.* The *vibrational motion* in a molecule is, thus, associated with energy = $2\times\frac{1}{2}kT = kT$ per molecule or RT per mole.

Thus, if a gaseous species has n_1 translational degrees of freedom, n_2 rotational degrees of freedom and n_3 vibrational degrees of freedom, then the total energy of the species is given by $n_1(kT/2) + n_2(kT/2) + n_3(kT)$.

Example 19. Using the principle of equipartition of energy, estimate the energy of (a) H_2 (b) H_2O and (c) CO_2 at room temperature, assuming that all the degrees of freedom are excited and contribute towards the energy of the molecules.

Solution : Ordinarily, at room temperature only translational and rotational degrees of freedom are excited and hence they alone contribute to the energy of the molecule. Here, however, we shall assume that vibrational degrees of freedom, too, are excited. According to the principle of equipartition of energy, each translational and rotational degree of freedom contributes $1/2\ kT$ and each vibrational degree of freedom contributes $2\times1/2kT = kT$ to the total energy.

(a) H_2 (3, 2, 1) : $E = 3(\frac{1}{2}kT) + 2(\frac{1}{2}kT) + 1(kT) = (7/2)kT$ per molecule or $(7/2)RT$ per mole

(b) H_2O (3, 3, 3) : $E = 3(\frac{1}{2}kT) + 3(\frac{1}{2}kT) + 3(kT) = 6kT$ per molecule or $6RT$ per mole

(c) CO_2 (3, 2, 4) : $E = 3(\frac{1}{2}kT) + 2(\frac{1}{2}kT) + 4(kT) = (13/2)kT$ per molecule or $(13/2)RT$ per mole

Contributions to Heat Capacity of an Ideal Gas. According to the **Born–Oppenheimer approximation**, the total energy of a molecule is given by

$$E_{total} = E_{tr} + E_{rot} + E_{vib} + E_{el} \qquad ...(123)$$

where E_{tr} is the translational energy, E_{rot} is the rotational energy, E_{vib} is the vibrational energy and E_{el} is the electronic energy. The translational energy is not quantized while the remaining three energies are quantized. E_{el} does not make any contribution towards heat capacity.

According to the *principle of equipartition of energy* discussed above, the kinetic energy of a single particle is equal to $\frac{1}{2}kT$. Since a particle can exhibit only translational motion (along a straight line), its translational energy is equal to its total energy. According to Clausius, the translational energy of a point-particle is distributed among three independent components of motion, say, the motion along the x, y and z axes of a Cartesian coordinates system. This is expressed by saying that the point-particle has *three translational degrees of freedom*, each degree of freedom contributing $\frac{1}{2}kT$ to the translational energy. Hence, the total translational energy of the point-particle (*i.e.*, the atom) is $\frac{3}{2}kT$. The energy per mole is evidently $\frac{3}{2}RT$.

As mentioned above, an n-atomic molecule (*i.e.*, a molecule containing n atoms) has 3n degrees of freedom. Since there are 3 translational degrees of freedom, therefore, the remaining 3n - 3 degrees of freedom are associated with rotational and vibrational motion.

As discussed earlier, a linear polyatomic molecule has only two rotational degrees of freedom while a non-linear polyatomic molecule has three rotational degrees of freedom. Hence, a linear molecule has 3n - 5 vibrational degrees of freedom and a non-linear molecule has 3n - 6 vibrational degrees of freedom.

Since heat capacity C_v is defined as $(\partial U/\partial T)_v$, hence, the total heat capacity is given by

$$C_{v,total} = C_{v,tr} + C_{v,rot} + C_{v,vib} \qquad ...(124)$$

(we neglect the electronic contribution to heat capacity at ordinary temperatures).

According to the principle of equipartition of energy, each translational and each rotational degree of freedom contributes $\frac{1}{2}R$ to C_v while each vibrational degree of freedom contributes $2\times\frac{1}{2}R=R$ to C_v. Here, an approximation is made that at room temperature, the contribution to C_v from vibrational motion is only 20%. The vibrational contribution becomes more prominent at high temperature.

Example 20. Estimate C_v for the following gases at room temperature : *(a)* Helium *(b)* HCl and *(c)* CO_2.

Solution : *(a)* **He :** Helium consists of atoms only. Atoms have only translational motion and the number of translational degrees of freedom = 3. Thus,

$$C_v = 3(R/2) = \frac{3}{2} \times 8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1} = \mathbf{12{\cdot}471 \text{ J K}^{-1} \text{ mol}^{-1}}$$

(b) **HCl :** HCl is a linear diatomic molecule. Number of atoms, n=2 so that 3n=6

Number of translational degrees of freedom = 3

Number of rotational degrees of freedom = 2

$\therefore$ Number of vibrational degrees of freedom = 6 - (3 + 2) = 1

Hence, at room temperature, assuming 20% vibrational contribution,

$$C_v = 3(R/2) + 2(R/2) + 0{\cdot}20 \times 1\,(R) = 3(R/2) + (R) + 0{\cdot}20R$$
$$= 2{\cdot}7\,R = 2{\cdot}7 \times 8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1} = \mathbf{22{\cdot}45 \text{ J K}^{-1} \text{ mol}^{-1}}$$

(c) **CO_2 :** CO_2 is a linear triatomic molecule. $\therefore$ n=3 ; 3n=9

Number of translational degrees of freedom = 3

Number of rotational degrees of freedom = 2

$\therefore$ Number of vibrational degrees of freedom = 9 - (3 + 2) = 4

$$C_v = 3(R/2) + 2(R/2) + 0{\cdot}20 \times 4(R) = 3{\cdot}3\,R = \mathbf{27{\cdot}44 \text{ J K}^{-1} \text{ mol}^{-1}}$$

Example 21. For ozone, $\gamma = 1{\cdot}17$ (where γ is C_p/C_v). Assuming that it is an ideal gas and the vibrational contribution is full (not just 20%), estimate its C_v and confirm whether the molecule is linear or non-linear.

Solution : $\gamma = C_p/C_v = 1{\cdot}15$. Also for an ideal gas, $C_p - C_v = R$

Suppose the molecule is non-linear. Then,

$$C_v = C_{v,tr} + C_{v,rot} + C_{v,vib} = 3(R/2) + 3(R/2) + 3(R) = 6R$$
$$C_p = C_v + R = 7R \text{ so that } \gamma = 7/6 = 1{\cdot}167$$

Suppose now that the molecule is linear. Then,

$$C_v = (3R/2) + 2(R/2) + 4R = (13/2)R$$
$$C_p = C_v + R = 15/2\,R \text{ so that } \gamma = 1{\cdot}154$$

Since the former value agrees with the given value, the ozone molecule is non-linear.

Example 22. Estimate γ at room temperature for *(a)* helium and *(b)* CH_4 gas, assuming that they are ideal gases.

Solution : *(a)* **Helium :** $C_v = C_{v,tr} = 3(R/2)$

For an ideal gas, $C_p - C_v = R \quad \therefore C_p = 5R/2$

$$\therefore \quad \gamma = C_p/C_v = \frac{5R/2}{3R/2} = \frac{5}{3} = 1{\cdot}66$$

(b) **CH_4 :** Assuming full vibrational contribution,

$$C_v = C_{v,tr} + C_{v,rot} + C_{v,vib} = 3(R/2) + 3(R/2) + 9(R) = 12R$$
$$\therefore \quad C_p = R + C_v = R + 12R = 13R \text{ so that } \gamma = 13/12 = 1{\cdot}02$$

Note. It is customary to neglect the vibrational contribution to C_v at ordinary temperatures. The vibrational degrees of freedom are excited at extremely high temperatures. The temperature above which vibrational degrees of freedom contribute to C_v is called the **characteristic vibrational temperature** of a molecule.

Table 4 lists the calculated and experimental values of the constant volume molar heat capacities of some common gases.

We see that the agreement is excellent for mono-atomic gases. However, considerable discrepancies are noticed for diatomic and polyatomic molecules.

TABLE 4

Calculated and Experimental Values of Molar Heat Capacities of Gases at 298 K

Gas	C_v (J K^{-1} mol^{-1}) (calculated)	C_v (J K^{-1} mol^{-1}) (experimental)
He	12·47	12·47
Ne	12·47	12·47
Ar	12·47	12·47
H_2	29·10	20·50
N_2	29·10	20·50
O_2	29·10	21·05
CO_2	54·06	28·82
H_2O	49·87	25·23
SO_2	49·87	31·51

Example 23. The speed of sound in a gas is given by $c_s = (\gamma\, RT/M)^{1/2}$ where $\gamma = C_p/C_v$ *(i)* Show that this relation can be written as $c_s = (\gamma\, P/\rho)^{1/2}$ where P is the pressure and ρ is the density *(ii)* Calculate the speed of sound in helium at room temperature.

Solution : *(i)* For an ideal gas, $PV = nRT = (m/M)RT$ where m is the mass of the gas. Hence,

$$P = mRT/MV = \rho RT/M \qquad (\because \text{density, } \rho = m/V)$$

or $$RT/M = P/\rho$$

$\therefore$ $$c_s = (\gamma\, RT/M)^{1/2} = (\gamma P/\rho)$$

(ii) For helium, $\gamma = C_p/C_v = 5/3$ and $M = 4{\cdot}0 \text{ g mol}^{-1} = 4{\cdot}0 \times 10^{-3} \text{ kg mol}^{-1}$

$\therefore$
$$c_s = \left[\frac{\gamma RT}{M}\right]^{1/2} = \left\{\frac{5 \times (8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1})(298 \text{ K})}{3 \times 4{\cdot}0 \times 10^{-3} \text{kg mol}^{-1}}\right\}^{1/2}$$
$$= (1{\cdot}03 \times 10^6 \text{ m}^{-1} \text{ s}^{-2})^{1/2} = \mathbf{1{\cdot}02 \text{ km s}^{-1}} \qquad [\because \text{J} = \text{kg m}^2 \text{ s}^{-1}]$$

Barometric Formula

It is found that as we go higher up the sea level, the pressure of the atmosphere decreases. The variation of pressure with altitude is given by the so called barometric formula.

The pressure difference, $-dP$, between altitude x and altitude $x+dx$ is equal to the weight (*not mass*) per unit area of a layer of gas of thickness dx and is given by

$$-dP = \rho g dx \qquad \ldots(125)$$

where ρ is the density of the gas and g is the acceleration due to gravity. We know that density of an ideal gas is given by $\rho = PM/RT$ where M is its molar mass. Hence,

$$-dP = (PMg/RT)\,dx \qquad \ldots(126)$$

or $$dP/P = -(Mg/RT)\,dx \qquad \ldots(127)$$

Integrating, $$\ln (P/P_0) = -Mgx/RT \qquad \ldots(128)$$

Taking antilog, $$P = P_0 \exp(-Mgx/RT) \qquad \ldots(129)$$

This is the barometric formula.

Example 24. Calculate the atmospheric pressure at Shimla whose height above the sea level is 2250 m if the pressure at the ground level is 1 atm and temperature is 25°C, assuming that there exist no complications such as turbulence or temperature gradients (M = 29 g mol^{-1}).

Solution : From the barometric formula (Eq. 129),

$$\ln \frac{P_0}{P} = \frac{Mgx}{RT} \qquad \ldots(i)$$

Substituting the given data in Eq. *(i)*, we have

$\therefore$
$$\log\left(\frac{1}{P}\right) = \frac{(29 \times 10^{-3} \text{ kg mol}^{-1})(9{\cdot}81 \text{ m s}^{-2})(2250 \text{ m})}{2{\cdot}303 \times (8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1})(298 \text{ K})} = 0{\cdot}1121 \qquad (\text{J} = \text{kg m}^2 \text{ s}^{-2})$$

$$\log P = -0{\cdot}1121 = \bar{1}{\cdot}8879$$

Taking antilog, $$P = \mathbf{0{\cdot}7725 \text{ atm}}$$

We conclude this chapter by offering a few remarks on Robert Boyle (1627-1691), the British chemist. He gave an entirely new approach to experimental science. Historians of chemistry say that he made no outstanding discoveries (he merely confirmed and publicized 'Boyle's law'). As K.J. Laidler wrote, "Boyle's great contribution was to transform chemistry from a subject in which there was much mysticism and charlatanism into an effective branch of natural philosophy, based firmly on experimental evidence. If Boyle was not the father of chemistry, as he has often been called, a good case be made for regarding him as the first physical chemist."

I. Review Questions

1. Starting from the basic postulates of the kinetic theory of gases, derive the kinetic gas equation. Calculate the value of the ideal gas constant.
2. Using the kinetic gas equation $PV = \frac{1}{3}mNc^2$, derive Boyle's law, Charles' Law, Graham's law of diffusion, Dalton's law of partial pressures, Avogadro's law and the ideal (perfect) gas equation.
3. Define average velocity, most probable velocity and root mean square velocity. Derive mathematical expressions for the three types of molecular velocities.
4. Using the expression for the Maxwell distribution of velocities, draw this distribution at three different temperatures and comment on the shapes of the distribution curves.
5. Explain the terms collision diameter, collision cross-section, collision number, collision frequency and mean free path. Show that the mean free path of a gas molecule increases by decrease in pressure.
6. Define the coefficient of viscosity of a fluid. Show that the viscosity of a gas is independent of pressure. How is this parameter used for calculating the mean free path and collision diameter in a gas ?
7. Discuss with the help of suitable illustrations translational, rotational and vibrational degrees of freedom of diatomic and triatomic gaseous molecules.
8. State the principle of equipartition of energy. Discuss the application of this principle in estimating *(i)* the total energy of a given gaseous molecule and *(ii)* the heat capacity of an ideal gas at room temperature.
9. Derive the Barometric formula for the variation of atmospheric pressure with altitude.

II. Problems

1. Calculate the kinetic energy of an ideal gas per molecule and per mole at 27°C. **[Ans. $6{\cdot}21\times10^{-21}$ J ; $3{\cdot}74\times10^{3}$ J]**
2. Calculate the kinetic energy of *(i)* a molecule of hydrogen at 0°C *(ii)* one gram of oxygen at 47°C. **[Ans. *(i)* $5{\cdot}678\times10^{-7}$ J *(ii)* $1{\cdot}24\times10^{2}$ J]**
3. Calculate the number of moles of N_2 contained in 20 dm^3 of the gas at 25°C and a pressure of 700 mm Hg. **[Ans. 0·753 mole]**
4. Calculate the density of CO_2 gas at 0°C and 1 atm pressure. **[Ans. 1·96 kg m^{-3}]**
5. Calculate the approximate molar mass of a gas if 560 ml weigh 1·80 g at N.T.P. **[Ans. 72·0 g mol^{-1}]**
6. Calculate the volume of CO_2 at 25°C and 765 torr required to produce 100 g of $Ca(HCO_3)_2$ by its reaction with $Ca(OH)_2$. **[Ans. 31·79 dm^3]**
7. A 10·0 dm^3 cylinder of O_2 gas at 4·00 atm pressure and 17°C developed a leak. When the leak was repaired, the gas which remained in the cylinder was found to register a pressure of 2·5 atm at 17°C. How many moles of the gas escaped ? **[Ans. 0·630 mole]**
8. At what temperature will the root mean square velocity of SO_2 be the same as that of O_2 at 27°C ? **[Ans. 327°C]**
9. Calculate the mean free path of O_2 molecules at 25°C and a pressure of 10^{-3} mm Hg, given that the collision diameter is 361 pm. **[Ans. 53 mm]**
10. The coefficient of viscosity of oxygen gas is 208 micropoise. Calculate the mean free path and collision diameter of oxygen molecules at N.T.P. **[Ans. $7{\cdot}17\times10^{-8}$ m ; $3{\cdot}57\times10^{-10}$ m]**
11. Determine the possible numbers of vibrational modes of CH_4, C_2H_6, C_6H_6 and SO_2 molecules. **[Ans. 9, 18, 30, 3]**
12. Estimate C_v for the following gases at room temperature, applying the principle of equipartition of energy : (1) Neon (2) Argon (3) Hydrogen bromide (4) Hydrogen sulphide. **[Ans. (1) 12·27 J K^{-1} mol^{-1} (2) Same as for neon (3) 22·45 J K^{-1} mol^{-1} (4) 49·88 J K^{-1} mol^{-1}]**

CHAPTER 10

THE GASEOUS STATE–II REAL GASES

Deviations of Real Gases from Ideal Behaviour. As already discussed in the last chapter, the equation of state $PV=nRT$, derived from the postulates of the kinetic theory, is valid for an ideal gas only. Real gases obey this equation only approximately and that too under conditions of low pressure and high temperature. The higher the pressure and the lower the temperature, the greater are the deviations from the ideal behaviour. In general, the most easily liquefiable and highly soluble gases show larger deviations. Thus, gases like carbon dioxide, sulphur dioxide and ammonia show much larger deviations than hydrogen, oxygen, nitrogen, etc.

The deviations from ideal behaviour are best represented in terms of the compressibility factor (also called the compression factor), Z, which is defined as

$$Z = \frac{PV}{(PV)_{ideal}} = \frac{PV}{nRT} = \frac{PV_m}{RT} \qquad ...(1)$$

where V_m ($= V/n$) is the molar volume, *i.e.*, the volume occupied by one mole of the gas.

For an ideal gas, $Z=1$ under all conditions of temperature and pressure. The deviation of Z from unity is, thus, a measure of the imperfection of the gas under consideration.

The graphs plotted for the compressibility factors determined for a number of gases over a range of pressures at a constant temperature (0°C) are shown in Fig. 1.

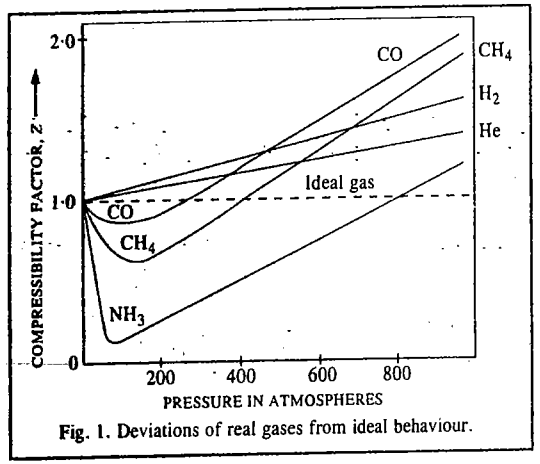

Fig. 1. Deviations of real gases from ideal behaviour.

At extremely low pressures, all the gases are known to have Z close to unity which means that the gases behave almost ideally. At very high pressures, all the gases have Z more than unity indicating that the gases are less compressible than an ideal gas. This is due to the fact that at high pressures, the molecular repulsive forces are dominant.

As can be seen from Fig. 1, at moderately low pressures, carbon monoxide, methane and ammonia are more compressible than an ideal gas, *i.e.*, PV is less than $(PV)_{ideal}$ so that $Z < 1$. This is due to the fact that at low pressures, the long range attractive forces are dominant and favour compression. The compressibility factor Z goes on decreasing with increase in pressure, passes through a minimum at a certain stage and then begins to increase with increase in pressure. The gases now become less compressible than an ideal gas, *i.e.*, PV is more than $(PV)_{ideal}$ so that $Z > 1$. It is evident from the figure that while carbon monoxide and methane exhibit marked deviations from ideal behaviour only at high pressures, ammonia shows large deviation even at low pressures.

Hydrogen and helium at 0°C, however, are seen to be less compressible than the ideal gas *at all pressures, i.e.*, $Z > 1$. However, if the temperature is sufficiently low (*e.g.*, below –48°C for hydrogen and below –242°C for helium), these gases also give the same type of Z—P plots as are shown by ammonia, carbon monoxide and methane at 0°C. On the other hand, if the temperature is sufficiently high, the Z—P plots of ammonia, carbon monoxide and methane will be similar to those of hydrogen and helium at 0°C, *i.e.*, the value of Z will increase continuously with increase in pressure.

Effect of Temperature on Deviations from Ideal Behaviour. The Z—P plots of nitrogen at different temperatures varying between –70° and 50°C, are shown in Fig. 2.

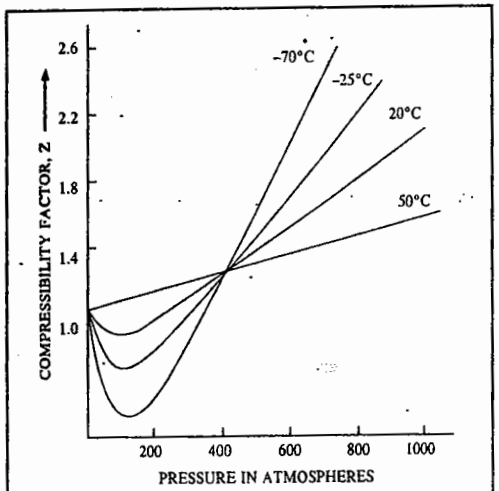

Fig. 2. Effect of temperature on deviation of nitrogen from ideal behaviour.

It is seen that as the temperature is raised, the dip in the curve becomes smaller and smaller. At 50°C, the curve seems to remain almost horizontal for an appreciable range of pressure varying between 0 and about 100 atmospheres, showing thereby that the compressibility factor Z becomes almost equal to unity under these conditions. In other words, the product PV remains constant and thus *Boyle's law is obeyed within this range of pressure at* 50°C. This temperature is called the **Boyle point** or **Boyle temperature.** Below this temperature, the value of Z at first decreases, approaches a minimum and then increases as the pressure is increased continuously. Above 50°C, the value of Z shows a continuous rise with increase in pressure.

The Boyle temperature is different for different gases. The Boyle temperature for helium is –250·4°C. Thus, at –250·4°C, helium obeys Boyle's law for an appreciable range of pressure. However, at any temperature below –250·4°C, the plot of Z *vs* P first shows a fall and then a rise as pressure is increased continuously. At a temperature above –250·4°C, however, Z shows a continuous rise with increase in pressure (see Z—P plot for helium in Fig. 1).

Explanation of the Deviations. In order to explain deviations from ideal behaviour, it is necessary to modify the kinetic theory of gases. The following two postulates of the kinetic theory do not appear to hold good under all conditions. Let us examine them more critically.

Postulate No. 1. *The volume occupied by the molecules themselves is negligibly small as compared to the total volume occupied by the gas.* This postulate can be justified only under ordinary conditions of temperature and pressure. It can be shown by calculations that in some of the common gases, the volume occupied by the molecules themselves, under ordinary conditions, is only 0·014 per cent of the total volume of the gas. This is a negligible fraction indeed. But, if the pressure becomes too high (say, 100 atmospheres or more), the total volume of the gas will decrease appreciably whereas the volume of the molecules will remain almost the same because the molecules are *incompressible.* Hence, under conditions of high pressure, the volume occupied by the gas molecules will no longer be negligible in comparison with the total volume of the gas.

The same thing happens when the temperature is lowered to a large exent. The total volume of the gas decreases considerably, no doubt, but the volume occupied by the molecules themselves remains practically the same. In this case, too, *the volume occupied by the molecules will no longer be negligible.* The postulate No. 1, therefore, is not valid at high pressures and low temperatures.

Postulate No. 2. *The forces of attraction between gas molecules are negligible.* This assumption is valid at low pressures or at high temperatures because under these conditions the molecules lie far apart from one another. But at high pressures or at low temperatures, the volume is small and molecules lie closer to one another. The intermolecular forces of attraction, therefore, are appreciable and *cannot be ignored.* Hence, the postulate No. 2 also does not hold under conditions of high pressure and low temperature.

It is necessary, therefore, to apply suitable corrections to the ideal gas equation so as to make it applicable to real gases.

EQUATIONS OF STATE FOR REAL (IMPERFECT) GASES

A number of equations of state have been suggested to describe the P–V–T relationship in real gases. The earliest and the best known equation is that of van der Waals.

van der Waals Equation of State

In 1873, van der Waals proposed his famous equation of state for a real, *i.e.*, imperfect gas. He modified the ideal gas equation by suggesting that the gas molecules were not mass points but behave like rigid spheres having a certain diameter and that there exist *intermolecular forces of attraction between them.* The two correction terms introduced by van der Waals are described below.

1. Correction due to volume of gas molecules. The ideal gas equation $PV=nRT$ is derived on the assumption that the gas molecules are mass points, *i.e.*, they do not have finite volume. van der Waals abandoned this assumption and suggested that a correction term nb should be subtracted from the total volume V in order to get the *ideal volume which is compressible.* In order to understand the meaning of the correction term nb, let us consider two gas molecules as unpenetrable and incompressible spheres, each of which has a diameter d, as shown in Fig. 3. It is evident that the centres of the two spheres cannot approach each other more closely than the distance d. For this pair of molecules, therefore, a sphere of radius d, and hence of volume $\frac{4}{3}\pi d^3$, constitutes what is known as the **excluded volume.** The excluded volume per molecule is thus half the above volume, *i.e.*, equal to $\frac{2}{3}\pi d^3$. The *actual volume* of one gas molecule of radius r is $\frac{4}{3}\pi r^3 = \frac{4}{3}\pi(d/2)^3 = \frac{1}{6}\pi d^3$.

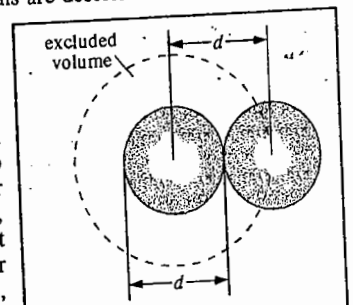

Fig. 3. Illustration of excluded volume.

$\therefore$ Excluded volume *per molecule* $= \frac{2}{3}\pi d^3 = 4\times\frac{1}{6}\pi d^3 = 4$ times the actual volume of the gas molecule

The excluded volume *per mole* of the gas would be $N_A\times 4\times\frac{4}{3}\pi r^3 = b$, where N_A is the Avogadro's number. The compressible volume per mole of the gas would thus be $V - b$. If volume V of the gas contains n moles, then the excluded volume would be nb. Hence the *ideal volume which is compressible* would be $V - nb$. The volume b per mole is also known as co-volume.

2. Correction due to intermolecular forces of attraction. In the derivation of the ideal gas equation, it was assumed that there are no intermolecular forces of attraction. Actually it is not so. In order to take into account the effect of intermolecular forces of attraction, let us consider a molecule lying somewhere in the midst of the vessel, as shown at the point C (Fig. 4). As can be seen, it is being attracted uniformly on all sides by the neighbouring molecules. These forces neutralize one another and there is no resultant attractive force on the molecule. However, as the molecule approaches the wall of the vessel, as shown at W, it experiences attractive forces from the bulk of the molecules behind it. Hence, *it will strike the wall with a lower velocity and will exert a lower pressure than it would have done if there was no force of attraction.* It is, therefore, necessary to

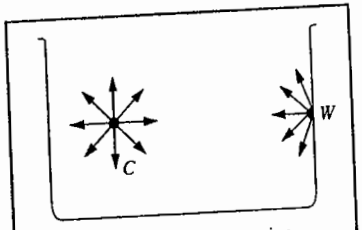

Fig. 4. Molecular attraction.

add a certain correction factor, p, to the pressure of the gas in order to get the *ideal pressure*. The correct pressure, therefore, should be $P + p$.

Calculation of the correction factor, p. The force of attraction exerted on a single molecule which is about to strike the wall evidently depends upon the *number of molecules per unit volume in the bulk of the gas, i.e.,* it depends directly upon the *density* of the gas. Further, the number of molecules striking the wall at any given instant also depends directly upon the *density* of the gas. Thus, the total inward attractive pull on the molecules which accounts for p is proportional to the square of the density (ρ) of the gas, *i.e.,*

$$p \propto \rho^2 \qquad ...(2)$$

But, density is inversely proportional to volume and if V is the volume occupied by *one mole* of a gas, the value of p for *one mole* of a gas will be inversely proportional to the square of volume. Hence,

$$p \propto 1/V^2 = a/V^2 \qquad ...(3)$$

where a is a constant depending upon the nature of the gas. The pressure correction factor p is also called the **internal pressure** of the gas.

The kinetic gas equation for *one mole* of a real gas, therefore, takes the form

$$(P + a/V_m^2)(V_m - b) = RT \qquad ...(4)$$

This is known as the **van der Waals equation.** The constants a and b are known as the **van der Waals constants.** These are characteristic of each gas.

Eq. 4 is valid for one mole of a gas only. If there are n moles of a gas occupying volume V, then, as illustrated above, the *excluded volume* will be given by nb and the compressible volume, will be $V - nb$. The pressure correction factor p for n moles, in the light of Eq. 2, will be proportional to $n^2\rho^2$, *i.e.,*

$$p \propto n^2\rho^2 \propto n^2 \times 1/V^2 = an^2/V^2 \qquad ...(5)$$

Hence, the van der Waals equation for n moles of a real gas becomes

$$(P + n^2a/V^2)(V - nb) = nRT \qquad ...(6)$$

Eq. 6 is more accurate than the ideal gas equation $PV=nRT$ for expressing the P–V–T behaviour of real gases.

The Dutch physicist J.D. van der Waals (1837 - 1923) was awarded the 1910 Physics Nobel Prize for his work on the equation of state for real gases.

The units for the van der Waals constants a and b depend upon the units in which P and V are expressed. It is evident from Eq. 5 that the constant a is expressed by the factor pV^2/n^2, *i.e.,* pressure $\times$ (volume)^2/mol^2. If pressure is expressed in atm and volume in dm^3, the value of a will be in dm^6 atm mol^{-2}. As regards b, it is incompressible volume per mole of a gas. Hence, it must have the same units as volume per mole, *e.g.,* dm^3 mol^{-1}.

The van der Waals constants for some common gases are given in Table 1.

TABLE 1

The van der Waals Constants for Some Common Gases

Gas	a (dm^6 atm mol^{-2})	b (dm^3 mol^{-1})	Gas	a (dm^6 atm mol^{-2})	b (dm^3 mol^{-1})
Ammonia	4·17	0·0371	Hydrogen chloride	3·67	0·0408
Argon	1·35	0·0322	Hydrogen bromide	4·45	0·0443
Carbon dioxide	3·59	0·0427	Methane	2·25	0·0428
Carbon monoxide	1·49	0·0399	Neon	0·21	0·0171
Chlorine	6·49	0·0562	Nitric oxide	1·34	0·0279
Ethane	5·49	0·0638	Nitrogen	1·39	0·0319
Ethylene	4·47	0·0571	Oxygen	1·36	0·0318
Helium	0·034	0·0237	Sulphur dioxide	6·71	0·0564
Hydrogen	0·246	0·0266	Nitrogen dioxide	5·28	0·0442

The constant a is a *measure of the van der Waals forces of cohesion* existing between the molecules of a given gas. The greater the value of a, the greater is the strength of the van der Waals forces. The values of a for hydrogen and helium are very small, being 0·024 and 0·246, respectively, indicating that the cohesive forces (van der Waals forces) in these gases are very weak. The values of a for ammonia, carbon dioxide, chlorine and sulphur dioxide are very high being 4·17, 3·59, 6·49 and 6·71, respectively. This shows that the van der Waals forces in these gases are very strong. The greater the value of a, the greater is the ease with which a gas can be liquefied.

Example 1. Calculate the pressure exerted by one mole of carbon dioxide gas in a 1·32 dm^3 vessel at 48°C using *(a)* the ideal gas equation and *(b)* the van der Waals equation. The van der Waals constants are : a=3·59 dm^6 atm mol^{-2} and b=0·0427 dm^3 mol^{-1}.

Solution : *(a)* For an ideal gas, $PV=nRT$, so that

$$P = \frac{nRT}{V} = \frac{(1\text{ mol})(0{\cdot}08206\text{ dm}^3\text{ atm K}^{-1}\text{ mol}^{-1})(321\text{ K})}{1{\cdot}32\text{ dm}^3} = \mathbf{19{\cdot}95\text{ atm}}$$

(b) For a van der Waals gas, from Eq. 6,

$$P = \frac{nRT}{V - nb} - \frac{n^2a}{V^2}$$

$$= \frac{(1\text{ mol})(0{\cdot}08206\text{ dm}^3\text{ atm K}^{-1}\text{ mol}^{-1})(321\text{ K})}{(1{\cdot}32\text{ dm}^3) - (1\text{ mol})(0{\cdot}0427\text{ dm}^3\text{ mol}^{-1})} - \frac{(1\text{ mol})^2(3{\cdot}59\text{ dm}^6\text{ atm mol}^{-2})}{(1{\cdot}32\text{ dm}^3)^2}$$

$$= 20{\cdot}62\text{ atm} - 2{\cdot}06\text{ atm} = \mathbf{18{\cdot}56\text{ atm}}$$

The experimental value of the pressure is 16·40 atm. Evidently, the van der Waals equation gives a better agreement with experiment than the ideal gas equation.

Discussion of the van der Waals Equation. We are now in a position to discuss the departure of real gases from ideal behaviour at different pressures and temperatures as depicted in Fig. 1.

1. When the pressure is not too high. When the pressure is not very high, the volume V_m will be sufficiently large and b may be ignored in comparison. The van der Waals equation for one mole of a gas, *viz.,*

$$(P + a/V_m^2)(V_m - b) = RT \qquad ...(7)$$

may then be written as $(P + a/V_m^2)V_m = RT$

or $$PV_m + a/V_m = RT \qquad ...(8)$$

or $$PV_m = RT - a/V_m \qquad ...(9)$$

Thus, the product PV_m is less than RT by an amount equal to a/V_m. As pressure increases, V_m decreases, a/V_m increases and, therefore, PV_m becomes smaller and smaller. This explains the dip in the isotherms of most of the gases, as shown in Fig. 1 for carbon monoxide, methane and ammonia.

2. When the pressure is too high. When the pressure is considerably high, the volume V_m will be quite small. Now it may not be possible to ignore b. But, as P is quite high, the pressure correction factor a/V_m^2 may become negligible in comparison with P in Eq. 7, which, therefore, reduces to

$$P(V_m - b) = RT \qquad ...(10)$$

or $$PV_m = RT + Pb \qquad ...(11)$$

Thus, PV_m is now greater than RT by an amount equal to Pb. As the pressure increases, the product Pb increases and, therefore, PV_m increases. This explains why the value of PV_m, after reaching a minimum, increases with further increase of pressure (Fig. 1).

It is evident from the above discussion that at ordinary temperatures, while the effect of the term a/V_m^2 is predominant at low pressures, that of Pb is predominant at high pressures. At some intermediate range of pressure, therefore, the two effects balance each other. In this range of pressure,

the gas shows the ideal behaviour. This explains the existence of a small horizontal portion in the isotherms of gases like carbon monoxide and methane, as shown in Fig. 1.

3. When the temperature is high. If, at a given pressure, the temperature is considerably high, the volume will become sufficiently large to make the value of a/V_m^2 negligibly small. At high temperature, b may also be negligible in comparison to V_m which is now sufficiently large. Under these conditions, the van der Waals equation approaches the ideal gas equation $PV_m=RT$. This explains why the deviations become less at high temperatures (Fig. 2).

4. Exceptional behaviour of hydrogen and helium. Since both hydrogen and helium have comparatively small masses, the attractive forces between their molecules are too small. This is indicated by very small values of the van der Waals constant a for these gases. As a result, the correction term a/V_m^2 due to the attraction factor remains negligible at ordinary temperatures. Thus,

$$PV_m = RT + Pb \qquad ...(12)$$

This explains why there is a continuous increase in PV_m with increase of pressure in the case of these two gases at ordinary temperatures (Fig. 1).

As can be seen from the above discussion, the van der Waals equation explains fairly satisfactorily the behaviour of real gases.

The Boyle Temperature. As already mentioned, the temperature at which a real gas obeys Boyle's law is known as the **Boyle temperature, T_B.** It is given by the expression

$$T_B = a/bR \qquad ...(13)$$

where a and b are the van der Waals constants. (Refer to Example 3 for the derivation of this expression).

Example 2. Calculate the Boyle temperature T_B for CO_2 gas, assuming it to be a van der Waals gas.

Solution : From Table 1, the van der Waals constants for CO_2 are

$$a = 3{\cdot}59 \text{ dm}^6 \text{ atm mol}^{-2} \quad \text{and} \quad b = 0{\cdot}0427 \text{ dm}^3 \text{ mol}^{-1}$$

$$T_B = \frac{a}{bR} = \frac{3{\cdot}59 \text{ dm}^6 \text{ atm mol}^{-2}}{(0{\cdot}0427 \text{ dm}^3 \text{ mol}^{-1})(0{\cdot}08206 \text{ dm}^3 \text{ atm K}^{-1} \text{ mol}^{-1})} = 1026 \text{ K}$$

Other Equations of State. Several other equations have been proposed from time to time to account for the *P-V-T* behaviour of real gases. A 'good' equation of state should be able to express the *P-V-T* behaviour under moderate ranges of pressure and temperature. Other criteria of a workable equation of state are its simplicity of form and the use of only a few adjustable constants or parameters. However, to represent the behaviour of gases to a sufficient degree of accuracy, the number of such parameters has to be at least more than two. A brief description of some of the equations of state, other than the van der Waals equation, is given below. In all these equations, the quantity of the gas is *one mole*.

Dieterici Equation. Dieterici introduced an exponential factor to account for the effect of molecular attraction on the pressure. He suggested the following relationship to account for the behaviour of real gases :

$$P\, e^{a/RTV_m}\, (V_m - b) = RT \qquad ...(14)$$

or

$$P\,(V_m - b) = RT\, e^{a/RTV_m} \qquad ...(15)$$

This equation agrees with the van der Waals equation at moderate pressures but differs appreciably at high pressures and gives more satisfactory agreement with the experimental data.

Berthelot Equation. Berthelot proposed the following empirical equation to explain the behaviour of real gases :

$$\{P + a/(TV_m^2)\}(V_m - b) = RT \qquad ...(16)$$

This equation is virtually the same as the van der Waals equation except that the correction term for intermolecular attraction is a/TV_m^2 instead of a/V_m^2.

The Berthelot equation has been found to be more accurate than the van der Waals equation for determining molar masses of gases.

Clausius Equation. Clausius, accounting for the variation of the van der Waals constant a with temperature, proposed the following equation :

$$\left(P + \frac{a}{T(V_m + c)^2}\right)(V_m - b) = RT \qquad ...(17)$$

where c is a new constant.

This equation is fairly satisfactory to explain the *P–V–T* relationship in some but not in all gases.

Redlich–Kwong Equation. This is a comparatively simple equation involving only two constants. In this equation also, the constant a is temperature-dependent. The equation may be written as

$$\left[P + \frac{a}{V_m(V_m + b)T^{1/2}}\right](V_m - b) = RT \qquad ...(18)$$

It has been shown that the above equation is the best two-parameter equation of state for real gases. Because of its simplicity and accuracy, it is being frequently used for expressing the *P–V–T* behaviour of gases.

The characteristic constants used in the Dieterici and the Redlich-Kwong equations for some common gases are listed in Table 2.

TABLE 2

Characteristic Constants of Dieterici and Redlich-Kwong Equations for Some Common Gases

Gas	Dieterici Equation		Redlich–Kwong Equation	
	a (dm^6 atm mol^{-2})	b (dm^3 mol^{-1})	a (dm^6 atm mol^{-2})	b (dm^3 mol^{-1})
Helium	0·045	0·0260	0·08	0.0170
Hydrogen	0·316	0·0289	1·44	0·0185
Neon	0·279	0·0191	1·47	0·0122
Argon	1·730	0·0350	16·80	0·0220
Nitrogen	1·730	0·0418	15·35	0·0268
Oxygen	1·748	0·0345	17·16	0·0221
Carbon monoxide	1·864	0·0427	16·98	0·0274
Carbon dioxide	4·620	0·0463	63·71	0·0296
Ammonia	5·390	0·0405	85·82	0·0259
Chlorine	8·340	0·0609	134·50	0·0390

It is important to keep in mind that the constants a and b are not strictly constant for a given gas. They vary somewhat with temperature and pressure. Further, the constant a appearing in the two equations is different dimensionally.

A feature common to all the equations of state described above is that regardless of the number of parameters occurring in them, they reduce to the ideal gas equation under conditions of low pressure. Thus, for all the above equations :

$$\lim_{P \to 0} (PV_m/RT) = 1 \qquad ...(19)$$

Virial Equation of State. The most general equation of state for real gases is the **virial equation,** proposed by **Kammerlingh-Onnes.** He expressed the product PV_m as a power series in $1/V_m$, as shown below :

$$PV_m = RT\left(1+\frac{B_2(T)}{V_m}+\frac{B_3(T)}{V_m^2}+\frac{B_4(T)}{V_m^3}+\cdots\cdots\right) \qquad \ldots(20)$$

where $B_2(T)$, $B_3(T)$, $B_4(T)$, etc., are the temperature-dependent second, third, fourth, etc., **virial coefficients,** respectively.

The various virial coefficients can be determined from the P–V–T data for real gases. It is possible to calculate them from a knowledge of intermolecular potential energy. Unfortunately, however, this potential energy is not accurately known and hence the calculation of higher virial coefficients is a formidable problem in theoretical chemistry. The first virial coefficient is, evidently, equal to RT.

The virial equation can also be expressed as a power series in pressure, as shown below :

$$PV_m = RT\{1 + A_2(T)P + A_3(T)P^2 + A_4(T)P^3 + \cdots\cdots\} \qquad \ldots(21)$$

where $A_2(T)$, $A_3(T)$, $A_4(T)$, etc., are new temperature-dependent virial coefficients. At low pressures, only the first virial coefficient (which is equal to RT) is important. It is always *positive.* It increases with increase in temperature. The second virial coefficient is *negative* at low temperatures, becomes zero at a particular temperature and then becomes increasingly positive as the temperature is raised continuously.

The temperature at which the second virial coefficient vanishes is known as the **Boyle temperature.** At this temperature while second virial coefficient disappears, the third, fourth and higher virial coefficients become insignificant so that PV_m becomes almost equal to RT. This implies that at the Boyle temperature, the gas behaves ideally over an appreciable range of pressure.

The physical significance of the virial coefficients is that the first coefficient neglects all molecular collisions, the second coefficient accounts for only bimolecular (binary) collisions and the third coefficient accounts for trimolecular (ternary) collisions, and so on.

Example 3. Show that for a van der Waals gas, the Boyle temperature $T_B = a/Rb$.

Solution : The Bolye temperature is the temperature at which the gas obeys Boyle's law, *i.e.*, the value of PV remains constant for an appreciable range of pressure from zero pressure. Mathematically, the Boyle temperature may be defined as the temperature at which $\underset{P\to 0}{\text{Limit}}[\partial(PV)/\partial P]_T = 0$.

The van der Waals equation for n moles of the gas may be written as

$$P = \frac{nRT}{V-nb} - \frac{n^2a}{V^2}$$

Multiplying throughout by V, we get

$$PV = \frac{nRTV}{V-nb} - \frac{n^2a}{V} \qquad \text{(Note this step)}$$

$$\therefore \quad \left[\frac{\partial(PV)}{\partial P}\right]_T = \left[\frac{nRT}{V-nb} - \frac{nRTV}{(V-nb)^2} + \frac{n^2a}{V^2}\right]\left(\frac{\partial V}{\partial P}\right)_T = 0 \text{ (at the Boyle temperature)}$$

Since $(\partial V/\partial P)_T$ is always negative (*i.e.*, it is not equal to zero), hence the expression in square brackets on the right hand side is equal to zero. Thus,

$$\frac{nRT}{V-nb} - \frac{nRTV}{(V-nb)^2} + \frac{n^2a}{V^2} = 0$$

$$\text{or } nRTV^2(V-nb) - nRTV^3 + n^2a(V-nb)^2 = 0$$

$$\text{or} \qquad n^2a(V-nb)^2 = -nRT[V^2(V-nb) - V^3]$$

$$\therefore \qquad RT = \frac{a}{b}\left(\frac{V-nb}{V}\right)^2 = \frac{a}{b}\left[1-\frac{nb}{V}\right]^2$$

Since at the Boyle temperature, $T = T_B$,

$$\therefore \qquad T_B = \frac{a}{Rb}\left[1-\frac{nb}{V}\right]^2$$

Since, when $P \to 0$, the volume V will be infinitely large so that $nb/V \to 0$, hence $T_B = a/Rb$

Intermolecular Forces

It is now fully established that forces of attraction exist between polar as well as nonpolar molecules. These intermolecular forces are known as **cohesive forces** or **van der Waals forces.** These forces originate from two types of interactions, *viz.*, 1. Dipole-Dipole Interaction and 2. Induced dipole - Induced dipole Interaction.

1. Dipole–Dipole Interaction. In the case of polar molecules which, though neutral, have permanent dipoles, the van der Waals forces are mainly due to electrical interaction between the dipoles known as dipole-dipole interaction. For instance, gases such as ammonia, sulphur dioxide, hydrogen fluoride, hydrogen chloride, etc., have permanent dipoles as a result of which there is appreciable dipole-dipole interaction between the molecules of these gases. The magnitude of this type of interaction depends upon the dipole moment of the molecule concerned. The greater the dipole moment, the greater is the dipole-dipole interaction. Because of the attractive interaction, these gases can be easily liquefied.

The average interaction energy of the two molecules with permanent dipole moments μ_1 and μ_2 is given by the expression

$$\text{Interaction energy, } \phi(r) = -2C/r^6 \qquad \ldots(22)$$

where $C = \frac{2}{3kT}\left[\frac{\mu_1\mu_2}{4\pi\varepsilon_0}\right]^2 r$ is their separation, k is Boltzmann constant and $4\pi\varepsilon_0$ is the permittivity factor of the medium.

2. Induced dipole–Induced dipole Interaction. London Forces or Dispersion Forces. As we know, the van der Waals forces exist even in nonpolar molecules such as O_2 and N_2 and also in nonpolar monoatomic molecules such as He, Ne, Ar, etc. This attraction is evident from the condensation of these gases into liquids at sufficiently high pressures and low temperatures. This could not be understood for several years.

In 1930, F. London provided a satisfactory explanation for the existence of forces of attraction between nonpolar molecules based on quantum mechanics. According to this view, electrons of a neutral molecule keep on oscillating with respect to the nuclei of the atoms. As a result of this, at a given instant, positive charge may be concentrated in one region and negative charge in another region of the same molecule. Thus, a nonpolar molecule may become momentarily self-polarised. This polarised molecule may induce a dipole moment in a neighbouring molecule with antiparallel orientation, as shown in Fig. 5.

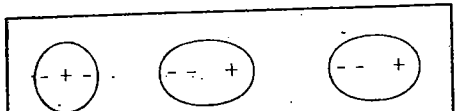

Fig. 5. Origin of cohesive forces in nonpolar molecules.

The electrostatic forces of attraction between induced dipoles and the original dipoles (due to electron oscillation) are known as the **London forces.** These forces are also called **dispersion forces** because the well known phenomenon of dispersion of light is also connected with these dipoles. The van der Waals attraction in nonpolar molecules is thus exclusively due to the London forces.

The average interaction energy in this case is given by

$$\text{Interaction energy, } \phi(r) = -C/r^6 \qquad \ldots(23)$$

where $C = \frac{3}{2}\alpha_1\alpha_2 \frac{(IE)_1(IE)_2}{(IE)_1 + (IE)_2}$. In this expression, $(IE)_1$ and $(IE)_2$ are the ionization energies of the two molecules. Other parameters have the same significance as mentioned above.

Nature of the van der Waals Interactions. Though the van der Waals constants a and b take into consideration the effect of attractive interactions in gaseous molecules, there is need for inquiring into the exact nature of these interactions. Since molecules are composed of positively charged nuclei and negatively charged electrons, whenever any two molecules come closer, interactions occur between the charge clouds of the nuclei and the electrons of the two molecules. At relatively large intermolecular distances, the attractive forces originating from attraction between electrons and atomic nuclei operate between the two molecules. At very small distances, however, the molecules strongly repel each other, the repulsion arising from the interaction between the similarly charged electron clouds. Thus, we expect the intermolecular potential energy to be composed of the long range *attractive term* and the short range *repulsive term*. One of the most widely used intermolecular potentials is the **Lennard-Jones (6–12) potential** given by

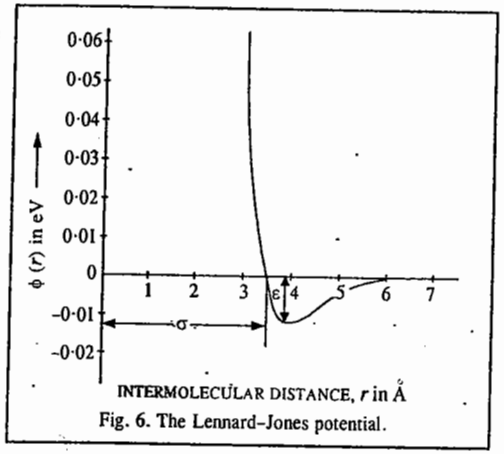

Fig. 6. The Lennard-Jones potential.

$$\phi(r) = 4\varepsilon\,[(\sigma/r)^{12} - (\sigma/r)^6] \qquad \ldots(24)$$

It is sketched in Fig. 6. Here, ε is the depth of the minimum in the potential energy curve, *i.e.*, ε is the *maximum* energy of attraction and σ is the intermolecular distance at which $\phi(r)=0$. For values of $r > \sigma$, the term $1/r^6$ predominates while for $r < \sigma$, the term $1/r^{12}$ predominates. The parameter σ is approximately equal to the sum of the average radii of the two molecules.

To understand the significance of ε, let us find the minimum of the Lennard-Jones potential by differentiating it and setting the derivative equal to zero :

$$d[\phi(r)]/dr = 4\varepsilon\,(-12\sigma^{12}r^{-13} + 6\sigma^6 r^{-7}) = 0, \text{ whence}$$

$$2\sigma^6 = r_m^6 \qquad \text{or} \qquad r_m = (2)^{1/6}\,\sigma = 1{\cdot}122\,\sigma$$

where r_m is the intermolecular distance corresponding to the *minimum* of the potential energy curve. At this distance, the forces of attraction and repulsion just balance each other. Substituting r by r_m in Eq. 24, we see that, at the potential energy minimum,

$$\phi(r_m) = 4\varepsilon\left[\frac{\sigma^{12}}{4\sigma^{12}} - \frac{\sigma^6}{2\sigma^6}\right] = 4\varepsilon\left(\frac{1}{4} - \frac{1}{2}\right) = -\varepsilon \qquad \ldots(25)$$

Second Virial Coefficient and Molecular Diameter. The second virial coefficient of the virial equation of state can be evaluated in terms of the volume of the gaseous molecule which permits easy determination of the molecular diameter of the gas. This is illustrated below.

Example 4. The second virial coefficient of an imperfect (non-ideal) gas is given by

$$B_2(T) = -2\pi N_A \int_0^\infty [e^{-\phi(r)/kT} - 1]r^2 dr$$

where $\phi(r)$ is the intermolecular potential for two molecules separated by the distance r. Evaluate it for a hard-sphere potential and illustrate how the diameter of a molecule can be calculated with its help.

Solution : If the two molecules are approximated as hard spheres or as hard billiard balls, the simplest hard-sphere potential (Fig. 7) is given by

$$\phi(r) = \begin{cases} 0, & r > d \\ \infty, & r < d \end{cases}$$

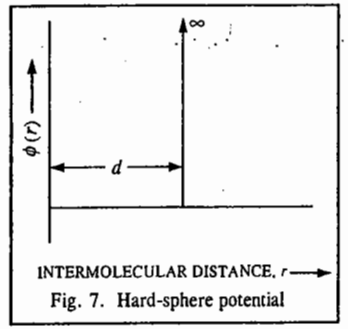

Fig. 7. Hard-sphere potential

where d is the sum of the radii of the molecules. Substituting this potential in the given expression, we have

$$B_2(T) = -2\pi N_A \int_0^d [e^{-\infty} - 1]r^2 dr - 2\pi N_A \int_d^\infty [e^0 - 1]r^2 dr$$

$$= -2\pi N_A \int_0^d -r^2 dr$$

[Since $e^0 = 1$, hence the second integral term vanishes]

$$= 2\pi N_A d^3/3 = 4N_A V_{\text{molecule}}$$

since the volume of one molecule is given by $V_{\text{molecule}} = (4/3)\pi(d/2)^3$.

Thus, knowing the second virial coefficient of the gas, its diameter d can be easily calculated.

CRITICAL PHENOMENA

Critical Constants of a Gas. The most characteristic property of gases is that their molecules lie far apart from one another and are in continuous rapid motion. Each molecule, therefore, leads almost an independent existence. This is particularly so when temperature is high and pressure is low. However, as the temperature of a gas is lowered, the kinetic energy of the molecules decreases. The volume occupied by the gas also decreases. At a sufficiently low temperature, some of the slow moving molecules cannot resist the force of attraction and they come closer and closer and ultimately the gas changes into the liquid state. Thus, liquefaction of gases results from decrease of temperature.

Increase of pressure has also the effect of bringing the gaseous molecules closer and closer to one another (due to decrease in volume). This is an additional helpful factor in converting a gas into liquid. Thus, *increase of pressure* and *decrease of temperature* both tend to cause liquefaction of gases. For instance, sulphur dioxide can be liquefied at -8°C if the pressure is 1 atm. But it can be liquefied even at a higher temperature of 20°C if the pressure is increased to 3·24 atm.

The effect of temperature, however, is more important than that of the pressure because for each gas there is a certain temperature above which it cannot be liquefied, no matter how high a pressure may be applied. This temperature is known as the *critical temperature*. Thus, the **critical temperature** *of a gas may be defined as that temperature above which it cannot be liquefied howsoever high the pressure may be.* For instance, the critical temperature of carbon dioxide is 31·1°C. This means that it is not possible to liquefy carbon dioxide above 31·1°C by any means.

At the critical temperature, a certain pressure is needed to liquefy the gas. This pressure is called the **critical pressure.** For instance, at 31·1°C, carbon dioxide can be liquefied under a pressure of 72·9 atm. Thus, the critical pressure of the gas is 72·9 atm.

The critical temperature of oxygen is -118°C and that of hydrogen is -240°C. These gases, therefore, cannot be liquefied at ordinary temperatures. Their critical pressures are 50·1 and 12·8 atm, respectively.

The volume occupied by *one mole* of a gas at its critical temperature and critical pressure is known as the **critical volume.** For example, critical volumes of carbon dioxide, oxygen and hydrogen are 94·0, 78·2 and 65·5 ml per mole, respectively.

The *P–V* Isotherms of Carbon Dioxide. The importance of critical temperature of a gas was first discovered by T. Andrews in his experiments on pressure-volume relationships (isotherms) of carbon dioxide gas at a series of temperatures. The isotherms of carbon dioxide determined by him at different temperatures are shown in Fig. 8. Consider first the isotherm at the lowest temperature, *viz.*, 13·1°C. The point *A* represents carbon dioxide in the gaseous state occupying a certain volume under a certain pressure. On increasing the pressure, its volume diminishes as is indicated by the curve *AB*. At *B*, which represents a pressure of 49·8 atm, liquefaction of the gas commences and thereafter a rapid decrease in volume takes place at the same pressure, as more and more of the gas is converted into the liquid state. At *C*, the gas has been completely liquefied. Now, as the liquid is only slightly compressible, further increase of pressure produces only a very small decrease in volume. This is shown by a steep line *CD* which is almost vertical.

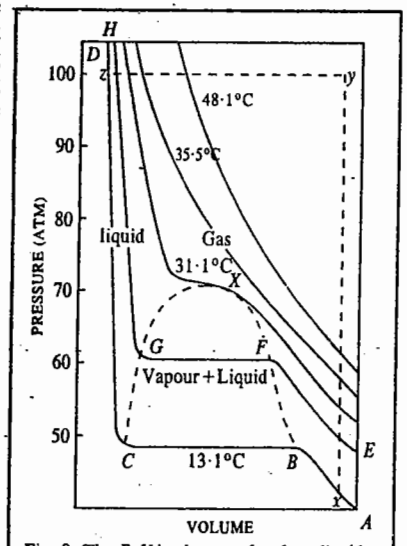

Fig. 8. The *P–V* isotherms of carbon dioxide.

Thus, along the curve *AB*, carbon dioxide exists as gas; along *BC*, it exists partly as gas and partly as liquid while along *CD*, it exists entirely as liquid. It may also be noted that a considerable decrease of volume (represented by *BC*) takes place when the gas changes into the liquid state at a constant pressure.

The isotherm *EFGH* at 21·5°C shows a similar behaviour except that now the liquefaction commences at a higher pressure and the horizontal portion *FG*, representing decrease in volume, becomes smaller. At still higher temperatures, the horizontal portion of the curve becomes shorter and shorter until at 31·1°C *it reduces just to a point* (represented by *X*). At this temperature, therefore, the gas passes into liquid state *imperceptibly*. Above 31·1°C, the isotherm is continuous. There is no evidence of liquefaction at all. Andrews concluded that if the temperature of carbon dioxide is above 31·1°C, it cannot be liquefied, no matter how high the pressure may be. He called 31·1°C as the **critical temperature** of carbon dioxide. Since then, other gases have been found to behave similarly. There is no fundamental difference between the so called 'permanent' gases such as hydrogen, oxygen, nitrogen, etc., and 'temporary' gases such as carbon dioxide, chlorine, hydrochloric acid, ammonia, etc. The difference lies in the fact that while the so-called 'permanent' gases have very low critical temperatures much below the ordinary range of temperature, the so called 'temporary' gases have critical temperatures well within the range of ordinary temperatures.

Continuity of State. A careful examination of the isotherms plotted in Fig. 8 shows that it is possible to convert liquid carbon dioxide into gas and vice-versa, *without any 'discontinuity'*, that is, without having, at any time, more than one phase present. On joining the ends of the horizontal portions of the various isotherms, a boundary curve *CGXFB*, represented by the dotted line, is obtained. At the top lies the critical point *X* (31·1°C). Within the area of the boundary curve, both liquid and gaseous states can coexist but outside this area, either liquid or gaseous state alone can exist. Suppose, a certain volume of carbon dioxide, represented by a point *x* on the 13·1°C isotherm *ABCD* is heated *at constant volume* to a temperature at which the pressure increases to a point *y*, lying above the critical pressure of the gas. Let the gas be now cooled at the *same pressure*. The temperature and volume both will decrease along *yz*. At *z*, the temperature is 21·5°C and carbon dioxide exists as liquid. During this transition from gas to liquid, *there has never been more than one phase present at any time.* As the temperature is decreased from *y* to *z*, the volume of the gas decreases *gradually* till the molecules are close enough for the van der Waals forces of attraction to cause their condensation into the liquid state. The process of transition from gaseous state to liquid state (or vice-versa), therefore, is regarded as **continuous.**

van der Waals Equation and Critical State. For one mole of a gas, the van der Waals equation

$$(P + a/(V_m)^2)(V_m - b) = RT \qquad ...(26)$$

may be written as

$$PV_m - Pb + \frac{a}{V_m} - \frac{ab}{(V_m)^2} - RT = 0 \qquad ...(27)$$

Multiplying by $(V_m)^2$ and dividing by P and rearranging in decreasing powers of V_m, it may be written as

$$(V_m)^3 - \left(b + \frac{RT}{P}\right)(V_m)^2 + \frac{a}{P}V_m - \frac{ab}{P} = 0 \qquad ...(28)$$

This is a cubic equation in the variable V_m and, therefore, for any single set of the values of P and T, there should be *three* values of V_m, all of which may be real or only one may be real and the other two imaginary. If, at a constant temperature, the values of V are plotted against P, then, according to Eq. 28, a curve similar to that marked I in Fig.9, should be obtained. It will be seen readily that, *for a certain pressure, there are three values of V marked as L, N and Q.* As the temperature increases, the isotherm moves up. When it is in position II, the three values of V get closer to one another. At a certain temperature (isotherm III), the three values of V become identical as shown by the point *X*. At a still higher temperature (isotherm IV), there is only one real value of V corresponding to a given pressure. Thus, below the critical temperature of a gas, the isotherm indicates three values of V for a given pressure, in accordance with the above equation.

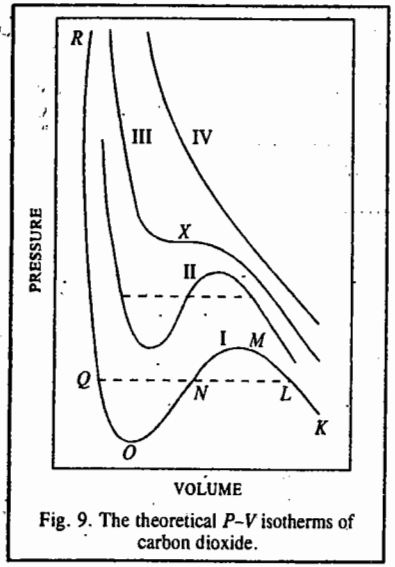

Fig. 9. The theoretical *P–V* isotherms of carbon dioxide.

It may be pointed out that the isotherms plotted in Fig. 9 are based on theoretical calculations of V corresponding to different values of P obtained by using the van der Waals equation. The isotherms for carbon dioxide, obtained by Andrews *experimentally*, were in close resemblance with these curves, with the difference that the wavelike portion *LMNOQ* (Fig. 9) was replaced by a horizontal line (*cf.* experimental isotherms of carbon dioxide represented in Fig. 8). Since then more careful experiments have shown that small portions corresponding to curves *LM* and *OQ* can be realized in practice also. These represent super-saturated vapour and superheated liquid, respectively.

As the temperature is raised, the loops become smaller and smaller, as already stated. At the critical point *X*, all the three values of V become identical. Since the temperature is now critical, this value of V represents the *critical volume* of the gas, that is,

$$V_m = V_{m.c.} \text{ or } (V_m - V_{m,c})^3 = 0 \qquad ...(29)$$

Expanding and writing in decreasing powers of V_m, we have

$$V_m^3 - 3V_{m,c}(V_m)^2 + 3(V_{m,c})^2V_m - (V_{m,c})^3 = 0 \qquad ...(30)$$

Eq. 30 must be identical with the van der Waals equation at critical temperature and pressure, which for 1 mole of the gas may be written as

$$(V_m)^3 - \left(b + \frac{RT_c}{P_c}\right)(V_m)^2 + \frac{a}{P_c}V_m - \frac{ab}{P_c} = 0 \qquad ...(31)$$

Hence, the coefficients of equal powers of V_m in Eqs. 30 and 31 must be equal to one another. Thus,

$$3V_{m,c} = b + RT_c/P_c \qquad ...(32)$$

$$3(V_{m,c})^2 = a/P_c \quad ...(33)$$

$$(V_{m,c})^3 = ab/P_c \quad ...(34)$$

From Eqs. 32, 33 and 34, the critical constants T_c, P_c and $V_{m,c}$ of a gas can be calculated in terms of the van der Waals constants a and b, as shown below.

Dividing Eq. 34 by Eq. 33, we have

$$V_{m,c} = 3b \quad ...(35)$$

Substituting this value in Eq. 33, we get

$$P_c = a/27b^2 \quad ...(36)$$

Inserting these values of $V_{m,c}$ and P_c in Eq. 32, we have

$$T_c = 8a/27Rb \quad ...(37)$$

Thus, knowing the critical constants of a gas, it is possible to calculate the van der Waals constants and *vice versa*.

Critical Compressibility Factor. The critical compressibility factor, Z_c, of a van der Waals gas is given by

$$Z_c = \frac{P_c V_{m,c}}{RT_c} = \frac{(a/27b^2)(3b)}{R[8a/27Rb]} = 0{\cdot}375 \quad ...(38)$$

Thus, we can test whether a gas behaves as a van der Waals gas by seeing whether its critical compressibility factor is equal to 0·375.

The critical constants of some common gases are given in Table 3. We see that although Z_c is less than 0·375, the discrepancy is rather small.

TABLE 3
Critical Constants of Gases

Gas	P_c (atm)	$V_{m,c}$ (dm^3 mol^{-1})	T_c (K)	Z_c
He	2·26	$57{\cdot}9\times10^{-3}$	5·2	0·307
Ne	26·9	$41{\cdot}7\times10^{-3}$	44·4	0·308
Ar	48·1	$75{\cdot}2\times10^{-3}$	150·7	0·292
Xe	58·0	$119{\cdot}0\times10^{-3}$	289·7	0·290
H_2	12·8	$65{\cdot}5\times10^{-3}$	33·0	0·309
O_2	50·1	$78{\cdot}2\times10^{-3}$	154·8	0·308
N_2	33·5	$90{\cdot}1\times10^{-3}$	126·2	0·291
CO_2	72·8	$94{\cdot}0\times10^{-3}$	304·2	0·274
NH_3	111·5	$72{\cdot}5\times10^{-3}$	405·0	0·243
CH_4	54·6	$98{\cdot}7\times10^{-3}$	190·6	0·288
C_2H_6	48·2	$148{\cdot}0\times10^{-3}$	305·4	0·284
C_2H_6	50·5	$127{\cdot}4\times10^{-3}$	282·4	0·278
C_6H_6	48·4	$254{\cdot}1\times10^{-3}$	562·3	0·266

Example 5.. Calculate the critical temperature of a van der Waals gas for which P_c is 100 atm and b is 50 cm^3 mol^{-1}.

Solution : From Eq. 36, $a = P_c\, 27\, b^2$

From Eq. 37, $T_c = \frac{8a}{27Rb} = \frac{(8)(P_c 27b^2)}{27Rb} = \frac{8P_c b}{R} = \frac{(8)(100\text{ atm})(0{\cdot}050\text{ dm}^3\text{ mol}^{-1})}{0{\cdot}08206\text{ dm}^3\text{ atm K}^{-1}\text{ mol}^{-1}} = 487{\cdot}2$ K

Example 6. The van der Waals constants of a gas are : a=0·751 dm^6 atm mol^{-2} and b=0·0226 dm^3 mol^{-1}. Calculate its critical constants.

Solution : $V_{m,c} = 3b = 3(0{\cdot}0226\text{ dm}^3\text{ mol}^{-1}) = 0{\cdot}0678$ dm^3 mol^{-1}

$$P_c = \frac{a}{27b^2} = \frac{(0{\cdot}751\text{ dm}^6\text{ atm mol}^{-2})}{27(0{\cdot}0226\text{ dm}^3\text{ mol}^{-1})^2} = 54{\cdot}5\text{ atm}$$

$$T_c = \frac{8a}{27Rb} = \frac{8(0{\cdot}751\text{ dm}^6\text{ atm mol}^{-2})}{27(0{\cdot}08206\text{ dm}^3\text{ atm K}^{-1}\text{ mol}^{-1})(0{\cdot}0226\text{ dm}^3\text{ mol}^{-1})} = 120\text{ K}$$

Example 7. A certain gas has the following values of its critical constants : P_c=45·6 atm, $V_{m,c}$=0·0987 dm^3 mol^{-1} and T_c=190·6 K. Calculate the van der Waals constants of this gas. Also, estimate the radius of the gas molecules assuming that they are spherical.

Solution :

$$b = \frac{V_{m,c}}{3} = \frac{0{\cdot}0987\text{ dm}^3\text{ mol}^{-1}}{3} = 0{\cdot}0329\text{ dm}^3\text{ mol}^{-1}$$

$$a = 3\,P_c\,(V_{m,c})^2 = 3(45{\cdot}6\text{ atm})(0{\cdot}0987\text{ dm}^3\text{ mol}^{-1})^2 = 1{\cdot}333\text{ dm}^6\text{ atm mol}^{-2}$$

The critical volume of one molecule ($v_{m,c}$) is, evidently, b/N_A where N_A is the Avogadro's number.

$$v_{m,c} = \frac{0{\cdot}0329\text{ dm}^3\text{ mol}^{-1}}{N_A} = \frac{0{\cdot}0329\times10^{-3}\text{ m}^3\text{ mol}^{-1}}{6{\cdot}022\times10^{23}\text{ mol}^{-1}} = 5{\cdot}46\times10^{-29}\text{ m}^3$$

The volume of a sphere $= (4/3)\pi r^3$ where r is its radius, so that $4/3\pi r^3 = 5{\cdot}46\times10^{-29}$ m^3

$$r = \left(\frac{3\times5{\cdot}46\times10^{-29}\text{ m}^3}{4\pi}\right)^{1/3} = 2{\cdot}35\times10^{-10}\text{ m}$$

$$= 235\text{ pm}$$

It may be of interest to know that normal boiling point T_b of a liquid is approximately two-thirds of its critical temperature T_c when both are expressed on Kelvin scale, *i.e.*,

$$T_b/T_c \approx \tfrac{2}{3} \quad ...(39)$$

Example 8. Estimate the critical temperature of *n*-hexane if its boiling point is 68·9°C.

Solution : From Eq. 39, $T_b = \frac{2}{3}T_c$

$$\therefore \quad T_c = \tfrac{3}{2}T_b = 3/2(68{\cdot}9 + 273)\text{ K}$$

$$= 512{\cdot}85\text{ K} = 239{\cdot}85°\text{C} \quad \text{(Experimental value is 234·7°C)}$$

It can also be shown that for a van der Waals gas, the Boyle temperature, $T_B = (27/8)T_c$.

Law (Principle) of Corresponding States

In 1881, van der Waals showed that if the pressure, volume and temperature of a gas are expressed in terms of its critical pressure, critical volume and critical temperature, we can obtain an important generalization called the principle of corresponding states.

Let $P/P_c = P_r$, $V_m/V_{m,c} = V_r$ and $T/T_c = T_r$ where P_r, V_r and T_r are called the *reduced pressure*, the *reduced volume* and the *reduced temperature*, respectively. Substituting in van der Waals equation for one mole of a gas, *viz.*,

$$(P + a/(V_m)^2)(V_m - b) = RT, \text{ we have}$$

$$\left(P_r P_c + \frac{a}{(V_r)^2(V_{m,c})^2}\right)(V_r V_{m,c} - b) = RT_r T_c \quad ...(40)$$

Substituting for P_c, $V_{m,c}$ and T_c from Eqs. 35, 36 and 37, we have

$$\left(\frac{aP_r}{27b^2} + \frac{a}{9(V_r)^2 b^2}\right)(3V_r b - b) = RT_r\left(\frac{8a}{27Rb}\right)$$

or $$(P_r + 3/V_r^2)\,(3V_r - 1) = 8T_r \qquad ...(41)$$

Eq. 41 involves neither R nor the van der Waals constants a and b. Hence, it is a general equation applicable to all substances. It follows from this equation that if *two or more substances have the same reduced temperature and the same reduced pressure, they would have the same reduced volume.* This statement is known as the **principle of corresponding states.**

Two or more substances having the same reduced temperature and the same reduced pressure and thus having the same reduced volume are said to be **in corresponding states.**

Example 9. Calculate the pressure exerted by one mole of CO_2 gas at 40°C, confined to a volume of 0·107 dm^3, using the law of corresponding states, given that the critical constants of the gas are $V_{m,c}$=0·0957 dm^3, T_c=304 K and P_c=73·0 atm.

Solution : From Eq. 41, $P_r = \dfrac{8T_r}{3V_r - 1} - \dfrac{3}{V_r^2} = \dfrac{8(T/T_c)}{3(V_m/V_{m,c}) - 1} - \dfrac{3}{(V_m/V_{m,c})^2}$

$$= \frac{8(313/304)}{3(0{\cdot}107/0{\cdot}0957) - 1} - \frac{3}{(0{\cdot}107/0{\cdot}0957)^2}$$

$$= \frac{(8)(1{\cdot}03)}{3 \times 1{\cdot}18 - 1} - \frac{3}{(1{\cdot}1)^2} = 3{\cdot}51 - 2{\cdot}40 = 1{\cdot}11$$

$$\therefore \quad P = P_r P_c = 1{\cdot}11 \times 73{\cdot}0 \text{ atm} = \mathbf{81{\cdot}03 \text{ atm}}$$

Example 10. Calculate the temperature and pressure that one mole of *(a)* ammonia and *(b)* helium will have in states corresponding to 1 mole of H_2 at 25°C and 1 atm pressure. For relevant data, use Table 3.

Solution : From Table 3, the critical constants of the given gases are

H_2 : T_c = 33·0 K P_c = 12·8 atm

He : T_c = 5·2 K P_c = 2·26 atm

NH_3 : T_c = 405·0 K P_c = 111·5 atm

For H_2 at 298 K and 1 atm pressure, the reduced parameters are

$$T_r = T/T_c = 298 \text{ K}/33{\cdot}0 \text{ K} = 9{\cdot}030$$

$$P_r = P/P_c = 1 \text{ atm}/12{\cdot}77 \text{ atm} = 0{\cdot}078$$

Ammonia and helium will be in their corresponding states when their reduced temperatures and reduced pressures are the same as those of H_2. Thus,

(a) For NH_3 : $T = T_r T_c = 9{\cdot}030 \times 405 \text{ K} = \mathbf{3657{\cdot}15 \text{ K}}$

$P = P_r P_c = 0{\cdot}078 \times 111{\cdot}5 \text{ atm} = \mathbf{8{\cdot}697 \text{ atm}}$

(b) For He : $T = T_r T_c = 9{\cdot}030 \times 5{\cdot}2 \text{ K} = \mathbf{46{\cdot}956 \text{ K}}$

$P = P_r P_c = 0{\cdot}078 \times 2{\cdot}26 \text{ atm} = \mathbf{0{\cdot}176 \text{ atm}}$

Example 13. Calculate the reduced pressure, reduced volume and reduced temperature of one mole of methane gas confined to a volume of 5 dm^3 under a pressure of 5 atm. Also calculate the temperature of the gas. The critical constants of methane are $V_{m,c}$ = 0·0988 dm^3 mol^{-1}, P_c = 54·6 atm, T_c=190·2 K.

Solution : $P_r = P/P_c = 5 \text{ atm}/54{\cdot}6 \text{ atm} = \mathbf{0{\cdot}1096}$

$V_r = V/V_{m,c} = 5 \text{ dm}^3 \text{ mol}^{-1}/0{\cdot}0988 \text{ dm}^3 \text{ mol}^{-1} = \mathbf{50{\cdot}607}$

From Eq. 41, $T_r = \dfrac{(P_r + 3/V_r^2)(3V_r - 1)}{8} = \dfrac{[0{\cdot}1096 + 3/(50{\cdot}607)^2][3 \times 50{\cdot}607 - 1]}{8} = \mathbf{2{\cdot}089}$

$\therefore \quad T = T_r T_c = (2{\cdot}089 \times 190{\cdot}2) \text{ K} = \mathbf{397{\cdot}3 \text{ K}}$

Molar Mass and Density of a Real Gas

We know that for a real gas, the PV versus P plot is not linear. Hence, ρ/P, *i.e.*, m/PV, is not independent of P. In order to calculate the density ρ and the molar mass M, we must obtain the value of ρ/P at P=0.

At low pressures, the van der Waals equation can be written as

$$P(V - nb) = nRT$$

or $$PV = n(RT + Pb) = (m/M)\,(RT + Pb)$$

$$\therefore \quad P = (m/V)\left[\frac{RT}{M} + \frac{Pb}{M}\right] = \rho\left[\frac{RT + Pb}{M}\right]$$

$$\therefore \quad \frac{\rho}{P} = \frac{M}{RT + Pb} = \frac{M/RT}{1 + Pb/RT}$$

Since $\dfrac{1}{1 + Pb/RT} = (1 + Pb/RT)^{-1} = 1 - Pb/RT$ when pressures are low, hence

$$\frac{\rho}{P} = \frac{M}{RT}\left(1 - \frac{Pb}{RT}\right) = \frac{M}{RT} - \frac{Mb}{(RT)^2}P$$

From this equation, we see that a plot of ρ/P verus P would be a straight line with slope = $Mb/(RT)^2$ and intercept = M/RT. The molar mass, M, is obtained from the intercept since as $P \to 0$, the gas behaves ideally and M is independent of P.

LIQUEFACTION OF GASES

As has already been explained, it is necessary to cool a gas below its critical temperature before it can be liquefied. In the case of a gas like ammonia, chlorine, sulphur dioxide or carbon dioxide, which has a fairly high critical temperature (Table 3), the application of a suitable pressure alone is sufficient to cause liquefaction. Gases such as hydrogen, oxygen, nitrogen and helium which have very low critical temperatures (Table 3) could not be liquefied by this simple technique. As the significance of critical temperature was not properly understood at that time, these gases were regarded as 'permanent'. But, now it is known that these gases can also be liquefied *if they are first cooled below their respective critical temperatures and then compressed.*

Two principles are usually applied in cooling gases below their critical temperatures.

1. Joule–Thomson Effect. The British physicists James P. Joule (1818-1889) and William Thomson (1824-1907), later honoured as Lord Kelvin, observed that when a gas under high pressure is made to expand into a region of low pressure, it suffers a fall in temperature. This phenomenon is known as the **Joule–Thomson effect** (see Chapter 13).

The Joule–Thomson effect offers further support to the view that attractive forces do exist between gas molecules. As the gas expands, the molecules fall apart from one another. Therefore, work has to be done in order to overcome the cohesive or attractive forces which tend to hold the molecules together. Thus work is done by the system at the expense of the kinetic energy of the gaseous molecules. Consequently, the kinetic energy decreases and since this is proportional to temperature, cooling results. It may be noted that in this case no external work has been done by the gas in expansion.

Experiment has shown that gases become cooler during the Joule–Thomson expansion only if they are below a certain temperature known as the **inversion temperature, T_i.** The inversion temperature is characteristic of each gas. It is related to the van der Waals constants a and b of the gas concerned by the following expression :

$$T_i = 2a/Rb \qquad ...(42)$$

At the inversion temperature, there is no Joule-Thomson effect. Thus, if a gas under pressure passes through a porous plug and expands adiabatically into a region of very low pressure at the inversion temperature, there is neither fall nor rise in temperature. If, however, the expansion takes place *above* the inversion temperature, there is a small *rise* of temperature and if it takes place *below* the inversion temperature there is a small fall of temperature.

In most gases, the inversion temperature lies within the range of ordinary temperatures, Hence, they get cooled in the Joule-Thomson expansion. Hydrogen and helium, however, have very low inversion temperatures. Thus, at ordinary temperatures, these gases get warmed up instead of getting cooled in the Joule-Thomson expansion. But if these gases are first cooled to their respective inversion temperatures, then these gases also get cooled on expansion in accordance with the Joule-Thomson effect.

2. Adiabatic Expansion Involving Mechanical Work. When a gas is made to expand against a pressure, as in an engine, it does some external work also at the expense of its kinetic energy which decreases. Hence, there is a fall of temperature. This principle, combined with Joule-Thomson effect, has been used in **Claude's process** for the liquefaction of air. George Claude (1870-1960) was a French engineer.

Production of Low Temperatures by Adiabatic Demagnetization of a Paramagnetic Substance. Very low temperatures in the vicinity of absolute zero have been obtained by *(i)* the Joule-Thomson expansion of hydrogen *(ii)* using liquid helium and *(iii) making use of the magnetic properties of paramagnetic substances* such as the salts of the rare earths. The paramagnetism of these substances is due to the presence of odd (unpaired) electrons. The method of adiabatic demagnetization of a paramagnetic substance, first suggested in 1926 by P. Debye and, independently in 1927 by W.F. Giauque, is based on the fact that the temperature of a thermally isolated paramagnetic substance drops when it is demagnetized. This can be best understood by considering the following equation for a magnetic system :

$$dS = \frac{C_B dT}{T} + \varepsilon_0 V \left(\frac{\partial M}{\partial T}\right)_B dB \qquad ...(43)$$

where M is the extent of magnetization in the presence of an external magnetic field B ; V is the volume, ε_0 is the permeability and C_B is the heat capacity of the system at constant magnetic field B.

The extent of magnetization of a paramagnetic substance at constant magnetic field B always decreases with increase in temperature T so that the partial derivative $(\partial M/\partial T)_B$ is always negative. Hence, when the substance is demagnetized reversibly and adiabatically (so that dB is negative and $(dS=0)$, we get

$$\frac{dT}{T} = -\frac{\varepsilon_0 V}{C_B}\left(\frac{\partial M}{\partial T}\right) dB \qquad ...(44)$$

or

$$\left(\frac{\partial T}{\partial B}\right)_S = -\frac{\varepsilon_0 TV}{C_B}\left(\frac{\partial M}{\partial T}\right)_B \qquad ...(45)$$

Eq. 45, which forms the basis of the principle of adiabatic demagnetization, gives the rate of change of temperature with magnetic field upon reversible adiabatic demagnetization. We see from Eq. 44 that dT/T is negative so that dT is also negative. Thus, a paramagnetic substance cools down upon adiabatic demagnetization.

The temperature-entropy (T—S) curve for a paramagnetic salt, such as gadolinium sulphate octahydrate, is shown in Fig. 10.

In the unmagnetized state (when $B=0$), the spins of the unpaired electrons of the paramagnetic material are oriented in a random manner in all directions. Thus, there is a disorder. When, however, the substance is magnetized, the spins and hence the magnetic moments associated with them, tend to align themselves with the magnetic field thereby reducing disorder. In other words, the unmagnetized substance has greater entropy than the magnetized substance at a given temperature. This is apparent from Fig. 10.

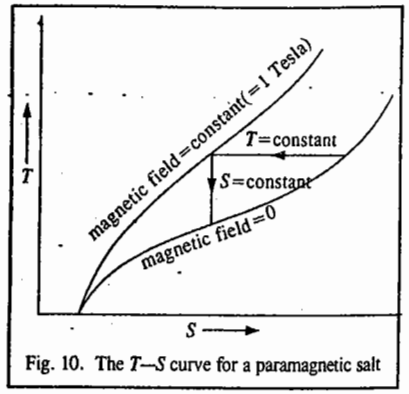

Fig. 10. The T—S curve for a paramagnetic salt

In the first stage of the process, the paramagnetic substance kept in contact with a liquid helium bath at 1 K, is *isothermally magnetized.* Under isothermal conditions (T=constant, $dT=0$), Eq. 43 reduces to

$$TdS = \varepsilon_0 TV(\partial M/\partial T)_B dB \qquad ...(46)$$

Since dB is positive and $(\partial M/\partial T)_B$ is always negative, an increase in B results in an overflow of heat and hence a *decrease* in entropy. This is shown by the T=constant line on the $T-S$ curve of Fig. 10.

In the second stage, the substance is removed and *adiabatically demagnetized.* As mentioned earlier, it cools. This is shown by the S=constant line on the $T-S$ curve. The extent of cooling depends upon the strength of the applied magnetic field, the intensity of magnetization and the heat capacity of the paramagnetic salt.

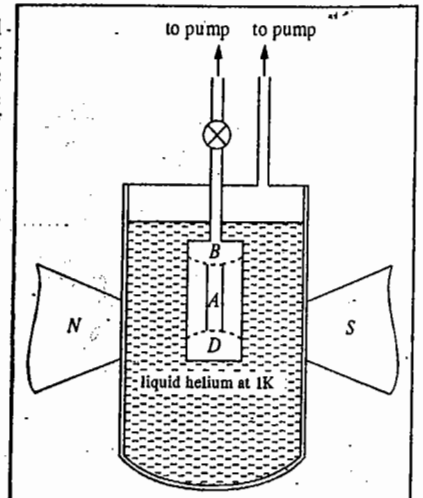

Fig. 11. Experimental set-up for adiabatic demagnetization of a paramagnetic salt.

The experimental set-up for adiabatic demagnetization is shown in Fig. 11. The paramagnetic substance A is suspended inside a cryostat which is cooled by liquid helium boiling under reduced pressure. During the first isothermal stage, the space D contains helium gas; this space allows heat exchange between the substance and liquid helium. During the second stage, the space D is evacuated to establish adiabatic conditions. The cycle of isothermal magnetization, followed by adiabatic demagnetization, is repeated to obtain milli degree temperatures.

Even in the absence of external field B, which is of the order of 1-4 tesla, there is a local magnetic field (or residual field) B_0 present in the paramagnetic substance which arises primarily from magnetic interactions between the dipoles. B_0 is very small as compared with B, its magnitude being of the order of 0·01 tesla. If T_1 is the initial temperature, then the final temperature T_2 is given by the formula

$$T_2/T_1 = B_0/B \qquad ...(47)$$

Suppose $T_1 = 1$ K, $B_0 = 10^{-2}$ tesla and $B = 1$ tesla, then $T_2 \approx 10^{-2}$ K.

We might mention here that the process of adiabatic demagnetization can also be applied to the magnetic moments of *nuclei*. The application of adiabatic demagnetization to nuclear magnetic moments has allowed a temperature of 10^{-6} K to be reached. However, we must remember that *it is not possible to attain absolute zero of temperature by means of a succession of adiabatic cooling processes.* This can be seen from the $T-S$ curve of Fig. 10.

The American chemist W.F. Giauque (1895–1982) was awarded the 1949 Chemistry Nobel Prize for his contributions to the magnetic behaviour of substances at extremely low temperatures.

I. Review Questions

1. Derive the van der Waals equation for describing the *P-V-T* relationship in real gases. Illustrate how this equation satisfactorily explains the departure of real gases from ideal behaviour at different pressures and temperatures.
2. Define excluded volume. Show that excluded volume, designated as b, is four times the actual volume of the gas molecules.
3. Define Boyle temperature. Derive an expression for the Boyle temperature of a van der Waals gas.
4. Write the virial equation of state of a real gas as a power series in *(i)* $1/V_m$ and *(ii)* pressure. Comment briefly.
5. What are van der Waals forces? Discuss them briefly. Using the concept of Lennard-Jones (6 - 12) potential, bring out the exact nature of van der Waals interactions.
6. Derive the expressions for the critical pressure, critical temperature and critical volume of a van der Waals gas.
7. State the principle of corresponding states. Derive an expression interconnecting P_r, V_r and T_r for a van der Waals.
8. Describe the two common methods for producing low temperatures. How have they been used in the liquefaction of gases?
9. Define inversion temperature. How is it related to van der Waals constants ?
10. Discuss production of low temperatures by adiabatic demagnetisation of a paramagnetic substance. Describe briefly the experimental set-up used in the process.

II. Problems

1. Using van der Waals equation, calculate the pressure exerted by one mole of carbon dioxide when it occupies a volume of 0·05 dm^3 at 100°C, given that a=3·59 dm^6 atm mol^{-2} and b=0·0427 dm^3 mol^{-1}. **[Ans. 2041 atm]**
2. Calculate the temperature at which 10 moles of CO_2 (assuming that it is a van der Waals gas) occupies a volume of 5·0 dm^3 under a pressure of 50·0 atm. Given : a=3·59 dm^6 atm mol^{-2}, b=0·4367 dm^3 mol^{-1}. **[Ans. 359 K]**
3. Calculate the pressure of 0·60 mole of NH_3 gas in a 3·00 dm^3 vessel at 25°C *(a)* using the ideal gas equation *(b)* using the van der Waals equation. The van der Waals constants are a = 4·17 dm^6 atm mol^{-2}, b = 0·0371 dm^3 mol^{-1}. **[Ans. *(a)* 4·9 atm *(b)* 4·8 atm]**
4. Calculate the Boyle temperature for oxygen assuming that it is a van der Waals gas. Given : a=1·36 dm^6 atm mol^{-2}, b=0·0318 dm^3 mol. **[Ans. 521·17 K]**
5. Assuming that C_2H_6 behaves as a Dieterici gas, calculate the pressure exerted by 10 moles of the gas confined to a volume of 4·86 dm^3 at 300 K. Given : a=6·97 dm^6 atm mol^{-2}, b=0·0694 dm^3 mol^{-1}. **[Ans. 33 atm]**
6. Calculate the critical constants of C_2H_2 gas using the van der Waals constants a=4·390 dm^6 atm mol^{-2}, b=0·05136 dm^3 mol^{-1}. **[Ans. V_c=0·1541 dm^3 mol^{-1} ; P_c=61·638 atm ; T_c=308·48 K]**
7. Calculate the reduced pressure, reduced volume and reduced temperature of one mole of carbon dioxide gas confined to a volume of 5 dm^3 under a pressure of 5 atm. Also calculate the temperature of the gas. The critical constants of carbon dioxide are $V_{m,c}$=0·094 dm^3 mol^{-1}, P_c=72·8 atm, T_c=304·2 K. **[Ans. P_r=0·069 ; V_r=53·19 ; T_r=1·387 ; T=421·9 K]**
8. The van der Waals constants a and b for a gas are respectively, 0·045 dm^6 atm mol^{-2} and 0·026 dm^3 mol^{-1}. Calculate the inversion temperature of the gas. **[Ans. 42·18 K]**

CHAPTER 11

THE LIQUID STATE

Gaseous, Liquid and Solid States. Of the three states of matter, the solid state in crystalline form exhibits a complete ordered arrangement of molecules, atoms or ions as the case may be and the gaseous state at high temperature and low pressure exhibits complete disorder or randomness. The liquid state lies in between these two extremes of order and disorder. The two-dimensional representation of the three states of matter is shown in Fig. 1.

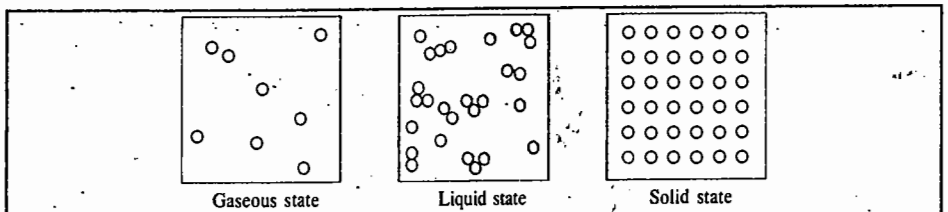

Fig. 1. Two-dimensional arrangement of molecules in gases, liquids and crystalline solids.

In solids, there is close packing of molecules or atoms or ions. This arrangement exists to some extent in the liquid state. In gases, there is no such arrangement of close packing of molecules or atoms considered as spheres.

The definite and ordered arrangement of the constituents of a solid extends over a large distance. This is termed as long range order. The liquids exhibit only a short range order while gases show no order at all.

A liquid may be regarded as a condensed gas or a molten solid. In a solid, the molecules are rigidly fixed and, therefore, it has a definite shape and a definite volume. In a gas, on the other hand, the molecules have random motion and, therefore, it has neither a definite shape nor a definite volume. In a liquid, the molecules are not as rigidly fixed as in solids. They have some freedom of motion which, however, is much more restricted than that in gases. A liquid, therefore, has a definite volume although not a definite shape. It is much less compressible and far denser than a gas.

Since the molecules in a liquid are not far apart from one another, the intermolecular forces are fairly strong. As we shall see shortly, characteristic properties of liquids arise from the nature and the magnitude of these intermolecular forces.

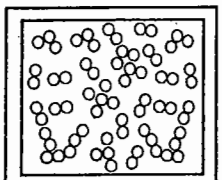

Fig. 2. The liquid as a random congregation of molecules and holes.

Vacancy Theory of Liquids. A liquid is generally less dense than the corresponding solid implying thereby that the intermolecular space in a liquid is more than that in a solid. In 1961, Ering and Ree proposed a simple theory that the intermolecular space in a liquid is not randomly distributed but contains molecular-sized 'holes' or vacancies. The liquid is considered as a random congregation of molecules and these holes, as shown in Fig. 2.

It is assumed that the molecules surrounding a given hole can easily jump into it and are thus 'gas-like' whereas those in immediate contact with the hole are 'solid-like'. If V_l and V_s are the respective molar volumes of the liquid and the solid, then,

$$\frac{\text{Number of holes}}{\text{Number of molecules}} = \frac{V_l - V_s}{V_s} \qquad ...(1)$$

The probability that a hole confers gas-like properties on its neighbouring molecules is proportional to the fraction of the neighbouring positions occupied by the molecules. For a random distribution of holes, this ratio is given by V_s/V_l. Hence,

$$x_g = \left(\frac{V_l - V_s}{V_s}\right)\left(\frac{V_s}{V_l}\right) = \frac{V_l - V_s}{V_l} \qquad ...(2)$$

and

$$x_s = V_s/V_l \qquad ...(3)$$

where x_g and x_s are the mole fractions of the gas-like and the solid-like molecules, respectively. Based on these ideas, Ering and Ree calculated the melting point, boiling point, critical constants and some typical thermodynamic properties of argon. The agreement of theory with experiment was found to be quite satisfactory.

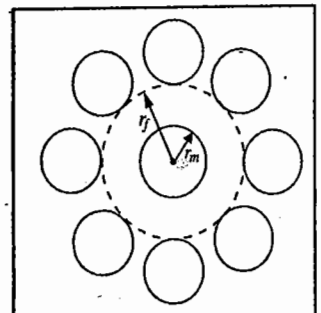

Fig. 3. The free volume in a liquid.

Free Volume in a Liquid. In contrast to a gas, in which under ordinary pressure the molecules move over considerable distances before colliding with one another, in a liquid the molecules move over an infinitesimally small distance before colliding with one another. This is due to the fact that each molecule in a liquid is tightly surrounded by almost 10 to 12 neighbours forming a sort of spherical cage which can be approximated to a spherical box of radius r_f which is only slightly bigger than the enclosed molecule of radius r_m (Fig. 3). It is evident that the centre of the caged molecule can move about in a very small volume. This volume for a mole of molecules is known as free volume.

It can be shown thermodynamically that the magnitude of the free volume is approximately 0·37 cm^3. The free volume per molecule is thus equal to 0·61 $Å^3$. Equating this to the volume of a sphere of radius r_f, we have

$$(4/3)\pi r_f^3 = 0{\cdot}61\ Å^3 \quad \text{whence} \quad r_f = 0{\cdot}54\ Å$$

The radius r_f represents the average distance traversed by a molecule between collisions with the walls of the spherical cage. If we assume that the average speed of the molecules of the liquid is $\approx 3\times10^4$ cm s^{-1}, then the molecule would make about $5{\cdot}6\times10^{12}$ collisions per second with the spherical cage.

Physical Properties of Liquids

The most important physical properties of liquids are :

1. Vapour Pressure 2. Surface Tension 3. Viscosity and 4. Refraction.

VAPOUR PRESSURE

While deriving kinetic gas equation it was assumed that, at a particular temperature, the gaseous molecules have a particular velocity known as the root mean square velocity. This is so in the case of liquid molecules as well. Only a few liquid molecules have lower or higher velocities, *i.e.*, lower or higher kinetic energies. The energy distribution of molecules in a liquid is shown in Fig. 4.

It is evident from the figure that the number of molecules with high kinetic energies, as shown by the shaded area *ABCD* below the dotted curve, is small. This number, however, increases with

rise in temperature, as shown by the shaded area *FBCE* below the bold line curve. The molecules with higher energies are of importance in determining the tendency of a liquid to escape as vapour into a free space if available.

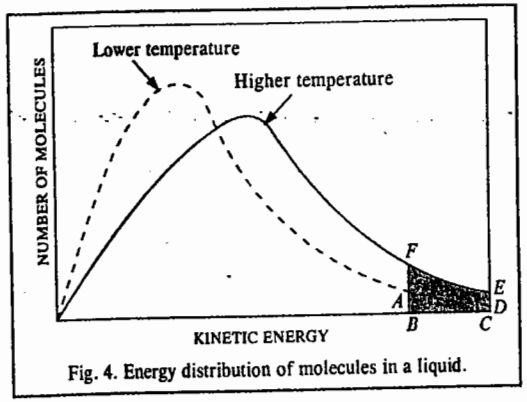

Fig. 4. Energy distribution of molecules in a liquid.

In order to understand this, imagine a liquid contained in an evacuated vessel connected to a manometer so that any pressure that is developed in the free space above the liquid can be measured. The entire system is placed in a thermostat maintained at a constant temperature.

Consider a molecule somewhere in the body of the liquid. It is being attracted by the molecules surrounding it. Since the attractive forces act equally in all directions, the net effect is zero and, therefore, the translatory motion of the molecule is not affected at all.

Now, consider a similar molecule near the surface of the liquid. In this case, the attractive forces operate more strongly in the downward direction because there are many more molecules below than in the space above it. This unbalanced attractive force tends to pull the molecule downwards towards the main bulk of the liquid. Thus, the tendency of the molecule, as a result of its translational energy, to pass into the free space above the surface of the liquid, is being prevented by the inward molecular attraction. However, if this molecule is the one associated with a higher kinetic energy corresponding to the shaded portion *ABCD* of the graph (Fig. 4) at a given temperature, it will be able to break through the forces of molecular attraction and escape into the free space as vapour. Thus, the molecules of a liquid with energy higher than the average energy have a greater tendency to pass into the vapour state. Since the fraction of such molecules increases with rise in temperature (*cf.* shaded portion *FBCE* in Fig. 4), it follows that a liquid has a greater tendency to pass into vapour state with rise in temperature. The escape of liquid molecules into vapour state constitutes a **change of phase.**

Let us suppose that in this phase-change process, all the molecules with high kinetic energies represented by the shaded portion of the graph in Fig. 4 escape from the liquid into the vapour phase. The average kinetic energy of the remaining molecules in the liquid phase will, evidently, go down. Hence, the temperature of the liquid shall fall. We conclude, therefore, that a liquid on evaporation cools itself.

Some of the escaping molecules may return to the body of the liquid, *i.e.*, may change back into liquid state. Ultimately, equilibrium is established at each temperature so that the number of molecules leaving the surface in a given time is equal to the number of molecules returning to it. This is called **phase equilibrium.**

The vapour molecules confined in the space above the liquid strike against the walls of the vessel and thus register a pressure on the manometer attached to the vessel. This pressure at the time when phase equilibrium has been established is found to be constant at a given temperature and is known as vapour pressure. Thus, **vapour pressure** *of a liquid at a given temperature is defined as the pressure of the vapour in equilibrium with the liquid at that temperature.*

The vapour pressure measures the ease with which a liquid can be converted into vapour, *i.e.*, it is a measure of the volatility of the liquid. Stated in other terms, *it is a measure of the escaping tendency of molecules from the surface of the liquid.*

As the temperature rises, the number of molecules escaping from the liquid surface increases and there is increase in the number of vapour molecules in the space above the liquid when phase equilibrium is attained. Hence, vapour pressure of a liquid increases with rise in temperature.

Heat of Vaporisation. The molecules in a liquid are much closer to one another than those in a gas. Intermolecular forces of attraction, therefore, are much stronger in liquids than in gases. When a liquid changes into vapour state, these intermolecular forces have to be overcome. Hence, a certain amount of energy has to be supplied to the liquid in the form of heat. The quantity of heat which has to be supplied to one mole of a liquid at its boiling point so as to change it into vapour state at the same temperature, is known as the **molar heat of vaporisation**, ΔH_{vap}, of the liquid at that temperature.

The molar heat of vaporisation of water at 100°C is 40·67 kJ. The same amount of heat is evolved when one mole of steam condenses into liquid water at 100°C.

The molar heats of vaporisation of some liquids together with their boiling points are given in Table 1.

TABLE 1

Molar Heats of Vaporisation and Normal Boiling Points of Liquids

Liquid	Molar heat of vaporisation ΔH_{vap} (kJ mol^{-1})	Boiling point T_b (K)	$\Delta H_{vap}/T_b$ (J mol^{-1} K^{-1})
Water	40·67	373	109·0
Ethyl alcohol	39·54	351	112·8
Acetic acid	24·31	391	62·2
Benzene	31·38	353	88·9
Carbon tetrachloride	29·96	350	85·6
Ether	25·64	307·6	83·3
Hydrogen fluoride	25·23	377	66·9

As can be seen, the molar heat of vaporisation of water is much higher than that of ether, benzene or carbon tetrachloride. This indicates that intermolecular forces of attraction operating in water are much stronger than those operating in most of the organic liquids.

The values of $\Delta H_{vap}/T_b$ for the various liquids are also included in Table 1 in an appropriate column.

The molar heat of vaporisation of a liquid expressed in joules divided by the normal boiling point of the liquid on the absolute scale is approximately equal to 88. This is known as **Trouton's rule** and may be expressed as

$$\Delta H_{vap}/T_b \approx 88 \text{ J mol}^{-1} \text{ K}^{-1} \quad \ldots(4)$$

Eq. 4 is only approximate as the values of $\Delta H_{vap}/T_b$ are seen to vary over a wide range, *viz.*, from about 60 to about 110 J mol^{-1} K^{-1} (Table 1). The deviations from Trouton's rule, thus, occur in both directions. The quantity $\Delta H_{vap}/T_b$ is also called **entropy of vaporisation**, ΔS_{vap}. Trouton's rule is useful for estimating the heat of vaporisation of a liquid if its boiling point is known.

Example 1. The boiling point of *n*-heptane is 36°C. Estimate its molar heat of vaporisation assuming that it obeys Trouton's rule.

Solution : From Trouton's rule,

$$\Delta H_{vap}/T_b = 88 \text{ J mol}^{-1} \text{ K}^{-1}$$

$$\Delta H_{vap} = (88 \text{ J mol}^{-1} \text{ K}^{-1})(309 \text{ K}) = 27192 \text{ J mol}^{-1} = 27{\cdot}192 \text{ kJ mol}^{-1}$$

SURFACE TENSION

Surface Tension. The existence of strong intermolecular forces of attraction in liquids gives rise to another important property known as **surface tension**. The phenomenon of surface tension may be explained by reference to Fig. 5.

Consider a molecule P somewhere in the body of the liquid. This is attracted equally in all directions by other molecules which surround it as shown and, therefore, cancel the effect of one another.

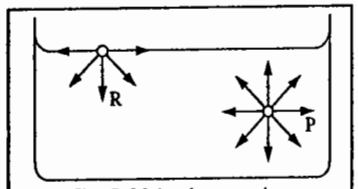

Fig. 5. Molecular attraction.

Consider, next, a molecule R at the surface of the liquid. The downward attractive forces are greater than the upward forces because there are more molecules of the liquid below than in the air above the surface. These unbalanced attractive forces acting downward tend to draw the surface molecules into the body of the liquid and, therefore, tend to reduce the surface to a minimum.

It is well known that *forces of attraction tend to decrease the energy of a system*. In the present case, the attractive forces are more predominant in the bulk of the liquid than at the surface. Therefore, the molecules in the bulk of the liquid are associated with lower energy than those at the surface. In other words, the molecules at the surface possess greater energy than those in the bulk. It is the extra energy of surface molecules which gives rise to their tendency to move into the bulk of the liquid, *i.e.*, the molecules tend to move from a state of higher energy to a state of lower energy. As a consequence of this transfer, the number of molecules at the surface becomes less than that in the bulk. The distance between any two molecules at the surface, therefore, becomes greater than that in the bulk. Consequently, the surface molecules tend to move closer to one another in order to acquire a normal distance between them as before. It is for this reason that drops of a liquid or bubbles of a gas are spherical in shape. A sphere has minimum surface for a given volume. As a result of the tendency to contract, surface of a liquid behaves as if it were in a state of tension. *The force that tends to contract the surface of a liquid is known as surface tension.*

Mathematically, **surface tension** is defined as the force in newtons acting at right angles to the surface of a liquid along 1 metre length of the surface. It is generally represented by the symbol γ.

Surface tensions of some common liquids are given in Table 2.

TABLE 2

Surface Tensions of Some Common Liquids in Nm^{-1} at 20°C

Liquid	Surface tension	Liquid	Surface tension
Water	0·0728	Chloroform	0·0271
Nitrobenzene	0·0418	Carbon tetrachloride	0·0268
Carbon disulphide	0·0335	Methyl alcohol	0·0226
Benzene	0·0289	Acetone	0·0237
Toluene	0·0284	Ethyl alcohol	0·0223
Acetic acid	0·0276	Ethyl ether	0·0170

As can be seen, for most liquids, surface tension at room temperature varies between 0·027 and 0·042 Nm^{-1}. For water, however, γ is 0·072 Nm^{-1} at 20°C. This high value is obviously due to strong intermolecular forces which exist in water *as a result of extensive hydrogen bonding*.

Surface Energy. The effect of surface tension is to reduce the area of the surface to a minimum. If we wish to increase the area of the surface of a liquid, we have to work *against* the force of surface tension. The work that is required to be done in order to extend the area of the surface of a liquid by one m^2, is called **surface energy** of the liquid.

Consider a soap film stretched over a wire-frame (Fig. 6) one end of which is movable. It is observed experimentally that force acts on the moveable membrane in a direction opposite to the arrow shown in the figure.

If the force per unit length is denoted by γ, then the work required to extend the movable membrane by a distance dx is given by the expression

$$\text{work} = \gamma \, 2l dx \quad \ldots(5)$$

Eq. 5 can be written as

$$\text{work} = \gamma \, dA \quad \ldots(6)$$

where dA $(=2l dx)$ is the change in area.

It may be noted that while in Eq. 5, γ is force per unit length, in Eq. 6, γ is work or energy per

unit area. Thus, surface of a liquid can be treated mathematically using either the concept of surface tension or the concept of surface energy. The term surface tension implies that a state of tension exists between the surface molecules whereas the term surface energy implies that work is required to bring molecules from the bulk to the surface of the liquid.

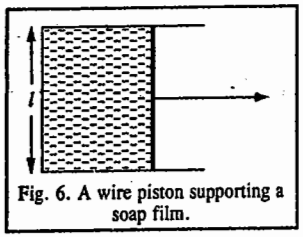

Fig. 6. A wire piston supporting a soap film.

While surface tension has units of force per unit length, *i.e.*, $N\,m^{-1}$, surface energy has units of work (energy) per unit area, *i.e.*, $J\,m^{-2}$.

The dimensions of surface energy, *viz.*, $J\,m^{-2}$ may also be put as $(N\,m)(m^{-2}) = N\,m^{-1}$, which are also the dimensions of surface tension. Thus, *surface tension is equal to surface energy numerically as well as dimensionally.*

Effect of Temperature on Surface Tension. According to the kinetic theory, molecular kinetic energy is proportional to absolute temperature. The rise in temperature of a liquid, therefore, is accompanied by *increase* in energy of its molecules. Since intermolecular forces decrease with increase in the energy of molecules, the intermolecular forces of attraction *decrease* with rise in temperature. Hence, *surface tension of a liquid decreases with rise in temperature.* At critical temperature, since the surface of separation between a liquid and its vapour disappears, the surface tension falls to zero.

Eotvos found that surface tension varies linearly with temperature. He suggested the following expression for the variation of surface tension with temperature :

$$\gamma\,(M/\rho)^{2/3} = a - kt \qquad \ldots(7)$$

where M is molar mass, ρ is density and γ is surface tension of the liquid at the temperature t ; a and k are constants.

At the critical temperature (*i.e.*, when $t = t_c$), the surface tension is zero. Substituting these values in Eq. 7, we may write

$$0 = a - kt_c \quad \text{or} \quad a = kt_c \qquad \ldots(8)$$

The Eotvos equation, therefore, may be written as

$$\gamma\,(M/\rho)^{2/3} = k(t_c - t) \qquad \ldots(9)$$

This equation has been found to be satisfactory in giving variation of surface tension with temperature in the case of a number of liquids over a wide range of temperature.

Since surface tension vanishes roughly 6° above the critical temperature rather than at the critical temperature, Ramsay and Shields proposed the following equation for the temperature-dependence of surface tension :

$$\gamma\,(M/\rho)^{2/3} = k(t_c - t - 6) \qquad \ldots(10)$$

Some Effects of Surface Tension. Some important effects of surface tension may now be considered.

1. The effect of surface tension is to *reduce the area of the surface to a minimum.* Hence, drops of a liquid or bubbles of a gas are spherical in shape, as stated before, A sphere has minimum surface area for a given volume.

2. The rise of a liquid in a capillary tube (*e.g.*, rise of oil in the wick of a lamp, rise of underground water on to the surface of earth, rise of water or sap in plants) is a well known phenomenon. This can be explained in terms of surface tension as shown below.

Consider a capillary tube lowered in a liquid that *wets its surface* (*e.g.*, water). The contact angle between the glass and the liquid is now zero. The liquid will rise almost instantaneously upto a certain height depending upon its surface tension and density. The column of the liquid in the capillary is, evidently, being supported by some force acting along the surface of the water. This is the force of surface tension.

Suppose, a liquid of density ρ, rises in a capillary tube of radius r, through a height h, as shown in Fig. 7.

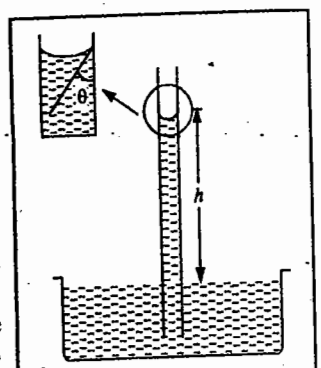

Fig. 7. Capillary rise in a liquid.

Let γ be the force of surface tension.

Then, the total force due to surface tension, raising the liquid column upward

$= \gamma \times$ inside circumference of the capillary

$= 2\pi r\gamma$

Force of gravity pulling the liquid downward = weight of the liquid column.

Weight of the liquid in the column $= V\rho g$ where V is the volume of the liquid in the tube. Since $V = \pi r^2 h$, hence, for equilibrium,

$$2\pi r\gamma = \pi r^2 h\rho g \quad \text{or} \quad \gamma = rh\rho g/2 \qquad \ldots(11)$$

For measuring surface tension, we have to measure the height (h) through which the liquid rises and the radius of the capillary tube both in centimetres. The height is measured by a cathetometer and the radius of the capillary tube by a travelling microscope.

It is assumed in the above derivation that the contact angle θ between the glass and the liquid is zero, that is, wetting is perfect. If this is not so, the vertical component of the upward force would be $2\pi r\gamma\cos\theta$ and hence

$$\gamma = \frac{r\,h\,\rho g}{2}\cos\theta \qquad \ldots(12)$$

As is well known, when a capillary is dipped in mercury, mercury does not rise in it. On the contrary, the upper level of mercury in the capillary is lower than the surface of the free liquid (Fig. 8). We can account for this phenomenon by assigning a value of 180° to the angle of contact θ between mercury and glass. Since $\cos 180° = -1$, hence according to Eq. 12, h would be negative.

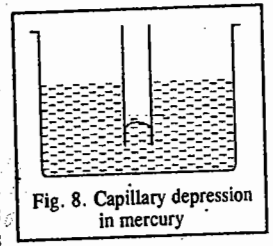

Fig. 8. Capillary depression in mercury

The rise or fall of a liquid in a capillary can be better understood by invoking the concepts of cohesion and adhesion. **Cohesion** means intermolecular attraction between like molecules in the liquid whereas **adhesion** means attraction between the liquid and the walls of the capillary. When adhesion is greater than cohesion, the liquid is said to wet the wall. This is what happens in the case of water and many other liquids. If cohesion is greater than adhesion, the liquid does not wet the wall. This is what happens in the case of mercury. Thus, when a drop of mercury or of water is put on a clean surface, the mercury drop becomes a truncated sphere since cohesion is greater than adhesion while the water drop spreads on the glass surface since adhesion is greater than cohesion.

Capillary-rise phenomenon is partially responsible for the rise of water in plants and soils. The other phenomenon responsible for the rise of water is **osmosis**, which we shall discuss later in this book.

Example 2. Calculate the height to which water will rise in a glass capillary if the radius of the tube is 0·02 cm. The surface tension of water is 0·0728 $N\,m^{-1}$.

Solution : Following Eq. 11,

$$h = \frac{2\gamma}{r\rho g} = \frac{2(0{\cdot}0728\ N\,m^{-1})}{(0{\cdot}02\times10^{-2}\ m)(10^3\ kg\,m^{-3})(9{\cdot}81\ m\,s^{-2})} = 7{\cdot}42\times10^{-2}\ m \qquad (N = kg\ m\ s^{-2})$$

Example 3. A plant has capillaries of radius 0·003 mm. The density of sap in the plant is 1·20 g cm^{-3} and its surface tension is 0·065 $N\,m^{-1}$. Assuming that surface tension alone is responsible for the rise of sap to the top of the plant, calculate how high this plant can grow.

Solution : The height upto which a wetting liquid of density ρ and surface tension γ can rise in a capillary tube of radius r is given by $h = 2\gamma / r\rho g$. Obviously, the height of the plant would also be equal to h.

$$\text{Thus, the height of plant, } h = \frac{2(0{\cdot}065\ \text{N m}^{-1})}{(0{\cdot}003\times10^{-3}\ \text{m})(1{\cdot}2\times10^{3}\ \text{kg m}^{-3})(9{\cdot}81\ \text{m s}^{-2})} = 3{\cdot}681\ \text{m} \qquad (\text{N} = \text{kg m s}^{-2})$$

Example 4. The surface tension of water at 20°C is 0·0728 N m^{-1}. Calculate the minimum amount of work needed to increase the surface area of water from 2·0 to 5·0 cm^2 at this temperature.

Solution : If w is the minimum work required to stretch the surface area by an amount A, then

$$w = \gamma A = (0{\cdot}0728\ \text{N m}^{-1})(3{\cdot}0\times10^{-4}\ \text{m}^2) = 218{\cdot}4\times10^{-5}\ \text{J}$$

Example 5. Consider two liquids A and B such that A has half the surface tension and twice the density of B. If liquid A rises to a height of 2·0 cm in a capillary, what will be the height to which liquid B will rise in the same capillary ?

Solution : It follows from Eq. 11 that

$$\frac{h_A}{h_B} = \frac{\gamma_A/\rho_A}{\gamma_B/\rho_B} = \frac{\gamma_A\rho_B}{\gamma_B\rho_A} = \left(\frac{1}{2}\right)\left(\frac{1}{2}\right) = \frac{1}{4}$$

$$\therefore \quad h_B = 4h_A = 4\times0{\cdot}02\ \text{m} = 0{\cdot}08\ \text{m}$$

Thus, the height to which liquid B would rise = **0·08 m**

Example 6. The surface tension of water is 0·0728 N m^{-1}. Calculate the energy required to disperse one spherical drop of radius 3·0 mm into spherical drops of radius 3·0×10^{-3} mm.

Solution : The surface area of the spherical drop of radius 3·0 mm $= 4\pi r_1^2$

$$= 4\pi(3{\cdot}0\times10^{-3}\ \text{m})^2 = 1{\cdot}13\times10^{-4}\ \text{m}^2$$

The surface area of the spherical drop of radius $3{\cdot}0\times10^{-3}$ mm $= 4\pi r_2^2$

$$= 4\pi(3{\cdot}0\times10^{-6}\ \text{m})^2 = 1{\cdot}13\times10^{-10}\ \text{m}^2$$

The number of drops of radius 3×10^{-3} mm that can be formed from one drop of radius 3 mm

$$= \frac{\text{Volume of bigger drop}}{\text{Volume of smaller drop}} = \frac{(4/3)\pi(3{\cdot}0\ \text{mm})^3}{(4/3)\pi(3{\cdot}0\times10^{-3}\ \text{mm})^3} = 1{\cdot}0\times10^{9}$$

The total surface area of all the small drops

$$= (1{\cdot}13\times10^{-10}\ \text{m}^2)(1{\cdot}0\times10^{9}) = 1{\cdot}13\times10^{-1}\ \text{m}^2$$

$$\text{Increase in surface area} = (1{\cdot}13\times10^{-1}\ \text{m}^2) - (1{\cdot}13\times10^{-4}\ \text{m}^2) = 1{\cdot}13\times10^{-4}\times999\ \text{m}^2$$

$$\therefore \text{ Work done in dispersion} = \text{surface tension} \times \text{increase in surface area}$$

$$= (0{\cdot}0728\ \text{N m}^{-1})(1{\cdot}13\times999\times10^{-4}\ \text{m}^2) = 8{\cdot}2\times10^{-3}\ \text{J} \qquad (\text{N m} = \text{J})$$

3. One of the most interesting consequences of surface tension is the fact that the vapour pressure of a liquid is greater when it is in the form of small droplets than when it has a plane surface. According to the **Kelvin equation**, the vapour pressure P for a very small droplet of radius r is given by the relation

$$\ln (P/P_0) = 2\gamma M/(r\rho RT) \qquad ...(13)$$

where P_0 is the vapour pressure of the bulk sample of the liquid, ρ is its density and R is the gas constant. The conclusions of this equation have been verified experimentally.

Excess Pressure in a Drop. Since the surface tension tends to decrease the surface area, the pressure P_1 inside a spherical drop is greater than the pressure P_2 of the surrounding liquid. The greater the surface tension, the greater is the pressure difference ΔP. If the radius of the bubble is increased by a small amount dr, then the increase in surface area, $dA = 4\pi(r+dr)^2 - 4\pi r^2 = 8\pi r dr$ and the increase in volume $dV = (4/3)\pi(r+dr)^3 - (4/3)\pi r^3 = 4\pi r^2 dr$. The net work done in increasing the surface area is given by

$$w = \gamma\, dA = 8\pi\gamma\, rdr \qquad ...(14)$$

Since the work done by the gas (air) inside the bubble is $P_1 dV$ while that done on the liquid outside the bubble is $P_2 dV$, the net work required to generate the additional surface area is given by

$$w = (P_1 - P_2)dV = \Delta P dV = \Delta P(4\pi r^2 dr) \qquad ...(15)$$

From Eqs. 14 and 15, $8\pi\gamma\, rdr = \Delta P(4\pi r^2 dr)$ or $\Delta P = 2\gamma / r$ ...(16)

Eq. 16 is known as the **Laplace equation.**

It is a special case of the general equation, called the **Young–Laplace equation,** *viz.*,

$$\Delta P = P_1 - P_2 = \gamma\,(1/r_1 + 1/r_2) \qquad ...(17)$$

where r_1 and r_2 are the maximum and the minimum radii of curvature at a point in the surface and P_1 and P_2 are the pressures on the concave and the convex sides of the surface, respectively. For a spherical body, $r_1 = r_2$ so that Eq. 17 reduces to Eq. 16.

From Eq. 16, we see that ΔP is inversely proportional to the radius r of the bubble or the droplet and would evidently become very large for very small droplets. For instance, the excess pressure in a bubble (or droplet) of radius 0·0001 cm in water at 20°C is given by

$$\Delta P = \frac{2\times0{\cdot}0728\ \text{N m}^{-1}}{(1\times10^{-6}\ \text{m})(101325\ \text{N m}^{-2}\ \text{atm}^{-1})} = 1{\cdot}44\ \text{atm}$$

where we have used the conversion factor 1 atm = 101325 N m^{-2}.

In the case of soap bubbles, the pressure difference between the two phases on the two sides of the soap film is *twice* the value obtained from the Laplace equation. This is because the two surfaces of the liquid film are parallel and also so close that their radii of curvature are almost equal.

When a liquid free from dust particles is heated in a container, small gas bubbles are formed for which ΔP is very large. As the bubble size increases, the pressure required to overcome the surface tension decreases and hence the bubble expands rapidly. This leads to bumping or violent heating in superheated liquids.

Interfacial Tension. Suppose, two immiscible liquids are present one above the other in a vessel. Then, the force acting per unit length along the interface is called **interfacial tension.** This is less than the surface tension of the liquid with a higher value. The reason is that the unbalanced forces acting along the surface of each liquid are partly compensated by the force of mutual attraction between the molecules of the two liquids.

Surface tension and interfacial tension involve the same type of force. When one speaks of surface tension of a liquid, it is understood that the force is acting along the surface of separation between the liquid and its vapour. When one speaks of interfacial tension, it is understood that the force is acting along the surface of separation of two immiscible liquids in contact with each other.

Surface Active Agents. A number of substances are known which, when added to water, lower its surface tension. These substances are called **surface active agents** or **surfactants.** Thus, liquids like methanol, ethanol, acetone and acetic acid when added to water, lower its surface tension, Similarly, soaps when mixed with water lower its surface tension. There are a host of other substances such as salts of higher sulphonic acids and higher amines which behave in this manner. They are all surface active materials. These substances act as **detergents.**

Let us explain the action of soap as a detergent. Most of the dirt or dust sticks on to grease or oily materials which somehow gather on cloth. As grease is not readily wetted by water, it is difficult to clean the garment by water alone. The addition of soap lowers the interfacial tension between water and grease so as to facilitate the mixing of the two. The soap molecules get oriented at the interface between water and oil (or grease) in such a way that their polar end (–COONa) is dipping in water and the hydrocarbon chain (R–) in the oil. This helps in bringing the two liquid

phases in more intimate contact with each other. In other words, *the presence of soap causes emulsification of grease in water*. The mechanical action, such as rubbing, releases the dirt. For emulsions and emulsifiers, see Chapter 30 on the Colloidal State.

Detergents are also added to medicinal emulsions, tooth pastes, mouth washes and toilet creams in order to enable them to spread evenly thereby increasing the efficiency of the antiseptic action.

VISCOSITY

The flow is a characteristic property of liquids. Consider a liquid flowing through a narrow glass tube (Fig. 9a). The flow of the liquid molecules can be analysed in terms of *molecular laminar layers* arranged one over another. A laminar layer has negligible thickness. The layer immediately in contact with the surface of the inner wall of the tube is *stationary*. However, the velocity of the successive layers increases as we move away from the surface. As a result, a velocity gradient is set up along the z-axis. If the distance between the two layers is r and the slow-moving layer moves with a velocity v, then the faster-moving layer moves with a velocity $v+r(dv/dz)$ (Fig. 9b).

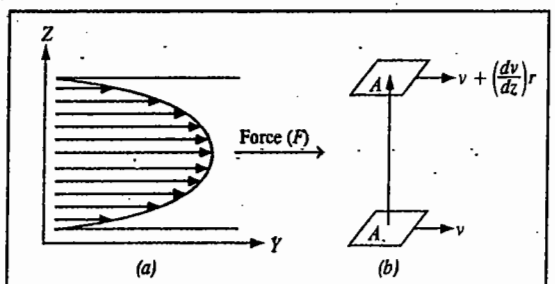

Fig. 9. The velocity profile during flow of a liquid in a glass tube.

When a molecule moves from the faster layer to the slower layer, it transports momentum to the latter thereby speeding it up. Conversely, when a molecule moves from the slower layer to the faster layer, it retards the latter. In this way, there arises a frictional force or drag between the two layers which gives rise to viscosity which may thus be defined as the resistance that one part of a liquid flowing with one velocity offers to another part of the liquid flowing with a different velocity. In simple words, viscosity *may be defined as the force of friction between two layers of a liquid moving past one another with different velocities*.

If we want to maintain the velocity gradient, we must apply an external force along the y-axis. This force is proportional to the area and the velocity gradient, that is,

$$F \propto A(dv/dz) = -\eta A(dv/dz) \qquad ...(18)$$

where the constant of proportionality η is called the **coefficient of viscosity**. The minus sign shows that the viscous force on the faster layer is in the opposite direction to its motion.

Eq. 18 is Newton's law of viscosity. It is experimentally obeyed by several liquids provided their rate of flow is not very high. The fluid flow to which this equation applies is called **laminar** (or streamlined) **flow**. The equation does not apply to turbulent flow. Liquids which do not obey Eq. 18 are called **non-Newtonian liquids**. For Newtonian liquids, η is independent of dv/dz whereas for non-Newtonian liquids, η changes as dv/dz changes.

Units of Viscosity. If F is measured in newtons, dz in metres, A in square metres and dv in metres sec^{-1}, then, we get the coefficient of viscosity in units of kg m^{-1} s^{-1}, as illustrated below :

$$\eta = \frac{Fdz}{Adv} = \frac{\text{kg m s}^{-2}\ \text{m}}{\text{m}^2\ \text{m s}^{-1}} = \text{kg m}^{-1}\ \text{s}^{-1}$$

It can be easily shown that 1 poise = 10^{-1} kg m^{-1} s^{-1}

Common units of viscosity are centipoise and millipoise.

Viscosities of some common liquids, at 20°C, are given in Table 3.

TABLE 3
Coefficients of Viscosity in Centipoises (20°C)

Liquid	η	Liquid	η
Water	1·008	Benzene	0·647
Chloroform	0·563	Acetone	0·329
Ethyl alcohol	1·216	Acetic acid	1·229
Methyl alcohol	0·593	Nitrobenzene	2·010
Ethyl ether	0·233	Carbon tetrachloride	0·968

Polyhydric alcohols like glycerol have high viscosities because of the formation of a network of hydrogen bonds between the molecules. The network which extends throughout the liquid makes the flow difficult.

The *reciprocal of viscosity* is called **fluidity** and is denoted by ϕ. Thus, $\phi = 1/\eta$.

Effect of Temperature on Viscosity. The 'Hole' Theory. The viscosity of a liquid generally decreases with rise in temperature. The decrease is appreciable, being about 2 per cent per degree rise of temperature in many cases. This has been explained in terms of the **'hole theory'** of liquids discussed earlier. According to this theory, there are *vacancies* or *'holes'* in a liquid. The liquid molecules keep on moving continuously into these vacancies. As a consequence, the vacancies also keep on moving around as otherwise the liquid will not be able to flow. This process, however, requires energy. A liquid molecule, therefore, needs some activation energy to move into a 'hole'. As the activation energy becomes increasingly available at increasing temperatures, a liquid can flow more easily at higher temperatures. The coefficient of viscosity, thus, falls appreciably with rise in temperature.

The relationship between coefficient of viscosity of a liquid and temperature is expressed mathematically as

$$\eta = Ae^{E_a/RT} \qquad ...(19)$$

where A and E_a are constants for a given liquid. Most of the experimental data fit in this equation very well. E_a is called the activation energy for viscous flow.

In contrast to liquids, η increases with increasing temperature in the case of gases. This suggests that the mechanism of flow is different for gases (Chapter 9) than for liquids. The concept of momentum transfer between two layers which is so successfully applicable to gases is less justified (and probably not even applicable) in the case of liquids.

Effect of Pressure. The viscosity of liquids, however, increases with increase in pressure. This is attributed to decrease in the number of 'holes' as the pressure is increased. Consequently, it becomes more difficult for liquid molecules to move around and thus it becomes more difficult for them to flow.

Reynolds Number. The flow of a fluid through a pipe of radius r has been associated with a number called **Reynolds number, N_R**, defined as

$$N_R = 2R\bar{v}\rho/\eta \qquad ...(20)$$

where $\bar{v}$ is the average bulk velocity of the fluid, ρ is the density and η is the coefficient of viscosity. If N_R is greater than 4000, the flow is **turbulent** and if it is less than 2100, the flow is **laminar**. In a laminar flow, a velocity profile given by

$$\bar{v} = \frac{\Delta P(R^2 - r^2)}{4\eta l} \qquad ...(21)$$

is observed in a pipe where ΔP is the pressure drop over a length l and r is the distance from the axis of the pipe of radius R.

The volume of liquid flowing in time t through a pipe of radius R is given by the **Poisseuille equation**

$$V = \frac{\pi R^4(\Delta P)t}{8\eta l} \qquad ...(22)$$

Example 7. Consider the flow of water through a horizontal pipe with $R = 2{\cdot}5$ cm and $\bar{v} = 3$ cm s^{-1}. If $\eta = 1{\cdot}008$ cP at 20°C and $\rho = 0{\cdot}9994$ g cm^{-3}, calculate the Reynolds number.

Solution : From Eq. 20, $N_R = 2R\bar{v}\rho/\eta$

$$= \frac{2(2{\cdot}5\times10^{-2}\text{ m})(3\times10^{-2}\text{ m s}^{-1})(0{\cdot}9994\times10^{-3}\times10^{6}\text{ kg m}^{-3})}{(1{\cdot}008\times10^{-2}\text{ Poise})(10^{-1}\text{ kg m}^{-1}\text{ s}^{-1}\text{ Poise}^{-1})} = 1487$$

Since N_R is less then 2100, the flow is **laminar.**

REFRACTION

Refractive Index or Index of Refraction. When a ray of light passes from one medium to another, it suffers *refraction*, that is, *a change of direction.* If it passes from a less dense to a more dense medium, as from air to water, it is refracted towards the normal so that the angle of refraction r is less than the angle of incidence i. The refractive index n_r of the second medium with respect to the first is then given by the relation

$$n_r = \sin i/\sin r \qquad ...(23)$$

The refractive index of a medium may also be defined as the ratio of the velocity of light in vacuum to that in the medium. Refractive indices can be measured easily with a high degree of accuracy.

The values depend upon the temperature as well as the wave length of light used. Generally, the D-line of sodium is used for standard measurements. The symbol $^{20}n_{r,D}$ indicates that the refractive index has been determined at 20°C using D-line of sodium as the source of light.

Instruments used for measuring refractive indices are known as refractometers. The refractive index of a liquid varies with the temperature. The magnitude of variation, however, is not as large as in the case of surface tension and viscosity.

Specific Refraction. The term specific refraction *(R)*, introduced by Lorenz and Lorentz, may be defined as

$$R = \frac{(n_r^2 - 1)}{\rho(n_r^2 + 2)} \qquad ...(24)$$

where ρ is the density and n_r, as usual, is the refractive index of the liquid. The advantage of this term is that it is independent of temperature. The variation in n_r with change in temperature is compensated by the variation in ρ, the density of the liquid.

Molar Refraction. The product of molar mass (M) of the liquid and specific refraction (R) is called *molar refraction* (R_m). Thus,

$$R_m = \frac{M(n_r^2 - 1)}{\rho(n_r^2 + 2)} \qquad ...(25)$$

Molar refraction of a solid is determined by dissolving it first in a suitable solvent so as to get a solution of a known concentration. The refractive index and the density of the solution are then determined experimentally. The molar refraction of the solution, $R_{m,sol}$, is given by

$$R_{m,sol.} = \frac{n_r^2 - 1}{n_r^2 + 2}\left[\frac{x_1M' + x_2M''}{\rho}\right] \qquad ...(26)$$

where M' and M'' are the molar masses of the solvent and the solute, respectively and x_1 and x_2 are their respective mole fractions, while n_r and ρ are the refractive index and density, respectively, of the solution. Since all the quantities on the right-hand side of Eq. 26 are known, $R_{m,sol.}$ can be evaluated.

The molar refraction of the solution $R_{m,sol.}$ is related to molar refractions $R_{1,m}$ and $R_{2,m}$ of the solvent and the solute, respectively, by the following equation :

$$R_{m,sol.} = x_1R_{1,m} + x_2R_{2,m} \qquad ...(27)$$

From Eq. 27, the molar refraction of the solid solute, $R_{2,m}$ can be easily calculated.

Optical Activity. The term optical activity refers to the rotation of the plane of plarized light when it passes through a substance or solution. A substance which rotates the plane of polarized light to the right (or clockwise) is called **dextro-rotatory** and the substance which rotates the plane of polarized light to the left (or anticlockwise) is called **laevo-rotatory.** Both dextrorotatory and laevorotatory substances are said to be optically active. The rotation of the plane polarized light is measured with a polarimeter that consists of a source of light, a linear polarizer (such as a Nichol prism), the sample and an analyzer (another linear polarizer). The rotation of the plane of polarization by the sample is measured by rotating the analyzer. The magnitude of the angle of rotation α is directly proportional to the length l of the sample and the concentration c of the optically active substance. It is convenient to define a term **specific rotation,** $[\alpha]_\lambda$, by

$$[\alpha]_\lambda^{20^\circ} = \frac{100\alpha}{cl} \qquad ...(28)$$

where l is the path length (in decimeters) and c is the percent concentration. The specific rotation varies with the wave length λ, temperature and solvent.

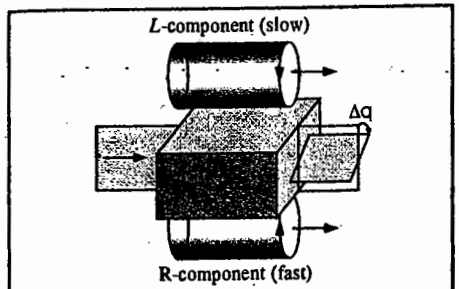

Fig. 10. Linearly polarized light viewed as the superposition of two counter-rotating circularly polarized components.

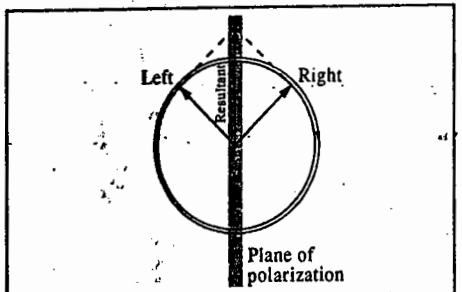

Fig. 11. The superposition as viewed by an observer facing the on-coming beam.

The concept of refractive index is closely related to optical activity. The angle of optical rotation is proportional to the difference between the refractive indices for left and right circularly polarized light (Fig. 10). We shall prove it as follows : Before entering the medium, the beam is plane polarized at an angle $\theta = 0$. This plane polarized light may be regarded as a superposition of two oppositely rotating circularly polarized components (Fig. 11).

On entering the medium, one component propagates faster than the other if their refractive indices are different. If the sample is of path length l, then the difference in the times of passage is given by

$$\Delta t = \frac{l}{c_R} - \frac{l}{c_L} \qquad ...(29)$$

where c_R and c_L are the speeds of the two components (right circularly polarized and the left circularly polarized components). In terms of the refractive indices, this difference is given by

$$\Delta t = (n_R - n_L)\,l/c \qquad ...(30)$$

The phase difference between the two components when they emerge from the sample is thus

$$\Delta\theta = c\,\Delta t = \frac{2\pi}{\lambda} = (n_R - n_L)\,2\pi l/\lambda \qquad ...(31)$$

where λ is the wave length of light (here $\Delta\theta$ is the angle of rotation which we have designated as α in the preceding discussion). The rotating electric vectors (of the electromagnetic radiation) have a different phase when they leave the sample from their initial value. Hence, their superposition gives rise to a plane polarized light rotated through an angle $\Delta\theta$ ($\equiv\alpha$) relative to the plane of the incoming beam. Thus, we see that the angle of optical rotation is proportional to the difference in refractive indices, $n_R - n_L$.

Fig. 12 gives the variation of refractive index (dispersion curve) and the variation of the absorption coefficient (absorption curve) for an optically active substance measured with left and right circularly polarized light. The difference in the refractive indices (Δn) for the two components is referred to as the ORD (optical rotatory dispersion) curve and the difference in the absorption ($\Delta\varepsilon$) is called the CD (circular dichroism) curve. In other words, the plot of Δn *versus* λ is called the ORD curve and the plot of $\Delta\varepsilon$ *versus* λ is called the CD curve. The analysis of ORD and CD curves may be used to determine the structure, configuration and conformations of optically active *d*-metal complexes and

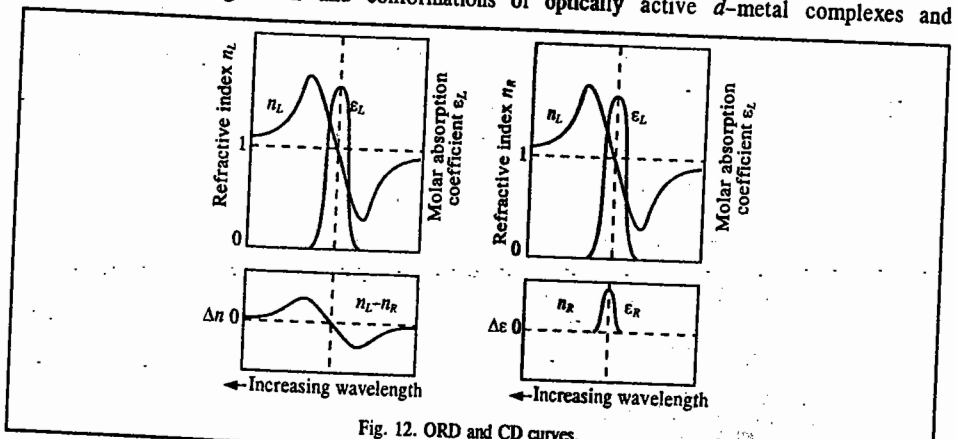

Fig. 12. ORD and CD curves.

other optically active molecules such as proteins, synthetic polypeptides and steroids. We may finally mention that chiral molecules have non-superimposable mirror images and hence are optically active. To be more precise, if we invoke symmetry arguments, then we can say that a molecule possessing any improper rotation axis (S_n), a mirror plane or a centre of symmetry, cannot be optically active.

Structure of Liquids. The structure of simple liquids such as liquid metals and simple monatomic liquefied gases like argon can be deduced from diffraction methods like X-ray diffraction, electron diffraction and neutron diffraction. These methods indicate the existence of **short-range order** and **long-range disorder** in the liquid state. While the short-range order assigns a certain structure, the long-range disorder gives rise to the fluidity of the liquid. The electron diffraction and the neutron diffraction methods are particularly useful for investigating monatomic liquids. The liquid diffraction patterns characteristically show one or two nicely formed small-range diffraction maxima that correspond to the short-range order. They also show rather diffuse diffraction rings corresponding to the farther removed molecules.

The theory of the liquid state is an extremely difficult problem of theoretical chemistry. However, some progress has been made in the **computer simulation of liquids**. The so-called **radial distribution function** characterizes the average structure of a liquid, or more precisely, the average distribution of its molecules relative to one another. For a completely uniform distribution of molecules, the number $N(r)$ of them lying within a spherical shell of radius r and thickness dr is give by

$$N(r) = 4\pi r^2 \rho\, dr \qquad \ldots(32)$$

where ρ is the number density of the species. The radial distribution function $g(r)$ measures the variation with r in the probability of observing one species at a distance r from another and is defined by

$$g(r) = N(r)/(4\pi r^2 \rho)dr \qquad \ldots(33)$$

More explicitly, consider a system of n atoms and take any one of them as an origin. For a sequence of values of r, count the number $N(r)$ of other atoms whose centres lie within spherical shells of volume $4\pi r^2 dr$. This procedure is repeated with each of the other $(n-1)$ atoms as centre and finally the results for each value of r are averaged. In this way one obtains a radial distribution function $g(r)dr$ as a function of the parameter r.

The molar internal energy U_m for a simple liquid consists of the kinetic energy (which is $\frac{3}{2}RT$) and the potential energy {(given by the Lennard-Jones (6-12) potential energy, $V(r)$} and may be written as

$$U_m = \tfrac{3}{2}RT + (4\pi\rho N_A/2)\int_0^\infty r^2 V(r)\, g(r) dr \qquad \ldots(34)$$

The factor $\frac{1}{2}$ arises because each pair of interactions in $V(r)$ must be included only once. The radial distribution function $g(r)$ can be obtained from diffraction studies with X-rays or neutrons, or by computer simulation techniques. The radial distribution function for liquid argon at 85 K, calculated using neutron scattering method, is shown in Fig. 13.

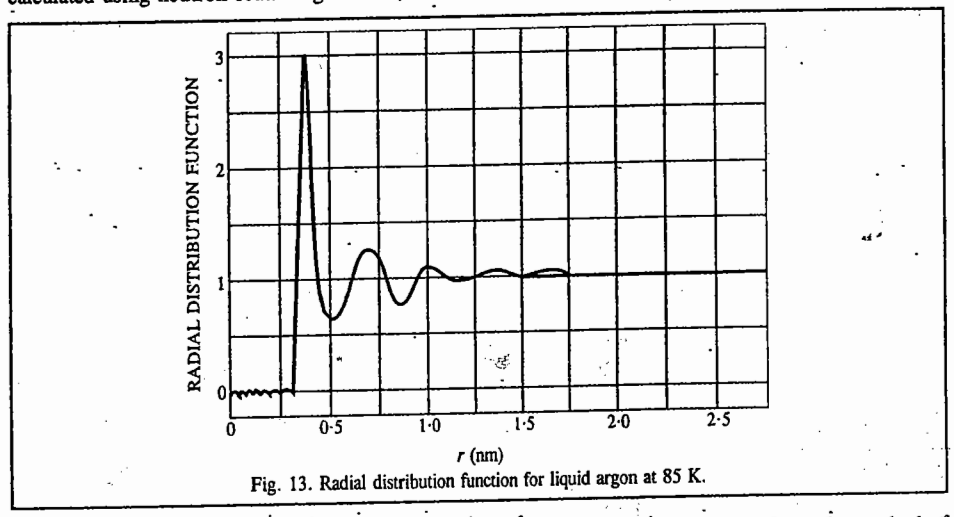

Fig. 13. Radial distribution function for liquid argon at 85 K.

Let us briefly comment on the equation of state for a simple liquid obtained from the method of statistical mechanics :

$$PV = NkT - (\rho N/6)\int_0^\infty g(r)\{r[dV(r)/dr]\}dr \qquad \ldots(35)$$

Recalling that an ideal gas equation is $PV = NkT$, we can appreciate how enormously complicated is the equation of state even for a simple liquid.

In Eq. 35, the second term on the right-hand side corresponds to the **configurational energy** and N is the number of molecules in the volume V ; ρ is, of course, the number density N/V ; the term $\{r[dV(r)/dr]\}$ is known as the **virial**. Eq. 35 has been investigated by computer simulation techniques.

Two methods that have received most attention are the **Monte Carlo (MC)** method and the **Molecular Dynamics (MD)** (time-dependent) method. They lead to the determination of $g(r)$.

In the Monte Carlo method for liquid structure, a model is set up in which an elementary cubic unit cell containing an initial configuration of approximately 10^3 atoms is repeated by side-by-side stacking in three dimensions so that the macroscopic liquid is generated by lattice-type translations of the cubic cell. Fig. 14 shows a projection of a configuration of atoms in a Monte Carlo simulation of a monatomic liquid. The positions of the atoms in any one cubic cell are random ; the other cells are formed by equal translations in three dimensions. After sufficient simulation time, an equilibrium arrangement is obtained. As one molecule, say B_2, moves out of its cell, B_3 moves in from an adjacent cell so as to preserve a constant number density.

Molecular dynamics method treats the evolution with time of systems of particles that interact through conservative forces operating under the laws of classical Newtonian mechanics. This method tracks the motion of molecules in condensed phases by solving the Newtonian equations of motion. Since solids are well represented by other theories, most applications of molecular dynamics have been to liquids, particularly in elucidating transport and equilibrium parameters. In applying molecular dynamics to a simulated liquid system, a set of initial coordinates is generated, usually from a face-centered Bravais lattice, at the required density.

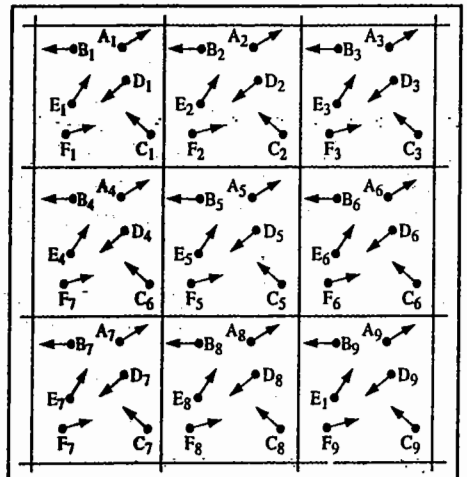

Fig. 14. Monte Carlo simulation of a monatomic liquid.

Many MD calculations have been carried out with the hard-sphere potential energy function, $V(r)$:

$$V(r) = \begin{cases} 0, & r > \sigma \\ \infty, & r \leq \sigma \end{cases} \qquad \ldots(36)$$

The hard-sphere potential energy is infinite when the separation of the two molecules, treated as hard spheres, is less than or equal to a certain value σ and is zero for greater separations. This potential is computationally simple and also shows that the structure of simple liquids is almost independent of their chemical nature and may be approximated by the interaction of rigid spheres.

We may mention in passing and in conclusion that the **so-called BBGKY hierarchy of equations** (abbreviated after the names of the five scientists who independently proposed them, *viz.*, Bogoliubov, Born, Green, Kirkwood and Yvon, during 1930–1945) have been used to derive the Boltzmann transport equation for gases and to study the transport phenomena. They involve a very advanced treatment of the subject. The extension of these methods to the liquid state is a formidable problem in statistical mechanics.

I. Review Questions

1. Define the term vapour pressure of a liquid. With the help of energy distribution of molecules in a liquid, explain why the vapour pressure of a liquid increases with increase in temperature and why a liquid cools down on evaporation.
2. State and explain Trouton's law.
3. Define the terms surface tension and surface energy. Show that surface tension is equal to surface energy numerically as well as dimensionally. Derive an expression for the determination of surface tension by the capillary rise method.
4. Discuss carefully the development of excess pressure in a liquid drop due to surface tension.
5. Explain the term viscosity of a liquid. What are Newtonian and non-Newtonian liquids. Discuss the effect of temperature on the viscosity of a liquid.

   "While the viscosity of a gas increases with increase in temperature, that of a liquid decreases with increase in temperature". How would you account for it.
6. Define the terms refractive index, specific refraction and molar refraction.
7. What is optical activity ? Write short notes on ORD and CD.
8. Briefly discuss the role of the radial distribution function in determining the structure of the liquid state.
9. Briefly discuss the Monte Carlo and the molecular dynamics methods for determining the structure of the liquid state.

II. Problems

1. Using Trouton's rule, estimate the vapour pressure of cyclohexane if its normal boiling point is 81·4°C. **[Ans. 103 torr]**
2. How far will a liquid of density 850 kg m^{-3} and surface tension 0·055 N m^{-1} rise in a glass capillary of 1·40 mm inside diameter ? **[Ans. 19 mm]**
3. The boiling point of an organic liquid is 54°C. Estimate the molar heat of vaporisation of the liquid assuming that it obeys Trouton's rule. **[Ans. 28·776 kJ mol^{-1}]**
4. A liquid rises to 1 cm in a glass capillary of radius r. How much will it rise if the cross-sectional area of the tube is *(a)* halved *(b)* doubled ? **[Ans. *(a)* 1·414 cm *(b)* 0·707 cm]**
5. How far will the mercury level be depressed when a glass capillary with 0·40 mm radius is placed in a dish of mercury ? Given that the surface tension of liquid mercury is 0·90 N m and its density is $13·6\times10^3$ kg m^{-3}. **[Ans. 18·3 mm]**
6. At 20°C, the densities of H_2O and $CHCl_3$ are 998·2 kg m^{-3} and 1595 kg m^{-3}, respectively and the surface tension of $CHCl_3$ is $27·4\times10^{-3}$ N m^{-1}. If the rise of H_2O and $CHCl_3$ in a glass capillary of a certain diameter is 9·9 cm and 2·33 cm, respectively, calculate the surface tension of H_2O. Also, calculate the radius of the tube. **[Ans. $72·86\times10^{-3}$ N m^{-1} ; 0·1505 mm]**
7. What is the excess pressure, in atm, due to surface tension in a drop of aniline 0·001 mm. in diameter at 25°C, given that its surface tension is 42·79 dynes cm ? **[Ans. 1·678 atm]**
8. Consider the flow of a liquid through a horizontal pipe of radius 2 cm with an average velocity of 5 cm s^{-1}. If η=1·23 cP at 25°C and ρ=0·913 g cm^{-3}, calculate the Reynolds number of the liquid. **[Ans. 1484]**
9. The refractive index of CCl_4 at 20°C is 1·4573. If its density at the given temperature is 1·595 g cm^{-3}, calculate the molar refraction. **[Ans. 26·51]**
10. To what height will water rise in a capillary of diameter 0·50 mm at 25°C if the surface tension of water is 71·97 dynes cm^{-1} ? **[Ans. 5·89 cm]**
11. Calculate the surface tension of a liquid which rises to a height of 1 cm in a capillary tube of radius 0·50 mm. The density of the liquid is 1·5 gm cm^{-3}. **[Ans. 36·7 dynes cm^{-1}]**
12. Calcualte the depression of mercury in a capillary tube of radius 0·5 mm if the surface tension of mercury is 460 dynes cm^{-1}. The density of mercury is 13·55 g cm^{-3}. **[Ans. 1·38 cm]**
13. What is the excess pressure, in atm, due to surface tension in a drop of benzene with a radius of 1×10^{-4} cm at 20°C, given that its surface tension is 28·86 dynes cm^{-1} ? **[Ans. 0·57 atm]**
14. The surface tension (γ) and the vapour pressure (P) of very small droplets of a liquid are related by the expression

$$\ln (P/P_0) = 2\gamma M/\rho r RT$$

where P_0 is the normal vapour pressure of the liquid of density ρ and r is the radius of the droplet. Using this equation calculate the vapour pressure of a water bubble of radius 10^{-8} m at 20°C if the vapour pressure of water at this temperature is 23·76 torr. The surface tension is $72·75\times10^{-3}$ N m^{-1} and density is 998·2 kgm^{-3}. **[Ans. P = 26·46 torr]**

CHAPTER 12

LIQUID CRYSTALS : THE MESOMORPHIC STATE

Liquid Crystals. Mesomorphic State. There are certain solids which when heated undergo two sharp phase transformations one after the other. They first fuse sharply yielding turbid liquids and then again equally sharply at a higher temperature yielding clear liquids. These changes are exactly reversed on cooling at the same temperatures. The turbid or transluscent liquids, however, show **anisotropy** (*i.e.*, they have different physical properties in different directions). The anisotropy is observed particularly in their optical behaviour. Thus, they exhibit double refraction and give *interference patterns* in polarised light. True liquids, on the contrary, are **isotropic** (*i.e.*, they have same properties in all directions). Since anisotropic properties like double refraction are associated with crystalline state, the turbid liquids are called **liquid crystals.** This term, however, is not satisfactory since the substances in this state do not have properties of crystalline state. Actually, they are more like liquids in having properties like mobility, surface tension, viscosity, etc. Amongst other names that have been suggested are crystalline liquids and anisotropic liquids, but these are also not satisfactory. The term **mesomorphic state** (meaning intermediate form, in Greek) probably fits best. However, the older term liquid crystals continues to be used even in the present day literature.

Substances showing the above behaviour are usually some long chain organic molecules either terminating in groups such as –OR, –COOR or having groups like –C=N–, –N=NO–, –C=C–, in the middle. Cholesteryl benzoate, $C_6H_5COOC_{27}H_{45}$, was amongst the first solids discovered, in 1888, to have this peculiar property. It fuses sharply at 145°C to give a turbid liquid which on further heating changes suddenly into clear liquid at 178°C. The above changes are reversed on cooling. The clear liquid when cooled first changes into turbid state at 178°C and then into solid state at 145°C.

A few years later, *p*-azoxy anisole and *p*-azoxy phenetole were found to show similar behaviour. Since then, hundreds of compounds capable of showing mesomorphic behaviour have been known. The 1991 Physics Nobel Prize was awarded to the French physicist P.G. de Gennes (1932-) for his contributions to the physics of liquid crystals and polymers.

Obviously, an essential requirement for mesomorphism to occur is that the molecule must be anisotropic in shape, like a *rod* or a *disc*. Industrial lubricants exist, more or less, in liquid crystalline, *i.e.*, mesomorphic state. The proteins and fats also exist or get changed into this state before digestion and are thus easily assimilated into the body. This state is believed to play an important role in nutritional and other processes. Depending upon the detailed molecular structure, the system may pass through one or more mesophases before it is transformed into the isotropic liquid. Transformation into the intermediate states may be brought about either by **thermotropic mesomorphism** (*i.e.*, by thermal processes) or by **lyotropic mesomorphism** (*i.e.*, by the intervention of the solvent).

The first temperature at which solid changes into turbid liquid is known as **transition point** and the second temperature at which turbid liquid changes into clear liquid is known as **melting point.** For *p*-cholesteryl benzoate, for instance, the changes may be represented as

$$\underset{\text{Solid}}{A} \overset{145^\circ C}{\rightleftharpoons} \underset{\text{Liquid crystal}}{A} \overset{178^\circ C}{\rightleftharpoons} \underset{\text{Liquid}}{A}$$

Here A is *p*-cholesteryl benzoate.

The substances showing liquid crystal character are highly stable and do not decompose on heating.

A few examples of compounds showing this behaviour are given in Table 1 together with their transition temperatures and melting points.

TABLE 1

Some Typical Substances Showing Liquid Crystal Character

Substance	Transition Point (°C)	Melting Point (°C)
Anisaldazine $CH_3OC_6H_4CH : NN : CHC_6H_4OCH_3$	165	180
p-Azoxyanisole $CH_3OC_6H_4NONC_6H_4OCH_3$	116	135
p-Azoxyphenetole $C_2H_5OC_6H_4NONC_6H_4OC_2H_5$	137	167
Diethylbenzidine $C_2H_5NHC_6H_4C_6H_4NHC_2H_5$	115	120
Mercury di-(*p*-ethoxybenzal-aminophenyl) $Hg(C_6H_4N : CHC_6H_4OC_2H_5)_2$	204	272
p-Methoxy cinnamic acid $CH_3OC_6H_4CH : CHCOOH$	170	186

There are, evidently, 4 phases or 4 states of matter to be considered. Besides solid, liquid and gaseous states, the fourth state is the **mesomorphic state.**

Vapour Pressure–Temperature Diagrams

The phase changes involved in the conversion of an ordinary solid into liquid and vapour state is usually represented as

$$\text{Solid} \rightleftharpoons \text{Liquid} \rightleftharpoons \text{Vapour}$$

The corresponding changes involved in the case of a solid showing mesomorphic behaviour may be represented as

$$\text{Solid} \rightleftharpoons \underset{\text{(Mesomorphic state)}}{\text{Liquid crystal}} \rightleftharpoons \text{Liquid} \rightleftharpoons \text{Vapour}$$

Such phase transformations are usually represented by pressure–temperature curves, as shown in Fig. 1 for an ordinary substance and in Fig. 2 for a substance capable of undergoing a mesomorphic change.

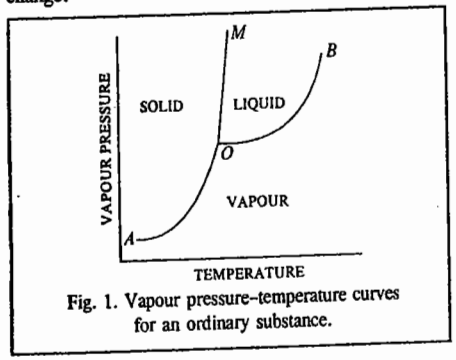

Fig. 1. Vapour pressure–temperature curves for an ordinary substance.

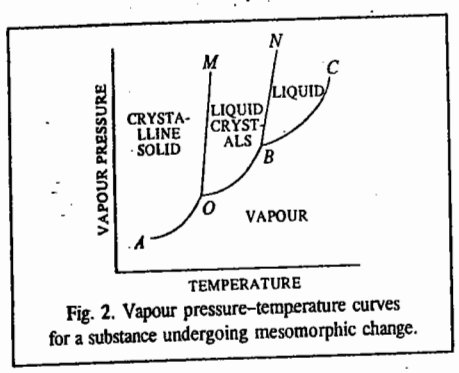

Fig. 2. Vapour pressure–temperature curves for a substance undergoing mesomorphic change.

In Fig. 1, *AO* is the vapour pressure curve of the substance in the solid (crystal) state while *OB* is that of the same substance in the liquid state. Thus, along *AO*, the solid (crystal) phase is in equilibrium with the vapour phase, while along *OB*, the liquid phase is in equilibrium with the vapour phase. At *O*, all the three phases, solid (crystal), liquid and vapour phases coexist in equilibrium with one another. *O* is, therefore, called a **triple point.** It is also the melting point of the solid, or which is the same thing as the freezing point of the liquid. *OM* traces the effect of varying pressure on the melting point (freezing point) of the substance. The areas in which solid, liquid or vapour phases exist singly, are marked as such in the figure.

In Fig. 2, *AO* is the vapour pressure curve of the solid crystal. *OB* is the vapour pressure cuve of the anisotropic liquid (*i.e.*, liquid crystal) and *BC* is that of the isotropic liquid. *O* is the transition point at which the solid crystal is converted into liquid crystal and *B* is the melting point at which the liquid crystal changes into clear liquid. *O* and *B* are two triple points. At *O*, the three phases, namely, *solid crystal, liquid crystal* and *vapour* coexist in equilibrium with one another. At *B*, the three phases, namely, *liquid crystal, liquid* and *vapour* coexist in equilibrium with one another. *OM* shows the effect of pressure on the transition temperature and *BN* that of pressure on the melting point of the substance. The areas within which solid crystal (crystalline solid), liquid crystal, liquid and vapour phases exist singly are marked as such in the figure.

Thermography. The phase changes observed on heating a solid showing mesomorphic behaviour are sometimes represented in the form of a temperature-time graph, as shown in Fig. 3. This is known as **thermography.** On heating a solid, its temperature starts rising (curve *AB*). This continues till the solid starts changing into the liquid crystals (point *B*). The temperature now remains constant as long as both the phases, *viz.*, solid and liquid crystals are present (curve *BC*). When the solid completely changes into liquid crystals, the temperature again starts rising (curve *CD*) and this continues till the liquid crystals start changing into the liquid (point *D*). The temperature again becomes constant and remains so as long as liquid crystals and the liquid are present together (curve *DE*). When the liquid crystals completely change into the liquid, the temperature again starts rising (curve *EF*) and this continues till the liquid starts changing into the vapour (point *E*). The temperature again becomes constant and remains so as long as the liquid and the vapour are present together (curve *FG*). The temperature would again begin to rise when vapour alone are present.

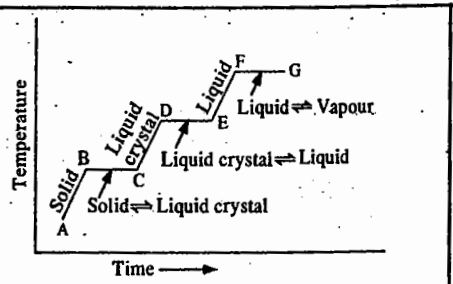

Fig. 3. Thermographic behaviour of a solid showing mesomorphism.

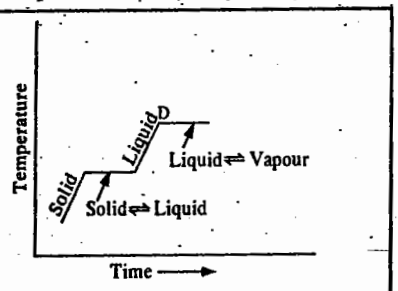

Fig. 4. Thermographic behaviour of an ordinary solid.

The thermographic behaviour of an ordinary solid is also shown for the sake of comparison (Fig. 4).

In recent years thermography has found extensive use in medical applications. It has helped in the detection and diagnosis of tumours and breast cancers and orthopaedic disorders such as back pain and arthritis. The diagnosis is based on the principle that heat changes produced in the affected skin are different from those in the healthy skin. The liquid crystals are pressed against the healthier part as well as the diseased part to be examined and colour photographs are taken of the resulting colour patterns and compared with each other.

LCDs and the Seven Segment Cell. In the electronic industry, the smectic and nematic types of liquid crystals have been used in thin light weight display devices such as digital watches and pocket

calculators; these are called **liquid crystal displays (LCDs).**

The LCDs work on the following principle : A thin film of a liquid crystal, not more than one-thousandth of an inch thick, is placed between two sheets of glass, one of which is coated on one side with a thin layer of an electrically conductive material such as tin oxide. When no current passes through the conductive coating, the molecules are uniformly oriented so that the light can pass through the cell (Fig. 5a). When the electric current is applied, the molecular alignment changes (since the liquid crystal molecules are polar) and the cell appears to be opaque or dark. Thus, a number or a letter is displayed in black against a silvery background. Since LCDs require a very small amount of current, the electronic watches and calculators can run for several years with the help of a small battery.

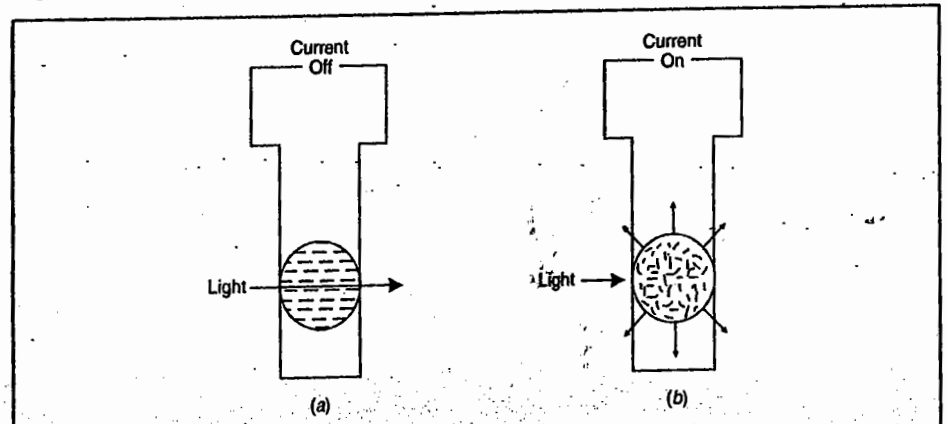

Fig. 5. Principle of working of a liquid crystal cell (*a*) Light passes through nematic liquid crystal when no electric current is passed (*b*) Light is scattered when molecules are disordered due to passing of electric current.

The LCD watches and calculators are generally composed of several 7-segment sections. Each 7-segment section can display one number. The combination of these sections (shown in Fig. 6) displays the numbers. A segment means an active area in the display or image area.

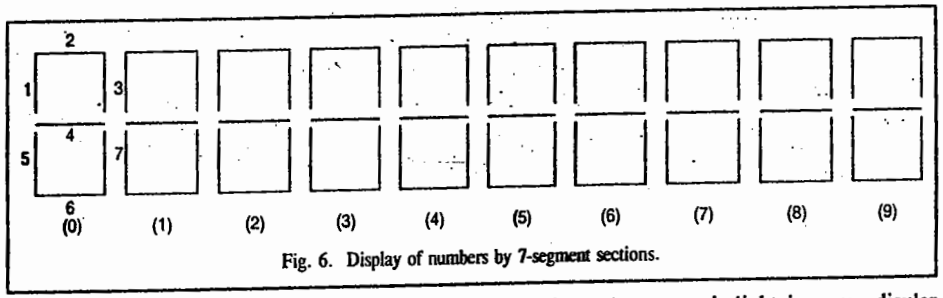

Fig. 6. Display of numbers by 7-segment sections.

The complete display panel is composed of two polarizers that transmit light in perpendicular directions, a mirrored surface and a layer of liquid crystal material between two glass plates (Fig. 7 *a*). In the absence of the applied voltage, the liquid crystal molecules in all the segments are precisely aligned (Fig. 7*a*) so that the entire panel appears silvery because light passes through both the polarizers and finally gets reflected from the mirror. However, when voltage is applied to the segment of a display, the precise alignment of liquid crystal molecules is lost (Fig. 7*b*). As a result, the light from the first polarizer fails to get rotated through the required angle of 90° to align with the second polarizer. The second polarizer thus blocks the passage of light. Since no light gets

reflected from the mirror, the panel appears dark.

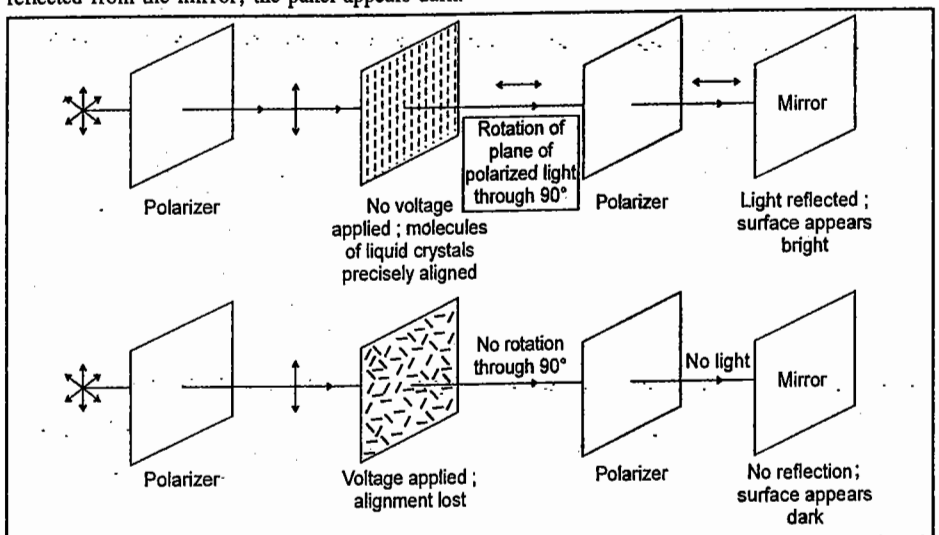

Fig. 7. (*a*) All liquid crystal molecules are precisely aligned in the absence of the applied voltage and light passes through both the polarizers and is reflected back form the mirror. (*b*) Alignment of the liquid molecules is lost when a voltage is applied to a segment in the panel. The segment then appears black against a silvery background.

Classification of Thermotropic Liquid Crystals

Further studies have shown that liquid crystals, *i.e.*, substances showing mesomorphic state, can be classified into two categories : smectic (*soap-like*, in Greek) liquid crystals and nematic (*thread-like*, in Greek) liquid crystals. Some substances are capable of existing in both forms. A few modifications of these forms are also known.

Smectic Liquid Crystals. The smectic liquid crystals do *not* flow as normal liquids. They have limited mobility. They flow in layers as if different planes or sheets are gliding over one another. The distribution of velocity in different layers is different from that found in a true liquid. To put it in other words, the flow of smectic liquid crystals is non-Newtonian while that of a true liquid is Newtonian. The concept of viscosity is, therefore, not applicable to the liquid crystals of this type. When spread over a clean glass surface, they form a series of *terraces* or *strata*, as shown in Fig. 8. The edges of these terraces often show a series of fine lines even in ordinary light, though more so in polarised light.

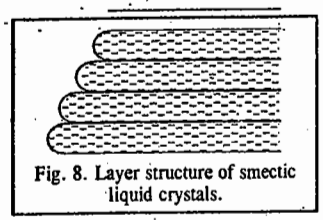

Fig. 8. Layer structure of smectic liquid crystals.

The existence of the layers suggests that the crystal lattice still exists though in somewhat distorted form. However, the spacing of the layers is different from that observed in the solid state.

Smectic liquid crystals also give X-ray diffraction patterns like solid crystals but it is in one direction only. Thus, smectic phase has a complex internal structure. When viewed in polarized light, smectic phases appear to have fan-like appearance. They are always uniaxial and are not affected by a magnetic field.

A few examples of compounds yielding smectic phases when heated at the transition temperatures are given in Table 2.

TABLE 2

Some Compounds giving Smectic Type of Liquid Crystals

Compound	Transition Point (°C)	Melting Point (°C)
Ethyl *p*-azoxy benzoate	114	121
Ethyl *p*-azoxy cinnamate	140	249
n-Octyl-*p*-azoxy cinnamate	94	175

Nematic Liquid Crystals. Nematic type of liquid crystals show near normal flow behaviour of liquids. They flow more readily than the smectic liquid crystals. Their flow is also Newtonian and the concept of viscosity is applicable to their flow. Their viscosity, however, is rather low as compared to that of liquids. Thus, nematic phases have liquid-like character and yet being turbid and anisotropic, they are unlike true liquids. This type is, therefore, regarded less truly anisotropic than the smectic type.

In polarised light, substances in nematic phase appear to have *thread-like structures*. They are uniaxial like smectic substances but unlike the latter, they are affected by a strong magnetic field. Thus, when viewed in the direction of the lines of force of a magnetic field, the turbid liquid appears quite clear. If the magnetic field is cut off, the liquid appears turbid again. Some of the compounds yielding nematic phases are given in Table 3.

TABLE 3

Some Compounds giving Nematic Type of Liquid Cystals

Compound	Transition Point (°C)	Melting Point (°C)
p-Azoxy anisole	116	135
p-Azoxy phenetole	137	167
p-Methoxy cinnamic acid	170	186
Anisaldazine	165	180
Dibenzal benzidine	234	260

Compounds Exhibiting both Smectic and Nematic Characters. Certain substances, notably the higher cholesteryl esters from the caprylate to the myristate, show, on heating, three phase transformations instead of the usual two. They melt sharply at a certain temperature to give smectic type of liquid crystals in the first instance. Then they change sharply at a higher temperature to give nematic type of liquid crystals which, in turn, melt sharply at a still higher temperature to give a clear liquid. Thus, there are three temperatures to be reckoned with : two transition temperatures and one true melting point. These temperatures for the myristate are 72°C, 78°C and 83°C, respectively. Some substances which show more than one smectic phase, are also known. For example, ethyl anisal-*p*-amino cinnamate passes through two smectic phases and one nematic phase before melting into the true liquid state. It, thus, undergoes the following changes :

$$\text{Solid Crystal} \underset{}{\overset{83°C}{\rightleftharpoons}} \text{Smectic Phase I} \overset{91°C}{\rightleftharpoons} \text{Smectic Phase II}$$

$$\overset{118°C}{\rightleftharpoons} \text{Nematic Phase} \overset{139°C}{\rightleftharpoons} \text{Liquid Phase}$$

The compound, evidently, exhibits three transition temperatures and one true melting point.

Cholesteric Liquid Crystals. Certain optically active compounds show many characteristics of nematic behaviour but at the same time they show strong colour effects in polarised light. This indicates that they have a *layer structure* like smectic liquid crystals. But they differ from smectic liquid crystals in having much thicker layers which are of the order of 500 to 5000 molecules thick. Such liquid crystals having some nematic and some smectic characters are called cholesteric liquid crystals. The first substance in which this type of mesomorphism was detected was cholesteryl benzoate. Its transition point is 145°C and melting point 178°C. The *l*-cholesteryl esters from formate to myristate are amongst other examples of compounds which form cholesteric type of liquid crystals.

Further, it has been found that solutions of some polypeptides in organic solvents, for example, poly-γ-benzyl-L-glutamate (PBLG) in dioxane or chloroform spontaneously adopt the cholesteric mesophase above a certain concentration. The same behaviour is shown by poly-γ-benzyl-D-glutamate (PBDG). In fact, the unique optical properties of the cholesteric phase, observed by Reinitzer and Lehmann, had culminated in the discovery of the liquid crystalline state.

Cholesteric mesophase displays a characteristic Lehmann rotation phenomenon. Lehmann had

found that droplets of the material, when heated from below, seemed to be rotating violently. However, from optical studies he concluded that the cholesteric mesophase also shows a highly non-Newtonian flow properties compared with the nematic phase.

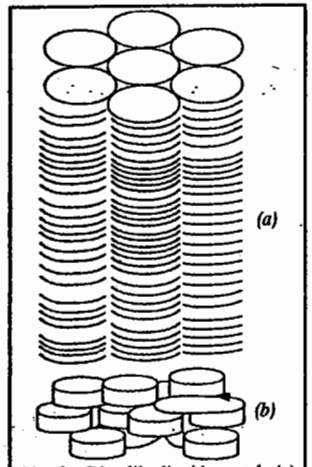

Fig. 9. Disc-like liquid crystals (*a*) Columnar phase (*b*) Nematic phase.

Disc-Shaped Liquid Crystals. In recent years, a number of discotic or disc-shaped liquid crystals have also been prepared which exist in more than one mesophase. They can be classified into two categories : *columnar* and *nematic*. The columnar phase consists of discs stacked one on top of the other aperiodically giving rise to liquid-like columns which form a two-dimensional lattice (Fig.9*a*). Several shapes of the columnar phase (such as hexagonal, tetragonal, tilted) exist. The nematic discotic phase consists of an orientationally ordered arrangement of discs without any long range translational order (Fig. 9*b*). Unlike the nematic rod-like phase, this mesophase is optically inactive.

Polymer Liquid Crystals. This is yet another class of liquid crystals reported recently. The basic monomer units of a polymer liquid crystal are low molar mass mesogens, rod-like or disc-like, which are attached to the polymer backbone in the main chain itself (Fig. 10*a*) or as side groups (Fig. 10*b*). If the repeating unit is rod-shaped, mesophases akin to the nematic, cholesteric and smectic types of rod-like molecules are found to exist.

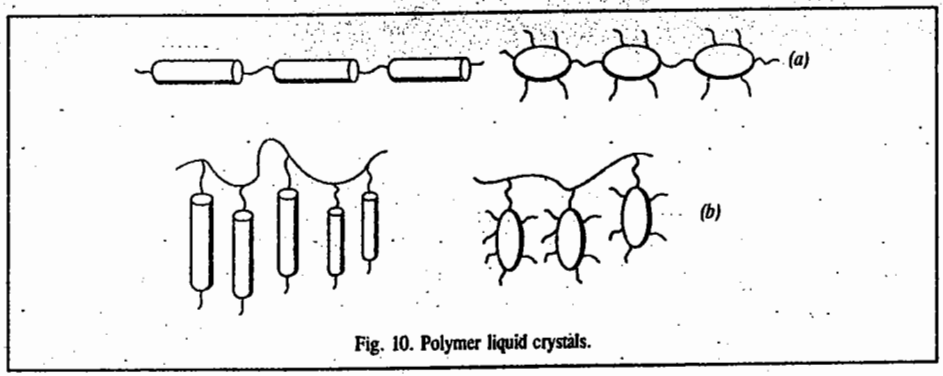

Fig. 10. Polymer liquid crystals.

Polymorphism in Thermotropic Liquid Crystals

Data on several mesogenic compounds with their transition temperatures and latent heats have recently been obtained. The following examples show the rich polymorphism shown by thermotropic liquid crystals. The figures given in kJ are the latent heats.

1. 4, 4′-Dimethoxyazoxy benzene (*p*-azoxyanisole) $CH_3O-C_6H_4-\overset{O}{\overset{\uparrow}{N}}=N-C_6H_4-OCH_3$:

$$\text{Solid} \underset{}{\overset{118{\cdot}2^\circ C,\ 29{\cdot}57\ kJ}{\rightleftharpoons}} \text{Nematic} \underset{}{\overset{135{\cdot}3^\circ C,\ 0{\cdot}57\ kJ}{\rightleftharpoons}} \text{Isotropic}$$

2. 4′-*n*-Pentyl-4-cyanobiphenyl $n\text{-}C_5H_{11}-C_6H_4-C_6H_4-CN$:

$$\text{Solid} \overset{225{\cdot}2^\circ C,\ 17{\cdot}2\ kJ}{\rightleftharpoons} \text{Nematic} \overset{35^\circ C,\ 0{\cdot}8\ kJ}{\rightleftharpoons} \text{Isotropic}$$

3. 4′-*n*-Octyl-4-cyanobiphenyl $n\text{-}C_8H_{17}-C_6H_4-C_6H_4-CN$:

$$\text{Solid} \overset{24^\circ C,\ 25{\cdot}3\ kJ}{\rightleftharpoons} \text{Smectic} \overset{34^\circ C,\ 0{\cdot}13\ kJ}{\rightleftharpoons} \text{Nematic} \overset{42{\cdot}6^\circ C,\ 0{\cdot}97\ kJ}{\rightleftharpoons} \text{Isotropic}$$

4. N-(4-*n*-Pentyloxy benzylidene-4′-*n*-hexylaniline) $C_5H_{11}O-C_6H_4-CH=N-C_6H_4-C_6H_{13}$:

$$\text{Solid} \overset{36^\circ C,\ 15{\cdot}2\ kJ}{\rightleftharpoons} \text{Smectic A} \overset{38{\cdot}4^\circ C,\ 0{\cdot}39\ kJ}{\rightleftharpoons} \text{Smectic B} \overset{42{\cdot}4^\circ C,\ 0{\cdot}15\ kJ}{\rightleftharpoons} \text{Smectic C}$$

$$\text{Isotropic} \overset{72{\cdot}8^\circ C,\ 0{\cdot}66\ kJ}{\rightleftharpoons} \text{Nematic} \overset{60{\cdot}3^\circ C,\ 0{\cdot}42\ kJ}{\rightleftharpoons} \text{Smectic E} \overset{51{\cdot}8^\circ C,\approx 0{\cdot}15\ kJ}{\rightleftharpoons} \text{Smectic D}$$

$$\text{Smectic C} \overset{50^\circ C}{\underset{25 kJ}{\rightleftharpoons}} \text{Smectic D}$$

All the transitions listed in the above examples are **enantiotropic**, *i.e.*, they take place reversibly on heating and cooling, though the reversal to the solid phase is generally accompanied by supercooling. The nematogenic compounds 1 and 2 are of special interest : the first has a permanent dipole moment inclined at an angle of about 60° with respect to the molecular axis, the second has a strong longitudinal dipole moment. These two compounds emphasize the major role played by molecular shape in determining the mesomorphic behaviour.

Melting of Nematic Crystals. When a solid is heated, its transformation to the nematic phase results in the break down of the positional order of the molecules but not of the orientational order. The mesophase is fluid and anisotropic as a result of the ease with which the molecules slide over one another while still preserving their parallelism. As heating continues, the degree of orientational order in the liquid crystal drops further. However, thermodynamic properties such as heat capacity, isobaric expansivity and isothermal compressibility increase rapidly as the temperature approaches the **nematic isotropic point** at which there is complete breakdown of the long orientational order.

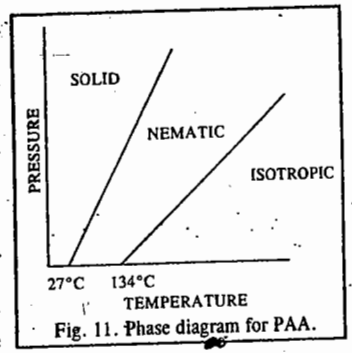

Fig. 11. Phase diagram for PAA.

Pressure-induced Mesomorphism. A very important quantity in the theory of liquid crystals is the so-called **order parameter.** If the molecules are aligned in a perfectly parallel arrangement, the order parameter is equal to unity and if the arrangement is random, the order parameter is zero. The phase diagram for *p*-azoxyanisole (PAA) is shown in Fig. 11.

As the pressure is raised, both the solid $\rightleftharpoons$ nematic and nematic $\rightleftharpoons$ isotropic transition temperatures increase. The slope dT/dP for the latter is greater than that of the former. The phase diagram for *p*-ethoxy benzoic acid (Fig. 12) is very interesting. At atmospheric pressure, it does not form a liquid crystal. However, as the pressure is raised, it exhibits mesophases—initially a nematic phase and at higher pressures a

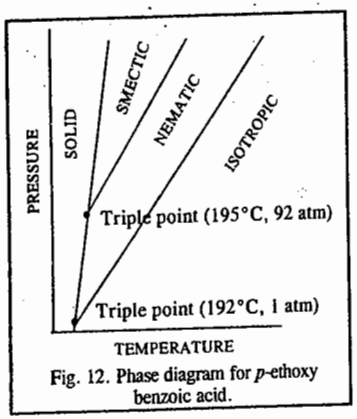

Fig. 12. Phase diagram for *p*-ethoxy benzoic acid.

smectic phase. These transitions have been detected by differential thermal analysis (DTA) and the mesophases have been identified by microscopic observations using a high pressure optical cell. The phase diagram shows the existence of two triple points : solid–nematic–isotropic and solid–smectic–nematic.

Molecular Arrangements in Various States of Liquid Crystals

In smectic state, the molecules are arranged in nearly parallel layers, as represented in Fig. 13*a*. The layers are held at regular distances from one another but the molecules within each layer are not regularly spaced. The anisotropic properties, such as double refraction, can thus be readily understood.

In nematic state, the arrangement of the molecules is still parallel but now there are no layers. The arrangement is irregular and the molecules now have greater freedom of motion, as shown in Fig. 13*b*. This arrangement would still lead to difference in properties in different directions, *i.e.*, it would lead to anisotropic character.

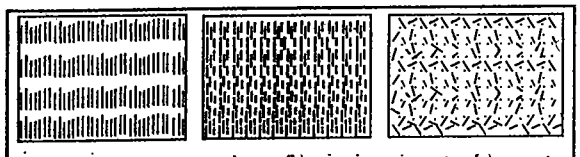

Fig. 13. Molecular arrangements in various states of liquid crystals.

In the case of a normal liquid, the arrangement of molecules is haphazard. The molecules move completely at random and, consequently, there is no scope for double refraction or any anisotropy. The material is now fully isotropic like a true liquid.

It is known that most of the industrial lubricants exist, more or less, in the mesomorphic, *i.e.*, liquid crystal state. In fact, it is believed that their functioning as lubricants is almost entirely due to their existence in this state. The proteins and fats, which are important constituents of food, also exist or get changed into this state before digestion and are, therefore, easily assimilated in the body. This state is believed to play an important role in nutritional and other processes. S. Chandrasekhar, a physicist at the Indian Institute of Science, Bangalore, has made important contributions to the physics of liquid crystals.

In recent years, the nematic and smectic types of liquid crystals have been widely adopted for liquid crystal display devices (LCDs), as already discussed. They operate through their interaction with natural light either in transmission or reflection. They consume very little power.

Review Questions

1. What are liquid crystals ? List their characteristics.
2. Draw and discuss the vapour pressure–temperature diagrams of true liquids and liquid crystals.
3. Describe the structures and main characteristics of 1. Smectic liquid crystals 2. Nematic liquid crystals 3. Cholesteric liquid crystals 4. Disc-shaped liquid crystals and 5. Polymer liquid crystals.
4. Give a brief account of the molecular arrangements which exist in various states of liquid crystals. How would you account for the turbidity observed in liquid crystals ?

CHAPTER 13

THE FIRST LAW OF THERMODYNAMICS

The word 'thermodynamics' implies *flow of heat*. The subject, however, is much more comprehensive. *It deals with energy changes accompanying all types of physical and chemical processes.*

Thermodynamics is based on two generalisations, called the First and the Second law of thermodynamics. These are based on human experience. There is no formal proof for these laws. All that one can say is that nothing contrary to these laws has been known to happen whenever we consider the behaviour of matter in bulk. Scientists are of the view that nothing contrary to these laws will ever be known. The laws of thermodynamics are not at all concerned with the atomic or molecular structure of matter.

Importance of Thermodynamics. Thermodynamics is a fundamental subject of great importance in physical chemistry. Most of the important generalisations of physical chemistry, including van't Hoff law of dilute solutions, Raoult's law of vapour pressure lowering, distribution law, law of chemical equilibrium, the phase rule and the laws of thermochemistry, can be deduced from the laws of thermodynamics.

Thermodynamics also helps to lay down the criteria for predicting feasibility or spontaneity of a process, including a chemical reaction, under a given set of conditions. In other words, it helps to predict whether a given process or a chemical reaction is feasible under the given conditions of temperature, pressure and concentration. It also helps us to determine the extent to which a process, including a chemical reaction, can proceed before attainment of equilibrium.

Limitations of Thermodynamics. The laws of thermodynamics apply only to matter in bulk and not to individual atoms or molecules. In other words, the laws of thermodynamics apply to behaviour of assemblages of a vast number of molecules and not to individual molecules.

Thermodynamics can only predict whether a given process, including a chemical reaction, is feasible under a given set of conditions ; it does not tell anything about the rate at which a given process may proceed. For example, thermodynamics predicts that hydrogen and oxygen gases would react at ordinary temperature to yield liquid water. But it does not tell whether the reaction will be fast or slow. We know only from experiment that in the absence of a catalyst, the reaction is extremely slow.

Some Basic Terms used in Thermodynamics. A few terms used frequently in thermodynamics are described below :

System. A system may be defined as any specified portion of matter under study which is separated from the rest of the universe with a bounding surface. A system may consist of one or more susbstances.

Surroundings. The rest of the universe which might be in a position to exchange energy and matter with the system is called the **surroundings.** In simple cases, surroundings generally imply air, or a water-bath in which a system under examination is immersed.

Isolated system. A system which can exchange neither energy nor matter with its surroundings is called an isolated system.

Closed System. A system which can exchange energy but not matter is called a closed system.

Open System. A system which can exchange matter as well as energy with its surroundings is said to be an open system.

Macroscopic Properties. The properties associated with a macroscopic system (*i.e.*, consisting of large number of particles) are called macroscopic properties. They are pressure, volume, temperature, composition, density, viscosity, surface tension, refractive index, etc.

Homogeneous and Heterogeneous Systems. A system is said to be **homogeneous** when it is completely uniform throughout, as for example, a pure solid or a liquid or a solution or a mixture of gases. In other words, a homogeneous system consists of only one phase.

A **phase** is defined as a homogeneous and physically distinct part of a system which is bounded by a surface and is mechanically separable from other parts of the system.

A system is said to be **heterogeneous** when it is not uniform throughout. In other words, a heterogeneous system is one which consists of two or more phases. Thus, a system consisting of two or more immiscible liquids, or a solid in contact with a liquid in which it does not dissolve, is a heterogeneous system. A liquid in contact with its vapour is also a heterogeneous system because it consists of two phases.

State of a System. When macroscopic properties of a system have definite values, the system is said to be in definite state. Whenever there is a change in any one of the macroscopic properties, the system is said to change into a different state. Thus, the state of a system is fixed by its macroscopic properties.

State Variables. Since the state of a system changes with change in any of the macroscopic properties, these properties are called state variables. It also follows that when a system changes from one state (called initial state) to another state (called final state), there is invariably a change in one or more of the macroscopic properties.

Pressure, temperature, volume, mass and composition are the most important state variables. In actual practice, it is not necessary to specify all the state variables because some of them are interdependent. In the case of a single gas, composition is not one of the variables because it remains always 100 per cent. Further, if the gas is ideal and one mole of the gas is under examination, it obeys the equation $PV=RT$, where R is the gas constant. Evidently, if only two of the three variables (P, V and T) are known, the third can easily be calculated. The two variables, generally specified, are temperature and pressure. These are called *independent variables*. The third variable, generally volume, is said to be a *dependent variable*, as its value depends upon the values of P and T. Thus, the thermodynamic state of a system consisting of a single *gaseous* substance may be completely defined by specifying any two of the three variables, *viz.*, temperature, pressure and volume.

Thermodynamic Equilibrium. A system in which the macroscopic properties do not undergo any change with time is said to be in thermodynamic equilibrium. Suppose a system is heterogeneous, *i.e.*, it consists of more than one phase. Then, if it is in equilibrium, the macroscopic properties in the various phases remain unaltered with time.

The thermodynamic equilibrium implies the existence of three kinds of equilibria in the system : *(i)* thermal equilibrium *(ii)* mechanical equilibrium and *(iii)* chemical equilibrium.

A system is said to be in **thermal equilibrium** if there is no flow of heat from one portion of the system to another. This is possible if the temperature remains the same throughout in all parts of the system.

A system is said to be in **mechanical equilibrium** if no mechanical work is done by one part of the system on another part of the system. This is possible if the pressure remains the same throughout in all parts of the system.

A system is said to be in **chemical equilibrium** if the composition of the various phases in the system remains the same throughout.

Extensive and Intensive Properties. An **extensive property** of a system is that which depends upon the amount of the substance or substances present in the system. The examples are mass, volume and energy.

An intensive property of a system is that which is independent of the amount of the substance present in the system. The examples are temperature, pressure, density, viscosity, refractive index, surface tension and specific heat.

In the light of the above definitions, extensive properties of a single (pure) substance will depend upon the number of moles (n) of the substance present and also on any two of the three variables P, V and T (called independent variables). If n is kept constant, the extensive properties of the system will depend only on the two independent variables.

If a system under examination is a mixture of two or more gases, the extensive properties will vary with the number of moles, n_A, n_B, n_C, etc., of the constituents A, B, C, etc., present in the system and also with the two independent variables. The intensive properties in such cases will depend upon the concentration of the various species, besides the two independent variables.

Thermodynamic Processes. The operation by which a system changes from one state to another is called a **process**. Whenever a system changes from one state to another it is accompanied by change in energy. In the case of open systems, there may be change of matter as well.

The following types of processes are known :

Isothermal process. A process is said to be isothermal if the temperature of the system remains constant during each stage of the process.

Adiabatic process. A process is said to be adiabatic if no heat enters or leaves the system during any step of the process.

Isobaric process. A process is said to be isobaric if the pressure of the system remains constant during each step of the process.

Reversible and Irreversible Processes. A process carried out infinitesimally slowly so that the driving force is only infinitesimally greater than the opposing force, is called a **reversible process.**

Any process which does not take place in the above manner, *i.e.*, a process which does not take place infinitesimally slowly, is said to be an **irreversible process.**

A reversible process cannot be realised in practice because it would require infinite time for its completion. Hence, almost all processes occurring in nature or laboratory are irreversible. A reversible process, therefore, remains imaginary and theoretical. Nevertheless, this concept is highly useful since it leads to some definite conclusions, as will be explained a little later in this chapter.

The following example may be given to illustrate the difference between reversible and irreversible processes.

Consider a cylinder provided with an air-tight, 'weightless' and frictionless piston, containing in it a certain quantity of a gas, as shown in Fig. 1. Let the pressure P on the piston be exactly equal to the pressure of the gas within. The piston will neither move downward nor upward and, consequently, there will be no change in the volume of the gas (Fig. 1*a*). Now, suppose the pressure on the piston is decreased by an infinitesimally small amount dP. The pressure on the piston, being $P - dP$, is now infinitesimally

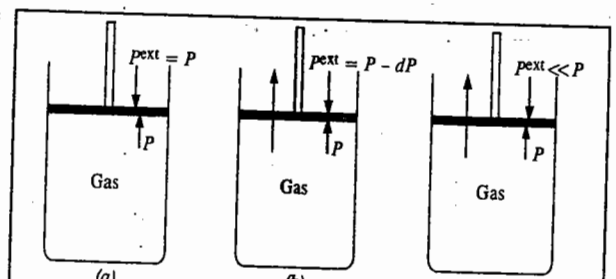

Fig. 1. Reversible and irreversible expansion of a gas.

smaller than the pressure of the gas P within the cylinder (Fig. 1*b*). Hence, the piston will move up and the gas will expand by an infinitesimally small amount. If the pressure on the piston is kept infinitesimally smaller than the pressure of the gas itself, the expansion of the gas will continue infinitesimally slowly, *i.e.*, in a thermodynamically reversible manner. If, however, the pressure on the piston (external pressure), is made much smaller than the pressure of the gas within the cylinder, then the gas will expand rapidly, pushing the piston upward suddenly (Fig. 1*c*). The expansion of the gas, in this case, is said to take place irreversibly.

Nature of Work and Heat. As is well known, whenever a system changes from one state to another, it is accompanied by change in energy. The change in energy may appear in the form of heat, work, light, etc.

The unit of energy is joule. It is defined as the work done when a resistance of 1 newton is moved through a distance of 1 metre. Thus, J = N m.

The British physicist James P. Joule (1818-1889) showed in 1850 that there is a definite relationship between mechanical work done W and heat produced H, *i.e.*,

$$W \propto H \quad \text{or} \quad W = JH$$

J is known as the **joule mechanical equivalent of heat.** Its numerical value is taken as 4·184 joules. Thus, with the expenditure of 4·184 joules of mechanical energy, 1 calorie of heat is produced. Thus, 1 calorie ≡ 4·184 joules. Heat is now invariably expressed in joules.

Energy manifests itself not only in the form of mechanical work (as in Joule's experiments) but also as heat energy, electrical energy and chemical energy. Whatever be the form, energy is composed of two factors : *(i)* an intensity factor and *(ii)* a capacity factor. The product of these two factors gives the energy.

Heat energy, for example, is measured by the product of temperature (*intensity factor*) and the heat capacity (*capacity factor*) of the system concerned. The product gives the energy of the system. If a substance of mass m kg and specific heat s kJ per kg, is heated through $t°$, the heat energy involved is given by *mst* kJ.

When a current flows in an electric circuit for a given interval of time, **electrical energy** produced is obtained by the product of the potential difference V causing the current to flow (*intensity factor*) and the quantity of electricity Q that flows for that interval of time (*capacity factor*). If V is measured in volts and Q in coulombs, the product of the two expresses the electrical energy (or work) in volt coulombs, *viz.*, joules.

When a body of mass m kg is moved through a height of h m, the work done against gravity is obtained by multiplying the intensity factor (mg newtons) with the capacity factor (h metres). The work performed is mgh joules. This work gets stored in the body as potential energy and is released when the body falls back to its original position.

THE FIRST LAW OF THERMODYNAMICS

The **first law of thermodynamics** states that energy can neither be created nor destroyed, although it can be transformed from one form to another. This is also known as the **law of conservation of energy.** Thus, whenever energy in one form disappears, an equal amount of energy in some other form must appear. The law is based on the cumulative experience of ages that *it is impossible to construct a* **perpetual motion machine,** *i.e., a machine which can produce energy without expenditure of energy.*

The equivalence of heat and mechanical work, established by Joule experimentally, also follows as a consequence of the First law. Suppose there is no such equivalence. Then, it may be possible at first to convert a certain amount of heat, say, x joules, into a certain amount of mechanical work and then, in the reverse process, to transform the same amount of mechanical work into heat, producing y joules of heat, where $y > x$. Then, the original state will have been restored but heat energy, equivalent to $y - x$ joules, will have been created. By repeating the above cycle, *energy can be continuously created* and in this way a perpetual motion machine can be fabricated. This is denied by human experience, as already stated. Hence, *there must be exact equivalence of heat and mechanical work.*

It is now known that energy can be produced by the destruction of mass, the two quantities being related by the expression $E = mc^2$ (Eistein equation) where E is the energy produced by the destruction of mass m and c is the velocity of light. *The* modified law, therefore, states that *the total mass and energy of an isolated system remains unchanged.*

It is to be kept in mind that in the entire ensuing discussion, *by the term* **system** *we shall mean an* **ideal gas.**

Internal Energy, U

Every substance is associated with a definite amount of energy which depends upon its chemical nature as well as upon its temperature, pressure and volume. This energy is known as **internal energy**. The exact magnitude of this energy is not known because the chemical nature includes such indeterminant factors as the translational, rotational and vibrational movements of the molecules, the manner in which the molecules are put together, the nature of the individual atoms, the arrangement and number of electrons, the energy possessed by the nucleus, etc. But, one thing is certain that the internal energy of a substance or a system is a definite quantity and it is a function only of the state (*i.e.*, chemical nature, composition, temperature, pressure and volume) of the system at the given moment, irrespective of the manner in which that state has been brought about. It is true that the actual value of internal energy cannot be determined but, fortunately, in thermodynamics the absolute value is not of any significance. It is the change in internal energy accompanying a chemical or a physical process that is of interest and this is a measurable quantity.

Internal Energy and the First Law. Suppose, a system is subjected to change of pressure and volume. Let the initial state be represented by A and the final state by B (Fig. 2) and let U_A and U_B represent energies associated with the system in its states A and B, respectively. These will be definite quantities as explained above. Then, the change in internal energy, ΔU, which is given by

$$\Delta U = U_B - U_A,$$

must also be a definite quantity, *irrespective of the path or the manner in which the change is brought about.* If it were not so, it would again be possible to construct a perpetual motion machine. Suppose, for example, that the system changes from state A to state B by following path I and is accompanied by change of energy equal to ΔU. Now suppose that the same change of state is brought about by another path, say, path II, and the change of energy is $\Delta U'$. Suppose, $\Delta U > \Delta U'$. Then, by a coupling of these two processes :

$A \longrightarrow B$ (by path I) and

$B \longrightarrow A$ (by path II),

as shown in Fig. 2, the system would return to its initial state and at the same time a surplus of energy equal to $\Delta U - \Delta U'$ would become available. By repeating the same cycle over and over again, energy would be generated continuously and a perpetual motion machine would be possible. This is contrary to the First law. Hence, $\Delta U' = \Delta U$. Thus, the energy change accompanying a process is a function only of the initial and the final states of the system and is independent of the path or the manner by which the change is brought about.

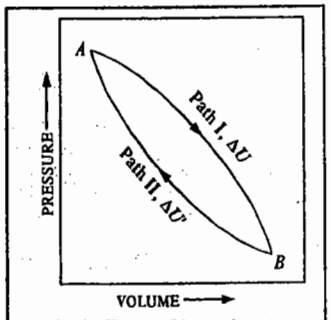

Fig. 2. Change of internal energy.

Energy changes in relation to work and heat changes. Let U_A be the energy of a system in its state A and U_B be the energy in its state B. Suppose the system while undergoing change from state A to state B *absorbs* heat q from the surroundings and also *performs* some work (mechanical or electrical), equal to w. The absorption of heat by the system tends to raise the energy of the system. The performance of work by the system, on the other hand, tends to lower the energy of the system because performance of work requires expenditure of energy. Hence, the change of internal energy, ΔU, accompanying the above process will be given by

$$\Delta U = U_B - U_A = q - w \qquad \ldots(1)$$

In general, if in a given process, the quantity of heat transferred from the surroundings to the system is q and the work done in the process is w, then the change in internal energy, ΔU, is given by

$$\Delta U = q + w \qquad \ldots(2)$$

Eq. 2 is the mathematical statement of the First law of thermodynamics.

If work is done by the surroundings on the system (as during the compression of a gas), w is taken as positive so that $\Delta U = q + w$ (Eq. 2). If, however, work is done by the system on the surroundings (as during the expansion of a gas), w is taken as negative so that $\Delta U = q - w$ (Eq.1).

Example 1. Calculate w and ΔU for the conversion of one mole of water at 100°C to steam at 1 atm pressure. Heat of vaporisation of water at 100°C is 40670 J mol^{-1}.

Solution : Heat required to convert 1 mole of water at 100°C to steam, q = 40670 J (given)

Calculation of w : P = 1 atm = 101,325 N m^{-2}

V_1 = Volume of 1 mole of liquid water at 1 atm pressure = 18 ml = 18×10^{-6} m^3

V_2 = Volume of 1 mole of steam at 100°C at 1 atm pressure

$= (22{\cdot}4 \text{ dm}^3 \times 373)/273 = 30{\cdot}60 \text{ dm}^3 = 0{\cdot}0306 \text{ m}^3$

$\therefore \quad w = P(V_2 - V_1) = 101{,}325 \text{ N m}^{-2} (0{\cdot}0306 \text{ m}^3 - 18 \times 10^{-6} \text{ m}^3)$

$= 101{,}325 \text{ N m}^{-2} \times 0{\cdot}0306 \text{ m}^3 = 3100 \text{ J mol}^{-1}$ (Neglected)

Since conversion of water to steam is accompanied by increase in volume, *work is done by the system on the surroundings*. Hence, w is *negative*, by convention. Thus, $w = -3100$ J mol^{-1}.

Calculation of ΔU : According to the First law equation,

$$\Delta U = q + w = 40670 \text{ J} + (-3100 \text{ J}) = 37570 \text{ J mol}^{-1}$$

State Functions, Exact and Inexact Differentials. The state function is a property of a thermodynamic system which has a definite value for a particular state of the system. It is independent of the manner in which the state is reached. The change in the state function accompanying the change in the state of the system depends only on the initial and the final states of the system and not on the path by which the change is brought about. Pressure, temperature, volume and energy are state functions. On the other hand, *work (w) is not a state function* because the work done in a given change of state depends upon the manner in which the change is brought about. For instance, the work in changing the volume of a gas by one cubic metre would be 100, 10 or 1 joule according as the external pressure is 100, 10 or 1 newton per square metre. The work done would be zero if the gas expands in vacuum. Since in the First law equation ($\Delta U = q + w$), ΔU is a definite quantity, hence, if w is not a state function, q also is not a state function. Mathematically, this is expressed by saying that while the differential of energy, *dU, is an exact differential,* the differentials of heat and work, *viz.*, dq and dw, respectively, are *inexact differentials*. Exact differentials can be integrated between the appropriate limits. This cannot be done in the case of inexact differentials, Thus,

$$\int_{U_1}^{U_2} dU = U_2 - U_1$$

But,

$$\int_{q_1}^{q_2} dq \neq q_2 - q_1 \quad \text{and} \quad \int_{w_1}^{w_2} dw \neq w_2 - w_1$$

Euler Reciprocal Relation. Let z be a state function of two independent variables x and y of the system, *i.e.*, $z = f(x, y)$. Since z is a state function, hence differential of z is *an exact differential* and can be written as

$$dz = (\partial z/\partial x)_y \, dx + (\partial z/\partial y)_x \, dy \qquad \ldots(3)$$

$$= M(x, y)\, dx + N(x, y)\, dy \qquad \ldots(4)$$

where $M(x, y) = (\partial z/\partial x)_y$ and $N(x, y) = (\partial z/\partial y)_x$.

Taking mixed second derivatives, we have

$$(\partial M/\partial y)_x = \partial^2 z/dydx \quad \text{and} \quad (\partial N/\partial x)_y = \partial^2 z/\partial x \partial y$$

Since $\partial^2 z/\partial y \partial x = \partial^2 z/\partial x \partial y$,

Hence, $(\partial M/\partial y)_x = (\partial N/\partial x)_y \qquad \ldots(5)$

Eq. 5 is called the **Euler reciprocal** (or **reciprocity**) **relation.** This is applicable to state functions only.

Since z is a state function, the finite change, Δz, as the system passes from initial state A to final state B, is given by $\Delta z = z_B - z_A$.

Also, $\oint dz = 0$ where cyclic integral $\oint$ means that the system is in the same state at the end of its path as it was at the beginning, *i.e.*, it has traversed a closed path. Thus, dz is an exact differential.

Example 2. Verify whether $dz = (5lx^2y + 47y^4)\, dx + (17x^3 + 188xy^3)\, dy$ is an exact differential or not.

Solution : Here $M(x, y) = 5lx^2y + 47y^4$ and $N(x, y) = 17x^3 + 188xy^3$

Hence, $(\partial M/\partial y)_x = 5lx^2 + 188y^3$ and $(\partial N/\partial x)_y = 51x^2 + 188y^3$

Thus, $(\partial M/\partial y)_x = (\partial N/\partial x)_y$

Hence, dz **is an exact differential.**

Example 3. Writing V as a function of T and P, show that for an ideal gas, dV is an exact differential.

Solution : $V = f(T, P)$

$$\therefore \quad dV = (\partial V/\partial T)_P \, dT + (\partial V/\partial P)_T \, dP \qquad \ldots(i)$$

For an ideal gas, $PV = RT$ so that $V = RT/P$. Hence,

$$(\partial V/\partial T)_P = R/P \quad \text{and} \quad (\partial V/\partial P)_T = -RT/P^2 \qquad \ldots(ii)$$

Substituting Eq. *(ii)* in Eq. *(i)*, we get

$$dV = (R/P)\, dT - (RT/P^2)\, dP \qquad \ldots(iii)$$

According to the Euler reciprocal relation, dV would be an exact differential if

$$\left[\frac{\partial(R/P)}{\partial P}\right]_T = -\left[\frac{\partial(RT/P^2)}{\partial T}\right]_P$$

or if $-R/P^2 = -R/P^2$ *which is true.*

Example 4. Show that for an ideal gas, the work differential dw is not an exact differential.

Solution : As we know, the work differential is given by

$$dw = PdV \qquad \ldots(i)$$

Since volume V is a state function [$V = f(T, P)$], hence dV is an exact differential.

$$\therefore \quad dV = (\partial V/\partial T)_P \, dT + (\partial V/\partial P)_T \, dP \qquad \ldots(ii)$$

For an ideal gas, $PV = RT$ so that $V = RT/P$. Hence,

$$(\partial V/\partial T)_P = R/P \quad \text{and} \quad (\partial V/\partial P)_T = -RT/P^2 \qquad \ldots(iii)$$

Substituting Eqs. *(ii)* and *(iii)* in Eq. *(i)*, we get

$$dw = PdV = RdT - (RT/P)dP = RdT - VdP \qquad \ldots(iv)$$

Applying the Euler reciprocal relation to Eq. *(iv)*, we have

$$\therefore \quad (\partial R/\partial P)_T = -(\partial V/\partial T)_P \qquad ...(v)$$

Since R is the gas constant, hence $(\partial R/\partial P)_T = 0$

Accordingly, from Eq. *v*, $(\partial V/\partial T)_P = 0$

But this is not true because there is always a change in volume with temperature at **constant pressure**. This leads to the conclusion that ***dw* is not an exact differential.**

The Cyclic Rule. From Eq. 3 we see that if the change occurs at constant z, then $dz=0$ so that

$$0 = (\partial z/\partial x)_y\, dx + (\partial z/\partial y)_x\, dy$$

Hence, $$(\partial x/\partial y)_z = -(\partial z/\partial y)_x/(\partial z/\partial x)_y$$

or $$(\partial z/\partial x)_y\,(\partial x/\partial y)_z\,(\partial y/\partial z)_x = -1 \qquad ...(6)$$

Eq. 6 is called the **cyclic rule.** This is applicable only in the case of state functions.

Example 5. Verify the cyclic rule for one mole of an ideal gas.

Solution : For one mole of an ideal gas, $PV = RT$.

Differentiating this equation, we have

$$PdV + VdP = RdT \qquad ...(i)$$

Again, at constant T, $dT=0$ so that $(\partial P/\partial V)_T = -P/V$ ...(ii)

At constant P, $dP=0$ so that $(\partial V/\partial T)_P = R/P$ ...(iii)

At constant V, $dV=0$ so that $(\partial T/\partial P)_V = V/R$ ...(iv)

Hence, from Eqs. *(ii)*, *(iii)* and *(iv)*,

$$(\partial P/V)_T\,(\partial V/\partial T)_P\,(\partial T/\partial P)_V = -(P/V)\,(R/P)\,(V/R) = -1 \quad \textit{which is the cyclic rule.}$$

Example 6. Using the cyclic rule, show that the thermal coefficients α and β are related as $\alpha = \beta\gamma P$ where γ is the pressure coefficient.

Solution : By definition, $\alpha = \frac{1}{V}\left(\frac{\partial V}{\partial T}\right)_P$; $\beta = -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_T$ and $\gamma = \frac{1}{P}\left(\frac{\partial P}{\partial T}\right)_V$

Hence, $$\left(\frac{\partial V}{\partial T}\right)_P = \alpha V\,; \quad \left(\frac{\partial P}{\partial V}\right)_T = -\frac{1}{\beta V} \quad \text{and} \quad \left(\frac{\partial T}{\partial P}\right)_V = \frac{1}{\gamma P} \qquad ...(i)$$

From the cyclic rule, $(\partial V/\partial T)_P\,(\partial T/\partial P)_V\,(\partial P/\partial V)_T = -1$ ...(ii)

Substituting Eq. *(i)* in Eq. *(ii)*, we have

$$(\alpha V)\,(1/\gamma P)(-1/\beta V) = -1 \qquad ...(iii)$$

or $$\alpha/\beta\gamma P = 1$$

or $$\alpha = \beta\gamma P$$

Example 7. Show that for a gaseous substance, $(\partial P/\partial T)_V = \alpha/\beta$.

Solution : From the cyclic rule, *viz.*, $(\partial P/\partial T)_V\,(\partial T/\partial V)_P\,(\partial V/\partial P)_T = -1$, we have

$$(\partial P/\partial T)_V = -\frac{1}{(\partial T/\partial V)_P(\partial V/\partial P)_T} = -\frac{(\partial V/\partial T)_P}{(\partial V/\partial P)_T}$$

Multiplying the numerator and the denominator on the R.H.S. by $1/V$, we obtain

$$\left(\frac{\partial P}{\partial T}\right)_V = -\frac{(1/V)(\partial V/\partial T)_P}{(1/V)(\partial V/\partial P)_T} = \frac{\alpha}{\beta}$$

Example 8. Show that for a van der Waals gas, $(\alpha/\beta) = R/(V - b)$.

Solution : We have shown above that $\alpha/\beta = (\partial P/\partial T)_V$

For a van der Waals gas, $(P + a/V^2)(V - b) = RT$

or $$P = \frac{RT}{V - b} - \frac{\alpha}{V^2}$$

$$\therefore \quad \left(\frac{\partial P}{\partial T}\right)_V = \frac{R}{V - b} = \frac{\alpha}{\beta}$$

Example 9. Show that $(\partial\alpha/\partial P)_T = -(\partial\beta/\partial T)_P$.

Solution : Let $$V = f(T, P)$$

$$\therefore \quad dV = (\partial V/\partial T)\,dT + (\partial V/\partial P)_T\,dP \qquad ...(i)$$

Since, by definition, $\alpha = \frac{1}{V}\left(\frac{\partial V}{\partial T}\right)_P$, hence $\left(\frac{\partial V}{\partial T}\right)_P = \alpha V$ ...(ii)

Also, since $\beta = -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_T$, hence $\left(\frac{\partial V}{\partial P}\right)_T = -\beta V$ ...(iii)

Substituting Eqs. *(ii)* and *(iii)* in Eq. *(i)*, we have

$$dV = \alpha V dT - \beta V dP \quad \text{or} \quad dV/V = \alpha\, dT - \beta\, dP$$

or $$d \ln V = \alpha\, dT - \beta\, dP$$

Since V and hence $\ln V$ is a state function, therefore, using the Euler reciprocal relation, we get

$$(\partial\alpha/\partial P)_T = -(\partial\beta/\partial T)_P$$

Enthalpy

Suppose the change of state of a system is brought about *at constant pressure.* In that case, there will be change of volume. Let the volume increase from V_A to V_B, at constant pressure P. Then, the work done (w) by the system will be given by

$$w = -P(V_B - V_A) \qquad ...(7)$$

Substituting in Eq. 2, we have

$$\Delta U = q - P(V_B - V_A) \quad \text{or} \quad U_B - U_A = q - P(V_B - V_A)$$

or $$(U_B + PV_B) - (U_A + PV_A) = q \qquad ...(8)$$

The quantity $U+PV$ is known as the **enthalpy** of the system and is denoted by H. It represents the **total energy** stored in the system. Thus,

$$H = U + PV \qquad ...(9)$$

Since, U is a definite quantity and P and V are also definite quantities which define the state of a system, hence H is also a definite quantity depending upon the state of the system.

From Eqs. 9 and 8, we have

$$H_B - H_A = \Delta H = q \qquad ...(10)$$

Since H_B and H_A are definite quantities, it is evident that ΔH, like ΔU, is a definite quantity depending only on the initial and final states of a system. Obviously, ΔH represents increase in the enthalpy of a system when it changes from state A to state B.

Since ΔH is a definite quantity, the heat absorbed (q) under the conditions of the experiment, *i.e.*, at constant pressure, is also a definite quantity.

Further, it follows from Eq. 8 that

$$(U_B - U_A) + P(V_B - V_A) = q$$

Incorporating the above value of q in Eq. 10. we have

$$\Delta H = (U_B - U_A) + P(V_B - V_A) \quad \text{or} \quad \Delta H = \Delta U + P\Delta V \qquad ...(11)$$

where ΔV is the *increase* in volume undergone by the system.

Enthalpy of Vaporisation. When a liquid evaporates, it *absorbs* some heat from the surroundings. Thus, evaporation of a liquid is accompanied by *increase* in enthalpy. The increase for the evaporation of one mole of water at 25°C is 40·70 kJ. We may express this result in the form of a

thermochemical equation :

$$H_2O(l) \longrightarrow H_2O(g) ; \qquad \Delta H_{vap} = +40{\cdot}70 \text{ kJ mol}^{-1}$$

When vapours condense to liquid state, they *give out* (*evolve*) heat. Thus, condensation of vapours is accompanied by *decrease* in enthalpy. The value for the condensation of one mole of water vapour at 25°C is also 40·70 kJ. Therefore; we may write

$$H_2O(g) \longrightarrow H_2O(l) ; \qquad \Delta H = -40{\cdot}70 \text{ kJ mol}^{-1}$$

The change in enthalpy (ΔH) when a liquid changes into vapour state or when vapours change into liquid state, is known as **enthalpy of vaporisation.** This has a positive sign in the former case and a negative sign in the latter case.

Enthalpy of Fusion. When a solid melts and changes into liquid state, it *absorbs* heat. On the contrary, when a liquid freezes and changes into solid state, it *gives out* heat. In the first case, enthalpy of the system *increases*. In the latter case, the enthalpy of the system *decreases*. The change in enthalpy for this type of phase-transformation is known as **enthalpy of fusion.**

The enthalpy of fusion for 1 mole of water at 0°C is 6·02 kJ. We may express this result in the following way :

$$H_2O(s) \longrightarrow H_2O(l) ; \qquad \Delta H_{fus} = +6{\cdot}02 \text{ kJ mol}^{-1}$$
$$H_2O(l) \longrightarrow H_2O(s) ; \qquad \Delta H = -6{\cdot}02 \text{ kJ mol}^{-1}$$

Heat Capacity

Heat capacity of a system, between any two temperatures, is defined as the quantity of heat (q) required to raise the temperature of the system from the lower to the higher temperature divided by the temperature difference.

If the mass of the system is one gram, the heat capacity is called the **specific heat** of the system. If, however, the mass of the system is one mole, as is generally the case in physical chemistry, then the heat capacity is termed as **molar heat capacity**. It is usually denoted by C. Thus, the molar heat capacity of a system between temperatures T_1 and T_2 will be expressed as

$$C = q/(T_2 - T_1) \qquad ...(12)$$

Since the heat capacity varies with temperature, hence the true molar heat capacity is defined by the differential equation

$$C = dq/dT \qquad ...(13)$$

The molar heat capacity of a gaseous system, determined at constant volume, is different from that determined at constant pressure. In the former case, no external work is done *by* the system or *on* the system (*i.e.*, $w=0$) since there is no change in volume. Hence, from the First law equation (Eq. 2),

$$q = \Delta U$$
$$C_V = (q/T_2 - T_1)_V = \Delta U/(T_2 - T_1)_V$$

or
$$C_V = (\partial U/\partial T)_V \qquad ...(14)$$

At constant pressure, however, there is change of volume and some work is done. Suppose, the volume *increases* by ΔV and the work done is w. Then, from the First law equation (Eq. 2),

$$q = \Delta U - w \quad \text{and} \quad C_P = \left(\frac{q}{T_2 - T_1}\right)_P \qquad ...(15)$$

Increase in volume means that the work is done *by the system* on the surroundings so that w, by convention, is *negative*. Hence, $w = -P\Delta V$.

$$\therefore \quad q = \Delta U - (-P\Delta V) = \Delta U + P\Delta V \qquad ...(16)$$

$$C_P = \left(\frac{\Delta U + P\Delta V}{T_2 - T_1}\right)_P = \left(\frac{\Delta H}{T_2 - T_1}\right)_P \qquad ...(17)$$

or
$$C_P = (\partial H/\partial T)_P \qquad ...(18)$$

Thus, while the molar heat capacity of a gaseous system of mass one mole at constant volume is defined as the increase in internal energy of the system per degree rise of temperature, that at constant pressure is defined as the increase in enthalpy of the system per degree rise of temperature.

Relation between C_P and C_V in Gaseous Systems. When a gas is heated at constant volume, no external work is done by the gas. In other words, all the heat supplied to the gas is used in increasing its internal energy. Thus, if the temperature of one mole of gas is raised through 1°C (say from T to $T+1$), the increase in its internal energy itself gives the molar heat capacity at constant volume. However, when a gas is heated *at constant pressure*, there will be increase in its volume, that is, the gas will expand and do some external work. Therefore, some extra heat (in addition to the heat required by it to increase the internal energy of its molecules) must be supplied to the gas to enable it to perform this external work. Hence, the molar heat capacity of a gas at constant pressure must be greater than that at constant volume, *i.e.*, $C_P > C_V$. Thus, $C_P - C_V$ = work done by one mole of the gas in expansion when heated through 1°C at constant pressure.

As we know, the work done by the gas in expansion at constant pressure is numerically given by $w = P\Delta V$.

For one mole of an ideal gas, $PV = RT$ ...(19)

When the temperature is raised by 1°C from T to $T+1$ so that the volume is $V+\Delta V$, then

$$P(V+\Delta V) = R(T+1) \qquad ...(20)$$

Subtracting Eq. 19 from Eq. 20, we have

$$P\Delta V = R \qquad ...(21)$$

Thus, the work done by one mole of an ideal gas in expansion at constant pressure when heated through 1°C is equal to R. Hence,

$$C_P - C_V = R \qquad ...(22)$$

Thus, the difference between the molar heat capacity of a gas at constant pressure (C_P) and at constant volume (C_V) is equal to the gas constant R.

EXPANSION OF AN IDEAL GAS AND CHANGES IN THERMODYNAMIC PROPERTIES

With the help of the First law of thermodynamics it is possible to calculate changes in thermodynamic properties such as q, w, ΔU and ΔH when an ideal gas undergoes expansion. The expansion may be isothermal or adiabatic and the process of expansion may be carried out reversibly or irreversibly.

A. Isothermal Expansion

Calculation of ΔU. In an isothermal process, the temperature of the system remains constant throughout the process of expansion. Since for an ideal gas, the internal energy U depends only on temperature, it follows that at constant temperature (isothermal process), the internal energy of the gas remains constant. This means that $\Delta U = 0$.

Calculation of ΔH. According to Eq. 9.

$$H = U + PV$$
$$\therefore \quad \Delta H = \Delta(U + PV) = \Delta U + \Delta PV = \Delta U + \Delta nRT \qquad ...(23)$$

Since for an isothermal process, ΔT as well as ΔU are equal to zero, hence, $\Delta H=0$.

Calculation of q and w. According to the First law of thermodynamics, $\Delta U=q+w$. Since, for an isothermal process, $\Delta U = 0$, hence $-w = q$. This shows that in an isothermal expansion, the work is done at the expense of the heat absorbed. The magnitude of w (or q) depends upon the manner in which the process of expansion is carried out, *i.e.*, whether it is carried out *reversibly* or *irreversibly*.

Work done in Reversible Isothermal Expansion. Consider a gas enclosed in a cylinder fitted with a 'weightless' and frictionless piston, as shown earlier in Fig. 1. The cylinder is not insulated. It is supposed to be in thermal equilibrium with the surroundings so that the temperature of the gas remains constant all along. The external pressure P on the piston is equal to the pressure of the gas within the cylinder, as shown earlier in (Fig. 1*a*). If the external pressure is lowered by an infinitesimal amount dP, *i.e.*, it falls from P to $P-dP$ (Fig. 1*b*), the gas will expand by an infinitesimal volume dV, *i.e.*, the volume changes from V to $V+dV$. As a result of expansion, the pressure of the gas within the cylinder falls to $P-dP$, *i.e.*, it becomes again equal to the external pressure. The piston then comes to rest.

If the external pressure is lowered again second time by the same infinitesimal amount dP, the gas will undergo the second infinitesimal expansion dV before the pressure again equals the new external pressure. The piston again comes to rest. The process is continued such that the external pressure is lowered by successive small amounts and, as a result, the gas undergoes a series of small successive increments of volume dV at a time.

It may be noted that since the system is in thermal equilibrium with the surroundings, the infinitesimally small cooling produced as a result of infinitesimally small expansion of the gas at each step, is offset by the heat absorbed from the surroundings and the temperature remains constant throughout the operation.

Since during expansion, pressure decreases and volume increases, these two parameters are assigned *opposite signs*. The work done by the gas in an infinitesimal expansion is thus given by

$$dw = -(P - dP)dV = -PdV \qquad ...(24)$$

ignoring the product $dPdV$, as both the quantities are infinitesimal.

The total work w done *by the gas* in expansion, say, from original volume V_1 to final value V_2, will be the sum of the series of the terms *PdV in which the pressure keeps on decreasing gradually*. The result may be expressed mathematically as

$$w = -\int_{V_1}^{V_2} PdV \qquad ...(25)$$

where V_1 is the volume of the gas in the initial state *and* V_2 in the final state.

The above integral can be evaluated by substituting $P=RT/V$ for one mole of an ideal gas. Thus,

$$w = -RT\int_{V_1}^{V_2}\frac{dV}{V} = -RT\ln\frac{V_2}{V_1} \qquad ...(26)$$

Since in an ideal gas, $P_1V_1=P_2V_2$, at constant temperature, the above equation may also be written as

$$w = -RT\ln(P_1/P_2) \qquad ...(27)$$

For n moles, the above expressions may be written as

$$w = -nRT\ln(V_2/V_1) = -nRT\ln(P_1/P_2) \qquad ...(28)$$

Since during expansion, V_2 is more than V_1 and P_2 is less than P_1, hence, from Eq. 28, the work w comes out to be *negative* in conformity with the convention used in this regard.

Work done in Reversible Isothermal Compression. Now suppose the gas undergoes isothermal reversible compression from volume V_2 to V_1. The external pressure will now be made infinitesimally higher than P, the pressure of the gas inside the cylinder. Let the external pressure be $P+dP$. There will be an infinitesimal contraction in volume, say dV, of the gas. Since during compression of a gas, the *pressure increases* and the *volume decreases*, hence these two parameters are assigned *opposite*

signs as before. Thus, the work done by the surroundings on the system for this infinitesimal step is given by

$$dw = -(P + dP)dV = -PdV \qquad ...(29)$$

ignoring the quantity $dPdV$, as before.

If compression is carried out reversibly in a series of steps from the initial volume V_2 to final volume V_1, the work done (w') by the surroundings on the gas will be given by

$$w' = -\int_{V_2}^{V_1} PdV \qquad ...(30)$$

Assuming the gas to be ideal, P, as before, may be substituted by RT/V in the above equation so that

$$w' = -RT\int_{V_2}^{V_1}\frac{dV}{V} = -RT\ln(V_1/V_2) \qquad ...(31)$$

$$= -RT\ln(P_2/P_1) \qquad ...(32)$$

For n moles of the gas, the above expressions may be written as

$$w' = -nRT\ln(V_1/V_2) = -nRT\ln(P_2/P_1) \qquad ...(33)$$

Since during compression, the initial volume V_2 is more than the final volume V_1 and also since the initial pressure P_2 is less than the final pressure P_1, hence, according to Eq. 33, the work done w' comes out to be *positive*, as was chosen as a convention in this regard.

Maximum Work. As discussed above, the work done by a gas during expansion is given by the product $P^{ext}\Delta V$ where ΔV is the increase in volume. If the external pressure P^{ext} is only infinitesimally smaller than the pressure P of the gas (Fig. 1*b*) then, expansion is said to take place *reversibly*. If, however, the external pressure is much smaller than the gas pressure (Fig. 1*c*), the expansion will take place rapidly, *i.e.*, *irreversibly* and the work done *for the same amount of expansion* will be much smaller since P^{ext} is now much smaller than before. Taking an extreme case, if the external pressure is zero (*i.e.*, the gas expands in vacuum), the work done will be zero. Hence, it follows that when a gas expands *freely*, *i.e.*, *when it expands against vacuum* such that $P^{ext}=0$, *no work is done by the gas*.

It is evident from the above discussion that the magnitude of work done by a system on expansion depends upon the magnitude of the opposing (external) pressure. The closer is the opposing pressure to the pressure of the gaseous system in the cylinder, the greater is the work performed by the system on expansion. In other words, maximum work is obtained when the two opposing pressures differ only by an infinitesimal amount from each other. This condition, evidently, is demanded for a thermodynamically reversible process, as discussed earlier. Hence, the condition for maximum work coincides with that for thermodynamic reversibility.

Work done in Irreversible Isothermal Expansion. We come across two types of irreversible isothermal expressions, *viz.*, expansion against zero pressure, *i.e.*, in vacuum (called *free expansion*) and expansion against a particular constant external pressure whose magnitude is less than the pressure of the gas, *i.e.*, $P^{ext} < P$ (called *intermediate expansion*).

Free Expansion. Since in free expansion, the external pressure is zero, therefore,

$$w = -\int dw = -\int P^{ext}dV = 0 \qquad ...(34)$$

Intermediate Expansion. Suppose the volume of the gas increases from V_1 to V_2 against a constant external pressure, P^{ext}. The work done is then given by

$$w = -\int_{V_1}^{V_2} P^{ext}dV = -P^{ext}(V_2 - V_1) \qquad ...(35)$$

Since P^{ext} is less than P, the work done during intermediate isothermal expansion is numerically less than the work done during reversible isothermal expansion in which P^{ext} is almost equal to P.

B. Adiabatic Expansion

In adiabatic expansion, by definition, no heat is allowed to enter or leave the system. Hence, $q=0$. Thus, according to Eq. 2,

$$\Delta U = 0 + w \quad \text{or} \quad w = \Delta U \qquad ...(36)$$

In expansion, work is done *by the system* on the surroundings, hence w is negative. Accordingly, ΔU is *negative, i.e.*, there is decrease in the internal energy of the system and consequently, *the temperature of the system falls*. Evidently, the work in this case is done at the expense of the internal energy of the gas.

If there is compression, w will be positive and hence ΔU would be positive, *i.e.*, there would be increase in internal energy and consequently an increase in temperature. Evidently, in this case work is done by the surroundings on the system and this work is stored in the system in the form of an increase in internal energy.

Calculation of ΔU. As discussed earlier, the molar heat capacity at constant volume of an ideal gas is given by

$$C_V = (\partial U/\partial T)_V \qquad ...(37)$$

Accordingly, $dU = C_V\,dT$ and, for a finite change,

$$\Delta U = C_V \Delta T \qquad ...(38)$$

Calculation of ΔH. According to Eq. 9,

$$H = U + PV$$

$$\therefore \quad \Delta H = \Delta U + \Delta(PV) = \Delta U + R\Delta T \text{ for one mole of the gas,}$$

Substituting the value of ΔU from Eq. 38, we get

$$\Delta H = C_V \Delta T + R\Delta T = (C_V + R)\Delta T \qquad ...(39)$$

$$= C_P \Delta T \qquad ...(40)$$

Calculation of w. Since in an adiabatic process, $q=0$, hence according to the First law equation, $\Delta U = q + w$, the work done in this case is given by the expression

$$w = \Delta U = C_V \Delta T \qquad ...(41)$$

It is evident from the above equations that the magnitude of ΔU, ΔH and w would depend upon the magnitude of ΔT. Since the final temperature and hence the value of ΔT varies with the nature of the process, whether reversible or irreversible, the magnitude of the thermodynamic properties would also vary with the nature of the process.

Final Temperatures in Reversible and Irreversible Adiabatic Expansions

Reversible Adiabatic Expansion. The final temperature in a reversible adiabatic expansion can be calculated from the expressions which relate the initial and final temperatures to the respective volumes or pressures.

Relation between Temperature and Volume. Let P be the external pressure against which expansion is taking place and ΔV be the increase in volume. Then, the external work done *by the system* is equal to $-P\Delta V$. Hence, according to the First law equation,

$$\Delta U = -P\Delta V \qquad ...(42)$$

If ΔT is the fall in temperature, then, since $\Delta U = C_V \Delta T$

$$C_V \Delta T = -PdV \qquad ...(43)$$

For infinitesimally small quantities, as in reversible expansion,

$$C_V dT = -PdV = -RT\,dV/V \qquad \text{(for 1 mole of the gas)}$$

or $$C_V dT/T = -R\,dV/V$$

or $$C_V d(\ln T) = -R\,d(\ln V) \qquad ...(44)$$

Integrating Eq. 44 between temperatures T_1 and T_2 when the corresponding volumes are V_1 and V_2, we have

$$C_V \ln (T_2/T_1) = -R \ln (V_2/V_1) = R \ln (V_1/V_2)$$

or $$\ln (T_2/T_1) = (R/C_V) \ln (V_1/V_2) \qquad ...(45)$$

Knowing that $C_P - C_V = R$ and putting $C_P/C_V = \gamma$, we get

$$\ln (T_2/T_1) = (\gamma - 1) \ln (V_1/V_2) = \ln (V_1/V_2)^{\gamma - 1}$$

$$\therefore \quad T_2/T_1 = (V_1/V_2)^{\gamma-1}$$

or $$T_1/T_2 = (V_2/V_1)^{\gamma-1} \quad \text{(Note that } \gamma > 1) \qquad ...(46)$$

Thus, since $V_2 > V_1$, $T_2 < T_1$. Hence, a gas cools during reversible adiabatic expansion.

Relation between Temperature and Pressure. Since $P_1V_1 = RT_1$ and $P_2V_2 = RT_2$, it follows from Eq. 46 that

$$P_1V_1^{\gamma} = P_2V_2^{\gamma} \qquad ...(47)$$

and $$(T_1/T_2)^{\gamma} = (P_2/P_1)^{1-\gamma} \qquad ...(48)$$

Thus, knowing γ, V_1, V_2 (or P_1, P_2) and the initial temperature T_1, the final temperature T_2 can be readily evaluated with the help of Eq. 46 or 48.

Irreversible Adiabatic Expansion. In this category, we shall consider two cases, *viz.*, the free expansion and the intermediate expansion.

Free Expansion. Since in a free expansion, the external pressure is zero, the work done w is also zero. Accordingly, ΔU which is equal to w, is also zero. Since in an ideal gas, the internal energy is a function of temperature, therefore, if ΔU is zero, ΔT is also zero. It follows, therefore, that ΔH, which is equal to $\Delta U + nR\Delta T$, is also zero. Thus, in a free adiabatic expansion $\Delta T=0$; $w=0$ and $\Delta H=0$.

Intermediate Expansion. Suppose the volume of the gas increases from V_1 to V_2 against a constant pressure P^{Ext} of the gas. The work done in this case would be given by

$$w = -P^{Ext}(V_2 - V_1) \qquad ...(49)$$

Further, from the First law equation (*viz.*, $\Delta U = q + w$), in adiabatic expansion,

$$w = \Delta U = C_V (T_2 - T_1) \qquad ...(50)$$

From Eqs. 49 and 50,

$$P^{Ext}(V_2 - V_1) = -C_V (T_2 - T_1)$$

or $$C_V(T_2 - T_1) = P^{Ext}(V_1 - V_2) = P^{Ext}(RT_1/P_1 - RT_2/P_2)$$

$$= R P^{Ext}(T_1P_2 - T_2P_1)/P_1P_2 \qquad ...(51)$$

Thus, knowing C_V, T_1, P_1, P_2 and P^{Ext}, we can readily calculate T_2, the final temperature of the gas.

Example 10. One mole of an ideal gas expands against a constant external pressure of 1 atm from a volume of 10 dm^3 to a volume of 30 dm^3. Calculate the work done by the gas in joules.

Solution : From Eq. 25, $w = -\int_{V_1}^{V_2} PdV = -P(V_2 - V_1) = -(1 \text{ atm})(30 \text{ dm}^3 - 10 \text{ dm}^3) = -20 \text{ dm}^3 \text{ atm}$

We have to get the result in joules. Recall that

$$R = 8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1} = 0{\cdot}08206 \text{ dm}^3 \text{ atm K}^{-1} \text{ mol}^{-1}$$

$$\therefore \quad 1 \text{ atm} = \frac{8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1}}{0{\cdot}08206 \text{ dm}^3 \text{ K}^{-1} \text{ mol}^{-1}}$$

$$\therefore \quad w = -20 \text{ dm}^3 \text{ atm} = -20 \text{ dm}^3 \times \frac{8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1}}{0{\cdot}08206 \text{ dm}^3 \text{ K}^{-1} \text{ mol}^{-1}} = -2026 \text{ J}$$

Example 11. A gas expands isothermally against a constant external pressure of 1 atm from a volume of 10 dm^3 to a volume of 20 dm^3. In this process it absorbs 800 J of thermal energy from its surroundings. Calculate ΔU for the process in joules.

Solution : From Eq. 25, $w = -\int_{V_1}^{V_2} P dV = -P(V_2 - V_1) = -$ (1 atm)(20 dm^3 – 10 dm^3) = – 10 dm^3 atm

$$= -10 \text{ dm}^3 \times \frac{8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1}}{0{\cdot}08206 \text{ dm}^3 \text{ K}^{-1} \text{ mol}^{-1}} = \mathbf{-1013 \text{ J}}$$

From the First law of thermodynamics,

$$\Delta U = q + w = 800 \text{ J} + (-1013 \text{ J}) = \mathbf{-213 \text{ J}}$$

Example 12. Six moles of an ideal gas expand isothermally and reversibly from a volume of 1 dm^3 to a volume of 10 dm^3 at 27°C. What is the maximum work done ? Express the result in joules.

Solution : Work done in this case is given by

$$w = -nRT \ln (V_2/V_1) \qquad \text{(Eq. 28)}$$

$$= -(6 \text{ mol})(0{\cdot}08206 \text{ dm}^3 \text{ atm K}^{-1} \text{ mol}^{-1})(300 \text{ K}) \ln (10 \text{ dm}^3/1 \text{ dm}^3)$$

$$= \mathbf{-340{\cdot}17 \text{ dm}^3 \text{ atm}} = -340{\cdot}17 \text{ dm}^3 \frac{8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1}}{0{\cdot}08206 \text{ dm}^3 \text{ K}^{-1} \text{ mol}^{-1}} = \mathbf{-34464{\cdot}8 \text{ J}}$$

Example 13. 10 moles of an ideal gas expand isothermally and reversibly from a pressure of 10 atm to 2 atm at 300 K. What is the largest mass which can be lifted through a height of 1 metre in this expansion ?

Solution : Work done in this case is given by

$$w = -nRT \ln (P_1/P_2) \qquad \text{(Eq. 28)}$$

$$= -10 \text{ mol}(8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1})(300 \text{ K}) \ln (10 \text{ atm}/2 \text{ atm}) = -40{\cdot}15 \times 10^3 \text{ J}$$

Let M be the mass which can be lifted through a height of 1m.

Work done in lifting the mass $= Mgh = M \times 9{\cdot}81 \text{ m s}^{-2} \times 1 \text{ m}$

$\therefore \quad M \times 9{\cdot}81 \times 1 \text{ m}^2 \text{ s}^{-2} = 40{\cdot}15 \times 10^3 \text{ J} \qquad (\text{J} = \text{kg m}^2 \text{ s}^{-2})$

$\therefore \quad M = 409{\cdot}28 \text{ kg}$

Example 14. A certain volume of dry air at N.T.P. is expanded reversibly to three times its volume (*a*) isothermally (*b*) adiabatically. Calculate the final pressure and temperature in each case, assuming ideal behaviour. (C_P/C_V for air is 1·4).

Solution : Let V_1 be the volume of dry air at N.T.P.

***a.* Isothermal expansion :**

Final Temperature : During isothermal expansion, there is no change of temperature. Hence, final temperature will be the same as the initial temperature.

Final Pressure : Since $P_1V_1 = P_2V_2$

$$\therefore \quad P_2 = P_1V_1/V_2 = 1 \times V_1/3V_1 = \mathbf{0{\cdot}333 \text{ atm}}$$

***b.* Adiabatic expansion :**

Final Temperature : Under adiabatic conditions,

$$T_1/T_2 = [V_2/V_1]^{\gamma-1}$$

$$273/T_2 = [3V_1/V_1]^{1{\cdot}4-1} = (3)^{0{\cdot}4}$$

Taking logs and solving, we get

$$\therefore \quad T_2 = 176 \text{ K} = -97°\text{C}$$

Final Pressure : Under adiabatic conditions,

$$P_1V_1^{\gamma} = P_2V_2^{\gamma} \quad \text{or} \quad P_1/P_2 = [V_2/V_1]^{\gamma}$$

$$1/P_2 = [3V_1/V_1]^{1{\cdot}4} = [3]^{1{\cdot}4}$$

Taking logs and solving, we get

$$\text{or} \quad P_2 = 1/[3]^{1{\cdot}4} = \mathbf{0{\cdot}217 \text{ atm}}$$

Example 15. A given mass of a gas at 0°C is compressed reversibly and adiabatically to a pressure 20 times the initial value. Calculate the final temperature of the gas. γ for the gas = 1·42.

Solution : $[T_1/T_2]^{\gamma} = [P_2/P_1]^{1-\gamma}$

$$(273/T_2)^{1{\cdot}42} = (20P_1/P_1) = (20)^{-0{\cdot}42}$$

Taking logs and solving, we get

$$T_2 = \mathbf{662{\cdot}2 \text{ K} = 389{\cdot}2°\text{C}}$$

Example 16. One mole of an ideal mono-atomic gas at 27°C expands reversibly and adiabatically from a volume of 10 dm^3 to volume of 20 dm^3. Calculate *(i)* q *(ii)* ΔU *(iii)* w and *(iv)* ΔH. Assume that $C_V = 3/2\ R$.

Solution : *(i)* Since the process is adiabatic, $q = 0$.

(ii) **Calculation of ΔU :** From Eq. 45,

$$(C_V/R) \ln (T_2/T_1) = \ln (V_1/V_2)$$

Since $C_V = 3/2R$ (given), hence $C_V/R = 3/2$

$$\therefore \quad (3/2) \ln (T_2/300) = \ln (10 \text{ dm}^3/20 \text{ dm}^3)$$

Hence, $T_2 = 189 \text{ K}$

$$C_V = (\partial U/\partial T)_V \quad \text{or} \quad dU = C_V dT$$

For a finite change involving n moles,

$$\Delta U = nC_V \Delta T = nC_V(T_2 - T_1) = n\ (3/2)R(189 - 300)$$

$$= (1 \text{ mol})(3/2)(8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1})(-111 \text{ K}) = \mathbf{-1384 \text{ J}}$$

(iii) **Calculation of w :** Since for an adiabatic process, $q = 0$, hence, $\Delta U = w$

$$\therefore \quad w = \mathbf{-1384 \text{ J}}$$

(iv) **Calculation of ΔH :** Since, $H = U + PV$

$$\therefore \quad \Delta H = \Delta U + \Delta(PV) = \Delta U + (P_2V_2 - P_1V_1)$$

Note that since the temperature in adiabatic process does not remain constant, we cannot put $P_2V_2 = P_1V_1$.

For n moles of an ideal gas,

$$P_2V_2 = nRT_2 \quad \text{and} \quad P_1V_1 = nRT_1$$

$$\therefore \quad P_2V_2 - P_1V_1 = nR(T_2 - T_1) = (1 \text{ mol})(8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1})(189 - 300) \text{ K} = \mathbf{-923 \text{ J}}$$

Hence, $\Delta H = \Delta U + (P_2V_2 - P_1V_1) = -1384 \text{ J} - 923 \text{ J} = \mathbf{-2307 \text{ J}}$

Note : We can also calculate ΔH as follows :

Since $C_P = (\partial H/\partial T)_p$ hence, $dH = C_P \Delta T$

$\therefore$ For a finite change involving n moles of the gas,

$$\Delta H = nC_p \Delta T = nC_p\ (T_2 - T_1)$$

Since for an ideal gas, $C_P - C_V = R$

$$\therefore \quad C_P = C_V + R = 3/2R + R = 5/2R$$

Hence, $\Delta H = (1 \text{ mol})(5/2) \times (8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1})(189 - 300) \text{ K} = \mathbf{-2307 \text{ J}}$

Example 17. One mole of an ideal gas (mono-atomic) at 27°C expands adiabatically against a constant external pressure of 1 atm from a volume of 10 dm^3 to a volume of 20 dm^3. Calculate *(i)* q *(ii)* w *(iii)* ΔU and *(iv)* ΔH for this process. Also calculate the final temperature of the gas. Assume that $C_V = 3/2R$.

Solution : *(i)* Since the process is adiabatic, $q = 0$

(ii) $w = -P(V_2 - V_1) = -$ (1 atm)(20 – 10) dm^3 = – 10 dm^3 atm = **– 1013 J** (Example 11)

(iii) Since $\Delta U = q + w$ and $q = 0$ hence, $\Delta U = w = \mathbf{-1013 \text{ J}}$

(iv) $C_V = (\partial U/\partial T)_V$ and $C_P = (\partial H/\partial T)_P$; hence, $dU = C_V dT$ and $dH = C_P dT$

For a finite change, $\Delta U = C_V \Delta T$ and $\Delta H = C_P \Delta T$

$$\therefore \quad \frac{\Delta H}{\Delta U} = \frac{C_P}{C_V} = \frac{(C_V + R)}{C_V} = \frac{5/2R}{3/2R} = 5/3$$

$$\therefore \quad \Delta H = 5/3\ \Delta U = 5/3(-1013 \text{ J}) = \mathbf{-1688 \text{ J}}$$

To evaluate the final temperature T_2, we proceed as follows :

$$\Delta U = nC_V \Delta T = nC_V(T_2 - T_1)$$

$$\text{or} \quad -1013 \text{ J} = (1 \text{ mol})(3/2 \times 8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1})(T_2 - 300) \text{ K}$$

$$\therefore \quad T_2 = \mathbf{291{\cdot}8 \text{ K}}$$

Example 18. Show that in an isothermal expansion of an ideal gas *(a)* $\Delta U = 0$ and *(b)* $\Delta H = 0$.

Solution : *(a)* We know that for one mole of an ideal gas, $C_V = (\partial U/\partial T)_V$, hence, $dU = C_V dT$

For a finite change, $\Delta U = C_V \Delta T$

For an isothermal process, T is constant so that $\Delta T = 0$. Hence, $\Delta U = 0$.

(b) We know that $\Delta H = \Delta U + \Delta(PV)$

Since for an ideal gas, $PV = RT$

$\therefore \quad \Delta H = \Delta U + \Delta(RT) = \Delta U + R\Delta T = R\Delta T \qquad (\because \Delta U = 0)$

Since T is constant, $\Delta T = 0$. Hence, $\Delta H = 0$.

Example 19. Calculate q, w, ΔU and ΔH for the reversible isothermal expansion of one mole of an ideal gas at 27°C from a volume of 10 dm³ to a volume of 20 dm³.

Solution : $T = 27°C = 27 + 273 = 300$ K

Since the process is isothermal,

$\Delta U = \Delta H = 0$ (Example 18)

$w = -nRT \ln (V_2/V_1)$ (Eq. 31)

$= -$ (1 mol)(8·314 J K^{-1} mol^{-1})(300 K) ln (20 dm³/10 dm³) $= -$ **1729 J**

From the First law, $\Delta U = q + w$

Since $\Delta U = 0$, $q = -w =$ **1729 J**

Example 20. Calculate q, w, ΔU and ΔH for the isothermal expansion of one mole of an ideal gas at 27°C from a volume of 10 dm³ to a volume of 20 dm³, against a constant external pressure of 1 atm.

Solution : Since the process is isothermal, $\Delta U = \Delta H = 0$ (Examples 18 and 19)

But, in this case, $w = P(V_2 - V_1) = -$ (1 atm)(20 dm³ − 10 dm³)

$= -$ **10 dm³ atm** $= -$ **1013 J** (Example 11)

Since $\Delta U = q + w$ and $\Delta U = 0$, hence $q = -w =$ **1013 J**

Example 21. Calculate the final volume of one mole of an ideal gas initially at 0°C and 1 atm pressure if it absorbs 1000 cal of heat during a reversible isothermal expansion.

Solution : The gas is under the conditions of S.T.P. so that $V_1 = 22{\cdot}4$ dm³. V_2 is to be determined.

Since the expansion is reversible and isothermal, $\Delta U = 0$ so that

$q = -w = 1000$ cal $= 1000 \times 4{\cdot}184$ J

Since $w = -nRT \ln (V_2/V_1)$

$\therefore \quad nRT \ln V_2/V_1 = -w = 1000 \times 4{\cdot}184$ J

(1 mol)(8·314 J K^{-1} mol^{-1})(273 K) ln (V_2/22·4 dm³) $= 1000 \times 4{\cdot}1804$ J

$V_2 =$ **121·25 dm³**

Comparison of Isothermal and Adiabatic Expansions

Let us consider isothermal and adiabatic expansions of an ideal gas from initial volume V_i and pressure P_i to a common final volume V_f. If P_{iso} and P_{adia} are the final pressures, then

$P_iV_i = P_{iso}V_f$ for isothermal expansion

and $P_iV_i^\gamma = P_{adia}(V_f)^\gamma$ for adiabatic expansion.

Accordingly, $V_f/V_i = P_i/P_{iso}$ ...(52)

and $V_f/V_i = P_i/P_{adia}$

Since for expansion $V_f > V_i$ and also for all gases $\gamma > 1$, hence

$(V_f/V_i)^\gamma > (V_f/V_i)$ ...(53)

$\therefore \quad P_i/P_{adia} > P_i/P_{iso}$ or $P_{adia} < P_{iso}$ ...(54)

The above conclusion receives support from the argument that since in adiabatic expansion, there is a fall of temperature, hence, according to the Charles law ($P \propto T$ at constant V), there is a corresponding fall of pressure so that $P_{adia} < P_{iso}$.

The two expansions are shown in Fig. 3*a*. Since in a P-V diagram, the work done is given by the area under the PV curve, the work done in isothermal expansion (shown by the area $ABCD$) is greater than the work done in adiabatic expansion (shown by the area $AECD$).

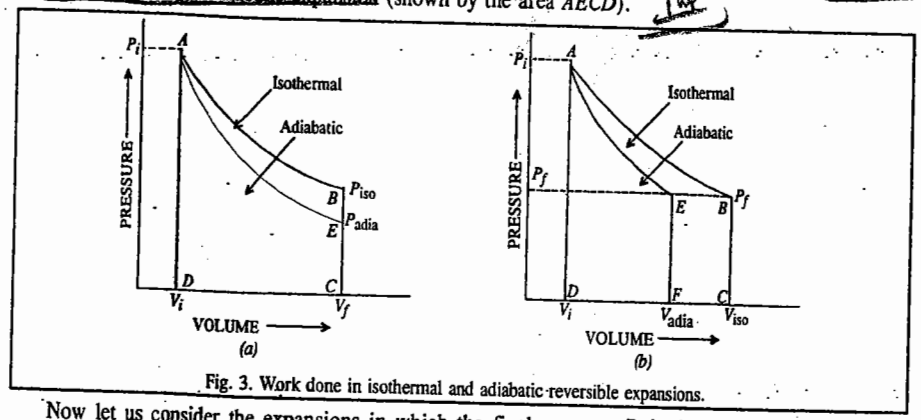

Fig. 3. Work done in isothermal and adiabatic reversible expansions.

Now let us consider the expansions in which the final pressure P_f is the same in both cases. If V_{iso} and V_{adia} are the final volumes in isothermal and adiabatic expansions, respectively, then

$P_iV_i = P_fV_{iso}$ for isothermal expansion

and $P_iV_i^\gamma = P_f(V_{adia})^\gamma$ for adiabatic expansion

Accordingly, $P_i/P_f = V_{iso}/V_i$ and $P_i/P_f = (V_{adia}/V_i)^\gamma$ ...(55)

From Eq. 55, $V_{iso}/V_i = (V_{adia}/V_i)^\gamma$ ...(56)

or $\ln (V_{iso}/V_i) = \gamma \ln (V_{adia}/V_i)$ ...(57)

Since $\gamma > 1$, it follows that

$V_{adia}/V_i < V_{iso}/V_i$ or $V_{adia} < V_{iso}$ ...(58)

This conclusion also receives support from the argument that since in adiabatic expansion, there is a fall of temperature, hence according to the Charles law ($V \propto T$ at constant P), there is a corresponding decrease in volume so that $V_{adia} < V_{iso}$.

The two expansions are shown in Fig. 3*b*. As expected, the work done in isothermal expansion, shown by area $ABCD$ is greater than the work done in adiabatic expansion shown by area $AEFD$.

Reversible Isothermal Expansion of a Real Gas

We shall now derive expressions for w, ΔU, ΔH and q for the reversible isothermal expansion of a real gas obeying the van der Waals equation of state.

Work of expansion, w. As discussed earlier, the work done in the expansion of a gas is given by $-dw = PdV$.

$\therefore \quad -w = \int_{V_1}^{V_2} PdV$ ...(59)

For the van der Waals gas,

$$\left(P + \frac{an^2}{V^2}\right)(V - nb) = nRT \quad \text{so that} \quad P = \frac{nRT}{V - nb} - \frac{an^2}{V^2} \qquad ...(60)$$

Hence,

$$-w = \int_{V_1}^{V_2}\left(\frac{nRT}{V-nb} - \frac{an^2}{V^2}\right)dV = \int_{V_1}^{V_2}\frac{nRT}{V-nb}dV - \int_{V_1}^{V_2}\frac{an^2}{V^2}dV$$

$$= nRT\ln\left(\frac{V_2 - nb}{V_1 - nb}\right) + an^2\left[\frac{1}{V_2} - \frac{1}{V_1}\right] \qquad ...(61)$$

Internal Energy Change, ΔU. For a van der Waals gas, the term $\alpha n^2/V^2$ is the internal pressure of the gas (Eq. 5, Chapter 9). Further, the quantity $(\partial U/\partial V)_T$ is also called the **internal** pressure of the gas. Thus,

$$(\partial U/\partial V)_T = an^2/V^2$$

$$\therefore \quad dU = an^2(dV/V^2) \text{ (at constant temperature)} \qquad ...(62)$$

Integrating between suitable limits,

$$\int dU = U_2 - U_1 = \Delta U = \int_{V_1}^{V_2} an^2 \frac{dV}{V^2} = -an^2\left(\frac{1}{V_2} - \frac{1}{V_1}\right) \qquad ...(63)$$

Enthalpy Change, ΔH. As described earlier, $H = U + PV$.

The enthalpy of the gas in the initial state

$$H_1 = U_1 + P_1V_1 \qquad ...(64)$$

The enthalpy of the gas in the final state

$$H_2 = U_2 + P_2V_2 \qquad ...(65)$$

$\therefore$ The enthalpy change

$$\Delta H = H_2 - H_1 = (U_2 + P_2V_2) - (U_1 + P_1V_1)$$
$$= (U_2 - U_1) + (P_2V_2 - P_1V_1) = \Delta U + (P_2V_2 - P_1V_1) \qquad ...(66)$$

For the van der Waals gas, $P = \dfrac{nRT}{V - nb} - \dfrac{an^2}{V^2}$ ..(67)

Multiplying both sides of this equation by V, we get

$$PV = \frac{nRTV}{V - nb} - \frac{an^2}{V} \qquad ...(68)$$

Substituting the expressions for P_2V_2 and P_1V_1 as obtained from Eq. 68 into Eq. 66, we obtain

$$\Delta H = \Delta U + nRT\left[\frac{V_2}{V_2 - nb} - \frac{V_1}{V_1 - nb}\right] + an^2\left[\frac{1}{V_1} - \frac{1}{V_2}\right] \qquad ...(69)$$

Now,
$$\frac{V_2}{V_2 - nb} - \frac{V_1}{V_1 - nb} = \frac{V_2(V_1 - nb) - V_1(V_2 - nb)}{(V_2 - nb)(V_1 - nb)}$$
$$= \frac{nb(V_1 - V_2)}{(V_2 - nb)(V_1 - nb)} = \frac{nb}{V_2 - nb} - \frac{nb}{V_1 - nb} \qquad ...(70)$$

Substituting Eq. 70 into Eq. 69, we have

$$\Delta H = \Delta U + nRT\left[\frac{nb}{V_2 - nb} - \frac{nb}{V_1 - nb}\right] + an^2\left[\frac{1}{V_1} - \frac{1}{V_2}\right] \qquad ...(71)$$

Substituting for ΔU from Eq. 63, we have

$$\Delta H = n^2bRT\left[\frac{1}{V_2 - nb} - \frac{1}{V_1 - nb}\right] - 2an^2\left[\frac{1}{V_2} - \frac{1}{V_1}\right]$$

Heat Change, q. From the First law we know that $\Delta U = q + w$ or $q = \Delta U - w$.
Substituting the expressions for w and ΔU from Eqs. 61 and 63, we obtain

$$q = nRT \ln\left(\frac{V_2 - nb}{V_1 - nb}\right) \qquad ...(72)$$

Comparison of Work of Expansion of an Ideal Gas and a van der Waals Gas. We know that for an ideal gas,

$$w_{ideal} = nRT \ln (V_2/V_1). \qquad \text{(Eq. 28)}$$

and for a van der Waals gas, from Eq. 61, *numerically*

$$w_{vdw} = nRT \ln\left(\frac{V_2 - nb}{V_1 - nb}\right) + an^2\left[\frac{1}{V_2} - \frac{1}{V_1}\right] \qquad ...(73)$$

If $V \gg nb$, then Eq. 73 reduces to

$$w_{vdw} = nRT \ln\left(\frac{V_2}{V_1}\right) + an^2\left[\frac{1}{V_2} - \frac{1}{V_1}\right] \qquad ...(74)$$

Hence,

$$\therefore \quad w_{ideal} - w_{vdw} = -an^2\left[\frac{1}{V_2} - \frac{1}{V_1}\right] = \frac{an^2(V_2 - V_1)}{V_1V_2} \qquad ...(75)$$

Since for the expansion of a gas, $V_2 > V_1$, it is evident from Eq. 75 that numerically, the work in the reversible isothermal expansion of an ideal gas is greater than that for a van der Waals gas. This result can also be explained physically. An ideal gas has no intermolecular forces whereas a real (van der Waals) gas has considerable intermolecular forces. Thus, in an ideal gas, the heat supplied is fully utilized in doing the work of expansion whereas in a real gas, a part of the heat supplied is used in overcoming the intermolecular forces of attraction between the molecules and the balance amount of heat is utilized in doing the work of expansion. Consequently, the work done in the expansion of an ideal gas is *numerically* greater than the work done in the expansion of a real gas.

Joule-Thomson Effect

If the stream of a gas at high pressure is allowed to expand by passing through a porous plug into vacuum or a region of low pressure, *under adiabatic conditions*, it gets cooled appreciably. Hydrogen and helium are exceptions as they get warmed up under similar circumstances. But, at very low temperatures, these gases also show the usual behaviour. The temperature below which a gas becomes cooler on expansion is known as the **inversion temperature**. Thus, –48°C is the inversion temperature of hydrogen and –242°C is the inversion temperature of helium. The phenomenon of change of temperature produced when a gas is made to expand adiabatically from a region of high pressure to a region of extremely low pressure is known as the **Joule-Thomson effect.** The Joule-Thomson expriment was performed in the 1850s by the two brilliant British physicists J.P. Joule (1818-1889) and William Thomson (1824-1907), later remembered as Lord Kelvin.

The cooling effect is due to decrease in the kinetic energy of the gaseous molecules since a part of this energy is used up in overcoming the van der Waals force of attraction existing between the molecules during expansion. The Joule-Thomson effect is very small when a gas approaches ideal behaviour. It has been concluded, therefore, that the Joule-Thomson effect is zero in an ideal gas. Hence, according to this view, when an ideal gas expands in vacuum, there is neither absorption nor evolution of heat, *i.e.*, q=0. This is quite reasonable since, in an ideal gas, the van der Waals forces are negligible and there is no expenditure of energy in overcoming these forces during expansion.

Further, when an ideal gas expands in vacuum, it does no work because the pressure against which it expands is zero. In other words, w=0. It follows from the general equation of the First law that ΔU=0. Thus, when an ideal gas undergoes expansion under adiabatic conditions in vacuum, no change takes place in its internal energy. In other words, the internal energy of a given quantity of an ideal gas at a constant temperature is independent of its volume, *i.e.*, $(\partial U/\partial V)_T = 0$.

An ideal gas may, therefore, be defined thermodynamically by the following two equations :

(i) PV = constant, at constant temperature

(ii) $(\partial U/\partial V)_T = 0$

The quantity $(\partial U/\partial V)_T$ is called the internal pressure, as already mentioned. Thus, internal pressure of an ideal gas is zero.

Joule-Thomson Coefficient (μ_{JT}). The experimental technique used by Joule and Thomson for deriving the mathematical relation between the fall of pressure of a gas on expansion and the resulting lowering of temperature is illustrated schematically in Fig. 4.

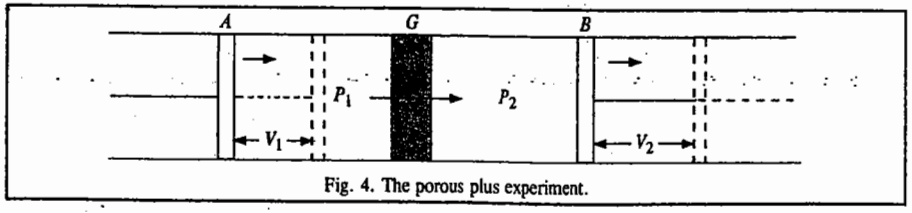

Fig. 4. The porous plus experiment.

A tube made of a non-conducting material is fitted with a porous plug G in the middle and two pistons A and B on the sides, as shown. The tube is thoroughly insulated to ensure adiabatic conditions. A volume V_1 of the gas enclosed between the piston A and the porous plug G at a pressure P_1 is forced *slowly* through the porous plug by moving the piston A inwards and is allowed to expand to a volume V_2 at a lower pressure P_2 by moving the pisten B outward, as shown.

$\therefore$ Work done on the system at the piston $A = + P_1V_1$

Work done by the system at the piston $B = - P_2V_2$

$\therefore$ Net work done by the system $= - P_2V_2 + P_1V_1$

Since the expansion of the gas has taken place adiabatically, the system is not in a position to absorb heat from the surroundings. The system, therefore, performs work at the expense of its internal energy. Consequently, the internal energy of the system changes, say, from U_1 to U_2.

$\therefore \quad - P_2V_2 + P_1V_1 = U_2 - U_1$

or $\quad U_2 + P_2V_2 = U_1 + P_1V_1$

or $\quad H_2 = H_1 \quad \text{or} \quad \Delta H = 0.$

Thus, the Joule-Thomson expansion of a real gas occurs not with constant internal energy but with constant enthalpy. This is, therefore, called an **isenthalpic process.**

Since H is a state function, dH is a complete differential. Taking H as a function of P and T,

$$dH = (\partial H/\partial P)_T\, dP + (\partial H/\partial T)_P\, dT \qquad ...(76)$$

But $\quad (\partial H/\partial T)_P = C_P$

$\therefore \quad dH = (\partial H/\partial P)_T\, dP + C_P\, dT$

Since for adiabatic expansion, $dH=0$, hence $(\partial H/\partial P)_T\, dP + C_P\, dT = 0$

or $$\frac{dT}{dP} = -\frac{(\partial H/\partial P)_T}{C_P} \qquad ...(77)$$

i.e., $$(\partial T/\partial P)_H = -(\partial H/\partial P)_T/C_P \qquad ...(78)$$

The quantity $(\partial T/\partial P)_H$ is called **Joule-Thomson coefficient** and is denoted as μ_{JT}

Assuming μ_{JT} to be constant over a small pressure range, Eq. 78 may be written as

$$\Delta T = -\frac{(\partial H/\partial P)_T}{C_P}\Delta P \qquad ...(79)$$

where ΔT is the fall of temperature produced as a result of the fall of pressure ΔP.

Joule and Thomson verified Eq. 79 experimentally by accurately measuring the fall of temperature (ΔT) accompanying the expansion of a number of real gases. In every case, ΔT was found to be proportional to the difference of pressure ΔP on the two sides of the porous plug, as demanded by Eq. 79.

Joule-Thomson Coefficient in an Ideal Gas. Since $H=U+PV$, Eq.78 may be written as

$$\left(\frac{\partial T}{\partial P}\right)_H = \mu_{JT} = -\frac{1}{C_P}\left(\frac{\partial (U+PV)}{\partial P}\right)_T$$

$$= -\frac{1}{C_P}\left[\left(\frac{\partial U}{\partial P}\right)_T + \left(\frac{\partial (PV)}{\partial P}\right)_T\right]$$

$$= -\frac{1}{C_P}\left[\left(\frac{\partial U}{\partial V}\times\frac{\partial V}{\partial P}\right)_T + \left(\frac{\partial (PV)}{\partial P}\right)_T\right] \qquad ...(80)$$

Since for an ideal gas, $(\partial U/\partial V)_T$ is zero,

$$\therefore \quad (\partial U/\partial V)_T(\partial V/\partial P)_T = 0 \qquad ...(81)$$

Also, since for an ideal gas, PV is constant at constant temperature, $\left(\frac{\partial (PV)}{\partial P}\right)_T = 0$. Hence, Eq. 80 reduces to $\mu_{JT}=0$. The Joule-Thomson coefficient for an ideal gas is thus zero.

Joule-Thomson Coefficient in a Real Gas. For real gases, $(\partial U/\partial V)_T$ is positive. This may be explained as follows.

Suppose a *real* gas expands in vacuum thus doing no external work. However, some work will definitely be done in separating the gas molecules against the forces of cohesion (the van der Waals forces) which exist between the molecules of a *real* gas. This work is stored in the gas in the form of potential energy. In other words, the potential energy of the gas increases. If no heat is gained from outside, the kinetic energy of the gas decreases by an equivalent amount and there would be a fall of temperature of the gas. But, in the present case, temperature is kept constant, evidently, by the absorption of heat from outside. Hence, the kinetic energy remains the same. Thus, during isothermal expansion of a real gas there is net increase in the energy of the gas (in the form of its potential energy). Hence, $(\partial U/\partial V)_T$ is positive. But the factor $(\partial V/\partial P)_T$ in Eq. 80 is negative because the volume of a gas invariably decreases as the pressure increases at constant temperature. Hence, the factor $[(\partial U/\partial V)_T(\partial V/\partial P)_T]$ *is* negative.

The plots of Z *vs* P represented in Fig. 1, Chapter 9, for some of the real gases show that at ordinary temperatures and when the pressure is not very high, the value of PV decreases as the pressure increases (except for H_2 and He), *i.e.*, $(\partial (PV)/\partial P)_T$ is negative, Thus, at ordinary temperatures and at low and moderate pressures, both the terms within the brackets of Eq. 80 are negative. Since the heat capacity is always positive, it follows that the Joule-Thomson coefficient, $(\partial T/\partial P)_H$ is positive for real gases at ordinary temperatures and at low and moderate pressures. Thus, if ΔP is negative, *i.e.*, there is a fall in pressure, then ΔT is also negative, *i.e.*, there is a fall in temperature. In other words, the temperature of a gas falls as a result of its throttled expansion.

Referring again to Fig. 1, it is evident that when the pressures are very high, the value of PV for all gases increases as the pressure increases *i.e.*, $(\partial (PV)/\partial P)_T$ becomes positive. The factor $[(\partial U/\partial V)_T(\partial V/\partial P)_T]$, which is negative as shown above, remains almost constant. Thus, of the two factors within the brackets of Eq. 80, one remains negative and practically constant but the other factor becomes positive and its magnitude increases with increase in pressure. Hence, as the pressure increases, the magnitude of Joule-Thomson coefficient goes on decreasing and becomes zero when the two factors become equal in magnitude. With continued increase in pressure, the magnitude of the positive term exceeds that of the negative term. Joule-Thomson coefficient in that case becomes *negative*. Therefore, if ΔP is negative, *i.e.*, there is fall in pressure, ΔT is positive, *i.e.*, there is increase in temperature. Under such conditions, the throttled expansion of a real gas is accompanied by increase in temperature.

Calculation of the Joule-Thomson Coefficient and the Inversion Temperature. The Joule-Thomson coefficient can be easily calculated with the help of the van der Waals equation. Since, both a and b are small, the term ab/V^2 in the van der Waals equation can be neglected provided the

pressure is not too high. The van der Waals equation may then be written in the form

$$PV = RT - a/V + bP \quad ...(82)$$

Replacing V by RT/P (the approximation used may be noted), we have

$$PV = RT - aP/RT + bP \quad ...(83)$$

or
$$V = RT/P - a/RT + b \quad ...(84)$$

Differentiating with respect to temperature at constant pressure, we get

$$(\partial V/\partial T)_P = R/P + a/RT^2 \quad ...(85)$$

Rearranging Eq. 83, we have

$$RT = P(V - b) + aP/RT \quad ...(86)$$

Dividing both sides by PT,

$$\frac{R}{P} = \frac{V - b}{T} + \frac{a}{RT^2} \quad ...(87)$$

Substituting the value of R/P from Eq. 87 in Eq. 85, we have

$$\left(\frac{\partial V}{\partial T}\right)_P = \frac{V}{T} - \frac{b}{T} + \frac{2a}{RT^2} \quad ...(88)$$

$$\therefore \quad T\left(\frac{\partial V}{\partial T}\right)_P - V = \frac{2a}{RT} - b \quad ...(89)$$

Using the well known thermodynamic relation

$$V = T\left(\frac{\partial V}{\partial T}\right)_P + \left(\frac{\partial H}{\partial P}\right)_P, \quad ...(90)$$

Eq. 89 may be written as

$$-\left(\frac{\partial H}{\partial P}\right)_T = \frac{2a}{RT} - b \quad ...(91)$$

From Eqs. 78 and 91 we have

$$\left(\frac{\partial T}{\partial P}\right)_H = \frac{1}{C_P}\left[\frac{2a}{RT} - b\right] \quad ...(92)$$

It is evident from Eq. 92 that Joule–Thomson coefficient is positive as long as $2a/RT$ is greater than b. It becomes zero if $2a/RT$ is equal to b and negative if $2a/RT$ is less than b. Since a, b and R are constants, it is evident that the magnitude and sign of the Joule–Thomson coefficient depends only upon the temperature at which the gas is allowed to expand.

The temperature at which the Joule–Thomson coefficient changes sign is known as the **inversion temperature**. At this temperature. $\mu_{J.T.}$ is zero so that

$$2a/RT_i = b \quad \text{or} \quad T_i = 2a/Rb \quad ...(93)$$

where T_i represents the inversion temperature. Thus, the inversion temperature depends upon the van der Waals constants a and b of the gas.

Example 22. The van der Waals constants a and b for hydrogen, are $0{\cdot}246\ dm^6\ atm\ mol^{-2}$ and $2{\cdot}67\times10^{-2}\ dm^3\ mol^{-1}$, respectively. Calculate the inversion temperature of hydrogen.

Solution :
$$T_i = 2a/Rb = \frac{2(0{\cdot}246\ dm^6\ atm\ mol^{-2})}{(0{\cdot}08206\ dm^3\ atm\ K^{-1}\ mol^{-1})(0{\cdot}0267\ dm^3\ mol^{-1})}$$
$$= 224{\cdot}72\ K = -48{\cdot}28°C$$

It is amply clear from the above discussion that the sign and magnitude of Joule–Thomson coefficient of a gas depends upon the conditions of temperature and pressure.

Zeroeth Law of Thermodynamics. This law was formulated after the enunciation of the First law of thermodynamics. But, since this law was considered to be of primary importance, it was called zeroeth law. The law states as follows :

If body A is in equilibrium with body C and body B is also in equilibrium with body C, then bodies A and B are in equilibrium with each other.

The common use of thermometer in comparing temperatures of any two or more systems is based on this principle. The thermometer may be likened to the body C in the above statement. While comparing temperatures of two bodies, say, A and B, it is allowed to come into equilibrium first with the body A and then with the body B, by placing it in contact with each other, turn by turn. The temperatures as read from the thermometer give *comparative ideas of degrees of hotness* of the two bodies A and B with which it had been allowed to come to equilibrium, one by one. Since thermometer is only a *very small body*, there is only an insignificant exchange of energy with large bodies B and C. Hence, the energies of bodies B and C remain unchanged during measurement of the temperature.

Temperature measurement by a thermometer rests on determination of some property of a fluid which changes with the degree of hotness. This property in a mercury thermometer involves change in length of the mercury column and in an air thermometer it involves change in volume (V) and pressure (P) of air (or gas) enclosed within.

Consider a fluid system B in a state defined by volume V_B and pressure P_B. Let it be in equilibrium with another fluid system A in a state defined by volume V_A and pressure P_A. The values of V_A and P_A are determined experimentally. There may be several values of V_A and P_A at which there may be an equilibrium with the system B, at constant temperature, say, θ_1. These values may be plotted against each other to get an isotherm, as shown in Fig.5. According to Zeroeth law, this isotherm is independent of the nature of the system B because the same values will be obtained by substituting B by any other system in equilibrium with A at the same temperature. The latter procedure is considered to be more accurate. If the temperature of B, still in equilibrium with A, is changed, say, from θ_1 to θ_2, then another set of values of V_A and P_A at temperature θ_2 will be observed and a new isotherm (Fig. 5.) will be obtained and so on. Three isotherms ($P_A - V_A$ graphs) obtained at three temperatures, θ_1, θ_2 and θ_3 are shown in the figure. Several such isotherms at various other temperatures can also be built. All systems, having the same temperature, will follow the same graph when brought into thermal contact with the body A or even with one another. In this way, the unknown temperature of a system at any time can be obtained by comparing its P–V isotherm determined experimentally with those plotted in Fig. 5.

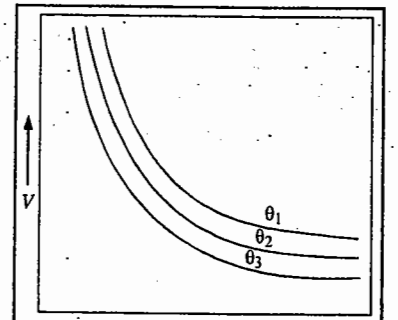

Fig. 5. Isothermals of a fluid obtained at different temperatures.

Absolute Temperature Scale. It may be worthwhile at this stage to define the true zero or natural zero of the temperature scale. Several temperature scales have been known but they are all *arbitrarily* based on freezing and boiling points of water or on some other transition temperatures. But a true scale is based on the observation that $PV - P$ graphs of all real gases when extrapolated

to zero pressure give the same value of PV at a given temperature. This value is denoted by $(PV)_0$, in general and by $(PV_m)_0$, if one mole of a gas is involved.

The values of $(PV_m)_0$ vary linearly with the temperature on the centigrade scale, as shown in Fig. 6. The variation is represented by the equation

$$(PV_m)_0 = a + bt \qquad ...(94)$$

where t is the centigrade temperature measured by a mercury thermometer and a and b are constants. The values of $(PV_m)_0$ at 0°C and 100°C have been found to be 22·4136 and 30·6192 dm^3 atm, respectively.

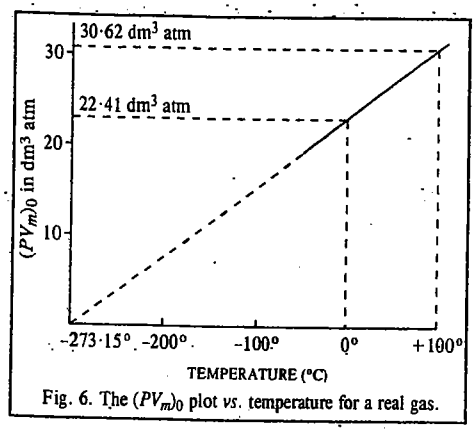

Fig. 6. The $(PV_m)_0$ plot *vs.* temperature for a real gas.

Substituting these values in Eq. 94, we have

$$22{\cdot}4136 \text{ dm}^3 \text{ atm} = a + 0 \qquad ...(95)$$

and $$30{\cdot}6192 \text{ dm}^3 \text{ atm} = a + 100b \qquad ...(96)$$

Hence, $$b = 0{\cdot}082056 \text{ dm}^3 \text{ atm} \qquad ...(97)$$

Substituting the values of a and b in Eq. 94, it is possible to calculate the temperature at which $(PV_m)_0 = 0$. Thus,

$$0 = 22{\cdot}4136 \text{ dm}^3 \text{ atm} + (0{\cdot}082056 \text{ dm}^3 \text{ atm})\, t$$

$$\therefore \quad t = -273{\cdot}15°\text{C}$$

The temperature -273·15° is the **natural** or **true zero**. It is defined *as the temperature at which the limiting value of PV_m, i.e., the product PV_m at pressures approaching zero, is zero itself.* This zero defines an **absolute temperature scale** which is known as the **Kelvin scale**. Thus, -273·15°C = 0 K or 0°C=273·15 K. The temperature t on the absolute scale is denoted by T. Thus, the boiling point of water on this scale is given by $T = 273{\cdot}15+100=373{\cdot}15$ K. We conclude this chapter with the insightful remarks of Schrödinger :

...[temperature] turns out to be a much more fundamental quantity than energy ; so much so, that the physicist is gratified to be given, in every particular case, energy as a function of it, rather than vice versa, which would be quite unnatural.

I. Review Questions

1. Define mathematically the first law of thermodynamics. Comment on the statement "while U is a definite property, q and w are not definite properties".
2. Derive the relation between ΔU and ΔH for an ideal gas.
3. Show that for one mole of an ideal gas $C_p - C_v = R$
4. Derive expressions for the work done in reversible isothermal expansion and reversible isothermal compression of an ideal gas.
5. Distinguish between isothermal and adiabatic processes. Derive the relation between temperature and volume and that between temperature and pressure in reversible adiabatic expansion of an ideal gas.
6. Derive an expression for the Joule-Thomson coefficient of a van der Waals gas.
7. Define the Joule-Thomson coefficient. Show that it is zero for an ideal gas and has a positive value for a real gas.

8. Define Inversion temperature. Show that for a van der Waals gas, the inversion temperature is given by $T_i = 2a/Rb$.
9. State and explain the zeroth law of thermodynamics.

II. Problems

1. In a certain process, 675 J of heat is absorbed by a system while 290 J of work is done on the system. What is the change in internal energy for the process ? **[Ans. 965 J]**
2. In a certain process, 600 J of work is done on a system which gives off 250 J of heat. Calculate the internal energy change for the process. **[Ans. 350 J]**
3. Calculate the internal energy change for the process in which 1·0 kJ of heat is added to 1·2 dm^3 of oxygen gas in a cylinder at a constant pressure of 1·0 atm and the volume changes to 1·5 dm^3. **[Ans. 0·993 kJ]**
4. Calculate ΔU and ΔH when 10·0 dm^3 of helium at N.T.P. is heated in a cylinder to 100°C assuming that the gas behaves ideally. $C_V = 3/2\ R$. **[Ans. 559·8 J ; 933·4 J]**
5. Calculate ΔU and ΔH when 0·42 mole of xenon gas, assumed ideal, is expanded from 27°C, to 127°C, assuming that $C_v = 12{\cdot}47$ J K^{-1} mol^{-1}. **[Ans. 523·7 J ; 873·4 J]**
6. One mole of nitrogen gas contained in a cylinder at 300 K is allowed to expand isothermally against an external pressure of 5 atm from a volume of 1·0 dm^3 to a volume of 3·0 dm^3. Assuming ideality, calculate q, w, ΔU and ΔH. **[Ans. $q=w=1013$ J, $\Delta U=\Delta H=0$]**
7. 3 moles of helium gas at 1 atm are compressed reversibly and isothermally at 400 K to 5 atm pressure. Calculate q, w, ΔU and ΔH. **[Ans. $q=w=1{\cdot}61\times10^4$ J, $\Delta U=\Delta H=0$]**
8. Calculate q, w, ΔU and ΔH for the reversible adiabatic compression of 0·2 mole of an ideal gas from a volume of 1 dm^3 to a volume of 0·25 dm^3. **[Ans. 0, - 98·8 J, 98·8 J ; 138 J]**
9. In a certain process, 6,000 J of heat is added to the system while the system does work equivalent to 9,000 J by expanding against the surrounding atmosphere. Calculate the internal energy change for the system. **[Ans. - 3,000 J]**
10. One mole of benzene is converted reversibly into vapour at the boiling point (80·2°C) by heating it. The vapour undergoes expansion against 1 atm pressure. Assuming that the vapour behaves ideally, calculate ΔH, w and ΔU for the process. The heat of vaporization of benzene is 396 J g^{-1}.

[Ans. ΔH = 30·180 kJ mol^{-1} ; w = 2·936 kJ mol ; ΔU = 2·787 kJ mol^{-1}]

CHAPTER 14

THERMOCHEMISTRY

Chemical reactions are almost invariably accompanied by energy changes which, ordinarily, appear in the form of evolution or absorption of heat. The branch of chemistry which deals with energy changes involved in chemical reactions is called **thermochemistry**. Thermochemistry, in fact, applies the First law of thermodynamics to chemical reactions. The energy change that occurs in a chemical reaction is largely due to change of bond energy, *i.e.*, it results from the breaking of bonds in reactants and formation of new bonds in products.

Change of Internal Energy in a Chemical Reaction. Let us consider a chemical reaction taking place at constant temperature and at constant volume. In such a case, $w=0$ and hence from the equation of the First law (*viz.*, $\Delta U = q + w$),

$$\Delta U = q_V \qquad ...(1)$$

where q_V is the heat exchanged at constant volume.

Suppose U_R is the internal energy of the reactants and U_P that of the products, then,

$$\Delta U = U_P - U_R \qquad ...(2)$$

We may represent this conclusion schematically as below :

Reactants (U_R)

$\downarrow \Delta U = U_P - U_R = q_v$ = Heat of reaction at constant volume

Products (U_P)

Change Enthalpy in a Chemical Reaction. Let q_p be the heat exchanged in the chemical reaction taking place at *constant pressure*. The heat exchanged at constant pressure is termed as the **enthalpy change.** Thus,

$$\Delta H = q_p \qquad ...(3)$$

In general, if H_R is the enthalpy of the reactants and H_P that of the products, then

$$\Delta H = H_P - H_R = q_p \qquad ...(4)$$

This statement is schematically represented as follows :

Reactants (H_R)

$\downarrow \Delta H = H_P - H_R = q_p$ = Enthalpy of reaction

Products (H_P)

Exothermic and Endothermic Reactions. Reactions that give out heat, *i.e.*, which are accompanied by evolution of heat, are called **exothermic reactions.** In such reactions $H_P < H_R$ so that ΔH is negative. On the other hand, reactions that take in heat, *i.e.*, which are accompanied by absorption of heat, are called **endothermic reactions.** In these reactions, $H_P > H_R$ so that ΔH is positive.

The energy level diagram for exothermic and endothermic reactions is shown in Fig. 1.

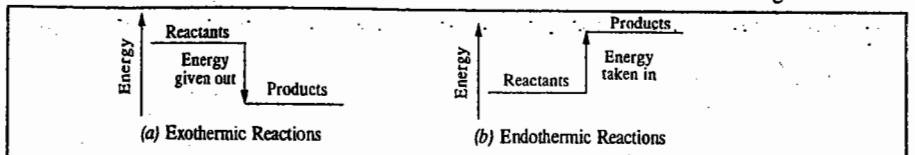

Fig. 1. Energy level diagram for exothermic and endothermic reactions.

Example 1. In an exothermic reaction, how do the strengths of the bonds in the reactants compare with the strengths of the bonds in the products ?

Answer : The bonds in the products are stronger than those in the reactants. The stronger the bonds, the greater is the energy released.

Example 2. In an endothermic reaction, how do the strengths of the bonds in the reactants compare with those of their counterparts in the products ?

Answer : The bonds in the products are weaker than those in the reactants.

Example 3. The two examples of endothermic reactions are the dissolution of $NaHCO_3(s)$ in water and the production of $NH_3(g)$ from the reaction between $Ba(OH)_2(s)$ and $NH_4SCN(s)$. Draw the energy level diagrams for these reactions.

Solution : See Fig. 2.

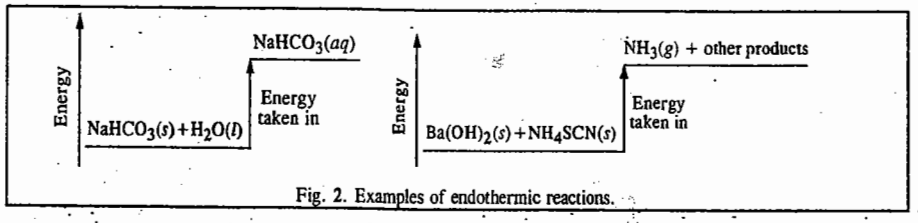

Fig. 2. Examples of endothermic reactions.

Example 4. Draw an energy level diagram for burning of petrol in air.

Solution : See Fig. 3.

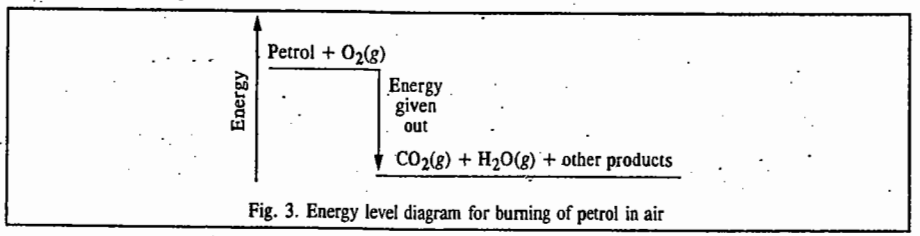

Fig. 3. Energy level diagram for burning of petrol in air

Example 5. A student makes the following comment on an endothermic reaction : *"If the heat is taken in during the reaction, the temperature should go up, not down."* How will you convince him ?

Answer : The reaction being endothermic, the energy taken in is being consumed to break the bonds in reactants so that it does not have a chance to appear as heat and raise the temperature.

Relation between Enthalpy of Reaction at Constant Volume and at Constant Pressure. The quantities ΔH and ΔU are related to each other by the expression

$$\Delta H = \Delta U + P\Delta V \qquad ...(5)$$

where ΔV is the change in volume that takes place in a given reaction.

Since, $q_V = \Delta U$ (vide Eq. 1) and $q_p = \Delta H$ (vide Eq. 3), we may write the above relationship also as

$$q_p = q_V + P\Delta V \qquad ...(6)$$

This relationship can be simplified further as follows :

For n moles of an ideal gas,

$$PV = nRT \qquad ...(7)$$

Let n_1 and n_2 represent the number of moles of *gaseous* reactants and *gaseous* products, respectively. Suppose n_2 is greater than n_1. Then the increase in the number of gaseous moles $= n_2 - n_1 = \Delta n_g$. The corresponding increase in volume (ΔV) will be given by $(V/n)\Delta n_g$. Hence,

$$P\Delta V = P(V/n)\,\Delta n_g = RT \times \Delta n_g \qquad (\because PV = nRT)$$

Thus,
$$P\Delta V = \Delta n_g \times RT \qquad ...(8)$$

Substituting in Eq. 6, we have

$$q_p = q_V + \Delta n_g RT \qquad ...(9)$$

In this equation, Δn_g, is the difference between the number of moles of the gaseous products and the gaseous reactants.

Let us take a few examples. In the reaction involving the dissociation of ammonia into nitrogen and hydrogen,

$$\underset{2\text{ moles}}{2NH_3(g)} \longrightarrow \underset{1\text{ mole}}{N_2(g)} + \underset{3\text{ moles}}{3H_2(g)}$$

$$\Delta n_g = 4 - 2 = 2$$

$$\therefore \quad q_p = q_V + 2RT$$

In the reaction involving combination of hydrogen and oxygen,

$$\underset{2\text{ moles}}{2H_2(g)} + \underset{1\text{ mole}}{O_2(g)} \longrightarrow \underset{2\text{ moles}}{2H_2O(g)}$$

$$\Delta n = 2 - 3 = -1$$

$$\therefore \quad q_p = q_V - RT$$

Example 6. Establish the relationship between q_p and q_v in the Haber synthesis of ammonia, assuming that the gaseous reactants and products are ideal.

Solution : $N_2(g) + 3H_2(g) \longrightarrow 2NH_3(g)$

Here $\Delta n_g = 2 - (1 + 3) = -2$

Hence, $q_p = q_V + \Delta n_g RT = q_v - 2RT$

Example 7. Establish the relationship between q_p and q_v in the synthesis of $H_2O(g)$ from the elements, assuming ideality.

Solution : $2H_2(g) + O_2(g) \longrightarrow 2H_2O(g)$

$$\Delta n_g = 2 - (2 + 1) = -1$$

$$\therefore \quad q_p = q_V + \Delta n_g RT = q_V - RT$$

Example 8. One mole of naphthalene was burnt in oxygen gas at constant volume to give carbon dioxide gas and liquid water at 25°C. The heat evolved was found to be 5138·8 kJ. Calculate the enthalpy of the reaction. $R = 8{\cdot}314\ J\ K^{-1}\ mol^{-1}$.

Solution : The thermochemical equation for the reaction may be written as

$$C_{10}H_8(s) + 12O_2(g) \longrightarrow 10CO_2(g) + 4H_2O(l) \; ; \qquad q_V = -5138{\cdot}8\ kJ$$

The number of moles of *gaseous* reactants, $n_1 = 12$

The number of moles of *gaseous* products, $n_2 = 10$

Hence, $\Delta n_g = n_2 - n_1 = 10 - 12 = -2$

Substituting the various values in Eq. 9, we have

$$q_p = -5138{\cdot}8\ kJ - 2\ mol \times 8{\cdot}314 \times 10^{-3}\ kJ\ K^{-1}\ mol^{-1} \times 298\ K = -5143{\cdot}8\ kJ$$

Standard Enthalpies of Reactions. Enthalpies of reactions determined at 25°C and one atm pressure (101·325 kPa) are denoted by $\Delta H°$ and are known as standard enthalpies of reactions. Examples include the following :

$$\tfrac{1}{2}N_2(g) + \tfrac{3}{2}H_2(g) \longrightarrow NH_3(g) \; ; \qquad \Delta H° = -46{\cdot}0\ kJ\ mol^{-1}$$

$$\tfrac{1}{2}H_2(g) + \tfrac{1}{2}Cl_2(g) \longrightarrow HCl(g) \; ; \qquad \Delta H° = -92{\cdot}3\ kJ\ mol^{-1}$$

$$Zn(s) + Cu^{2+}(aq) \longrightarrow Zn^{2+}(aq) + Cu(s) \; ; \qquad \Delta H° = -210\ kJ\ mol^{-1}$$

$$Mg(s) + \tfrac{1}{2}O_2(g) \longrightarrow MgO(s) \; ; \qquad \Delta H° = -601{\cdot}7\ kJ\ mol^{-1}$$

Standard Enthalpy of Combustion. This is defined as the enthalpy change (ΔH) accompanying complete combustion of one mole of the substance at 25°C and 1 atm pressure. Thus,

Combustion of Methane :

$$CH_4(g) + 2O_2(g) \longrightarrow CO_2(g) + 2H_2O(l) \; ; \qquad \Delta H°_{comb} = -890{\cdot}3\ kJ\ mol^{-1}$$

Combustion of Hydrogen :

$$H_2(g) + \tfrac{1}{2}O_2(g) \longrightarrow H_2O(l) \; ; \qquad \Delta H°_{comb} = -285{\cdot}29\ kJ\ mol^{-1}$$

Standard Enthalpy of Neutralization. Enthalpy of neutralisation of one mole of a base such as NaOH and KOH by an acid such as HCl, H_2SO_4 and HNO_3 in dilute solutions at 25°C and 1 atm pressure is called the standard enthalpy of neutralization of the base by the acid. Thus,

$$NaOH(aq) + HCl(aq) \longrightarrow NaCl\,(aq) + H_2O(l) \; ; \qquad \Delta H = -57{\cdot}3\ kJ\ mol^{-1}$$

$$KOH(aq) + \tfrac{1}{2}H_2SO_4(aq) \longrightarrow KHSO_4\,(aq) + H_2O(l) \; ; \qquad \Delta H = -57{\cdot}4\ kJ\ mol^{-1}$$

Similarly, the enthalpy change accompanying the neutralisation of 1 mole of an acid by a base in dilute solutions at 25°C and 1 atm pressure is known as the standard enthalpy of neutralisation of the acid by the base.

The neutalisation of hydrochloric acid by sodium hydroxide in dilute solutions when the acid, alkali and the salt formed are completely dissociated, may be represented as :

$$H^+ + Cl^- + Na^+ + OH^- \longrightarrow Na^+ + Cl^- + H_2O(l)$$

or
$$H^+ + OH^- \longrightarrow H_2O(l)$$

Considering neutralisation of strong acids by strong bases, it will be seen that in every case, the neutralisation reaction is the same as it simply involves the combination of H^+ ions and OH^- ions to form unionised H_2O. It is expected, therefore, that the enthalpy of neutralization of every strong acid by a strong base and vice versa should be identical. That this is actually so, is evident from the data given in Table 1.

TABLE 1

Standard Enthalpies of Neutralisation of Strong Acids by Strong Bases (kJ mol^{-1})

Acid	Alkali	Enthalpies of neutralisation
HCl	NaOH	−57·32
HNO_3	NaOH	−57·28
HCl	KOH	−57·45
HCl	LiOH	−57·38

If, however, the acid or alkali is weak, the enthalpy of neutralisation is different because the reaction now involves dissociation of the weak acid or the weak alkali as well. The neutralisation of acetic acid by sodium hydroxide, for example, involves the dissociation of the acid as well as the usual neutralisation of H^+ and OH^- ions, as represented below :

$$(i) \quad CH_3COOH\,(aq) \rightleftharpoons CH_3COO^-(aq) + H^+(aq)$$

$$(ii) \quad H^+(aq) + OH^-(aq) \longrightarrow H_2O(l)$$

As H^+ ions are neutralised by OH^- ions furnished by the completely dissociated sodium hydroxide, more H^+ ions are formed by the dissociation of acetic acid to re-establish the equilibrium. Thus, both the reactions proceed side by side till acetic acid is completely neutralised.

The enthalpy of neutralisation of acetic acid by sodium hydroxide has been found to be $-55{\cdot}23$ kJ mol^{-1}. Since the average value for the combination of H^+ and OH^- ions is taken as $-57{\cdot}32$ kJ mol^{-1}, the standard enthalpy of dissociation of acetic acid may be taken as $+ 2{\cdot}09$ kJ mol^{-1}.

The enthalpy of neutralisation of hydrochloric acid by ammonium hydroxide at 25°C is $- 51{\cdot}34$ kJ mol^{-1}. Therefore, the standard enthalpy of dissociation of ammonium hydroxide is taken as $+ 5{\cdot}98$ kJ mol^{-1}.

Standard enthalpies of neutralisation of a few weak acids with sodium hydroxide are given in Table 2. The enthalpies of dissociation obtained from these values are included in the last column.

TABLE 2

Standard Enthalpies of Neutralisation of Weak Acids with Sodium Hydroxide

Acid	Enthalpy of Neutralisation (kJ mol^{-1})	Enthalpy of Dissociation (kJ mol^{-1})
Acetic acid	− 55·23	+ 2·09
Formic acid	− 56·06	+ 1·26
Hydrocyanic acid	− 12·13	+ 45·19
Hydrogen sulphide	− 15·90	+ 41·42

Enthalpy of Solution. It is well known that when a solute is dissolved in a solvent, heat is either absorbed or evolved. Thus dissolution of a solute in a solvent is accompanied by enthalpy change (ΔH) of the system. If the heat is absorbed from the solution, *i.e.*, the solution is cooler, ΔH is given a positive sign. If heat is evolved and given to the solution, *i.e.*, the solution is warmer, ΔH is given a negative sign, as usual.

The amount of heat evolved or absorbed when 1 mole of a solute is dissolved in a sufficient amount of the solvent is called the **enthalpy of solution** of the solute.

The enthalpy change per mole of a solute dissolved varies with the concentration of the solution. It is necessary, therefore, to express the enthalpy change with reference to the concentration of the solution. For this purpose, a term **integral enthalpy of solution** is often used. It is defined as the enthalpy change when one mole of a solute is dissolved in a solvent to give a solution of a specified concentration. If, for example, one mole of potassium chloride is dissolved in 200 moles of water, heat absorbed, *viz.*, 18·58 kJ, is the integral heat of solution of potassium chloride at this concentration. This is expressed by a thermochemical equation as :

$$KCl(s) + 200\ H_2O(l) \longrightarrow KCl\ (200\ H_2O)\ ; \qquad \Delta H = +18{\cdot}58\ kJ$$

Similarly, when one mole of gaseous hydrogen chloride is dissolved in 50 moles of water, heat evolved is 72·2 kJ. Thus, integral enthalpy of solution of gaseous hydrogen chloride per mole when dissolved in 50 moles of water is 72·0 kJ and ΔH has a negative sign. The thermochemical equation is written as :

$$HCl\ (g) + 50\ H_2O\ (l) \longrightarrow HCl\ (50\ H_2O)\ ; \qquad \Delta H = -72{\cdot}0\ kJ$$

The integral enthalpies of solution of a few solutes dissolved in specified moles of water are given in Table 3.

TABLE 3

Integral Enthalpies of Solution in Water at 25°C

Substance	H_2O moles	Enthalpy of Solution kJ mol^{-1}	Substance	H_2O moles	Enthalpy of Solution kJ mol^{-1}
KCl	200	+ 18·6	HCl	200	− 72·9
NaCl	200	+ 5·3	HBr	200	− 83·3
KNO_3	200	+ 35·4	HNO_3	200	− 31·2
Na_2SO_4	400	+ 23·1	NH_3	200	− 35·3
$Na_2SO_4.10H_2O$	390	+ 79·1	$CaCl_2$	400	− 78·6
NH_4NO_3	200	+ 26·5	$CaCl_2.6H_2O$	394	+ 18·8
K_2SO_4	400	+ 27·4	$CuSO_4$	800	− 65·5
KOH	200	− 55·6	$CuSO_4.5H_2O$	795	+11·7

It is evident from the above Table that when gases (*e.g.*, HCl, HBr and NH_3) are dissolved in water, ΔH has a negative value, *i.e.*, the dissolution is accompanied by evolution of heat. The dissolution of hydrated salts (*e.g.*, $Na_2SO_4.10H_2O$, $CuSO_4.5H_2O$) as well as salts which do not form hydrates (*e.g.*, KNO_3, NaCl) is accompanied by increase in the enthalpy of the system (ΔH has a positive value), *i.e.*, the dissolution is accompanied by absorption of heat. However, when an anhydrous salt which is capable of forming hydrates (*e.g.*, $CaCl_2$, $CuSO_4$) is dissolved, ΔH has a negative value, *i.e.*, the dissolution is accompanied by evolution of heat. The difference in the behaviour of hydrated and anhydrous salts is due to the heat evolved in the formation of hydrates. This heat is known as the **enthalpy of hydration** of the salt.

By measuring integral enthalpy of solution of a salt in its hydrated as well as anhydrous state, it is possible to calculate the enthalpy of hydration of the salt. Suppose, it is required to calculate the enthalpy of hydration of $CuSO_4$ to form $CuSO_4.5H_2O$. Taking the data from Table 3, we have :

$$CuSO_4\ (anhydrous) + 800\ H_2O\ (l) \longrightarrow CuSO_4\ (800\ H_2O)\ ; \qquad \Delta H = -66{\cdot}5\ kJ$$

$$CuSO_4.5H_2O + 795\ H_2O\ (l) \longrightarrow CuSO_4\ (800\ H_2O)\ ; \qquad \Delta H = +11{\cdot}7\ kJ$$

By subtracting, we have

$$CuSO_4 + 5H_2O\ (l) \longrightarrow CuSO_4.5H_2O\ ; \qquad \Delta H = -78{\cdot}2\ kJ.$$

Thus, heat evolved when 1 mole of solid anhydrous copper sulphate combines with water to form solid pentahydrate is 78·2 kJ. Thus, the enthalpy of hydration of $CuSO_4$ to form $CuSO_4.5H_2O$ is 78·2 kJ.

When a solution is so dilute that further dilution causes no noticeable heat change, it is said to be at infinite dilution. The thermochemical equations for solutions of infinite dilutions are written as :

$$KCl\ (s) + aq \longrightarrow KCl\ (aq)\ ; \qquad \Delta H = -19{\cdot}7\ kJ$$

$$HCl\ (g) + aq \longrightarrow HCl\ (aq)\ ; \qquad \Delta H = -75{\cdot}4\ kJ$$

Differential Enthalpy of Solution. Another term, frequently used in processes of dissolution, is the differential enthalpy of solution. It is defined as the enthalpy change produced when 1 mole of a solute is dissolved in a large volume of solution of a specified concentration.

To illustrate, consider a solution containing one mole of potassium chloride dissolved in 10 moles of water. Now if we take a large volume of this solution, say, 200 litres and dissolve one mole more of potassium chloride in it, the heat change produced will be called the differential enthalpy of solution of potassium chloride when the solution is already at the given concentration.

Standard Enthalpy of Formation. The standard enthalpy of formation, ΔH_f°, is defined as the enthalpy change when one mole of a substance is formed from its elements in their standard states.

ΔH_f° may be negative or positive (Table 4).

TABLE 4
Standard Enthalpies of Formation of Some Common Compounds

Reaction	ΔH_f° (kJ mol^{-1}) for the compound formed
$C(s) + O_2(g) \longrightarrow CO_2(g)$	- 393·5
$C(s) + \frac{1}{2}O_2(g) \longrightarrow CO(g)$	- 110·5
$H_2(g) + \frac{1}{2}O_2(g) \longrightarrow H_2O(l)$	- 285·9
$H_2(g) + \frac{1}{2}O_2(g) \longrightarrow H_2O(g)$	- 241·9
$\frac{1}{2}H_2(g) + \frac{1}{2}F_2(g) \longrightarrow HF(g)$	- 271·1
$C(s) + 2H_2(g) \longrightarrow CH_4(g)$	- 74·9
$2C(s) + 3H_2(g) \longrightarrow C_2H_6(g)$	- 89·2
$2C(s) + 2H_2(g) \longrightarrow C_2H_4(g)$	+52·3
$2C(s) + H_2(g) \longrightarrow C_2H_2(g)$	+226·8
$6C(s) + 3H_2(g) \longrightarrow C_6H_6(l)$	+49·0
$8C(s) + 4H_2(g) \longrightarrow C_8H_8(l)$	- 224·4
$Si(s) + O_2(g) \longrightarrow SiO_2(s)$	- 910·0
$S(s) + O_2(g) \longrightarrow SO_2(g)$	- 297·5
$Na(s) + \frac{1}{2}Cl_2(g) \longrightarrow NaCl(s)$	- 411·0
$Ca(s) + \frac{1}{2}O_2(g) \longrightarrow CaO(s)$	- 635·5
$1/2N_2(g) + \frac{3}{2}H_2(g) \longrightarrow NH_3(g)$	- 46·0
$N_2(g) + 2H_2(g) \longrightarrow N_2H_4(l)$	+50·6
$C(s) + 2H_2(g) + 1/2\ O(g) \longrightarrow CH_3OH(l)$	- 238·9
$2C(s) + 3H_2(g) + 1/2\ O_2(g) \longrightarrow C_2H_5OH(l)$	- 277·7
$10C(s) + 4H_2(g) \longrightarrow C_{10}H_8(s)$	+60·2

Determination of Enthalpies of Reactions. Enthalpies of reactions at 25°C can be determined if ΔH_f° values of reactants and products involved in the reactions are known since

$$\Delta H^\circ = \Sigma \Delta H_f^\circ \text{(products)} - \Sigma \Delta H_f^\circ \text{(reactants)}$$

By convention, ΔH_f° values for elements in their standard states are taken as zero.

Example 9. The enthalpy of combustion of glucose $C_6H_{12}O_6(s)$ is - 2816 kJ mol^{-1} at 25°C. Calculate $\Delta H_f^\circ(C_6H_{12}O_6)$. The ΔH_f° values for $CO_2(g)$ and $H_2O(l)$ are - 393·5 and - 285·9 kJ mol^{-1}, respectively.

Solution : $C_6H_{12}O_6(s) + 6O_2(g) \longrightarrow 6CO_2(g) + 6H_2O(l)$; ΔH° = -2816 kJ

Since, $\Delta H = \Sigma \Delta H_f^\circ$ (products) - $\Sigma \Delta H_f^\circ$ (reactants), we find that

$$-2816 \text{ kJ} = 6(-393{\cdot}5 \text{ kJ mol}^{-1}) + 6(-285{\cdot}9 \text{ kJ mol}^{-1}) - \Delta H_f^\circ(C_6H_{12}O_6) - 6\Delta H_f^\circ(O_2)$$

which, on simplification and recalling that $\Delta H_f^\circ(O_2) = 0$, gives $\Delta H_f^\circ(C_6H_{12}O_6) = -1260{\cdot}4$ kJ mol^{-1}

Example 10. Using the ΔH_f° values given in Table 4, calculate the enthalpy of combustion of methane at 25°C and 1 atm pressure.

Solution : The combustion of methane is represented as :

$$CH_4(g) + 2O_2(g) \longrightarrow CO_2(g) + 2H_2O(l) \ ; \ \Delta H = ?$$

$$\therefore \quad \Delta H^\circ = \Delta H_f^\circ(CO_2) + 2\Delta H_f^\circ(H_2O) - \Delta H_f^\circ(CH_4) - 0$$
$$= (-393{\cdot}5 \text{ kJ mol}^{-1}) + 2(-285{\cdot}9 \text{ kJ mol}^{-1}) - (-74{\cdot}8 \text{ kJ mol}^{-1})$$
$$= -890{\cdot}5 \text{ kJ mol}^{-1}$$

Thus, enthalpy of combustion of methane at 25°C and 1 atm pressure = - 890·5 kJ mol^{-1}

Example 11. Calculate ΔH for each of the following reactions :

(a) $BaCO_3(s) + 2HCl(aq) \longrightarrow BaCl_2(aq) + CO_2(g) + H_2O(l)$

(b) $AgNO_3(aq) + NaCl(aq) \longrightarrow NaNO_3(aq) + AgCl(s)$

(c) $HNO_3(aq) + NaOH(aq) \longrightarrow NaNO_3(aq) + H_2O(l)$

Given : $\Delta H_f^\circ(BaCO_3(s)) = -1216{\cdot}7$ kJ mol^{-1}, $\Delta H_f^\circ(Ba^{2+}(aq)) = -538{\cdot}3$ kJ mol^{-1}

$\Delta H_f^\circ(Ag^+(aq)) = -105{\cdot}9$ kJ mol^{-1}, $\Delta H_f^\circ(OH^-(aq)) = -230{\cdot}0$ kJ mol^{-1}

$\Delta H_f^\circ(H^+(aq)) = 0$, by convention.

Solution : $\Delta H = \Sigma \Delta H_f^\circ$ (products) - $\Sigma \Delta H_f^\circ$ (reactants)

It is best to use the ionic equations here. Thus,

(a) $BaCO_3(s) + 2H^+(aq) \longrightarrow Ba^{2+}(aq) + CO_2(g) + H_2O(l)$:

$$\Delta H = [\Delta H_f^\circ(Ba^{2+}(aq)) + \Delta H_f^\circ(CO_2) + \Delta H_f^\circ(H_2O)] - [\Delta H_f^\circ(BaCO_3(s)) + 2\Delta H_f^\circ(H^+(aq))]$$
$$= [(-538{\cdot}3) + (-393{\cdot}5) + (-285{\cdot}9) - [-1216{\cdot}7 + 0]] = -1217{\cdot}7 + 1216{\cdot}7 = -1{\cdot}0 \text{ kJ}$$

(b) $Ag^+(aq) + Cl^-(aq) \longrightarrow AgCl(s)$:

$$\Delta H = [\Delta H_f^\circ(AgCl(s))] - [\Delta H_f^\circ(Ag^+(aq)) + \Delta H_f^\circ(Cl^-(aq))]$$
$$= [(-127{\cdot}0)] - (-105{\cdot}9) + (-167{\cdot}5)] = 146{\cdot}4 \text{ kJ}$$

(c) $H^+(aq) + OH^-(aq) \longrightarrow H_2O(l)$:

$$\Delta H = [\Delta H_f^\circ(H_2O)] - [\Delta H_f^\circ(H^+(aq)) - \Delta H_f^\circ(OH^-(aq))] = [(-285{\cdot}9)] - [0 + (-230{\cdot}0)]$$
$$= -55{\cdot}8 \text{ kJ}$$

Example 12. The heat evolved on dissolving $CuSO_4(s)$ in water is 86·6 kJ mol^{-1}. If $\Delta H_f^\circ(Cu^{2+})$ is 64·4 kJ mol^{-1}, what is $\Delta H_f^\circ(SO_4^{2-})$? $\Delta H_f^\circ(CuSO_4(s)) = -770{\cdot}0$ kJ mol^{-1}

Solution : $CuSO_4(s) \longrightarrow Cu^{2+}(aq) + SO_4^{2-}(aq)$

$$\Delta H = \Delta H_f^\circ(Cu^{2+}) + \Delta H_f^\circ(SO_4^{2-}) - \Delta H_f^\circ(CuSO_4(s))$$

On rearranging and using the given data, we find that

$$\Delta H_f^\circ(SO_4^{2-}) = -747{\cdot}8 \text{ kJ}$$

Example 13. In a bomb calorimeter, cyanamide was subjected to combustion at constant volume and the heat evolved was found to be 742·7 kJ at 25°C. Calculate q_p for the reaction.

Solution : $NH_2CN(s) + 3/2O_2(g) \longrightarrow N_2(g) + CO_2(g) + H_2O(l)$

$$\Delta n_g = 1 + 1 - 3/2 = 1/2$$

$$q_p = q_v + \Delta n_g RT = -742{\cdot}7 \text{ kJ} + (0{\cdot}5 \text{ mol})(8{\cdot}314 \text{ J K}^{-1}\text{mol}^{-1})(298\text{K})/1000 \text{ J kJ}^{-1}$$
$$= [-742{\cdot}7 \text{ kJ} + 1{\cdot}240 \text{ kJ}] = -741{\cdot}5 \text{ kJ}$$

Example 14. Calculate the enthalpy change for the transition graphite $\rightleftharpoons$ diamond from the ΔH_{comb}° values of - 393·5 kJ mol^{-1} and - 395·4 kJ mol^{-1} for graphite and diamond, respectively.

Solution : $C(s, \textit{graphite}) + O_2(g) \longrightarrow CO_2(g)$; $\Delta H_{comb}^\circ = -393{\cdot}5$ kJ mol^{-1}

$C(s, \textit{diamond}) + O_2(g) \longrightarrow CO_2(g)$; $\Delta H_{comb}^\circ = -395{\cdot}4$ kJ mol^{-1}

Subtracting the second reaction from the first,

$C(s, \textit{graphite}) \longrightarrow C(s, \textit{diamond})$; $\Delta H_{tr}^\circ = +1{\cdot}9$ kJ mol^{-1}

Example 15. Calculate the enthalpy of formation of OH^- ions at 25°C from the following thermochemical data :

$$H_2O(l) \longrightarrow H^+(aq) + OH^-(aq) ; \qquad \Delta H^\circ = 57{\cdot}3 \text{ kJ}$$

$$H_2(g) + \tfrac{1}{2}O_2(g) \longrightarrow H_2O(l) ; \qquad \Delta H^\circ = -285{\cdot}9 \text{ kJ}$$

Solution : Adding the above two equations, we get

$$H_2(g) + 1/2O_2(g) \longrightarrow H^+(aq) + OH^-(aq) \qquad \Delta H^\circ = -228{\cdot}6 \text{ kJ}$$

$\therefore \Delta H^\circ = -228{\cdot}6 \text{ kJ} = 0 + \Delta H_f^\circ(OH^-(aq)) - (0 + 0)$, since, by convention, $\Delta H_f^\circ[H^+(aq)] = 0$,

$\therefore \quad \Delta H_f^\circ[OH^-(aq)] = -228{\cdot}6 \text{ kJ}$

The standard enthalpies of formation of a few ions at 25°C are given in Table 5.

TABLE 5

Standard Enthalpies of Formation of Ions in Aqueous Solutions

Cation	ΔH_f° (kJ mol^{-1})	Anion	ΔH_f° (kJ mol^{-1})
H^+	0	OH^-	- 229·9
Li^+	- 278·5	Cl^-	- 167·5
Na^+	- 329·7	Br^-	- 121·5
K^+	- 251·2	I^-	- 56·0
Cu^{2+}	+ 64·4	SO_4^{2-}	- 907·5
Mg^{2+}	- 461·9	NO_3^-	- 206·6
Zn^{2+}	- 154·0	PO_4^{3-}	- 1284·0

Variation of Enthalpy of a Reaction with Temperature : The Kirchhoff Equation

The enthalpy of any process, whether physical or chemical, varies with temperature. The exact influence of temperature can be worked out as follows.

The enthalpy of the reaction

$$aA + bB \longrightarrow cC + dD$$

is given by $\Delta H = \Sigma H_{products} - \Sigma H_{reactants} = (cH_C + dH_D) - (aH_A + bH_B)$ ...(10)

Differentiating with respect to temperature, keeping pressure constant, we have

$$\left[\frac{\partial(\Delta H)}{\partial T}\right]_P = c\left(\frac{\partial H_C}{\partial T}\right)_P + d\left(\frac{\partial H_D}{\partial T}\right)_P - a\left(\frac{\partial H_A}{\partial T}\right)_P - b\left(\frac{\partial H_B}{\partial T}\right)_P$$

$$= cC_{P,C} + dC_{P,D} - aC_{P,A} - bC_{P,B} = \Delta C_P \qquad (\because C_P = (\partial H/\partial T)_P) \quad ...(11)$$

where ΔC_P = Sum of heat capacities of products - Sum of heat capacities of reactants

Eq. 11 is called the **Kirchhoff equation.** It states that *the variation of ΔH of a reaction with temperature at constant pressure is equal to ΔC_P of the system.* We can write it as

$$[\partial(\Delta H)/\partial T]_P = \Delta C_P \quad \text{or} \quad d(\Delta H) = \Delta C_P\, dT \qquad ...(12)$$

Analogously, the temperature-dependence of enthalpy of reaction at constant volume is given by

$$[\partial(\Delta U)/\partial T]_v = \Delta C_v \quad \text{or} \quad d(\Delta U) = \Delta C_v\, dT \qquad ...(13)$$

If the temperature range of interest is small, Eqs. 12 and 13 can be easily integrated by assuming that the heat capacities are independent of temperature. Accordingly,

$$\int_{T_1}^{T_2} d(\Delta H) = \int_{T_1}^{T_2} \Delta C_P dT = \Delta C_P \int_{T_1}^{T_2} dT \quad \text{or} \quad \Delta H_2 - \Delta H_1 = \Delta C_P(T_2 - T_1) \qquad ...(14)$$

$$\int_{T_1}^{T_2} d(\Delta U) = \int_{T_1}^{T_2} \Delta C_v dT = \Delta C_v \int_{T_1}^{T_2} dT \quad \text{or} \quad \Delta U_2 - \Delta U_1 = \Delta C_v(T_2 - T_1) \qquad ...(15)$$

If, however, the temperature range is not small, *i.e.*, if it is desired to determine the enthalpy of reaction at a far higher temperature than the initial temperature, then the constancy of heat capacities is no longer a valid assumption and we must express the heat capacities as a function of temperature before carrying out the integration. It is convenient to express the heat capacity as a power series in T, *viz.*,

$$C_P = \alpha + \beta T + \gamma T^2 \qquad ...(16)$$

where α, β and γ are constants for a given species. Hence,

$$\Delta C_P = [(c\alpha_C + d\alpha_D) - (a\alpha_A + b\alpha_B)] + [(c\beta_C + d\beta_D) - (a\beta_A + b\beta_B)]T + \cdots\cdots$$

$$= \Delta\alpha + \Delta\beta T + \Delta\gamma T^2 + \cdots\cdots \qquad ...(17)$$

Substituting Eq. 17 in Eq. 12 and integrating between T_1 and T_2, we have

$$\int_{T_1}^{T_2} d(\Delta H) = \int_{T_1}^{T_2} (\Delta\alpha + \Delta\beta T + \Delta\gamma T^2) dT$$

or $$\Delta H_2 - \Delta H_1 = \Delta\alpha(T_2 - T_1) + (1/2)\Delta\beta(T_2^2 - T_1^2) + 1/3\Delta\gamma(T_2^3 - T_1^3) \qquad ...(18)$$

Eq. 18 is the **integrated Kirchhoff equation.**

Example 16. The enthalpy of reaction (ΔH) for the formation of ammonia according to the reaction : $N_2 + 3H_2 = 2NH_3$ at 27°C was found to be -91·94 kJ. What will be the enthalpy of reaction (ΔH) at 50°C ? The molar heat capacities at constant pressure and at 27°C for nitrogen, hydrogen and ammonia are 28·45, 28·32 and 37·07 joules, respectively.

Solution : According to the Kirchhoff equation, $d(\Delta H) = \Delta C_P\, dT$ or $\Delta H_2 - \Delta H_1/(T_2 - T_1) = \Delta C_P$

In the present case, $\Delta H_1 = -91{\cdot}94$ kJ ; $T_1 = 27 + 273 = 300$ K and $T_2 = 50 + 273 = 323$ K

ΔC_P = Heat capacities of products *minus* heat capacities of reactants

$= 2\times37{\cdot}07 \text{ J K}^{-1} - (28{\cdot}45 \text{ J K}^{-1} + 3\times28{\cdot}32 \text{ J K}^{-1})$

$= -39{\cdot}28 \text{ J K}^{-1} = -39{\cdot}28\times10^{-3} \text{ kJ K}^{-1}$

Assuming that the heat capacities do not change with temperature, ΔH_2, at 50°C, will be given is

$\Delta H_2 = \Delta H_1 + (T_2 - T_1)\Delta C_P$

$= -91{\cdot}94 \text{ kJ} + (323 \text{ K} - 300 \text{ K})(-39{\cdot}28\times10^{-3} \text{ kJ K}^{-1}) = -92{\cdot}85 \text{ kJ}$

Example 17. Calculate the enthalpy change at 125°C for the reaction

$$N_2(g) + 3H_2(g) \longrightarrow 2NH_3(g) ; \qquad \Delta H_{298} = -92{\cdot}41 \text{ kJ}$$

The molar heat capacities (in J K^{-1} mol^{-1}) for the various gases involved in the reaction vary with temperature as follows :

$$C_p(N_2) = 27{\cdot}26 + 5{\cdot}23\times10^{-3}\,T - 4{\cdot}18\times10^{-9}\,T^2$$

$$C_p(H_2) = 29{\cdot}02 - 8{\cdot}35\times10^{-4}\,T + 20{\cdot}80\times10^{-7}\,T^2$$

$$C_p(NH_3) = 25{\cdot}86 + 32{\cdot}94\times10^{-2}\,T - 30{\cdot}42\times10^{-7}\,T^2$$

Solution : We know that $\Delta H_2 - \Delta H_1 = \int_{T_1}^{T_2} \Delta C_p dT$

It is only when ΔC_p is independent of temperature that it can be taken outside the integral sign, giving the result $\Delta H_2 - \Delta H_1 = \Delta C_p(T_2 - T_1)$. In the present case, ΔC_p is *not* independent of temperature. Let us first calculate ΔC_p.

$$\Delta C_p = 2C_p(NH_3) - [C_p(N_2) + 3C_p(H_2)]$$

Substituting the given data, the value of ΔC_p is given by

$$\Delta C_p = -62{\cdot}60 + 63{\cdot}14\times10^{-3}T - 123{\cdot}20\times10^{-7}T^2$$

Hence, $$\Delta H_2 - \Delta H_1 = \int_{T_1}^{T_2} [-62{\cdot}60 + 63{\cdot}14\times10^{-3}\,T - 123{\cdot}20\times10^{-7}\,T^2]\,dT$$

or $$\Delta H_{398} - \Delta H_{298} = \left[-62{\cdot}60 + 63{\cdot}14 \times 10^{-3} T^2/2 - 123{\cdot}20 \times 10^{-7} T^3/3\right]_{298}^{398}$$

Simplifying and putting $\Delta H_{298} = -92{\cdot}41$ kJ, we obtain $\Delta H_{398} = -96{\cdot}50$ kJ

Example 18. For the hypothetical reaction : $2B(g) \longrightarrow B_2(g)$, ΔC_P (in joules) $= 6{\cdot}0 + 2{\cdot}0 \times 10^{-3} T$ and $\Delta H^\circ_{298} = -20{\cdot}0$ kJ mol^{-1}. Estimate the temperature at which $\Delta H^\circ = 0$ for this reaction.

Solution : Using the Kirchhoff equation, $\Delta H_2 = \Delta H_1 + \int_{T_1}^{T_2} (\Delta C_p) dT$

or $$0 = -20{,}000 - \int_{298}^{T} (6{\cdot}0 + 2{\cdot}0 \times 10^{-3} T)\, dT$$

or $$20{,}000 = [(6{\cdot}0)(T - 298)] + [(1{\cdot}0 \times 10^{-3})(T^2 - (298)^2] = 6T - 1788 + 1 \times 10^{-3} T^2 - 88{\cdot}8$$

or $$10^{-3} T^2 + 6T - 1{,}876{\cdot}8 = 0$$

This is a quadratic equation in T which, when solved, gives two roots — one positive and the other negative. The negative root has no physical significance. The positive root gives $T = 2557$ K.

Flame and Explosion Temperatures

The combustion of a gaseous fuel in air takes place so suddenly that the heat produced during combustion does not get any opportunity to be dissipated to the surroundings. The combustion process is, therefore, practically equivalent to an adiabatic process. The entire amount of heat produced thus goes to heat the gases produced during combustion as also the unreacted nitrogen. The maximum temperature attained by the flame-zone (containing the resultant gases) due to the heat liberated by the combustion of the fuel under adiabatic conditions *at constant pressure* is known as the **flame temperature.** If, on the other hand, the combustion is carried out under adiabatic conditions at *constant volume*, the maximum temperature attained is called **explosion temperature.**

For an isobaric (constant pressure) adiabatic process, the flame temperature can be calculated using the Kirchhoff equation, *viz.*,

$$d(\Delta H)/dT = \Delta C_P \quad \text{or} \quad d(\Delta H) = \Delta C_P\, dT \qquad ...(19)$$

Integration of Eq. 19 yields

$$\int d(\Delta H) = \Delta C_P \int_{T_i}^{T_f} dT \quad \text{or} \quad \Delta H = \Delta C_p\, (T_f - T_i) \qquad ..(20)$$

Here we have assumed that over the given temperature range, ΔC_p remains constant so that it can be taken outside the integral sign. Hence, knowing ΔH, ΔC_p and the initial temperature T_i, the final temperature T_f (which in this case is the flame temperature) can be calculated.

We must comment on ΔC_p here. The flame temperature would obviously depend upon the composition and the heat capacities of only the *resultant gases*. In the flames produced by combustion of fuels in air, there is present in gaseous products unreacted nitrogen which is also heated up along with the gaseous products to the flame temperature. Since air contains about 20% by volume of O_2 and 80% by volume of N_2, the combustion reaction involving 1 mole of O_2 is associated with 4 moles of unreacted N_2 in the products. Thus, the combustion of H_2 gas in air can be schematically represented as

$$2H_2(g) + O_2(g) + 4N_2(g) \longrightarrow 2H_2O(g) + 4N_2(g)$$

Hence, ΔC_p is considered as equal to the sum of the C_ps of the *products* plus the C_p of four moles of unreacted N_2 per mole of O_2 used during combustion. Therefore,

$$\Delta C_P = \Sigma C_{P,\,\text{products}} + 4C_{P,\,N_2}$$

Accordingly, for determining flame temperature, ΔC_P in Eq. 19 is replaced by ΣC_p where ΣC_p is the summation of the heat capacities of products of combustion and the unreacted nitrogen.

Example 19. In a Bunsen burner, CH_4 gas is premixed with sufficient air to allow complete combustion and at the flame temperature water is converted into steam. Using the following thermochemical data :

$$CH_4(g) + 2O_2(g) \longrightarrow CO_2(g) + 2H_2O(l)\ ; \qquad \Delta H^\circ_{298} = -890{\cdot}3 \text{ kJ}$$

$$H_2O(l) \longrightarrow H_2O(g)\ ; \qquad \Delta H^\circ_{298} = +40{\cdot}7 \text{ kJ}$$

calculate the flame temperature. Assume that the gaseous products behave ideally. $\Sigma C_P = 41{\cdot}8$ J K^{-1} mol^{-1} and the initial temperature = 25°C.

Solution : From the given thermochemical reactions, we have, at the flame temperature (when water is in *gaseous* state) :

$$CH_4(g) + 2O_2(g) \longrightarrow CO_2(g) + 2H_2O(g)\ ; \qquad \Delta H^\circ_{298} = -890{\cdot}3 + 2(40{\cdot}7) = -802{\cdot}3 \text{ kJ}$$

ΔC_P of the gaseous products (CO_2, H_2O and N_2) $= 41{\cdot}8$ J K^{-1} mol^{-1}

Since for every mole of O_2 reacted, 4 moles of unreacted N_2 remain, hence total number of moles of gaseous products $= 1 + 2 + (4 \times 2) = 11$. Thus, flame temperature, T_f, is attained if 802·3 kJ of heat liberated above is completely utilized to heat (at constant pressure) 1 mole of CO_2, 2 moles of steam and 8 moles of unreacted N_2 (*i.e.*, a total of 11 moles). Using Kirchhoff equation,

$$(11 \text{ mol}) \times (41{\cdot}8 \text{ J K}^{-1} \text{ mol}^{-1})\ (T_f - T_i) = 802{\cdot}3 \text{ kJ}$$

$$T_f - T_i = 802{\cdot}3 \times 10^3 \text{ J}/459{\cdot}6 \text{ J K}^{-1} = 1746 \text{ K}$$

Since $T_i = 25°C = 298$ K, $T_f = (1746 + 298)$ K $= 2{,}043$ K (The experimental value is 1820 K)

It should be noted that if ΔH°_{298} is the enthalpy of the reaction at 298 K and T_f is the final temperature, then the heat required to raise the temperature of the products from 298 K to T_f must be equal in magnitude but opposite in sign to ΔH°_{298}, *i.e.*, $\Delta H_{\text{heating}} = -\Delta H^\circ_{298}$ so that the sum $\Delta H^\circ_{298} + \Delta H_{\text{heating}} = 0$ because, for the adiabatic process, $\Delta H = 0$.

The calculation of explosion temperature is similar to that of the flame temperature except that ΔH is replaced by ΔU. The pressure required for the reacting system at the explosion temperature is called the **explosion pressure.**

Example 20. H_2 gas is mixed with air at 25°C under a pressure of one atmosphere and exploded in a closed vessel. The enthalpy of the reaction $H_2(g) + 1/2\ O_2(g) \longrightarrow H_2O(g)$ at constant volume, $\Delta U_{298} = -240{\cdot}6$ kJ and C_ps for H_2O vapour and N_2 in the temperature range 298 K and 3,200 K are 39·1 J K^{-1} and 26·4 J K^{-1}, respectively. Calculate the explosion temperature under adiabatic conditions.

Solution. For a constant volume process under adiabatic conditions,

$$\Delta U = \Delta U_{\text{heating}} + \Delta U_{298} = 0$$

Hence, $$\Delta U_{\text{heating}} = -\Delta U_{298} = -\int_{298}^{T_f} \Sigma n C_v dT = -240{\cdot}60 \text{ kJ} \qquad ...(i)$$

Since 2 moles of unreacted N_2 are associated with 1/2 mole of O_2, we have

$$\Sigma n C_v = C_v(H_2O,\, g) + 2C_v(N_2,\, g) = (39{\cdot}1 + 2 \times 26{\cdot}4) \text{ J K}^{-1} = 91{\cdot}9 \text{ J K}^{-1}$$

Hence, from Eq. *(i)*, on integrating, we have

$$91{\cdot}9 \text{ J K}^{-1} (T_f - 298) = 240{,}600 \text{ J}$$

$$T_f - 298 = 240{,}600 \text{ J}/91{\cdot}9 \text{ J K}^{-1} = 2618 \text{ K}$$

$$T_f = (2618 + 298) \text{ K} = 2916 \text{ K}$$

Hess's Law of Constant Heat Summation

This law states that the amount of heat evolved or absorbed in a process, including a chemical change, is the same whether the process takes place in one or several steps.

Suppose in a process, the system changes from state A to state B in *one step* and the heat exchanged in this change is q. Now suppose the system changes from state A to state B in *three steps* involving a change from A to C, C to D and finally from D to B. If q_1, q_2 and q_3 are the heats

exchanged in the first, second and third step, respectively, then, according to Hess's law,

$$q_1 + q_2 + q_3 = q \qquad ...(20)$$

This generalisation means, in effect, that the enthalpy of reaction depends only on the initial reactants and final products and not at all on the intermediate products that may be formed.

Applications of Hess's Law. 1. Calculation of enthalpies of reactions. Hess's law makes it possible to calculate enthalpies of many reactions which cannot be determined experimentally. For example, it is extremely difficult to measure the heat evolved when carbon burns in oxygen to form carbon monoxide

$$C(s) + \tfrac{1}{2}O_2(g) \longrightarrow CO(g)\,; \qquad \Delta H = ?$$

Hess's law, starts that the heat *evolved* in the combustion of 1 mole of carbon is the same, *viz.*, 393·5 kJ (*i.e.*, $\Delta H = -393{\cdot}5$ kJ), whether the reaction takes place in a single step as

$$C(s) + O_2(g) \longrightarrow CO_2(g)\,; \qquad \Delta H = -393{\cdot}5 \text{ kJ}$$

or in two steps as

$$C(s) + \tfrac{1}{2}O_2(g) \longrightarrow CO(g)\,; \qquad \Delta H = x \text{ kJ (say)}$$

$$CO(g) + \tfrac{1}{2}O_2(g) \longrightarrow CO_2(g)\,; \qquad \Delta H = y \text{ kJ(say)}$$

Although x, the heat change involved in the combustion of carbon to carbon monoxide cannot be determined easily, y, the heat change involved in the combustion of carbon monoxide to give carbon dioxide can be measured and has been found to be –282·0 kJ. According to Hess's law

$$x + y = -393{\cdot}5 \text{ kJ}$$

or

$$x = -393{\cdot}5 - y = -393{\cdot}5 - (-282{\cdot}0) = -111{\cdot}5 \text{ kJ}$$

Thus, ΔH for the combustion of carbon to give carbon monoxide is – 111·5 kJ.

2. Determination of enthalpies of slow reactions. Hess's law is extremely useful in determining enthalpies of those reactions which take place extremely slowly. For example, the transformation of rhombic sulphur into monoclinic sulphur is so slow that direct measurement of enthalpy is not possible. But the enthalpies of combustion of rhombic sulphur and monoclinic sulphur are known to be – 297·5 and – 300·0 kJ mol^{-1}, respectively, *i.e.*,

(i) $S(rhombic) + O_2(g) \longrightarrow SO_2(g)\,;$ $\Delta H = -297{\cdot}5$ kJ

(ii) $S(monoclinic) + O_2(g) \longrightarrow SO_2(g)\,;$ $\Delta H = -300{\cdot}0$ kJ

Subtracting *(i)* from *(ii)* and transposing, we get

$$S(monoclinic) \longrightarrow S(rhombic)\,; \qquad \Delta H = -2{\cdot}5 \text{ kJ}$$

or

$$S(rhombic) \longrightarrow S(monoclinic)\,; \qquad \Delta H = +2{\cdot}5 \text{ kJ}$$

Thus, transformation of one mole of rhombic sulphur into monoclinic sulphur is accompanied by absorption of 2·5 kJ of heat.

3. Calculation of enthalpies of formation. The enthalpies of formation of compounds can be calculated by the application of Hess's law when it is not possible to determine these experimentally.

For example, it is impossible to determine experimentally the enthalpy of formation of benzene from its elements : carbon and hydrogen. However, it can be calculated from the enthalpy of combustion of benzene and the enthalpies of formation of water and carbon dioxide. The solution is

carried out in two steps :

Step 1. The thermochemical equations for the known values are written as

(i) $C_6H_6(l) + \frac{15}{2}O_2(g) \longrightarrow 6CO_2(g) + 3H_2O(l)\,;$ $\Delta H = -3267{\cdot}7$ kJ

(ii) $C(s) + O_2(g) \longrightarrow CO_2(g)\,;$ $\Delta H = -393{\cdot}5$ kJ

(iii) $H_2(g) + \frac{1}{2}O_2(g) \longrightarrow H_2O(l)\,;$ $\Delta H = -285{\cdot}9$ kJ

Step 2. Equation *(ii)* is multiplied by 6 and equation *(iii)* is multiplied by 3 :

(iv) $6C(s) + 6O_2(g) \longrightarrow 6CO_2(g)\,;$ $\Delta H = -2361{\cdot}0$ kJ

(v) $3H_2(g) + \frac{3}{2}O_2(g) \longrightarrow 3H_2O(l)\,;$ $\Delta H = -857{\cdot}7$ kJ

Adding *(iv)* and *(v)* and subtracting *(i)*, we get

$$6C(s) + 3H_2(g) \longrightarrow C_6H_6(l) \qquad \Delta H = +49{\cdot}0 \text{ kJ}$$

Thus, the enthalpy of formation of benzene is **+ 49·0 kJ.**

Measuring the Enthalpy of Combustion.

Calorimetry is the study of heat transfer during physical and chemical processes. A **calorimeter** is a device for measuring energy transferred as heat. The most common device for measuring D*U* is the **adiabatic bomb calorimeter,** shown in Figs. 5 and 6. The inner vessel or the 'bomb' (Fig. 6) and its cover are made of strong steel coated inside with gold or platinum or some other non-oxidisable material. The cover can be fitted tightly to the vessel by means of a metal lid screwed down on a lead washer. A weighed amount of the substance is taken in a platinum cup *C* which is supported on a rod *R*.

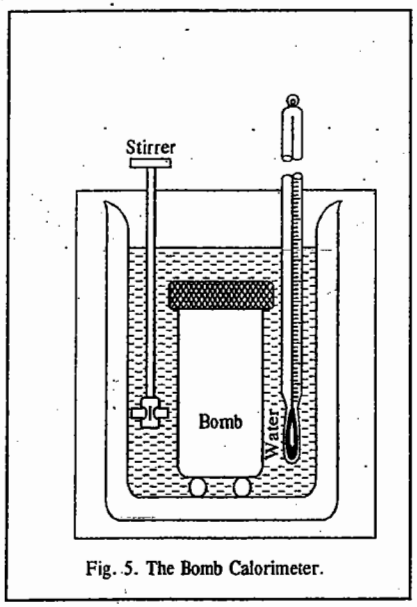

Fig. 5. The Bomb Calorimeter.

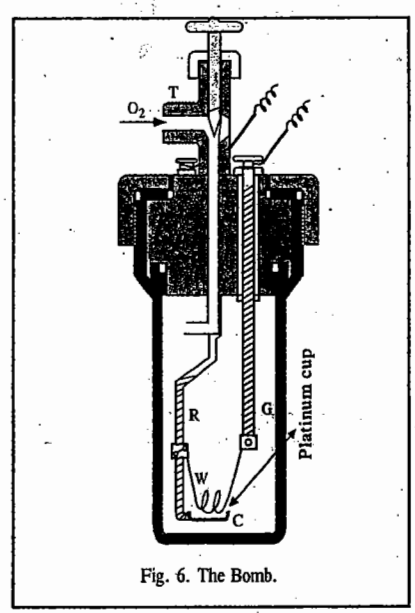

Fig. 6. The Bomb.

A thin platinum wire W is connected between the rods R and G, as shown. This serves to initiate the combustion when heated electrically. The bomb is tightly closed and oxygen introduced through the inlet tube T until a pressure of about 20—25 atmospheres is attained. The bomb is then lowered in water placed in a double jacketed and polished metallic calorimeter so as to minimise error due to radiation. The arrangement ensures that there is no net loss of heat from the calorimeter to the surroundings (the bath) and hence that the process is adiabatic. A mechanical stirrer is provided as shown (Fig. 5). When the temperature of the water has become steady, the substance is ignited by passing electric current through the platinum wire W. The rise of temperature of the water in the calorimeter is noted after every minute by means of a Beckmann thermometer graduated to read up to a hundredth of a degree. The final temperature when corrected for the radiation error in the usual way, *minus* the initial temperature, gives the rise of temperature. The heat capacity of the calorimeter system, called the **calorimeter constant**, C, is obtained by burning a known mass of a substance of known enthalpy of combustion. For this purpose, usually benzoic acid of high grade purity is taken. Its q_v which has been very carefully measured is taken as $-3226{\cdot}7$ kJ mol^{-1}. Suppose the thermal capacity of the calorimeter system including water is C and θ is the change in temperature produced by burning a quantity m of the given substance of molar mass M. Then, the constant volume heat of combustion, q_v of the substance is given by $C\times\theta\times M/m$. The enthalpy of combustion q_p is then obtained with the help of the equation $q_p = q_v + \Delta n_g RT$.

Example 21. 0·50 g of benzoic acid was subjected to combustion in a bomb calorimeter when the temperature of the calorimeter system (including water) was found to rise by 0·55°C. Calculate the enthalpy of combustion of benzoic acid. The ΔT calorimeter constant was found to be 23·85 kJ K^{-1}.

Solution : $q_v = C\times\theta\times M/m$

$= 23{\cdot}85$ kJ K$^{-1}\times 0{\cdot}55$ K$\times 122$ g mol$^{-1}/0{\cdot}50$ g $= 3200{\cdot}7$ kJ mol^{-1} $= -\,3200{\cdot}7$ kJ mol^{-1}

(Heat of combustion has always a negative sign)

$$C_6H_5COOH(s) + \tfrac{15}{2}O_2(g) \longrightarrow 7CO_2(g) + 3H_2O(l)$$

We know that $q_p = q_v + \Delta n_g RT$; $\Delta n = 7 - 7{\cdot}5 = -0{\cdot}5$

$q_p = -\,3200{\cdot}7$ kJ mol^{-1} $+ (-0{\cdot}5)\,(8{\cdot}314\times10^{-3}$ kJ K^{-1} mol^{-1}) (298 K) $= -\,3201{\cdot}9$ kJ mol^{-1}

Example 22. Explain why the following statement, made by a student doing an experiment on bomb calorimeter, is wrong :

"$\Delta H = \Delta U + P\Delta V$. Since in the experiment, $\Delta V=0$, hence, $\Delta H=\Delta U$."

Explanation : The error is due to the fact that the student has applied the equation $\Delta H=\Delta U+P\Delta V$, which holds at constant pressure, to a process which occurs at constant volume.

We know that $H = U + PV$

$\therefore \quad \Delta H = \Delta U + \Delta(PV) = \Delta U + P\Delta V + V\Delta P$

For a constant pressure process, $\Delta P = 0$ so that $\Delta H = \Delta U + P\Delta V$

However, for a constant volume process, $\Delta V = 0$ so that $\Delta H = \Delta U + V\Delta P$

We may mention here that a calorimeter for studying processes at constant pressure, called an **isobaric calorimeter** is also available commercially. A simple example is a thermally insulated vessel, open to the atmosphere; the heat released in the reaction is monitored by measuring the change in temperature of the contents. For a combustion reaction, an adiabatic flame calorimeter can be used to measure ΔT when a given amont of substance burns in oxygen.

Bond Energies

Bond energy for any particular type of bond in a compound may be defined as the average amount of energy required to dissociate (*i.e.*, break) one mole of bonds of that type present in the compound. Bond energy is also called the **enthalpy of formation of the bond.**

It has been found by experiment that isomeric compounds have the same value for enthalpy of formation. Also, in any homologous series, the increase in enthalpy of formation for each CH_2 group is almost constant. This shows that enthalpy of formation of a bond of a particular type is largely an **additive property.**

In order to calculate bond energies (*i.e.*, enthalpies of formation of bonds) of different types of bonds, it is necessary, in the first instance, to know the enthalpies of dissociation of molecules of common elements into atoms. These have been obtained spectroscopically and are given below for hydrogen, oxygen, nitrogen and carbon :

(i) $H_2(g) \longrightarrow 2H(g)$; $\Delta H = 435{\cdot}1$ kJ

(ii) $O_2(g) \longrightarrow 2O(g)$; $\Delta H = 489{\cdot}5$ kJ

(iii) $N_2(g) \longrightarrow 2N(g)$; $\Delta H = 937{\cdot}4$ kJ

(iv) $C(s) \longrightarrow C(g)$; $\Delta H = 719{\cdot}6$ kJ

Suppose, it is required to calculate enthalpy of formation of C—H bond in methane. We should know the enthalpy of formation of methane. This has been calculated from the enthalpy of combustion of methane to be $-74{\cdot}9$ kJ. Thus,

(v) $C(s) + 2H_2(g) \longrightarrow CH_4(g)$; $\Delta H = -74{\cdot}9$ kJ

Multiplying equation *(i)* by 2, we have

(vi) $2H_2(g) \longrightarrow 4H(g)$; $\Delta H = 870{\cdot}2$ kJ

Adding equations *(iv)* and *(vi)* and subtracting from equation *(v)*, we have

$C(g) + 4H(g) \longrightarrow CH_4(g)$; $\Delta H = -\,1664{\cdot}7$ kJ

It follows from above that 1664·7 kJ of energy is required to break four moles of C—H bonds in methane. Therefore, the average bond energy per mole of C—H bonds is $1664{\cdot}7/4 = 416{\cdot}2$ kJ. This is also the **enthalpy of formation** of the C—H bond.

The enthalpy of formation of ethane is known to be $-89{\cdot}2$ kJ, *i.e.*,

(vii) $2C(s) + 3H_2(g) \longrightarrow C_2H_6(g)$; $\Delta H = -\,89{\cdot}2$ kJ

Multiplying equation *(iv)* by 2 and equation *(i)* by 3, we have

(viii) $2C(s) \longrightarrow 2C(g)$; $\Delta H = 1439{\cdot}2$ kJ

(ix) $3H_2(g) \longrightarrow 6H(g)$; $\Delta H = 1305{\cdot}3$ kJ

Adding equations *(viii)* and *(ix)* and subtracting from equation *(vii)*, we have

$2C(g) + 6H(g) \longrightarrow C_2H_6(g)$; $\Delta H = -\,2833{\cdot}7$ kJ

This means that the enthalpy of formation of six moles of C—H bonds and one mole of C—C bonds is 2833·7 kJ. The enthalpy of formation of six moles of C—H bonds is $6\times416{\cdot}2 = 2497{\cdot}2$ kJ. Therefore, the enthalpy of formation of C—C bond is $2833{\cdot}7 - 2497{\cdot}2 = 336{\cdot}5$ kJ per mole of bonds. The average value of enthalpy of formation of C—C bond is taken as 347·3 kJ.

Similarly, the enthalpy of formation of other bonds, such as C—O, C=O and C—OH, can be obtained by knowing the enthalpies of formation of ethers, ketones and alcohols, respectively. Some of the results are given in Table 6. It is to be remembered that each value pertains to one mole

(*i.e.*, Avogadro's number) of bonds of the particular type. Also, these values are considered to be *approximate* since additivity of bond energies has not been established finally.

TABLE 6
Enthalpies of Formation of Bonds, *viz.*, Bond Energies at 25°C

Bond	Enthalpy of formation (kJ mol^{-1})	Bond	Enthalpy of formation (kJ mol^{-1})
H—H	435·1	C—Cl	330·5
H—F	564·8	C—Br	276·1
H—Cl	430·9	C—S	259·4
H—Br	368·2	C=S	477·0
O—O	138·1	C—N	292·9
O=O	493·7	C=N	615·0
O—H	464·4	C≡N	878·6
C—H	416·2	N—N	159·0
C—O	351·4	N=N	418·4
C=O	711·3	N≡N	945·6
C—C	347·3	N—H	389·1
C=C	615·0	F—F	154·8
C≡C	811·7	Cl—Cl	242·7
C—F	439·3	Br—Br	192·5

Applications of Bond Energies. 1. Determination of enthalpies of reactions. The bond energies can be used for determining enthalpies of reactions. This may be illustrated by the following example.

Suppose we want to determine the enthalpy of the reaction

$$H_2C{=}CH_2(g) + H_2(g) \longrightarrow H_3C{-}CH_3(g)\,; \qquad \Delta H = ?$$

In this reaction, the four C—H bonds of C_2H_4 remain unaffected. A double bond breaks in ethylene and an H—H bond breaks in H_2. In turn, one C—C bond and two C—H bonds are formed in C_2H_6. Thus,

$$\Delta H = -\Delta H_{C\text{-}C} - 2\Delta H_{C\text{-}H} + \Delta H_{C=C} + \Delta H_{H\text{-}H}$$

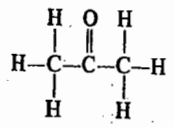
Substituting the bond energies from Table 6, we get

$$\Delta H = -(347{\cdot}3 + 832{\cdot}4) + (615{\cdot}0 + 435{\cdot}1) = \mathbf{-129{\cdot}6\ kJ}$$

The above value is quite close to the experimental value of −133 kJ.

2. Determination of enthalpies of formation of compounds. The bond energies can also be used for determination of enthalpies of formation of compounds. As an example, we may consider the formation of acetone :

$$3C(g) + 6H(g) + O(g) \longrightarrow$$



The formation of acetone, evidently, involves

1. Breaking of three H—H bonds to give six atoms of H, breaking of half O—O bond to give one atom of O and sublimation of three atoms of C(*s*) to give three atoms of C(*g*).
2. Formation of two C—C bonds, six C—H bonds and one C=O bond.

The enthalpy of formation of acetone is thus given by

$$\Delta H_f = [3(\Delta H_{H\text{-}H}) + 1/2(\Delta H_{O\text{-}O}) + 3(\Delta H_{C(s)\to C(g)})] - [2(\Delta H_{C\text{-}C}) + 6(\Delta H_{C\text{-}H}) + \Delta H_{C=O}]$$

Incorporating the data given in Table 6, we have

$$\Delta H_f = [3(435{\cdot}1) + 1/2(138{\cdot}1) + 3(719{\cdot}6)] - [2\times347{\cdot}3 + 6\times416{\cdot}2 + 711{\cdot}3]$$
$$= \mathbf{-369{\cdot}95\ kJ\ mol^{-1}}$$

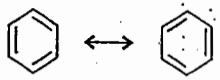
3. Determination of resonance energy. Generally, there is a good agreement between the enthalpies of formation as calculated from bond energies and those determined experimentally. However, if a compound exhibits resonance, there is a considerable difference between the two values. This difference gives a measure of the resonance energy of the compound. As an example, we may consider the dissociation of benzene.:

$$C_6H_6(g) \longrightarrow 6C(g) + 6H(g)$$

Assuming that benzene ring consists of three single and three double bonds.(Kekule's structure), the calculated dissociation energy comes out to be 5384·1 kJ, as illustrated below :

$$\Delta H_d = 3(\Delta H_{C-C}) + 3(\Delta H_{C=C}) + 6(\Delta H_{C-H})$$
$$= 3\times347{\cdot}3 + 3\times615{\cdot}0 + 6\times416{\cdot}2 = \mathbf{5384{\cdot}1\ kJ\ mol^{-1}}$$

The experimental value is known to be 5535·1 kJ mol^{-1}. Evidently, the actual energy required for the dissociation of benzene is 151 kJ more than the calculated value. This clearly shows that the actual structure of benzene is more stable than the Kekule structure by 151 kJ. The actual structure is now known to be a resonance hybrid of the two Kekule structures and may be represented as



The difference of 151 kJ gives the resonance energy of benzene.

I. Review Questions

1. Derive the relation between ΔH and ΔU for a thermodynamic system.
2. Derive the relation between enthalpy of reaction at constant volume and at constant pressure for an ideal gas.
3. Define the terms $\Delta H_{comb.}$, $\Delta H_{neut.}$, $\Delta H_{soln.}$ and ΔH_f°.
4. Derive Kirchhoff's equation relating the variation of enthalpy of a reaction with temperature. Write down the integrated form of the equation.
5. Define the terms : Flame and explosion temperatures. How are these temperatures determined ?
6. State and explain Hess's law of constant heat summation. Discuss the applications of this law.
7. Define bond energy. Discuss the applications of bond energies.
8. How would you determine the following from bond energies :
   (i) Enthalpies of reactions *(ii)* Enthalpies of formation of compounds and *(iii)* Resonance energy.

II. Problems

1. The $\Delta H°$ for the reaction $C_2H_5OH(l) + 3O_2(g) \longrightarrow 2CO_2(g) + 3H_2O(l)$ is -1,366·5 kJ. Calculate $\Delta U°$.
[Ans. -1,364 kJ]

2. The enthalpy of formation of ethane at 25°C is -84·68 kJ. Calculate the heat of formation at constant volume at this temperature.
[Ans. - 79·70 kJ]

3. The heat of combustion of C_2H_4 at 17°C and at constant volume is -1389·9 kJ. What is the enthalpy of combustion ?
[Ans. - 1394·7 kJ]

4. The enthalpies of combustion of CH_4 and C_2H_6 are - 890·3 and - 1,559·7 kJ mol^{-1}, respectively. Which of the two has greater efficiency as fuel per gram ?
[Ans. CH_4]

5. Calculate ΔH_f for methane, *i.e.*, ΔH for the reaction C(graphite) + $2H_2(g) \longrightarrow CH_4(g)$ from the following data :

$CH_4(g) + 2O_2(g) \longrightarrow CO_2(g) + 2H_2O(l)$; $\Delta H = -890·3$ kJ

$H_2(g) + 1/2\ O_2(g) \longrightarrow H_2O(l)$; $\Delta H = -285·9$ kJ

$C(graphite) + O_2(g) \longrightarrow CO_2(g)$; $\Delta H = -393·5$ kJ

[Ans. - 75·56 kJ mol^{-1}]

6. The enthalpy of neutralization of NH_4OH with HCl is - 51·46 kJ mol^{-1}. Calculate the enthalpy of ionization of NH_4OH. Assume that the enthalpy of neutralization of a strong acid with a strong base is - 57·35 kJ mol^{-1}.
[Ans. 5·89 kJ mol^{-1}]

7. $\Delta H°_{neutr}$ for CH_3COOH with NaOH is - 51·63 kJ mol^{-1}. Calculate ΔH_{ioniz} of CH_3COOH. Assume that the enthalpy of neutralization of a strong acid with a strong base is -57·35 kJ mol^{-1}. **[Ans. 5·72 kJ mol^{-1}]**

8. When H_2 gas is burnt in O_2 gas, 240·5 kJ heat is liberated per mole of the explosion products at 27°C. Calculate the maximum temperature of explosion. Given $C_v(H_2O, g) = 24·15\ J\ K^{-1}$ and the reaction involved is $H_2(g) + 1/2\ O_2(g) \longrightarrow H_2O(g)$; $\Delta U_{300} = -240·5$ kJ. **[Ans. Approx 10^4 K]**

9. 2 gram of $C_6H_6(g)$ was burnt in excess of oxygen in a bomb calorimeter according to the reaction :

$$C_6H_6(g) + 7·5O_2(g) \longrightarrow 6CO_2(g) + 3H_2O(l)$$

If the temperature rise is 42·1°C and the heat capacity of the system is 2·0 kJ K^{-1}, calculate the enthalpy of combustion of benzene at 25°C.
[Ans. - 3920 kJ mol^{-1}]

10. Calculate $\Delta H°$ for the reaction $CH_2=CH_2(g) + 3O_2(g) \longrightarrow 2CO_2(g) + 2H_2O(l)$ at 25°C. Given the following bond energies :

Bond	C—H	O=O	C=O	O—H	C=C
Bond energy (kJ (mol^{-1})	416·2	493·7	711·3	464·4	615·0

[Ans. - 941·9 kJ]

11. For the reaction $CH_4(g) + 2O_2(g) \longrightarrow CO_2(g) + 2H_2O(g)$; $\Delta H° = -802·8$ kJ. Calculate $\Delta H_{C=O}$ from the following bond energy data :
$\Delta H_{C-H} = 416·2$ kJ mol^{-1} ; $\Delta H_{O=O} = 493·7$ kJ mol^{-1} ; $\Delta H_{O-H} = 464·4$ kJ mol^{-1} **[Ans. 798·5 kJ mol^{-1}]**

CHAPTER 15

THE SECOND LAW OF THERMODYNAMICS

Limitations of the First law. Need for the Second law.

The First law of thermodynamics, though exact, has certain limitations, as discussed below.

1. The First law establishes definite relationship between the heat absorbed and the work performed by a system in a given process. But *it puts no restriction on the direction of flow of heat.* According to the first law, for example, it is not impossible to extract heat from ice by cooling it to a low temperature and then use it for warming water. But it is known from experience that such a transfer of heat from a lower to a higher temperature is not possible without expenditure of energy, *i.e.*, without doing some external work. It is known, on the other hand, that heat flows spontaneously, *i.e.*, of its own accord, from a higher to a lower temperature.

2. According to the First law, the energy of an isolated system remains constant during a specified change of state. But it does not tell whether a specified change or a process including a chemical reaction can occur spontaneously, *i.e.*, whether it is feasible.

3. The First law states that energy of one form can be converted into an equivalent amount of energy of another form. But it does not tell that heat energy cannot be completely converted into an equivalent amount of work. There is thus need for another law, *viz.*, the Second law of thermodynamics.

The Second law helps us to determine the direction in which energy can be transferred. It also helps us to predict whether a given process or a chemical reaction can occur spontaneously. It introduces a new concept of entropy. It also helps us to know the equilibrium conditions.

It is known from experience that although various forms of energy can be completely transformed into one another, yet heat is a typical form of energy which cannot be completely transformed into work. The Second law helps us to calculate the maximum fraction of heat that can be converted into work in a given process. Entropy can be thought of as arising from the *dispersal* or *degradation* of the total energy of an isolated system.

Spontaneous or Irreversible Processes

Natural processes are spontaneous and irreversible. A few examples are given below.

1. Water flows downhill spontaneously. We cannot reverse the direction of flow without some external aid.

2. If a bar of metal is hot at one end and cold at the other end, heat flows spontaneously from the hot end to the cold end until the temperature of the rod becomes uniform throughout, *i.e.*, until equilibrium is attained. This process, evidently, cannot be reversed. Our experience does not show that a metal bar having uniform temperature can become hot at one end and cold at the other end spontaneously.

3. The diffusion of a solute from a more concentrated solution to a less concentrated solution when these are brought into contact proceeds spontaneously till the concentration becomes uniformly

the same, *i.e.*, till the equilibrium is attained. This process also cannot be reversed because once the concentration becomes uniform, it is not possible to make spontaneously one part of the solution more concentrated than any other part.

4. Heat flows spontaneously from a hot reservoir to a cold reservoir. For the reverse process, *i.e.*, for the transfer of heat from a cold reservoir to a hot reservoir, as in a refrigerator, energy has to be supplied from outside the system.

5. Electricity flows spontaneously from a point at a higher potential to a point at a lower potential. The direction of flow of current can be reversed only by applying an external field in the opposite direction,

6. A gas expands spontaneously from a region of high pressure to a region of low pressure or in vacuum.

Thus, we see that all natural processes proceed spontaneously and are thermodynamically irreversible in character.

Work can be obtained from spontaneous processes. But since these proceed irreversibly, the work obtained is much less than that obtained from thermodynamically reversible processes in which case the work obtained is maximum.

Cyclic Process. When a system, after completing a series of changes, returns to original state, it is said to have completed a **cycle.** The entire process is known as a **cyclic process.** Since the internal energy of a system depends only upon its state, it follows that in a cyclic process, the net change of internal energy is zero, *i.e.*, $\Delta U=0$. Therefore, according to the First law,

$$\Delta U = 0 = q + w \qquad \text{or} \qquad q = -w$$

If the series of changes in a cycle are conducted at constant temperature, the cycle is said to be an **isothermal cycle.** If the changes are carried out reversibly, the cycle is said to be a **reversible cycle.**

Although the reversible cyclic processes are merely theoretical and imaginary, the concept is highly useful in deriving certain important relationships. The most well known cyclic process is the **Carnot cycle.**

Carnot employed a reversible cycle to demonstrate the maximum convertibility of heat into work. The system consists of one mole of an ideal gas which is subjected to a series of four successive operations, commonly termed as **four strokes,** as given below.

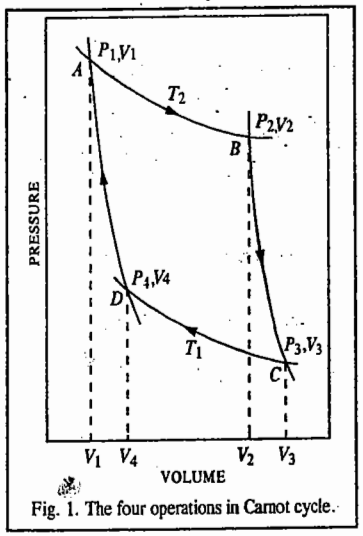


Fig. 1. The four operations in Carnot cycle.

I. Stroke 1. Isothermal Expansion. The gas is allowed to expand reversibly and isothermally at the temperature T_2 so that the volume increases from V_1, represented by the point A, to V_2 represented by the point B (Fig. 1.). Since in the isothermal expansion of an ideal gas $\Delta U=0$, it follows from the First law equation (*viz.*, $\Delta U=q+w$) that $q=-w$, *i.e.*, the heat absorbed is equal to the work done by the system on the surroundings. Let q_2 be the heat absorbed by the system at the temperature T_2 and w_1 be the work done by the system on the surroundings. Then

$$q_2 = -w_1 = RT_2 \ln (V_2/V_1) \qquad ...(1)$$

II. Stroke 2. Adiabatic Expansion. The gas is then allowed to expand reversibly and adiabtically from the volume V_2 to V_3, *i.e.*, from the point B to C.

Since work is done by the system adiabatically, it is not in a position to absorb heat. The temperature of the system, therefore, falls from T_2 to say, T_1. As q is equal to zero in this case, it follows from the First law equation (*viz.*, $\Delta U = q+w$) that $\Delta U=w$. Since the process involves expansion of the gas, therefore, work is done by the system on the surroundings. Hence, by convention, w is negative so that $\Delta U = -w$.

Now, by definition, $C_v = (\partial U/\partial T)_v$ ...(2)

$$\therefore \qquad \Delta U = C_v \Delta T = C_v(T_1 - T_2) = -w \qquad ...(3)$$

(change in temperature, ΔT = final temperature - initial temperature)

or $$-w = C_v(T_1 - T_2) = -C_v(T_2 - T_1) \qquad ...(4)$$

If the work done in this stage is denoted by w_2, then

$$\therefore \qquad -w_2 = -C_v(T_2 - T_1) \qquad ...(5)$$

III. Stroke 3. Isothermal Compression. After this, the gas is subjected to a reversible and isothermal compression at the lower temperature T_1 so that the volume decreases from V_3 to V_4 (*i.e.*, from the point C to D). In this case, evidently, work is done on the system. Hence, heat will be produced and *given up* to the surroundings. Since compression takes place isothermally and reversibly, $\Delta U=0$. Therefore, if q_1 is the heat *given out* to the surroundings at the temperature T_1 and w_3 is the work done on the system in this process, then remembering signs of q and w,

$$-q_1 = w_3 = RT_1 \ln (V_4/V_3) \qquad ...(6)$$

IV. Stroke 4. Adiabatic Compression. Finally, by an adiabatic and reversible compression, the gas is restored to its original volume V_1 and temperature T_2. Thus, the gas is compressed adiabatically from D to A. In this case, work is done on the system. Hence, w is positive. According to the First law, $\Delta U=q+w$. Since in adiabatic process, $q=0$, hence,

$$\Delta U = w = C_v\Delta T = C_v(T_2 - T_1)$$

Let w_4 be the work done in this stage. Then,

$$w_4 = C_v(T_2 - T_1) \qquad ...(7)$$

where $T_2 - T_1$ is the increase in temperature produced by the adiabatic compression.

The net heat absorbed (q) by the ideal gas in the whole cycle is given by

$$q = q_2 + (-q_1) = RT_2 \ln (V_2/V_1) + RT_1 \ln (V_4/V_3)$$
$$= RT_2 \ln (V_2/V_1) - RT_1 \ln (V_3/V_4) \qquad ...(8)$$

In the light of adiabatic expansion of an ideal gas discussed in Chapter 12, the following equations can be written :

$$C_v \ln (T_2/T_1) = R \ln (V_3/V_2) \qquad \text{(For stage II)}$$
$$C_v \ln (T_2/T_1) = R \ln (V_4/V_1) \qquad \text{(For stage IV)}$$

or $$V_3/V_2 = V_4/V_1 \quad \text{or} \quad V_2/V_1 = V_3/V_4 \qquad ...(9)$$

Hence, the net heat absorbed, according to Eq. 8, may be put as

$$q = q_2 - q_1 = R(T_2 - T_1) \ln (V_2/V_1) \qquad ...(10)$$

Similarly, the net work done by the gas is given by

$$w = -w_1 + (-w_2) + w_3 + w_4$$
$$= RT_2 \ln V_2/V_1 - C_v(T_2 - T_1) + RT_1 \ln (V_4/V_3) + C_v(T_2 - T_1)$$
$$= RT_2 \ln (V_2/V_1) - RT_1 \ln (V_3/V_4) \qquad ...(11)$$

Since $$V_2/V_1 = V_3/V_4$$

Hence, $$w = R(T_2 - T_1) \ln (V_2/V_1) \qquad ...(12)$$

It follows from Eqs.10 and 12 that $q=w$. Thus, *the essential condition for a cyclic process that the net work done is equal to the net heat absorbed is fully satisfied.*

The relationship between w, the net work done by the system and q_2, the quantity of heat absorbed at the higher temperature T_2, in Carnot cycle, can be obtained from the following two equations :

$$w = R(T_2 - T_1) \ln (V_2/V_1) \qquad \text{(Eq. 12)}$$

and

$$q_2 = RT_2 \ln (V_2/V_1) \qquad \text{(Eq. 1)}$$

Hence, dividing Eq. 12 by Eq. 1,

$$w = q_2 (T_2 - T_1)/T_2 \qquad (13)$$

Since $(T_2 - T_1)/T_2 < 1$, it follows that $w < q_2$, *i.e.*, work done is less than the heat absorbed. This means that only a part of the heat absorbed by the system at the higher temperature T_2 is transformed into work. The rest of the heat q_1 is given out by the system to the surroundings which is at the lower temperature T_1.

Thus, Kelvin stated the **second law of thermodynamics** as follows :

It is impossible to use a cyclic process to extract heat from a reservoir and to convert it into work without transferring at the same time a certain amount of heat from a hotter to a colder part of the system.

Efficiency of a Heat Engine. *The fraction of the heat absorbed by an engine which it can convert into work gives the* **efficiency** (η) *of the engine.*

From Eq. 13, it is seen that

$$\text{Efficiency, } \eta = w/q_2 = (T_2 - T_1)/T_2 \qquad ...(14)$$

Since $(T_2 - T_1)/T_2$ is invariably less than 1, the efficiency of a heat engine is always less than 1. No heat engine has yet been constructed which has an efficiency equal to unity. Mathematically, however, if $T_1=0$, efficiency=1.

It follows from Eq. 14 that the efficiency depends upon the difference between T_2 and T_1. Thus, the greater the difference between the temperature of the 'source' and the 'sink', the greater is the efficiency. This explains why superheated steam is used in a steam engine.

The net heat absorbed by the system, q, is equal to $q_2 - q_1$ and according to the First law of thermodynamics, this must be equivalent to the net work done by the system. Thus,

$$w = q_2 - q_1$$

Combining this with Eq. 14, we get

$$(q_2 - q_1)/q_2 = (T_2 - T_1)/T_2 \qquad ...(15)$$

Thus,

$$\text{efficiency, } \eta = \frac{q_2 - q_1}{q_2} = \frac{T_2 - T_1}{T_2} \qquad ...(16)$$

Eq. 16 has been arrived at by assuming that the series of changes in the cycle are brought about in a thermodynamically reversible manner so as to obtain maximum possible work. But, in actual practice, it is not possible to carry out the process infinitesimally slowly so that the efficiency is even less than that given by the above equation.

Carnot Theorem. According to Eq. 16, the efficiency of a machine working reversibly depends only on the temperature of the source and the sink. It is independent of the nature of the substance or substances used for operations. The same idea may be expressed by saying that *all periodic machines working reversibly between the same two temperatures have the same efficiency.* This statement is commonly known as the **Carnot theorem,** in honour of S. Carnot (1796-1832), the brilliant French physicist, known for important contributions to thermodynamics.

It may be noted that while the First law states that when one form of energy is transformed into another, the amount of energy that disappears is exactly equivalent to the amount of energy that is produced, it is silent about the extent to which such conversion can take place. The Second law of thermodynamics gives information about this point. It tells us that while all other forms of energy can be *completely* converted into heat, the complete conversion of heat into any other form of energy cannot take place without leaving some lasting change in the system. This has led to the following enunciation of the **Second law of thermodynamics :**

It is impossible to convert heat into work without compensation.

Example 1. Calculate the maximum efficiency of an engine operating between 110°C and 25°C.

Solution : Maximum efficiency of an engine working between temperatures T_2 and T_1 is given by

$$\eta = (T_2 - T_1)/T_2 = (383 \text{ K} - 298 \text{ K})/383 \text{ K} = 0{\cdot}222 = 22{\cdot}2\%$$

Example 2. Heat supplied to a Carnot engine is 1897·8 kJ. How much useful work can be done by the engine which works between 0°C and 100°C ?

Solution :

$$T_2 = 100 + 273 = 373 \text{ K} \; ; \; T_1 = 0 + 273 = 273 \text{ K} \; ; \; q_2 = 1897{\cdot}8 \text{ kJ}$$

$$w = q_2 (T_2 - T_1)/T_2 = 1897{\cdot}8 \text{ kJ} \times (373 \text{ K} - 273 \text{ K})/373 \text{ K} = 508{\cdot}7 \text{ kJ}$$

$\therefore$ Work done by the engine = **508·7 kJ**

An important generalisation. Eq. 16 derived from the Carnot cycle may be rearranged as

$$1 - (q_1/q_2) = 1 - (T_1/T_2)$$

or

$$q_1/T_1 = q_2/T_2 \qquad ...(17)$$

Eq. 17 may also be written, in the general form, as

$$q_{rev}/T = \text{constant} \qquad ...(18)$$

where q_{rev} is the quantity of heat exchanged in a process carried out *reversibly* at a temperature T. This is an important generalisation since the quantity q_{rev}/T, as we shall see presently, represents a definite quantity or state function, *viz.*, the entropy change of the system.

Concept of Entropy

Eq. 17 has been derived by giving positive sign to the heat absorbed (q_2) and negative sign to the heat lost (q_1) by the system. Describing q_1 and q_2 merely as *heats exchanged* (may be evolved or absorbed), Eq.17 may be written as

$$q_1/T_1 + q_2/T_2 = 0 \qquad ...(19)$$

Thus, when the isothermal and adiabatic processes in a Carnot cycle are carried out infinitesimally slowly (*i.e.*, reversibly), the summation of q/T terms is equal to zero.

Any cyclic process, if carried out reversibly, can be shown to consist of a series of Carnot cycles. Consider a cyclic process in which the change from the state A to state B and back to the state A (Fig. 2) is carried out reversibly. The path ABA may be considered to comprise of a number of small Carnot cycles, *i.e.*, of a series of isothermals and adiabatics, as shown in the figure.

The lines slanting horizontally stand for a diabatics and those slanting vertically stand for isothermals of the small

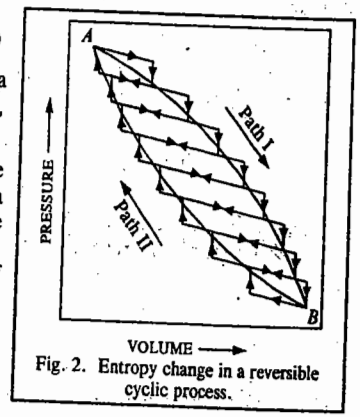

Fig. 2. Entropy change in a reversible cyclic process.

Carnot cycles. If each isothermal and adiabatic change is made extremely minute, *i.e.*, each Carnot cycle is made extremely small by increasing their number, the paths inside the loop cancel one another and the cycle corresponds to the continuous isothermal curve *ABA*. Thus, any reversible cycle can be regarded as being made up of infinite number of small Carnot cycles.

Knowing that for each Carnot cycle, $q_1/T_1 + q_2/T_2 = 0$, it follows that in the case of the reversible cycle *ABA*, comprising of a series of Carnot cycles, the summation term takes the form

$$\Sigma q/T = 0 \qquad ...(20)$$

i.e., the sum of all the q/T terms of the Carnot cycles involved is zero. When the changes are infinitesimal, the above equation may be put as

$$\Sigma dq/T = 0 \qquad ...(21)$$

Since the cycle is performed in two steps, *viz.*, from *A* to *B* and back from *B* to *A*, it follows that

$$\sum \frac{dq}{T} = \int_A^B \frac{dq}{T} + \int_B^A \frac{dq}{T} = 0 \qquad ...(22)$$

The integral $\int_A^B \frac{dq}{T}$ is the summation of all the $\frac{dq}{T}$ terms when the system changes from *A* to *B* along path I and $\int_B^A \frac{dq}{T}$ is the similar summation when the system returns from state *B* to the original state *A* along path II.

From Eq. 22,

$$\int_A^B \frac{dq}{T} = -\int_B^A \frac{dq}{T}$$

or

$$\int_A^B \frac{dq}{T}(\text{path I}) = \int_A^B \frac{dq}{T}(\text{path II}) \qquad ...(23)$$

It follows from above that $\int_A^B \frac{dq}{T}$ *is a definite quantity independent of the path followed for the change and depends only upon the initial and final states of the system.* This quantity, therefore, like ΔU and ΔH, should represent the change in some single-valued function of the states *A* and *B* of the system. This function is called **entropy** and is denoted by the symbol, *S*. If S_A is the entropy in the initial state *A* and S_B is the entropy in the final state *B*, then the change in entropy, ΔS, is given by the equation

$$\Delta S = S_B - S_A = \int_A^B \frac{dq}{T} \qquad ...(24)$$

For each infinitesimally small change,

$$dS = dq/T \qquad ...(25)$$

At constant temperature, for a finite change, dS becomes ΔS and dq becomes q.

$$\therefore \quad \Delta S = q/T \qquad ...(26)$$

It may be emphasised that since entropy is a function of the state only, the change of entropy (ΔS) for the change of state from *A* and *B* will invariably be the same whether the change is reversible or not. However, mathematically, it will be given by the equation

$$\Delta S = \int_A^B \frac{dq}{T} \qquad ...(27)$$

only when the change has been brought about reversibly. This is because the above equation has been derived from Carnot cycle in which all the changes are brought about reversibly.

Thus, the entropy change for a finite change of state of a system at constant temperature is given by

$$\Delta S = q_{rev}/T \qquad ...(28)$$

Unit of entropy. Since entropy change is expressed by a heat term divided by the absolute temperature, entropy is expressed in terms of joules per degree Kelvin ($J\ K^{-1}$). This is known as **entropy unit, e.u.**

Entropy is an extensive property. Its value, therefore, depends upon the amount of the substance involved. It is necessary, therefore, to make a mention of the quantity of the substance taken. This quantity is usually taken as one mole.

Entropy Change in an Isothermal Expansion of an Ideal Gas. In isothermal expansion of an ideal gas carried out *reversibly*, there will be no change in internal energy, *i.e.*, $\Delta U=0$ and hence from the First law equation (*viz.*, $\Delta U=q+w$),

$$q_{rev} = -w \qquad ...(29)$$

In such a case, the work done in the expansion of *n moles* of a gas from volume V_1 to V_2 at constant temperature *T*, is given by

$$-w = nRT \ln (V_2/V_1) \qquad \text{(Eq. 1)}$$

$$\therefore \quad q_{rev} = -w = nRT \ln (V_2/V_1) \qquad ...(30)$$

Hence,

$$\Delta S = q_{rev}/T = 1/T \times nRT \ln V_2/V_1 = nR \ln (V_2/V_1) \qquad ...(31)$$

Example 3. 5 moles of an ideal gas expand reversibly from a volume of 8 dm^3 to 80 dm^3 at a temperature of 27°C. Calculate the change in entropy.

Solution : From Eq. 31, $\Delta S = nR \ln (V_2/V_1)$

$$= (5 \text{ mol})\ (8{\cdot}314\ J\ K^{-1}\ mol^{-1})\ \ln\ (80\ dm^3/8\ dm^3) = 95{\cdot}73\ J\ K^{-1}$$

Entropy Changes in Reversible and Irreversible (Spontaneous) Processes. Consider isothermal expansion of an ideal gas at constant temperature into vacuum. This will, evidently, proceed spontaneously, *i.e.*, irreversibly. Since there is no opposing force, the work done (*w*) by the system will be *zero*. Further, since there is no change in temperature during the process, there will be no change in the internal energy of the system, *i.e.*, $\Delta U=0$. Hence, from the First law equation, $q=0$, *i.e.*, no heat is absorbed or evolved in the process. In other words, no heat is supplied to or removed from the surroundings. The entropy of the surroundings, therefore, remains unchanged.

As has already been stated, entropy of a system is a function only of the state of the system, *i.e.*, its temperature and pressure (or volume) and is independent of the previous history of the system. In the process under consideration, the volume of the gas increases, say, from V_1 to V_2 at constant temperature *T*. Hence, entropy increase of the system, considering that one mole of the gas is involved, would be given by

$$\Delta S = R \ln (V_2/V_1) \qquad \text{(Eq. 31)}$$

The total increase in entropy of the system and its surroundings during the spontaneous process of expansion considered above is, thus, $R \ln(V_2/V_1) + 0 = R \ln V_2/V_1$. Since $V_2 > V_1$, it is obvious that the spontaneous (irreversible) isothermal expansion of a gas is accompanied by an increase in the entropy of the system and its surroundings considered together.

Now consider isothermal expansion of the ideal gas from volume V_1 to V_2 carried out reversibly at the same temperature *T*. The expansion is now carried out infinitesimally slowly, *i.e.*, the pressure on the frictionless piston is so adjusted that it remains always less than that of the gas by an infinitesimally small amount. In this case, the gas does some external work given by $w = -P\Delta V$. Consequently, an equivalent amount of heat (q_{rev}) is absorbed reversibly by the system from the surroundings at temperature *T*. Hence, *increase* in the entropy of the system is q_{rev}/T.

The heat lost reversibly at temperature T by the surroundings is also q_{rev}. Hence, decrease in the entropy of the surroundings is q_{rev}/T. Giving appropriate sign, positive for increase and negative for decrease of entropy, the net entropy change of the system and its surroundings is given by

$$q_{rev}/T - q_{rev}/T = 0 \qquad ...(32)$$

Thus, in the reversible isothermal expansion of a gas, the total entropy change of the system and its surroundings considered together is zero. We may thus conclude that :

A thermodynamically irreversible process is always accompanied by an increase in the entropy of the system and its surroundings taken together while in a thermodynamically reversible process, the entropy of the system and its surroundings taken together remains unaltered. Thus, we can write :

$$(\Delta S_{sys} + \Delta S_{sur}) = 0 \qquad \text{(for reversible process)}$$

$$(\Delta S_{sys} + \Delta S_{sur}) > 0 \qquad \text{(for irreversible process)}$$

Combining the two, we have

$$\Delta S_{sys} + \Delta S_{sur} \geq 0 \qquad ...(33)$$

where 'equal to' sign refers to a reversible process while the 'greater than' sign refers to an irreversible process. Eq. 33. may be stated as follows :

In a reversible process, the entropy of the system and the surroundings taken together remains constant while in an irreversible process, the entropy of the system and the surroundings taken together increases.

This conclusion is of great importance as it helps us to predict whether a given process can take place spontaneously or not, *i.e.*, whether it is thermodynamically feasible or not. We shall discuss this aspect shortly. Since all processes in nature occur spontaneously, *i.e.*, irreversibly, it follows that the entropy of the universe is increasing continuously. This is another statement of the second law. Entropy can infact, be considered as a sort of *degradation* of total energy of an isolated system.

The essentials of the First law and the Second law of thermodynamics were thus summed up by the German physicist Rudolf Clausius (1822-1888) as follows :

The energy of the universe remains constant ; the entropy of the universe tends towards a maximum.

Entropy Changes Accompanying Changes of Phase

a. From Solid Phase to Liquid Phase. Consider a case when a solid changes into liquid state at its fusion point. The process requires *absorption* of heat (heat of fusion).

Consider melting of one mole of a substance reversibly at the fusion point T_{fus}, at constant pressure. Let ΔH_{fus} be the molar heat of fusion. The entropy change of the process, ΔS_{fus}, will then be given by

$$\Delta S_{fus} = \Delta H_{fus}/T_{fus} \qquad ...(34)$$

b. From Liquid Phase to Vapour Phase. Suppose one mole of a substance changes from liquid to vapour state reversibly at its boiling point T_b, under a constant pressure. If ΔH_v is the molar heat of vaporisation, then the entropy change accompanying the process will be given by

$$\Delta S_{vap} = \Delta H_{vap}/T_b \qquad ...(35)$$

Since ΔH_{fus} and ΔH_{vap} are both positive, the processes of fusion and vaporisation are both accompanied by increase of entropy.

If we consider the change of state from vapour to liquid or from liquid to solid, then ΔH_{vap} and ΔH_{fus} will both be negative and hence the process of condensation of vapour or freezing of a liquid would be accompanied by decrease of entropy.

Example 4. Calculate the entropy change in the melting of 1 kg of ice at 0°C. Heat of fusion of ice = 334·72 J g^{-1}.

Solution : From Eq. 34,

$$\Delta S_{fus} = \Delta H_{fus}/T_{fus} = 334{\cdot}72 \text{ J g}^{-1}/273 \text{ K} = 1{\cdot}226 \text{ J K}^{-1} \text{g}^{-1} = 1226 \text{ J K}^{-1} \text{kg}^{-1}$$

Example 5. Calculate the entropy increase in the evaporation of one mole of water at 100°C. Heat of vaporisation of water at 100°C = 2259·4 J g^{-1}.

Solution : From Eq. 35,

$$\Delta S_{vap} = \frac{\Delta H_{vap}}{T_b} = \frac{2259{\cdot}4 \text{ J g}^{-1} \times 18 \text{ g mol}^{-1}}{373 \text{ K}} = 109{\cdot}03 \text{ J K}^{-1} \text{ mol}^{-1}$$

Example 6. Calculate the entropy change accompanying the freezing of one mole of water at 25°C to ice at –10°C; given that the heat of fusion of ice at its fusion point (0°C) is 6·00 kJ mol^{-1}, the heat capacity of ice is 36·82 J K^{-1} mol^{-1} and heat capacity of liquid water is 75·31 J K^{-1} mol^{-1}.

Solution : The irreversible freezing of water at – 10°C can be split into the following three reversible processes :

(i) $H_2O(l)$ at 25°C $\longrightarrow$ $H_2O(l)$ at 0°C ; $\quad \Delta S = \int_{298}^{273} C_{P(l)} \frac{dT}{T}$

(ii) $H_2O(l)$ at 0°C $\longrightarrow$ $H_2O(s)$ at 0°C ; $\quad \Delta S = -\frac{\Delta H_{fus}}{T}$

(iii) $H_2O(s)$ at 0°C $\longrightarrow$ $H_2O(s)$ at – 10°C ; $\quad \Delta S = \int_{273}^{263} C_{P(s)} \frac{dT}{T}$

The total entropy change is the sum of the entropies involved in the three steps indicated above. Thus,

$$\Delta S_{total} = \int_{298}^{273} (75{\cdot}31 \text{ J K}^{-1} \text{ mol}^{-1}) \frac{dT}{T} - \frac{6000 \text{ J mol}^{-1}}{273 \text{ K}} + \int_{273}^{263} 36{\cdot}82 \text{ J K}^{-1} \text{ mol}^{-1} \frac{dT}{T}$$

$$= (75{\cdot}31 \text{ J K}^{-1} \text{ mol}^{-1}) \ln \frac{T_2}{T_1} - \frac{6000 \text{ J mol}^{-1}}{273 \text{ K}} + (36{\cdot}82 \text{ J K}^{-1} \text{ mol}^{-1}) \ln \frac{T_2}{T_1}$$

$$= (75{\cdot}31 \text{ J K}^{-1} \text{ mol}^{-1}) \ln \frac{273 \text{ K}}{298 \text{ K}} - 21{\cdot}98 \text{ K}^{-1} \text{ mol}^{-1} + (36{\cdot}82 \text{ J K}^{-1} \text{ mol}^{-1}) \ln \frac{263 \text{K}}{273 \text{K}}$$

$$= -29{\cdot}96 \text{ J K}^{-1} \text{ mol}^{-1}$$

Example 7. Calculate ΔS when one mole of steam at 100°C is converted into ice at 0°C. Average specific heat of water = $4{\cdot}184 \times 10^3$ J K^{-1} kg^{-1}; heat of vaporisation at boiling point = $2490{\cdot}6 \times 10^3$ J kg^{-1}; heat of fusion at freezing point = $333{\cdot}555 \times 10^3$ J kg^{-1}.

Solution :

$$C_P = (4{\cdot}184 \times 10^3 \text{ J K}^{-1} \text{ kg}^{-1})\ (18{\cdot}0 \times 10^{-3} \text{ kg mol}^{-1}) = 75{\cdot}31 \text{ J K}^{-1} \text{ mol}^{-1}$$

$$\Delta H_{vap} = (2490{\cdot}6 \text{ J} \times 10^3 \text{ J kg}^{-1})\ (18{\cdot}0 \times 10^{-3} \text{ kg mol}^{-1}) = 44831{\cdot}56 \text{ J mol}^{-1}$$

$$\Delta H_{fus} = (333{\cdot}555 \times 10^3 \text{ J kg}^{-1})\ (18{\cdot}0 \times 10^{-3} \text{ kg mol}^{-1}) = 6004{\cdot}00 \text{ J mol}^{-1}$$

The process consists of the following reversible steps :

(i) H_2O (steam, at 100°C) $\longrightarrow$ H_2O (*l*, at 100°C) ; $\Delta S = -\Delta H_{vap}/T_b$

(ii) H_2O (*l*, at 100°C) $\longrightarrow$ H_2O (*l*, at 0°C); $\Delta S = \int_{373}^{273} C_P \frac{dT}{T}$

(iii) H_2O (*l*, at 0°C) $\longrightarrow$ H_2O (*s*, at 0°C) ; $\Delta S = -\Delta H_{fus}/T_{fus}$

The total entropy is the sum of the three contributions. Thus,

$$\Delta S_{total} = -\Delta H_{vap}/T_b + C_p \ln 273 \text{ K}/373 \text{ K} - \Delta H_{fus}/T_{fus}.$$

$$= -\frac{44831{\cdot}56 \text{ J mol}^{-1}}{373 \text{ K}} + (75{\cdot}31 \text{ J K}^{-1} \text{ mol}^{-1}) \ln \frac{273 \text{ K}}{373 \text{ K}} - \frac{6004{\cdot}00 \text{ J mol}^{-1}}{273 \text{ K}}$$

$$= -165{\cdot}73 \text{ J K}^{-1} \text{ mol}^{-1}$$

c. From One Crystalline Form to Another. The change in entropy when one mole of a solid substance undergoes change of state from one crystalline form (say, rhombic form) to another crystalline from (say, monoclinic form) at the transition temperature T, is given by

$$\Delta S_{tr} = \Delta H_{tr}/T \qquad \ldots(36)$$

where ΔH_{tr} is the molar heat of transition of the substance. Molar heat of transition is the amount of heat absorbed or evolved by one mole of a substance when it undergoes change of state from one crystalline form to another at the transition temperature T.

Example 8. Calculate entropy change accompanying change of state of one mole of sulphur from rhombic to monoclinic state. Heat of transition of the process carried out reversibly is 322·17 joules per mole at the transition temperature 95·6°C.

Solution : From Eq. 36, $\Delta S_{tr} = 322{\cdot}17 \text{ J mol}^{-1}/368{\cdot}6 \text{ K} = 0{\cdot}874 \text{ J K}^{-1} \text{ mol}^{-1}$

Calculation of Entropy Change of an Ideal Gas with Change in P, V and T. Since entropy of a system varies with the state of the system, its value for a pure gaseous substance will depend upon any two of the three variables T, P and V. Since T is taken generally as one of the variables, the second variable to be considered may be V or P. Thus, the two variables to be considered are either T and V or T and P.

When T and V are the two variables. The increase in entropy of the gas for an infinitesimally small change is given by the expression

$$dS = dq_{rev}/T \qquad \text{(Eq. 25)}$$

where dq_{rev} is the small amount of heat *absorbed* by the gas (system) *reversibly* from the surroundings at temperature T.

According to the equation of the First law of thermodynamics, *viz.*, $\Delta U = q + w$, we have

$$dq_{rev} = dU - dw \qquad \ldots(37)$$

If the work involved is due to *expansion of the gas*, then, for an infinitesimal increase in volume dV against a pressure P,

$$-dw = PdV \qquad \ldots(38)$$

Substituting the value of dU from $C_V = (\partial U/\partial T)_v$ and $-dw$ from Eq. 38, we have

$$dq_{rev} = C_V\,dT + PdV \qquad \ldots(39)$$

For one mole of an ideal gas,

$$dq_{rev} = C_V\,dT + RT\,dV/V$$

$$\therefore \quad dq_{rev}/T = dS = C_V\,dT/T + R\,dV/V \qquad \ldots(40)$$

For a finite change of state of a system, the entropy change (ΔS) is obtained by integrating the above equation between the limits of the initial state 1 and the final state 2. Assuming C_V to be constant within the temperature range T_1 and T_2, for one mole of the gas we have

$$\Delta S = S_2 - S_1 = C_V \int_{T_1}^{T_2} \frac{dT}{T} + R \int_{V_1}^{V_2} \frac{dV}{V} \qquad \ldots(41)$$

Thus,
$$\Delta S = C_V \ln T_2/T_1 + R \ln V_2/V_1 \qquad \ldots(42)$$

For n moles of the ideal gas, the above equation may be written as

$$\Delta S = nC_V \ln (T_2/T_1) + nR \ln (V_2/V_1) \qquad \ldots(43)$$

It is evident that the entropy change for the change of state of an ideal gas depends upon the initial and final volumes as well as on the initial and final temperatures.

When T and P are the two variables. If P_1 is the pressure of the ideal gas in the initial state and P_2 in the final state, then

$P_1V_1 = RT_1$ for one mole of the gas in the initial state

$P_2V_2 = RT_2$ for one mole of the gas in the final state.

$$\therefore \quad V_2/V_1 = P_1T_2/(P_2T_1) \qquad \ldots(44)$$

Substituting in Eq. 42, for one mole of the gas, we have

$$\Delta S = C_V \ln T_2/T_1 + R \ln T_2/T_1 - R \ln P_2/P_1 \qquad \ldots(45)$$

Remembering that $C_P - C_V = R$

$$\Delta S = C_P \ln T_2/T_1 - R \ln P_2/P_1 \qquad \ldots(46)$$

For n moles of the ideal gas,

$$\Delta S = nC_P \ln (T_2/T_1) - nR \ln (P_2/P_1) \qquad \ldots(47)$$

It is evident from the above equations that the entropy change for the change of state of an ideal gas depends on the initial and final pressure as well as on the initial and final temperature.

Example 9. Calculate the change in entropy accompanying the heating of one mole of helium gas, assumed ideal, from a temperature of 298 K to a temperature of 1000 K at constant pressure. Assume that $C_V = \frac{3}{2}R$.

Solution : Since for an ideal gas, $C_P - C_V = R$, hence, $C_P = C_V + R = \frac{3}{2}R + R = 2{\cdot}5R$

When pressure is constant, Eq. 46 takes the form

$\Delta S = C_P \ln (T_2/T_1) = (2{\cdot}5 \times 8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1}) \ln (1000 \text{ K}/298 \text{ K}) = 25{\cdot}17 \text{ J K}^{-1} \text{ mol}^{-1}$

Example 10. One mole of an ideal gas is heated from 100 K to 300 K. Calculate ΔS if (*a*) the volume is kept constant (*b*) the pressure is kept constant Assume that $C_V = 1{\cdot}5R$.

Solution : When volume is kept constant, Eq. 42 reduces to

$\Delta S = C_V \ln (T_2/T_1) = (1{\cdot}5 \times 8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1}) \ln (300 \text{ K}/100 \text{ K}) = 13{\cdot}17 \text{ J K}^{-1}$

When pressure is kept constant, Eq. 46 takes the form

$$\Delta S = C_P \ln (T_2/T_1) = (C_V + R) \ln (T_2/T_1) = 2{\cdot}5\,R \ln (T_2/T_1)$$

$$= (2{\cdot}5 \times 8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1}) \ln (300 \text{ K}/100 \text{ K}) = 22{\cdot}8 \text{ J K}^{-1} \text{ mol}^{-1}$$

Entropy Changes of an Ideal Gas in Different Processes. We may consider processes of three special kinds. These are :

(1) Isothermal processes (2) Isobaric processes and (3) Isochoric processes.

1. Isothermal Process. In an isothermal process, there is no change in temperature. Hence, from Eqs. 42 and 46,

$$\Delta S_T = R \ln (V_2/V_1) = -R \ln (P_2/P_1) = R \ln (P_1/P_2) \qquad \ldots(48)$$

The subscript T in ΔS_T is used to indicate that the temperature of the ideal gas remains constant during the process. If $V_2 > V_1$, ΔS_T will be positive. This means that isothermal expansion of an ideal gas is accompanied by increase in entropy. Conversely, isothermal compression of an ideal gas is accompanied by decrease in entropy.

2. Isobaric Processes. Isobaric processes are those which proceed at constant pressure. In this case, therefore, $P_1 = P_2$. Hence, Eq. 46 reduces to

$$\Delta S_P = C_P \ln (T_2/T_1) \qquad \ldots(49)$$

The subscript P in ΔS_P indicates that the pressure remains constant during the process. It follows from Eq. 49 that the increase in temperature of an ideal gas at constant pressure is accompanied by increase in entropy of the ideal gas.

3. Isochoric Processes. Isochoric processes are those in which volume of the gas remains constant. Since in this case, $V_1 = V_2$, Eq. 42 reduces to

$$\Delta S_V = C_V \ln (T_2/T_1) \quad ...(50)$$

Thus, increase in temperature of an ideal gas at constant V is accompanied by increase in entropy.

We may mention that an adiabatic process is an **isentropic process** in which entropy remains constant.

Example 11. One mole of an ideal gas expands reversibly from a volume of 10 dm^3 and temperature 298 K to a volume of 20 dm^3 and temperature 250 K. Assuming that $C_V = 3/2\ R$, calculate the entropy change for the process.

Solution : From Eq. 42, $\Delta S = C_v \ln (T_2/T_1) + R \ln (V_2/V_1)$

$= 1{\cdot}5\ (8{\cdot}314\ \text{J K}^{-1}\ \text{mol}^{-1}) \ln (250\ \text{K}/298\ \text{K}) + (8{\cdot}314\ \text{J K}^{-1}\ \text{mol}^{-1}) \ln (20\ \text{dm}^3/10\ \text{dm}^3)$

$= -2{\cdot}19\ \text{J K}^{-1}\ \text{mol}^{-1} + 5{\cdot}76\ \text{J K}^{-1}\ \text{mol}^{-1} = 3{\cdot}57\ \text{J K}^{-1}\ \text{mol}^{-1}$

Example 12. If the gas in the above example expands reversibly and adiabatically, what would be the value of ΔS for the process ?

Solution : Since for a reversible adiabatic process, $q_{rev} = 0$, hence $\Delta S = 0$.

Example 13. One mole of an ideal gas expands reversibly from a temperature of 25°C and pressure of 1 atm to a temperature of 0°C and pressure of 500 mm Hg. Calculate ΔS for the process. Assume that $C_V = 3/2\ R$.

Solution : From Eq. 46, $\Delta S = C_P \ln (T_2/T_1) + R \ln (P_1/P_2)$

For an ideal gas, $C_P - C_V = R$

$\therefore \quad C_P = C_V + R = 3/2\ R + R = 2{\cdot}5\ R = 2{\cdot}5 \times 8{\cdot}314\ \text{J K}^{-1}\ \text{mol}^{-1}$

$\therefore \quad \Delta S = (2{\cdot}5 \times 8{\cdot}314\ \text{J K}^{-1}\ \text{mol}^{-1}) \ln (273\ \text{K}/298\ \text{K}) + (8{\cdot}314\ \text{J K}^{-1}\ \text{mol}^{-1}) \ln 760\ \text{mm Hg}/500\ \text{mm Hg}$

$= -1{\cdot}82\ \text{J K}^{-1}\ \text{mol}^{-1} + 3{\cdot}48\ \text{J K}^{-1}\ \text{mol}^{-1} = \mathbf{1{\cdot}66\ J\ K^{-1}}$

Entropy of a Mixture of Ideal Gases. As mentioned above, for one mole of an ideal gas,

$$dS = C_V\, dT/T + R\, dV/V \quad \text{(Eq. 40)}$$

Integrating Eq. 40, assuming that C_v remains constant for an ideal gas, we have

$$S = C_V \ln T + R \ln V + S_0 \quad ...(51)$$

where S_0 is the integration constant.

Remembering that $C_P - C_V = R$ and $V = RT/P$, we get

$$S = C_P \ln T - R \ln P + R \ln R + S_0 \quad ...(52)$$

$$= C_P \ln T - R \ln P + S_0' \quad ...(53)$$

where S_0' ($= R \ln R + S_0$) is another constant.

Entropy of a system consisting of a mixture of gases would evidently be given by the sum of the individual entropies of the constituents at pressures (or concentrations) existing in the mixture. If n_1, n_2, n_3, etc., are the numbers of moles of the various gases present in the mixture and p_1, p_2, p_3, etc., are their partial pressures, then, the entropy of the mixture is given by

$$S = n_1 (C_P \ln T - R \ln p_1 + S_0') + n_2 (C_P \ln T - R \ln p_2 + S_0') + n_3 (C_P \ln T - R \ln p_3 + S_0') \ldots$$

$$= \Sigma n\ (C_P \ln T - R \ln p + S_0') \quad ...(54)$$

The partial pressure (p) of an ideal gas is given by the expression

$$p = xP \quad ...(55)$$

where x is the mole fraction of that particular gas in the mixture and P is the total pressure.

Substituting p by xP in Eq. 54, we have

$$S = \Sigma n (C_P \ln T - R \ln P - R \ln x + S_0') \quad ...(56)$$

Eq. 56 gives the entropy of a mixture of ideal gases.

Entropy of Mixing. Entropy of mixing is defined as the difference between the entropy of the mixture of gases and the sum of the entropies of the separate gases, each at a pressure P. Thus,

$$\Delta S_{mix} = \Sigma n (C_P \ln T - R \ln P - R \ln x + S_0') - \Sigma n\ (C_P \ln T - R \ln P + S_0') \quad ...(57)$$

$$= -R\ \Sigma n \ln x = -R\ (n_1 \ln x_1 + n_2 \ln x_2 + n_3 \ln x_3 + \cdots) \quad ...(58)$$

$$= -R\ \Sigma n_i \ln x_i \quad ...(59)$$

where n_i and x_i represent the number of moles and the mole fraction, respectively, of each constituent of the mixture.

If n is the total number of moles, then, evidently,

$$n = n_1 + n_2 + n_3 + \cdots \quad ...(60)$$

Dividing both sides by n, we have

$$1 = n_1/n + n_2/n + n_3/n + \cdots = x_1 + x_2 + x_3 + \ldots = \Sigma x_i \quad ...(61)$$

Thus, for a total of 1 mole of the gaseous mixture ($\Sigma n_i = \Sigma x_i$), the entropy of mixing is given by

$$\Delta S_{mix} = -R\ \Sigma x_i \ln x_i \quad ...(62)$$

Since x_i is a fraction, the entropy of mixing is always **positive.**

Example 14. Calculate the entropy of mixing of one mole of oxygen gas and two moles of hydrogen gas, assuming that no chemical reaction occurs and the gas mixture behaves ideally.

Solution : $n = 1$ mole ; $n_2 = 2$ moles

The mole fractions are : $x_1 = 1/(1+2) = 0{\cdot}33$; $x_2 = 1 - 0{\cdot}33 = 0{\cdot}67$

From Eq. 62,

$$\Delta S_{mix} = -R\ \Sigma n_i \ln x_i = -R\ (n_1 \ln x_1 + n_2 \ln x_2)$$

$$= -(8{\cdot}314\ \text{J K}^{-1}\ \text{mol}^{-1})\ [(1\ \text{mol})\ (\ln 0{\cdot}33) + (2{\cdot}0\ \text{mol})\ (\ln 0{\cdot}67)] = \mathbf{15{\cdot}88\ J\ K^{-1}}$$

Example 15. One mole of nitrogen gas is mixed with three moles of oxygen gas at 25°C to form a mixture at the final pressure of 1 atm, the initial pressure of each being also 1 atm. Calculate the molar entropy of mixing.

Solution : In this case, we are interested in calculating ΔS for one mole of the mixture.

The mole fractions are : $x_1 = 1/(1+3) = 0{\cdot}25$; $x_2 = 1 - 0{\cdot}25 = 0{\cdot}75$

From Eq. 62, $\Delta S_{mix} = -R\ \Sigma x_i \ln x_i = -R\ (x_1 \ln x_1 + x_2 \ln x_2)$

$$= -(8{\cdot}314\ \text{J K}^{-1}\ \text{mol}^{-1})\ [0{\cdot}25 \ln 0{\cdot}25 + 0{\cdot}75 \ln 0{\cdot}75] = \mathbf{4{\cdot}676\ J\ K^{-1}\ mol^{-1}}$$

Standard Entropies. Entropy of one mole of a substance in pure state at one atmospheric pressure and 25°C, is termed as **standard entropy** of that substance and is denoted as $S°$. When a reaction involves each reactant and each product in its standard state, the entropy change is said to be standard entropy change. This is denoted by $\Delta S°$. The general equation is then written as

$$\Delta S° = \Sigma S°_{products} - \Sigma S°_{reactants} \quad ...(63)$$

Entropies of various substances at any given temperature and pressure can be calculated by applying the Third law of thermodynamics. Standard entropies of some of the important substances obtained in this manner are recorded in Table 2 of Chapter 15.

Physical Significance of Entropy

1. Entropy as a Measure of the Disorder of the System. It has already been shown that all spontaneous processes, such as flow of heat from a hot end to a cold end of a conductor, flow of electricity from a point at a higher potential to a point at a lower potential, expansion of a gas in vacuum, diffusion of a solute from a concentrated to a dilute solution, are accompanied by increase in the 'disorder' of the system. Spontaneous processes are accompanied by increase in entropy as well as increase in the disorder of the system.

It has also been shown that melting of a solid or evaporation of a liquid is accompanied by increase of entropy. At the same time, it is known that a solid has a definite crystal lattice, *i.e.*, the atoms or ions or molecules in a solid are arranged in a definite order. The order is much less in a liquid and least in a gas. Thus, increase of entropy implies increase in disorder.

Thus, entropy is regarded as a measure of the disorder of a system. The great thermodynamicist Gibbs described entropy as a measure of the "mixed-up-ness" of a system.

2. Entropy as a Measure of Probability. As seen above, all spontaneous processes lead to increase in entropy and also to increase in disorder. A little consideration will show that when a process is spontaneous it means that it is proceeding from a less probable to a more probable state. It appears, therefore, that there is a close relation between entropy S and the thermodynamic probability W of the state of the system both of which increase at the same time. This relationship was expressed by Boltzamm as

$$S = k \ln W + \text{constant} \qquad ...(64)$$

where k is Boltzmann constant, *i.e.*, gas constant per single molecule ($=R/N_A$). Boltzmann defined **thermodynamic probability** of a system as *the ratio of the probability of the actual state to the probability of the state in which there is complete order* for the same energy and volume.

According to Planck, the constant in Eq. 64 is zero. Hence,

$$S = k \ln W \qquad ...(65)$$

Eq. 65 is called the **Boltzmann entropy equation.** A solid at absolute zero temperature is considered to be in a most ordered state. In this case, evidently, W is unity and hence $S_0=0$. The entropy of crystalline solids at absolute zero is, therefore, taken as zero.

Example 16. In the solid state at 0 K, nitric oxide is capable of existing in two orientations, *viz.*, NONO and NOON, which have practically equal probabilities. Calculate the molar entropy of NO at 0 K.

Solution : At 0 K, the probability of orientation of *one molecule* of NO is, evidently, 2. Thus, $W=2$. Hence, from the Boltzmann equation, for *one mole, i.e.*, for Avogadro's number of molecules,

$$S = N_A k \ln 2 = R \ln 2 = (8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1}) (\ln 2) = 5{\cdot}74 \text{ K}^{-1} \text{ mol}^{-1}$$

Work and Free Energy Functions

We have seen earlier that the sum total of the entropy change of the system and the surroundings (*viz.*, $\Delta S_{sys} + \Delta S_{sur}$) serves as a criterion of spontaneity or feasibility of a process. If the total entropy change is positive, the process is feasible. If it is *zero*, the system remains in a state of *equilibrium*. However, in order to decide about the feasibility of a process, we shall have to know the entropy change of the system as well as that of the surroundings. This is not always convenient. We, therefore, consider entropy change in terms of other state functions which can be determined more conveniently. Two such functions are the **work function** and the **free energy function** represented by A and G, respectively. These are defined by the equations

$$A = U - TS \qquad ...(66)$$

$$G = H - TS \qquad ...(67)$$

Since, U, H and S depend only upon the state of a system (the temperature is included in the state), it is evident that the functions A and G also depend upon the state of the system only. Let the three functions in Eq. 66. at constant T, be A_1, U_1 and S_1 so that

$$A_1 = U_1 - TS_1 \qquad ...(68)$$

Let an appreciable change take place at the same temperature T so that the three functions in another state of the system become A_2, U_2 and S_2. Then,

$$A_2 = U_2 - TS_2 \qquad ...(69)$$

Subtracting Eq. 68 from Eq. 69, we have

$$A_2 - A_1 = (U_2 - U_1) - T(S_2 - S_1) \quad \text{or} \quad \Delta A = \Delta U - T\Delta S \qquad ...(70)$$

where ΔA is the change in the function A, ΔU is the corresponding change in internal energy and ΔS is the change in entropy of the system.

Suppose the change under reference is brought about reversibly at the constant temperature T and that the heat *absorbed* is equal to q_{rev}.

Since from Eq. 28, $\Delta S = q_{rev}/T$, hence, substituting in Eq. 70, we have

$$\Delta A = \Delta U - q_{rev} \qquad ...(71)$$

From the equation of the First law of thermodynamics, *viz.*, $\Delta U = q + w$, it follows that

$$w_{rev} = \Delta U - q_{rev} \qquad ...(72)$$

If work is done by the system, it is negative so that

$$-w_{rev} = \Delta U - q_{rev} \qquad ...(73)$$

Comparing Eq. 71 with Eq. 73,

$$-\Delta A = w_{rev} \qquad ...(74)$$

Since the process is carried out reversibly, w represents the maximum work. It is thus clear that *decrease in the function A (i.e., $-\Delta A$) gives the maximum work that can be done by the system during the given change.* The function A is, therefore, termed as the **work function.** This is also referred to as **Helmholtz free energy** or **Helmholtz function.**

The German physicist Hermann von Helmholtz (1821-1894) was a versatile scientist who made contributions to optics, thermodynamics, acoustics and physiology.

If G_1, H_1 and S_1 represent the thermodynamic functions in the initial state and G_2, H_2 and S_2 in the final state, the temperature remaining constant at T, we have from Eq. 67,

$$G_2 - G_1 = (H_2 - H_1) - T(S_2 - S_1) \quad \text{or} \quad \Delta G = \Delta H - T\Delta S \qquad ...(75)$$

But, as already shown in Chapter 13, at constant pressure

$$\Delta H = \Delta U + P\Delta V$$

$$\therefore \quad \Delta G = \Delta U + P\Delta V - T\Delta S \qquad ...(76)$$

Comparing with Eq. 70,

$$\Delta G = \Delta A + P\Delta V \qquad ...(77)$$

Since ΔA is equal to $-w$ (Eq. 74), hence

$$\Delta G = -w + P\Delta V \quad \text{or} \quad -\Delta G = w - P\Delta V \qquad ...(78)$$

The quantity $P\Delta V$ is the work done by the gas on expansion against the constant external pressure P. Therefore, $-\Delta G$ gives the maximum work obtainable from a system other than that due to change of volume, at constant temperature and pressure. The work other than that due to change of volume is called the **net work.** Thus,

$$\text{Net work} = w - P\Delta V = -\Delta G \qquad ...(79)$$

Hence, $-\Delta G$ is a measure of the net work that can be obtained from a system at constant temperature and pressure. The quantity G is called the **Gibbs function** or **Gibbs free energy** or merely **free energy**. Thus, $-\Delta G$ is a measure of the decrease in free energy. The net work that it measures may be electrical work or chemical work. This quantity is of great importance in physical chemistry ; it is named in honour of the great American physicist, J.W. Gibbs (1839-1903).

Variation of Free Energy Change with Temperature and Pressure. The variation of free energy change with variation of temperature and pressure may now be considered. According to Eq. 67,

$$G = H - TS$$

Since $H = U + PV$, hence $G = U + PV - TS$ ...(80)

Upon differentiation, $dG = dU + PdV + VdP - TdS - SdT$ ... (81)

The First law equation for an infinitesimal change may be written as

$$dq = dU - dw \quad ...(82)$$

If the work done is only due to expansion, then, $-dw = PdV$

$$\therefore \quad dq = dU + PdV \quad ...(83)$$

For a reversible process,

$$dS = dq/T \quad \text{or} \quad TdS = dq = dU + PdV \quad ...(84)$$

Combining Eqs. 81 and 84, we have

$$dG = VdP - SdT \quad ...(85)$$

This equation gives change of free energy when a system undergoes, reversibly, a change of pressure as well as change of temperature.

If pressure remains constant, *i.e.*, $dP=0$, then, from Eq. 85

$$dG = -SdT \quad \text{or} \quad (\partial G/\partial T)_P = -S \quad ...(86)$$

On the other hand, if temperature remains constant, *i.e.*, $dT=0$, then, from Eq. 85,

$$dG = VdP \quad \text{or} \quad (\partial G/\partial P)_T = V \quad ...(87)$$

Let the free energy of a system be G_1 in the initial state and G_2 in the final state when an appreciable change in pressure has taken place, at constant temperature. Then, integrating Eq. 87, the free energy change, ΔG, is given by

$$\Delta G = G_2 - G_1 = \int_{P_1}^{P_2} VdP \quad ...(88)$$

where P_1 and P_2 are the initial and final pressures, respectively.

If one mole of an ideal gas is under consideration, then $PV = RT$.

$$\therefore \quad \Delta G = RT\int_{P_1}^{P_2}\frac{dP}{P} = RT \ln\frac{P_2}{P_1} = RT \ln\frac{V_1}{V_2} \quad ...(89)$$

where V_1 and V_2 are the initial and final volumes, respectively.

For n moles of the gas,

$$\Delta G = nRT \ln (P_2/P_1) = nRT \ln (V_1/V_2) \quad ...(90)$$

Example 17. Calculate the free energy change (ΔG) which occurs when 1 mole of an ideal gas expands reversibly and isothermally at 37°C from an initial volume of 55 dm^3 to 1000 dm^3.

Solution : Substituting the given data in Eq. 90, we have

$$\Delta G = (8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1})\ (310 \text{ K}) \ln (55 \text{ dm}^3/1000 \text{ dm}^3) = -7476{\cdot}8 \text{ J mol}^{-1}$$

The Maxwell Relations. The various expressions connecting internal energy (U), enthalpy (H), Helmholtz free energy (A) and Gibbs free energy (G), with relevant parameters such as entropy,

pressure, temperature and volume, may be put as

(i) $dU = TdS - PdV$

(ii) $dH = TdS + VdP$

(iii) $dA = -SdT - PdV$

(iv) $dG = -SdT + VdP$

If V is constant so that dV is zero, then, Eq. *(i)* yields the result

$$(\partial U/\partial S)_V = T \quad ...(91)$$

If S constant so that dS is zero, then Eq. *(i)* yields the result

$$(\partial U/\partial V)_S = -P \quad ...(92)$$

Differentiating Eq. 91 with respect to V keeping S constant and differentiating Eq. 92 with respect to S keeping V constant, we get

$$\partial^2 U/(\partial S)(\partial V) = (\partial T/\partial V)_S \quad ...(93)$$

and $$\partial^2 U/(\partial V)(\partial S) = -(\partial P/\partial S)_V \quad ...(94)$$

It follows from Eqs. 93 and 94 that

$$(\partial T/\partial V)_S = -(\partial P/\partial S)_V \quad ...(95)$$

Following the same mathematical procedure as above, the following expressions can be easily derived :

$(\partial T/\partial P)_S = (\partial V/\partial S)_P$ from *(ii)* ...(96)

$(\partial S/\partial V)_T = (\partial P/\partial T)_V$ from *(iii)* ...(97)

$(\partial S/\partial P)_T = -(\partial V/\partial T)_P$ from *(iv)* ...(98)

Eqs. 95 to 98 are known as **Maxwell's relations.**

Another set of Maxwell's relationships, which can also be derived from equations *(i)* to *(iv)*, are as follows :

$(\partial U/\partial S)_V = (\partial H/\partial S)_P$ from *(i)* and *(ii)* ...(99)

$(\partial U/\partial V)_S = (\partial A/\partial V)_T$ from *(i)* and *(iii)* ...(100)

$(\partial H/\partial P)_S = (\partial G/\partial P)_T$ from *(ii)* and *(iv)* ...(101)

$(\partial A/\partial T)_V = (\partial G/\partial T)_P$ from *(iii)* and *(iv)* ...(102)

Example 18. Show that $(\partial U/\partial S)_P = T - P(\partial T/\partial P)_S$.

Solution : From the combined form of the First and the Second laws of thermodynamics, we know that in a system undergoing *expansion*,

$$dU = TdS - PdV \quad \text{(Eq. 84)}$$

Dividing by dS, keeping P constant, we have

$$(\partial U/\partial S)_P = T - P(\partial V/\partial S)_P$$

Since $(\partial V/\partial S)_P = (\partial T/\partial P)_S$ [Maxwell's relation, Eq. 96]

$$\therefore \quad (\partial U/\partial S)_P = T - P(\partial T/\partial P)_S$$

Example 19. Using the combined form of the First and the Second laws of thermodynamics and appropriate Maxwell relations, derive the two thermodynamics equations of state.

Solution : $dU = TdS - PdV$ [Eq. 84]

Dividing by dV, keeping T constant, we have

$$(\partial U/\partial V)_T = T(\partial S/\partial V)_T - P$$

Since $(\partial S/\partial V)_T = (\partial P/\partial T)_V$ [Maxwell's relation, Eq. 97]

$\therefore \quad (\partial U/\partial V)_T = T(\partial P/\partial T)_V - P$

This is the **First thermodynamic equation of state.**

Again, $dH = TdS + VdP$

Dividing by dP, keeping T constant, we have

$(\partial H/\partial P)_T = T(\partial S/\partial P)_T + V$

Since, $(\partial S/\partial P)_T = -(\partial V/\partial T)_P$ [Maxwell's relation, Eq. 98]

$\therefore \quad (\partial H/\partial P)_T = V - T(\partial V/\partial T)_P$

This is the **Second thermodynamic equation of state.**

Example 20. Show that for an ideal gas

(*a*) $(\partial U/\partial V)_T = 0$ (*b*) $(\partial H/\partial P)_T = 0$ (*c*) $(\partial U/\partial P)_T = 0$ (*d*) $(\partial H/\partial V)_T = 0$

Solution : (*a*) For an ideal gas, $PV = nRT$ or $P = nRT/V$

$\therefore \quad (\partial P/\partial T)_V = nR/V = P/T$

Substituting this value in the First thermodynamic equation of state (Example 19), we have

$(\partial U/\partial V)_T = T(\partial P/\partial T)_V - P = T(P/T) - P = 0$

(*b*) For an ideal gas, $PV = nRT$ or $V = nRT/P$

$\therefore \quad (\partial V/\partial T)_P = nR/P = V/T$

Substituting this value in the Second thermodynamic equation of state (Example 19), we have

$(\partial H/\partial P)_T = V - T(\partial V/\partial T)_P = V - T(V/T) = 0$

(*c*) Since $H = U + PV$, hence, $U = H - PV = H - nRT$

or $(\partial U/\partial P)_T = (\partial(H - nRT)/\partial P)_T = (\partial H/\partial P)_T - (\partial(nRT)/\partial P)_T = 0 - 0 = 0$

(*d*) Since $H = U + PV = U + nRT$

$\therefore \quad (\partial H/\partial V)_T = (\partial(U+nRT)/\partial V)_T = (\partial U/\partial V)_T + (\partial(nRT)/\partial V)_T = 0 + 0 = 0.$

Example 21. Show that for an ideal gas, $(\partial V/\partial S)_P = nRT/(PC_P)$

Solution : $(\partial V/\partial S)_P = (\partial T/\partial P)_S$ [Maxwell's relation, Eq. 96] ...(*i*)

Also, $(\partial T/\partial P)_S (\partial P/\partial S)_T (\partial S/\partial T)_P = -1$ [The cyclic rule, Chapter 12] ...(*ii*)

$$\left(\frac{\partial T}{\partial P}\right)_S = -\frac{1}{(\partial P/\partial S)_T(\partial S/\partial T)_P} = -\frac{(\partial S/\partial P)_T}{(\partial S/\partial T)_P} \quad ...(iii)$$

We know that $dS = C_P\,dT/T$ so that $(\partial S/\partial T)_P = C_P/T$ ...(*iv*)

Also, $(\partial S/\partial P)_T = -(\partial V/\partial T)_P$ [from Maxwell's relation, Eq. 98]

and $$\left(\frac{\partial T}{\partial P}\right)_S = \frac{(\partial V/\partial T)_P}{C_P/T} \quad ...(v)$$

For an ideal gas, $PV = nRT$ or $V = nRT/P$ so that $(\partial V/\partial T)_P = nR/P$

From Eqs. (*i*), (*v*) and (*vi*),

$(\partial V/\partial S)_P = nRT/(PC_P).$

Example 22. Show that for an ideal gas, the internal pressure $(\partial U/\partial V)_T = 0$.

Solution : $dU = TdS - PdV$ ...(*i*)

Let $S = f(T, V)$, hence, $dS = (\partial S/\partial T)_V\,dT + (\partial S/\partial V)_T\,dV$ ...(*ii*)

Substituting for dS in Eq. (*i*),

$dU = T[(\partial S/\partial T)_V\,dT + (\partial S/\partial V)_T\,dV] - PdV$ ...(*iii*)

Also, since $U = f(T, V)$, hence, $dU = (\partial U/\partial T)_V\,dT + (\partial U/\partial V)_T\,dV$ ...(*iv*)

Equating the coefficients of dV in Eqs. (*iii*) and (*iv*),

$(\partial U/\partial V)_T = T(\partial S/\partial V)_T - P = T(\partial P/\partial T)_V - P$ [$(\partial S/\partial V)_T = (\partial P/\partial T)_V$; Maxwell's relation Eq. 97]

For one mole of an ideal gas,

$PV = RT$ or $P = RT/V$; $\therefore (\partial P/\partial T)_V = R/V$

Hence, $(\partial U/\partial V)_T = T(R/V) - P = P - P = 0$

Criteria for Reversible and Irreversible Processes. We have seen earlier that the net entropy change of a process determines whether the process would proceed irreversibly (*i.e.*, spontaneously) or not. If there is net increase in the entropy of the system and the surroundings taken together, the process would proceed irreversibly, *i.e.*, it would be thermodynamically feasible. If there is no net change in the entropy of the system and the surroundings put together, the process will be reversible, *i.e.*, the system will remain in a state of equilibrium.

We can express the criteria for reversibility and irreversibility in terms of entropy of the system (alone) as well as in terms of other fundamental thermodynamic properties, namely, U, H, A and G.

It was stated earlier that change of entropy for a given change of state is a definite quantity, independent of the fact whether the change is brought about reversibly or irreversibly. But, mathematically, it is given (for a small change) by the equation

$$dS = dq_{rev}/T = (dU + PdV)/T \quad ...(103)$$

only if the change (involving expansion of an ideal gas) is brought about reversibly.

Suppose the small change of state is brought about *irreversibly*. Now the heat absorbed by the system will be *less* ($\because q_{irr} < q_{rev}$). But the entropy change dS will have the same value. Hence, for an *irreversible* process,

$TdS > dq_{rev}$

We may thus write $TdS = dU + PdV$ (For a reversible process)

$TdS > dU + PdV$ (For an irreversible process)

Combining the two, we have

$$TdS \geq dU + PdV \quad ...(104)$$

The 'equal to' sign refers to a reversible process while the 'greater than' sign refers to an irreversible process.

(i) Criterion in Terms of Change of Entropy. If U and V (internal energy and volume) remain constant, then, for an isothermal process (*i.e.*, T is constant),

$$dS \geq 0$$

The 'equal to' sign refers to reversible process while the 'greater than' sign refers to an irreversible process.

(ii) Criterion in Terms of Change of Internal Energy. If S and V (entropy and volume) are kept constant, then, for an isothermal process (*i.e.*, T is constant).

$$dU \leq 0$$

The 'equal to' sign refers to a reversible process while 'less than' sign refers to an irreversible process.

(iii) Criterion in Terms of Change of Enthalpy. If S and P are kept constant, the expression $TdS \geq dU + PdV$ may be written as

$dU + PdV \leq 0$

But $dU + PdV = dH$

$\therefore \quad dH \leq 0$

where the sign 'equal to' refers to a *reversible* process while the sign 'less than' refers to an irreversible process.

(iv) Criterion in Terms of Change of Work Function. Combining Eq. 104, *viz.*, $TdS \geq dU + PdV$ with Eq. 70, *viz.*, $dA = dU - TdS$ for an infinitesimally small change, we have

$dA \leq -PdV$

At constant volume, therefore, $dA \leq 0$

where the sign 'equal to' refers to a reversible process while the sign 'less than' refers to an irreversible process.

(v) Criterion in Terms of Change of Free Energy. Substituting $TdS \geq dU + PdV$ in Eq. 85, we have

$$dG \leq VdP - SdT$$

$\therefore$ At constant temperature and pressure, $dG \leq 0$ ...(105)

where, as usual, the sign 'equal to' refers to a reversible process while the sign 'less than' refers to an irreversible process.

The criterion in terms of free energy change *viz.*, $(\partial G)_{T,P} \leq 0$, is the most useful criterion to decide between reversibility and irreversibility of a process. If free energy change of a process has a negative value, the process is irreversible, *i.e.*, it can take place spontaneously. If, on the other hand, the free energy change of a process is *zero*, then the process is reversible, *i.e.*, a state of equilibrium exists. Lastly, if the free energy change of process is positive, *i.e.*, there is likely to be an increase in the free energy change, then the process will not proceed.

Limitation of the above criteria. Each of the above thermodynamic criteria for determining spontaneity of a process has a limitation. It only helps to *predict* whether a given reaction or a process is thermodynamically feasible or not. It *cannot predict the rate at which a reaction will proceed.* There are other considerations, outside the realm of thermodynamics, which can tell whether the process will take place rapidly or slowly. It is because of this limitation that in the above treatment, we have used the word 'feasible' as synonymous for 'spontaneous' or 'irreversible'. A process may be thermodynamically *feasible*, yet it may not proceed spontaneously under the given experimental conditions. For example, the reaction

$$2H_2(g) + O_2(g) \longrightarrow 2H_2O(l)$$

is thermodynamically *feasible* at room temperature but a mixture of hydrogen and oxygen at room temperature will remain as such almost indefinitely without reacting. The two gases will react only if the reaction is *initiated*, say, by passing an electric spark.

The Gibbs-Helmholtz Equation

Let G_1 represent the free energy of a system in its initial state at temperature T. Suppose the temperature rises to $T+dT$ where dT is infinitesimally small. Let the free energy at the new temperature be G_1+dG_1.

Now suppose that when the system is in its final state, its free energy is given by G_2 at the temperature T and by G_2+dG_2 at the temperature $T+dT$. If the pressure remains constant all along, Eq. 86 is applicable, *i.e.*,

$$dG_1 = -S_1 dT \quad ...(106)$$

and

$$dG_2 = -S_2 dT \quad ...(107)$$

where S_1 and S_2 are the entropies of the system in the initial and final states of the system, respectively.

Subtracting Eq. 106, from Eq. 107, we have

$$d(G_2 - G_1) = -(S_2 - S_1)\, dT$$

$$d(\Delta G) = -\Delta S dT \quad ...(108)$$

As the pressure is constant, therefore,

$$(\partial(\Delta G)/\partial T)_P = -\Delta S \quad ...(109)$$

Also, since from Eq. 75, $-\Delta S = (\Delta G - \Delta H)/T$, hence, Eq. 109 becomes

$$(\Delta G - \Delta H)/T = (\partial(\Delta G)/\partial T)_P \quad ...(110)$$

or

$$\Delta G = \Delta H + T(\partial(\Delta G)/\partial T)_P \quad ...(111)$$

This equation is known as the **Gibbs-Helmholtz equation.** It is applicable to all processes occurring at constant pressure. It has been used for calculating the enthalpy change ΔH for a process or a reaction provided the values of free energy changes at two different temperatures are known.

For a reaction at constant volume, the corresponding equation will be

$$\Delta A = \Delta U + T(\partial(\Delta A)/\partial T)_V \quad ...(112)$$

Example 23. The free energy change (ΔG) accompanying a given process is – 85·77 kJ at 25°C and – 83·68 kJ at 35°C. Calculate the change in enthalpy (ΔH) for the process at 30°C

Solution : ΔG at 25°C = – 85·77 kJ and at 35°C = – 83·68 kJ

$$\therefore \quad \left(\frac{\partial(\Delta G)}{\partial T}\right)_P = \frac{-83{\cdot}68\,\text{kJ} - (-85{\cdot}77\,\text{kJ})}{308\,\text{K} - 298\,\text{K}} = 0{\cdot}209\ \text{kJ K}^{-1}$$

ΔG at 30°C may be taken as the average of the values at 25°C and 35°C,

$$\therefore \quad \Delta G \text{ at } 30°C = -\left(\frac{85{\cdot}77\,\text{kJ} + 83{\cdot}68\,\text{kJ}}{2}\right) = -84{\cdot}725\ \text{kJ}$$

$$-84{\cdot}725\ \text{kJ} = \Delta H + (303\ \text{K})\ (0{\cdot}209\ \text{kJ K}^{-1})$$

Hence,

$$\Delta H = -148{\cdot}05\ \text{kJ}$$

Thermodynamics of Open Systems. Partial Molar Properties

The thermodynamic properties, *U*, *H*, *S*, *A* and *G* are extensive properties because their values change with change in the mass (*i.e.*, the number of moles) of the system. In the derivation of the various thermodynamic equations described earlier, the change of state was considered to be due to change in temperature and pressure only. A tacit assumption was made that the system under consideration was a closed system, *i.e.*, there could be no change in the mass of the system. However, in the case of an **open system** containing two or more components, there can be change in the number of moles of various components as well. In that case, an extensive property, say, *X*, must be a function not only of temperature and pressure but also of the number of moles of the various components present in the system.

Let T and P be the temperature and pressure, respectively, of a system and let $n_1, n_2, n_3 \ldots\ldots n_j$ be the respective numbers of moles of the constituents, 1, 2, 3, $\ldots\ldots j$. Then, in view of what has been said above, the property X must be a function of temperature, pressure and the number of moles of the various constituents, *i.e.*,

$$X = f(T, P, n_1, n_2, n_3, \ldots\ldots n_j) \quad ...(113)$$

where $n_1+n_2+n_3\ldots\ldots+n_i$ = Total number of moles = N (say).

For a small change in temperature, pressure and the number of moles of the components, the change in property dX will be given by the expression

$$dX = (\partial X/\partial T)_{P,N}\, dT + (\partial X/\partial P)_{T,N}\, dP + (\partial X/\partial n_1)_{T,P,n_2\ldots\ldots n_j} dn_1 + (\partial X/\partial n_2)_{T,P,n_1,n_3\ldots n_j} dn_2$$
$$+ (\partial X/\partial n_i)_{T,P,n_1,n_2\ldots\ldots n_{j\neq i}} dn_i \ldots\ldots + (\partial X/\partial n_j)_{T,P,n_1,n_2\ldots\ldots n_{i\neq j}\ldots\ldots} dn_j \quad ...(114)$$

The quantity $(\partial X/\partial n_i)_{T,P,n_1,n_2\ldots\ldots n_{j\neq i}}$ is called the **partial molar property** of the ith component. This is represented as $\overline{X}_i$.

Thus, for the ith component in a system

$$\text{partial molar internal energy} = (\partial U/\partial n_i)_{T,P,n_1,n_2,n_3\ldots\ldots} = \overline{U}_i$$

$$\text{partial molar enthalpy} = (\partial H/\partial n_i)_{T,P,n_1,n_2,n_3\ldots\ldots} = \overline{H}_i$$

$$\text{partial molar entropy} = (\partial S/\partial n_i)_{T,P,n_1,n_2,n_3\ldots\ldots} = \overline{S}_i$$

$$\text{partial molar volume} = (\partial V/\partial n_i)_{T,P,n_1,n_2,n_3\ldots\ldots} = \overline{V}_i$$

A tangent to the curve $\bar{Y}_{total} = f(x_2)$ at any point x_2 has an intercept on the $\bar{Y}_{total}$ axis of $\bar{Y}_1$ (Eq.150) whereas a tangent to the curve $\bar{Y}_{total} = f(x_1)$ at any point x_1 has an intercept on the $\bar{Y}_{total}$ axis of $\bar{Y}_2$ (Eq.151). The slope-intercept method is depicted graphically in Fig. 4.

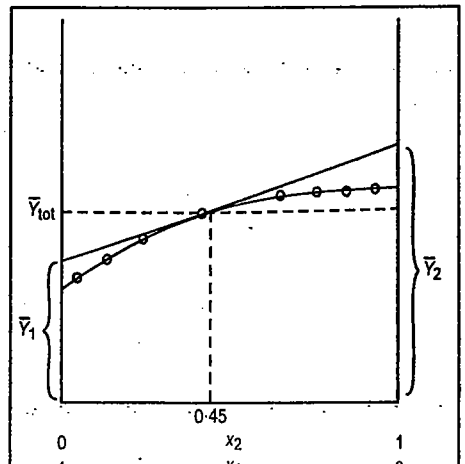

Fig. 4. Slope-intercept method for the determinaiton of partial molar quantities. The tangent to the curve at $x_2 = 0{\cdot}45$ yields as intercepts $\bar{Y}_1$ and $\bar{Y}_2$ at $x = 0{\cdot}45$.

Another useful graphical technique for obtaining partial molar quantities in two-component systems is the following : We define a quantity called the *apparent molar value* of $\bar{Y}$, designated as $^{\phi}Y$, by the expression

$$\phi Y = Y - n_1 \bar{Y}_1 / n_2 \qquad ...(152)$$

where $\bar{Y}_1$ is the molar value of Y for pure component 1 at constant T' and P (we distinguish partial molar quantities from molar quantities by means of a prime on the latter). Thus, $\bar{Y}_i$ and $\bar{Y}_1'$ refer, respectively, to the partial molar value of Y in the solution and the molar value of pure Y for the ith component. From Eq. 152, we obtain

$$Y_2 = \phi_Y + n_2 \left(\frac{\partial \phi Y}{\partial n_2} \right)_{n_1} = \phi_Y + n_2 \frac{d\phi Y}{dn_2} \qquad ...(153)$$

Thus the slope of a plot of ϕY versus n_2 at any particular composition can be inserted into Eq. 153, together with ϕY and n_2 appropriate to that composition, and $\bar{Y}_2$ results. If Y is a thermodynamic coordinate, then, Eq. 152 takes the form

$$\phi \Delta Y = \frac{\Delta Y - n_1 \Delta \bar{Y}_1}{n_2} \qquad ...(154)$$

Fig. 5 shows the reciprocal of the density of ethanol+water solutions versus the mass percent of ethanol. Inspection of Eqs. 150 and 151 shows that, in such a case, the intercepts of a tangent to the curve at a particular mass percent, multiplied by the molar masses of the respective compounds, yields $\bar{V}_1$ and $\bar{V}_2$ at that composition. From Fig 5 at 50·0 mass percent, we find that $\bar{V}_{H_2O} = 0{\cdot}964 \times 18 = 17{\cdot}35$ cm^3 mol^{-1} ; $\bar{V}_{C_2H_5OH} = 1{\cdot}232 \times 46 = 56{\cdot}75$ cm^3 mol^{-1}, compared with the values for the pure compounds *viz.*, $\bar{V}_{H_2O} = 1{\cdot}0029 \times 18 = 18{\cdot}05$ cm^3 mol^{-1} and $\bar{V}_{C_2H_5OH} = 1{\cdot}273 \times 46 = 58{\cdot}56$ cm^3 mol^{-1}.

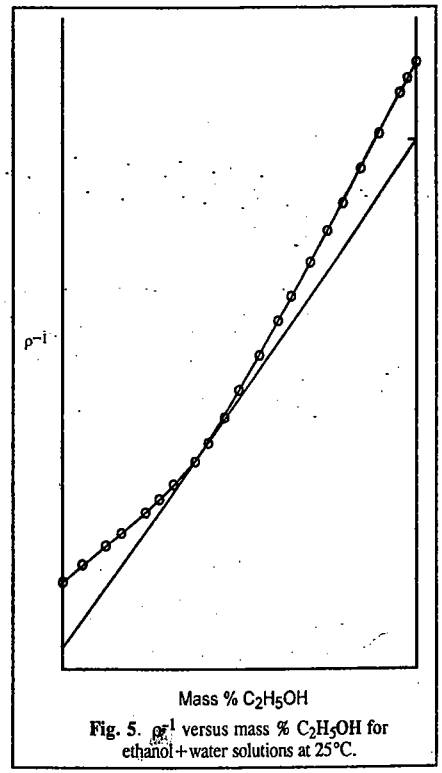

Fig. 5. ρ^{-1} versus mass % C_2H_5OH for ethanol+water solutions at 25°C.

It is worth noting that partial molar volumes can be negative also. A possible physical interpretation of this effect is that if $\bar{V}_i < 0$, then $\Delta V_{mix} < 0$. Hence, molecules of component 1 can be thought of either as entering 'cavities' in the other liquid or the molecules of component 1 cause the partial collapse of an 'open' solution structure to a more compact packing arrangement or possibly, a combination of both of these effects operate simultaneously.

Clapeyron Equation

An important equation for one-component two-phase systems was derived in the nineteenth century by Clapeyron from the Second law of thermodynamics. It is known as the Clapeyron equation. The two phases in equilibrium may be any of the following types :

(i) *Solid and Liquid,* $S \rightleftharpoons L$, at the melting point of the solid.

(ii) *Liquid and Vapour,* $L \rightleftharpoons V$, at the boiling point of the liquid.

(iii) *Solid and Vapour,* $S \rightleftharpoons V$, at the sublimation temperature of the solid.

(iv) *One Crystalline Form and Another Crystalline Form* as, for example, rhombic and monoclinic sulphur, $S_R \rightleftharpoons S_M$, at the transition temperature of the two allotropic forms.

Consider any two phases (say, liquid and vapour) of one and the same substance in equilibrium with each other at a given temperature and pressure. It is possible to transfer any definite amount of the substance from one phase to the other in a thermodynamically reversible manner, *i.e.*, infinitesimally slowly, the system remaining in a state of equilibrium all along. For example, by supplying heat infinitesimally slowly to the system, it is possible to change any desired amount of the substance from the liquid to the vapour phase at the same temperature and pressure. Similarly, by withdrawing heat infinitesimally slowly from the system, it is possible to change any desired amount of the substance from the vapour to the liquid phase without any change in temperature and pressure. Since the system remains in a state of equilibrium, the free energy change of either process will be zero. We may conclude, therefore, that *equal amounts of a given substance must have exactly the same free energy in the two phases at equilibrium with each other.*

Consider, in general, the change of a pure substance from phase A to another phase B in equilibrium with it at a given temperature and pressure. If G_A is the free energy per mole of the substance in the initial phase A and G_B is the free energy per mole in the final phase B, then, since $G_A = G_B$, hence, there will be no free energy change, *i.e.*, $\Delta G = G_B - G_A = 0$.

If the temperature of such a system is raised, say, from T to $T+dT$, the pressure will also have to change, say, from P to $P+dP$, in order to maintain the equilibrium. The relationship between dT and dP can be derived from thermodynamics.

Let the free energy per mole of the substance in phase A at the new temperature and pressure be $G_A + dG_A$ and that in phase B be $G_B + dG_B$. Since the two phases are still in equilibrium, hence,

$$G_A + dG_A = G_B + dG_B \qquad ...(155)$$

According to thermodynamics,

$$dG = VdP - SdT \qquad ...(156)$$

Eq. 152 for phase A may be written as

$$dG_A = V_A\, dP - S_A\, dT \qquad ...(157)$$

and for phase B, as $dG_B = V_B\, dP - S_B\, dT$ ...(158)

Since $G_A = G_B$, hence, from Eq. 151

$$dG_A = dG_B \qquad ...(159)$$

$$\therefore \quad V_A\, dP - S_A\, dT = V_B\, dP - S_B\, dT \qquad ...(160)$$

Chemical Potential

The most important **partial molar property** in physical chemistry is the **partial molar free energy**, designated as **chemical potential** and represented as

$$(\partial G/\partial n_i)_{T,P,n_1 \ldots n_j} = \overline{G}_i = \mu_i \qquad \ldots(115)$$

The chemical potential of a given substance is, evidently, the change in free energy of the system that results on the addition of one mole of that particular substance at a constant temperature and pressure, to such a large quantity of the system that there is no appreciable change in the overall composition of the system.

For an infinitesimal free energy change, we can write

$$dG = (\partial G/\partial T)_{P,N}\, dT + (\partial G/\partial P)_{T,N}\, dP + \mu_1 dn_1 + \mu_2 dn_2 + \cdots\cdots \mu_j dn_j \qquad \ldots(116)$$

where μ_1, $\mu_2 \cdots$ and μ_j are chemical potentials of components 1, 2, $\cdots$ and j, respectively.

If temperature and pressure remain constant, then

$$(dG)_{T,P} = \mu_1 dn_1 + \mu_2 dn_2 + \cdots\cdots \mu_j dn_j \qquad \ldots(117)$$

If a system has a definite composition having n_1, n_2, $\cdots\cdots$ n_j moles of constituents 1, 2, $\cdots\cdots j$, respectively, then, on integrating Eq. 117, we have

$$(G)_{T,P,N} = n_1\mu_1 + n_2\mu_2 + \cdots\cdots n_j\mu_j \qquad \ldots(118)$$

From Eq. 118, **chemical potential** may be defined as the contribution per mole of each particular constituent of the mixture to the total free energy of the system under conditions of constant temperature and pressure. It readily follows that for a total of one mole of a pure substance, $G = \mu$, *i.e.*, free energy is identical with chemical potential.

Gibbs-Duhem Equation. Eq. 118 shows that the free energy of a system, at constant temperature and pressure, can be expressed as a sum of $n\mu$ terms for the individual components of the system.

The total differential of G of Eq. 118 is written as

$$dG = \mu_1 dn_1 + n_1 d\mu_1 + \mu_2 dn_2 + n_2 d\mu_2 \cdots\cdots \mu_j dn_j + n_j d\mu_j$$
$$= (\mu_1 dn_1 + \mu_2 dn_2 + \cdots\cdots \mu_j dn_j) + (n_1 d\mu_1 + n_2 d\mu_2 + \cdots\cdots n_j d\mu_j) \qquad \ldots(119)$$

But, according to Eq. 117, the first term on right hand side of Eq. 119 is equal to dG, at constant temperature and pressure. It follows, therefore, that at constant temperature and pressure, for a system of a definite composition

$$n_1 d\mu_1 + n_2 d\mu_2 + \cdots\cdots n_j d\mu_j = 0 \quad \text{or} \quad \Sigma n_i\, d\mu_i = 0 \qquad \ldots(120)$$

This simple relationship is known as **Gibbs-Duhem equation.**

For a system having only two components (*e.g.*, *a* binary solution), the above equation reduces to

$$n_1 d\mu_1 + n_2 d\mu_2 = 0 \quad \text{or} \quad d\mu_1 = -(n_2/n_1)\, d\mu_2 \qquad \ldots(121)$$

Eq. 121 shows that variation in chemical potential of one component affects the value for the other component as well. Thus, if $d\mu_1$ is positive, *i.e.*, if μ_1 increases, then $d\mu_2$ must be negative, *i.e.*, μ_2 must decrease and *vice versa*.

Some Important Results. In a special case when there is no change in the number of moles of the various constituents of a system, that is, when the system is closed one, then dn_1, dn_2, $\cdots\cdots dn_j$ are all zero. In such a case, Eq. 116 reduces to

$$dG = (\partial G/\partial T)_{P,N}\, dT + (\partial G/\partial P)_{T,N}\, dP \qquad \ldots(122)$$

For a closed system, $dG = VdP - SdT$ (Eq. 85)

Hence, by equating co-efficients of dT and dP in the above two equations, we get

$$(\partial G/\partial T)_{P,N} = -S \qquad \ldots(123)$$

and

$$(\partial G/\partial P)_{T,N} = V \qquad \ldots(124)$$

These results are important as they help us in deriving expressions for the variation of chemical potential with temperature and pressure, as illustrated below.

Variation of chemical potential with temperature. The variation of chemical potential of any constituent i of a system with temperature can be derived by differentiating Eq. 115 with respect to temperature and Eq. 123 with respect to n_i. The results are :

$$\frac{\partial^2 G}{\partial n_i\, \partial T} = \left(\frac{\partial \mu_i}{\partial T}\right)_{P,N} \qquad \ldots(125)$$

$$\frac{\partial^2 G}{\partial T\, \partial n_i} = -\left(\frac{\partial S}{\partial n_i}\right)_{T,P,n_1 \cdots\cdots n_j} = -\overline{S}_i \qquad \ldots(126)$$

where $\overline{S}_i$, by definition, is the partial molar entropy of the component i,

If follows from Eqs. 125 and 126 that

$$(\partial \mu_i/\partial T)_{P,N} = -\overline{S}_i \qquad \ldots(127)$$

Eq. 127 gives the variation of chemical potential (μ_i) of any constituent i of the system with temperature.

Since the entropy of a substance is always positive, hence, according to Eq. 127, the chemical potential would decrease with increase in temperature. This is illustrated in Fig. 3 for a substance in solid, liquid and gaseous states. It is evident that at the melting point (T_m), the chemical potentials of the solid and liquid phases are the same. Similarly, at the boiling point (T_b), the chemical potentials of the liquid and gaseous phases are the same. These observations are extremely useful in the Phase rule studies.

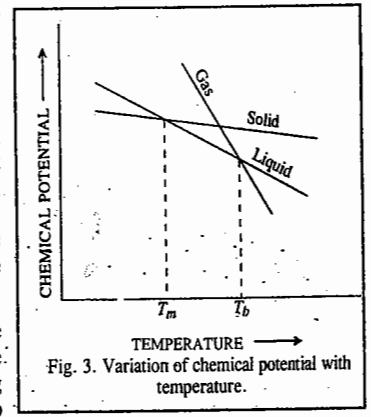

Fig. 3. Variation of chemical potential with temperature.

Variation of chemical potential with pressure. The variation of chemical potential of any constituent i of the gaseous system with pressure may be derived bydifferentiating Eq. 115 with respect to pressure and Eq. 124 with respect to n_i. The results are :

$$\frac{\partial^2 G}{\partial P\, \partial n_i} = \left(\frac{\partial \mu_i}{\partial P}\right)_{T,N} \qquad \ldots(128)$$

and

$$\frac{\partial^2 G}{\partial n_i\, \partial P} = \left(\frac{\partial V}{\partial n_i}\right)_{T,P,n_1 \cdots\cdots n_j} = \overline{V}_i \qquad \ldots(129)$$

where $\overline{V}_i$, by definition, is the partial molar volume of the component i.

If follows from Eqs. 128 and 129 that

$$(\partial \mu_i/\partial P)_{T,N} = \overline{V}_i \qquad \ldots(130)$$

Eq. 130 gives the variation of chemical potential (μ_i) of any constituent of the system with pressure.

Chemical Potential in a System of Ideal Gases. For a system of ideal gases, a further development of Eq. 130 is also possible. In an ideal gas, $PV=nRT$. Consider a system consisting of a number of ideal gases. Let n_1, n_2 $\cdots\cdots$ be the numbers of moles of various constituents present in the

mixture. Then, in the ideal gas equation, n, the total number of moles, may be replaced by $(n_1+n_2+\cdots\cdots)$. Hence,

$$V = nRT/P = (n_1 + n_2 + \cdots\cdots)\, RT/P \qquad \ldots(131)$$

Differentiating Eq. 131 with respect to n_i, at constant temperature and pressure, we have

$$(\partial V/\partial n_i)_{T,P,n_1,n_2\ldots\ldots} = \overline{V}_i = RT/P \qquad \ldots(132)$$

Substituting the value of $\overline{V}_i\,(= RT/P)$ in Eq. 130, we have

$$(\partial \mu_i/\partial P)_{T,N} = RT/P \qquad \ldots(133)$$

For a constant composition of the gas and at a constant temperature, Eq. 133 may also be expressed in the form

$$d\mu_i = (RT/P)\, dP = RT\, d \ln P \qquad \ldots(134)$$

Let p_i be the partial pressure of the constituent i present in the mixture. Since each constituent behaves as an ideal gas, therefore,

$$p_i V = n_i RT \text{ or } p_i = (n_i/n)\, P \qquad \ldots(135)$$

Since n_i and n are constants, therefore, on taking logarithms and then differentiating, we get

$$d \ln p_i = d \ln P \qquad \ldots(136)$$

Substituting in Eq. 134, we have

$$d\mu_i = RT\, d \ln p_i \qquad \ldots(137)$$

Integrating Eq. 137, we get

$$\mu_i = \mu^\circ_{i(p)} + RT \ln p_i \qquad \ldots(138)$$

where $\mu^\circ_{i(p)}$ is the integration constant, the value of which depends upon the nature of the gas and on the temperature.

It is evident from Eq. 138 that the chemical potential of any constituent of a mixture of ideal gases is determined by its partial pressure in the mixture. If the partial pressure of the constituent i is unity, *i.e.*, $p_i = 1$, then

$$\mu_i = \mu^\circ_{i(p)} \qquad \ldots(139)$$

Thus, $\mu^\circ_{i(p)}$ gives the chemical potential of the gaseous constituent i when the partial pressure of the constituent is unity, at a constant temperature.

According to Eq. 135, $p_i = (n_i/V)\, RT \qquad \ldots(140)$

Now n_i/V represents molar concentration, *i.e.*, the number of moles per unit volume of the constituent i in the mixture. If this concentration is represented by c_i, then Eq. 140 gives

$$p_i = c_i RT \qquad \ldots(141)$$

Introducing this value of p_i in Eq. 138, we have

$$\mu_i = \mu^\circ_{i(p)} + RT \ln (c_i\, RT) = \mu^\circ_{i(p)} + \underbrace{RT \ln RT}_{\text{constant}} + RT \ln c_i$$

$$= \mu^\circ_{i(c)} + RT \ln c_i \qquad \ldots(142)$$

where $\mu^\circ_{i(c)}\,(= \mu^\circ_{i(p)} + RT \ln RT)$ is a constant depending upon the nature of the gas and the temperature. If $c_i=1$, then $\mu_i=\mu^\circ_{i(c)}$. Thus, $\mu^\circ_{i(c)}$ represents the chemical potential of the constituent i when the concentration of the constituent in the mixture is unity, at a constant temperature. Lastly, since n_i/n represents the mole fraction (x_i) of the constituent i in the mixture, Eq. 135 may be represented as

$$p_i = x_i P \qquad \ldots(143)$$

Substituting this value of p_i in Eq. 138, at a constant pressure, we have

$$\mu_i = \mu^\circ_{i(p)} + RT \ln (x_i P) = \mu^\circ_{i(p)} + \underbrace{RT \ln P}_{\text{constant}} + RT \ln x_i$$

or $$\mu_i = \mu^\circ_{i(x)} + RT \ln x_i \qquad \ldots(144)$$

where the quantity $\mu^\circ_{i(x)}\,(=\mu^\circ_{i(p)} + RT \ln P)$ is also a constant which depends both on the temperature and the total pressure. If $x_i=1$, $\mu_i=\mu^\circ_{i(x)}$. Thus, $\mu^\circ_{i(x)}$ represents the chemical potential of the constituent i when its mole fraction, at a constant T and P, is unity.

Determination of Partial Molar Quantities. A straightforward, but not precise, method of determining partial molar quantities involves plotting the extensive thermodynamic variable Y at constant T and P versus the number of moles of all components except i, *viz.*, $Y(n_i)$. The slope of the resulting curve at any point is given by $\overline{Y}_i = (\partial Y/\partial n_i)_{T,P,nj\neq i}$ at that particular composition from which $\overline{Y}_i$ can be evaluated. Such a plot is easily obtained for a two-component system by using the molality composition scale which fixes the number of moles of the solvent at $1000/M_1$.

A more precise method for the determination of partial molar quantities is the so-called **slope-intercept method**, which we shall illustrate by taking into consideration the case of a two-component system. In slope-intercept method, we begin by computing the molar value of Y for the solution as a whole, a quantity that we shall designate as $\overline{Y}_{\text{total}}$ where

$$\overline{Y}_{\text{total}} = \overline{Y} \Big/ \sum_i n_i \qquad \ldots(145)$$

For a two-component system, we have

$$\overline{Y} = (n_1 + n_2)\overline{Y}_{\text{total}} \qquad \ldots(146)$$

$$\therefore \quad \overline{Y}_1 = \left(\frac{\partial \overline{Y}}{\partial n_1}\right)_{n_2} = \overline{Y}_{\text{total}} + (n_1 + n_2)\left(\frac{\partial \overline{Y}_{\text{total}}}{\partial n_1}\right)_{n_2} \qquad \ldots(147)$$

where we have omitted T and P as subscripts on the partial derivatives in the interest of simplicity. It is to be understood, however, that the development applies to a system at fixed T and P. Since

$$\left(\frac{\partial \overline{Y}_{\text{total}}}{\partial n_1}\right)_{n_2} = \left(\frac{\partial \overline{Y}_{\text{total}}}{\partial x_2}\right)_{n_2}\left(\frac{\partial x_2}{\partial n_1}\right)_{n_2} \qquad \ldots(148)$$

and mole fraction $x_2 = n_2/(n_1+ n_2)$, we have

$$\left(\frac{x_2}{\partial n_1}\right)_{n_2} = -\frac{x_2}{(n_1 + n_2)} \qquad \ldots(149)$$

Again, since an arbitrary change in x_2 gives rise to a definite change in $\overline{Y}_{\text{total}}$ (for a two-component system), we can write $\left(\partial \overline{Y}_{\text{total}}/\partial x_2\right)_{n_2} = d\overline{Y}_{\text{total}}/dx_2$ and hence,

$$\overline{Y}_{\text{total}} = \overline{Y}_1 + x_2 \frac{d\overline{Y}_{\text{total}}}{dx_2} \qquad \ldots(150)$$

A similar treatment for $\overline{Y}_2$ gives

$$\overline{Y}_{\text{total}} = \overline{Y}_2 + x_1 \frac{d\overline{Y}_{\text{total}}}{dx_1} \qquad \ldots(151)$$

or $$\frac{dP}{dT} = \frac{S_B - S_A}{V_B - V_A} \quad ...(161)$$

It may be noted that since V_A and V_B are the molar volumes of the pure substance in the two phases A and B, respectively, $V_B - V_A$ represents the change in volume when one mole of the substance passes from the initial phase A to the final phase B. It may be represented by ΔV. Similarly, $S_B - S_A$, being the change in entropy for the same process, may be put as ΔS. Hence,

$$dP/dT = \Delta S/\Delta V \quad ...(162)$$

If q is the heat exchanged reversibly per mole of the substance during the phase transformation at temperature T, then the change of entropy (ΔS) in this process is given by $\Delta S = q/T$.

Hence, $$\frac{dP}{dT} = \frac{q}{T\Delta V} \quad ...(163)$$

Thus, $$\frac{dP}{dT} = \frac{q}{T(V_B - V_A)} \quad ...(164)$$

This is the **Clapeyron equation,** named after the French engineer Benoit P. Clapeyron (1799-1864). This equation is useful in the chapter on Phase Equilibria.

This equation, evidently, gives change in pressure dP which must accompany the change in temperature dT or *vice versa,* in the case of a system containing two phases of a pure substance in equilibrium with each other. Suppose the system consists of water in the two phases, *viz.*, liquid and vapour, in equilibrium with each other at the temperature T, *i.e.*,

Water (*liquid*) $\rightleftharpoons$ Water (*vapour*)

Then, q = Molar heat of vaporisation, ΔH_{vap}

V_B = Volume of one mole of water in the vapour state, say, V_g

V_A = Volume of one mole of water in the liquid state, say, V_l

Eq. 164, therefore, takes the form

$$\frac{dP}{dT} = \frac{\Delta H_{vap}}{T(V_g - V_l)} \quad ...(165)$$

If the system consists of water at its freezing point, then, the two phases in equilibrium will be

Water (*Solid*), *i.e.*, ice $\rightleftharpoons$ Water (*liquid*)

Eq. 164 may then be written as

$$\frac{dP}{dT} = \frac{\Delta H_{fus}}{T(V_l - V_s)} \quad ...(166)$$

where ΔH_{fus} is the molar heat of fusion of ice.

Integrated Form of Clapeyron Equation for Liquid $\rightleftharpoons$ Vapour Equilibrium. Clapeyron-Clausuis Equation. The Clapeyron equation (165), as applied to liquid $\rightleftharpoons$ vapour equilibrium, can be easily integrated. The molar volume of a substance in the vapour state is considerably greater than that in the liquid state. In the case of water, for example, the value of V_g at 100°C is $18 \times 1670 = 30060$ ml while that of V_l is only a little more than 18 ml. Thus, $V_g - V_l$ can be taken as V_g without introducing any serious error. The Clapeyron equation (165), therefore, may be written as

$$\frac{dP}{dT} = \frac{\Delta H_{vap}}{TV_g} \quad ...(167)$$

Assuming that the ideal gas law is applicable, *i.e.*, $PV = RT$ (per mole), $V_g = RT/P$. Hence,

$$\frac{dP}{dT} = \frac{\Delta H_{vap}}{T} \times \frac{P}{RT} = P\frac{\Delta H_{vap}}{RT^2} \quad ...(168)$$

or $$\frac{1}{P} \times \frac{dP}{dT} = \frac{\Delta H_{vap}}{RT^2} \quad \text{or} \quad \frac{d(\ln P)}{dT} = \frac{\Delta H_{vap}}{RT^2} \quad ...(169)$$

Assuming that ΔH_v remains constant over a small range of temperature, we have

$$\int d(\ln P) = \frac{\Delta H_{vap}}{R}\int \frac{dT}{T^2} \quad \text{or} \quad P = -\frac{\Delta H_{vap}}{R}\left(\frac{1}{T}\right) + C \quad ...(170)$$

where C is integration constant.

Eq. 170 is, evidently, the equation of a straight line. Hence, the plot of ln P against $1/T$ should yield a straight line with slope $= -\Delta H_{vap}/R$ and intercept $= C$. This enables evaluation of ΔH_{vap}. Eq. 169 can also be integrated between limits of pressures P_1 and P_2 corresponding to temperatures T_1 and T_2. Thus,

$$\int_{P_1}^{P_2} d(\ln p) = \frac{\Delta H_{vap}}{R}\int_{T_1}^{T_2} \frac{dT}{T^2} \quad ...(171)$$

$$\therefore \quad \ln \frac{P_2}{P_1} = -\frac{\Delta H_{vap}}{R}\left[\frac{1}{T}\right]_{T_1}^{T_2} = \frac{\Delta H_{vap}}{R}\left[\frac{1}{T_1} - \frac{1}{T_2}\right] = \frac{\Delta H_{vap}}{R}\left[\frac{T_2 - T_1}{T_1 T_2}\right] \quad ...(172)$$

The integrated form of Clapeyron equation is known as **Clapeyron-Clausius equation.**

Applications of Clapeyron-Clausius Equation for Liquid $\rightleftharpoons$ Vapour Equilibria. Eq. 172 can be used for calculating the molar heat of vapourisation, ΔH_{vap}, of a liquid if we know the vapour pressures at two temperatures. Further, if ΔH_{vap} is known, vapour pressure at a desired temperature can be calculated from the knowledge of a single value of vapour pressure at a given temperature.

1. Calculation of molar heat of vaporisation, ΔH_{vap}.

Example 24. Vapour pressures of water at 95°C and 100°C are 634 and 760 mm, respectively. Calculate the molar heat of vapourisation, ΔH_{vap}, of water between 95°C and 100°C.

Solution : Substituting the given data in Eq. 172, we have

$$\ln \frac{760\,\text{mm}}{634\,\text{mm}} = \left(\frac{\Delta H_{vap}}{8{\cdot}314\,\text{J K}^{-1}\text{mol}^{-1}}\right)\left[\frac{373\,\text{K} - 368\,\text{K}}{(368\,\text{K})(373\,\text{K})}\right]$$

$$\therefore \quad \Delta H_{vap} = 41{,}363\ \text{J mol}^{-1} = 41{\cdot}363\ \text{kJ mol}^{-1}$$

2. Effect of temperature on vapour pressure of a liquid. If vapour pressure of a liquid at one temperature is known, that at another temperature can be calculated.

Example 25. The vapour pressure of water at 100°C is 760 mm. What will be the vapour pressure at 95°C ? The heat of vaporisation of water in this temperature range is 41·27 kJ per mole.

Solution : Substituting the given data in Eq. 172, we have

$$\ln \frac{P_2}{760\,\text{mm}} = \frac{41{\cdot}27 \times 10^3\ \text{J mol}^{-1}}{8{\cdot}314\ \text{J K}^{-1}\ \text{mol}^{-1}}\left[\frac{368\,\text{K} - 373\,\text{K}}{(368\,\text{K})(373\,\text{K})}\right]$$

$$\therefore \quad P_2 = 634{\cdot}3\ \text{mm}$$

3. Effect of pressure on boiling point. If the boiling point of a liquid at one pressure is known, that at another pressure can be calculated.

Example 26. Ether boils at 33·5°C at one atmosphere pressure. At what temperature will it boil at a pressure of 750 mm, given that the heat of vaporisation of ether is 369·86 joules per gram.

Solution : Substituting the given data in Eq. 172, we have

$$\ln \frac{750\,\text{mm}}{760\,\text{mm}} = \frac{(369{\cdot}86\,\text{J g}^{-1})(74\,\text{g mol}^{-1})}{8{\cdot}314\,\text{J K}^{-1}\text{mol}^{-1}}\left[\frac{T_2 - 306{\cdot}5\,\text{K}}{306{\cdot}5\ \text{K}\,(T_2)}\right]$$

$$\therefore \quad T_2 = 305{\cdot}9\ \text{K} = 32{\cdot}9°\text{C}$$

The Clapeyron–Clausius Equation for Solid $\rightleftharpoons$ Vapour Equilibria. The Clapeyron equation for solid $\rightleftharpoons$ vapour equilibrium may be put as

$$\frac{dP}{dT} = \frac{\Delta H_{sub}}{T(V_g - V_s)} \qquad ...(173)$$

where ΔH_{sub} stands for the molar heat of sublimation of the substance. Since the molar volume of a substance in the gaseous state is very much greater than that in the solid state, $V_g - V_s$ can be safely taken as V_g. Eq. 173 can thus be easily integrated, as before, to give the following expression :

$$\ln \frac{P_2}{P_1} = \frac{\Delta H_{sub}}{R}\left[\frac{T_2 - T_1}{T_1 T_2}\right] \qquad ...(174)$$

Eq.174 can be put to the same use for solid $\rightleftharpoons$ vapour equilibria as Eq.172 for liquid $\rightleftharpoons$ vapour equilibria.

Application of Clapeyron-Clausius Equation for Solid $\rightleftharpoons$ Liquid Equilibria. The Clapeyron equation (166) for solid $\rightleftharpoons$ liquid equilibrium cannot be integrated easily since V_s cannot be ignored in comparison with V_l. Also the laws of liquid state are not so simple as those for gaseous state. However, this equation as such can be used for calculating the effect of pressure on the melting point of a solid and also for calculating heats of fusion from vapour pressure data obtained at different temperatures.

Example 27. Calculate the value of *dT/dP* for the ice $\rightleftharpoons$ water system at 0°C. ΔH_{fus} for water is 6007·8 J·mol^{-1} (1 J=9·87×10^{-3} dm^3 atm); molar volume of water=18·00 cm^3 and that of ice 19·63 cm^3).

Solution : From the Clapeyron equation (166),

$$\frac{dP}{dT} = \frac{\Delta H_{fus}}{T(V_l - V_s)}$$

V_l = 18·0 cm^3 mol^{-1} = 0·01800 dm^3 mol^{-1}; V_s = 19·63 cm^3 mol^{-1} = 0·01963 dm^3 mol^{-1}

1 J = 9·87×10^{-3} dm^3 atm

Hence, $$\frac{dT}{dP} = \frac{T(V_l - V_s)}{\Delta H_{fus}}$$

$$= \frac{(273\,\text{K})(0{\cdot}01800\ \text{dm}^3\,\text{mol}^{-1} - 0{\cdot}01963\ \text{dm}^3\,\text{mol}^{-1})}{(6007{\cdot}8\,\text{J mol}^{-1})(9{\cdot}87\times10^{-3}\,\text{dm}^3\,\text{atm J}^{-1})} = -0{\cdot}0075\ \text{K atm}^{-1}$$

Thus, the melting point of ice *decreases* by 0·0075° if pressure is *increased* by 1 atm. It is because of this reason that ice-skating becomes possible. The weight of the skater would exert appreciable pressure on ice due to very small area of the blades of the skates so that if the temperature is not too low, ice would melt. The film of water formed between the skates and ice acts as a lubricant to facilitate movement over ice.

Example 28. The pressure exerted on ice by a skater weighing 330 kg is about 1000 atm. Calculate the depression in freezing point, assuming ΔH_{fus} to remain constant.

Solution : As shown in the last example, the melting point of ice is lowered by 0·0075 K if the pressure is increased by 1 atm. Hence, the depression in freezing point caused by a pressure of 1000 atm would be

$$\Delta T = -(0{\cdot}0075\ \text{K atm}^{-1})\ (1000\ \text{atm}) = -7{\cdot}42\ \text{K}$$

Example 29. At what pressure will ice melt at –1·0°C assuming that ΔH_{fus} is independent of pressure and is equal to 6·0095 kJ mol^{-1} ? Given that the density of water is 0·9998 g cm^{-3} and that of ice is 0·917 g cm^{-3}.

Solution : Density of water = 0·9998 g cm^{-3} = 0·9998×10^{-3} kg m^{-3}

Density of ice = 0·917 g cm^{-3} = 0·917×10^{-3} kg m^{-3}

Molar mass of water = 18·015 g mol^{-1} = 18·015×10^{-3} kg mol^{-1}

$$\frac{dP}{dT} = \frac{\Delta H_{fus}}{T(V_l - V_s)} \qquad \text{(Eq.166)}$$

$$\therefore \quad \int_{P_1}^{P_2} dP = \frac{\Delta H_{fus}}{V_l - V_s}\int_{T_1}^{T_2}\frac{dT}{T}$$

or $$P_2 - P = \frac{\Delta H_{fus}}{V_l - V_s}\ln\frac{T_2}{T_1}$$

T_1 = 0°C = 273 K ; T_2 = – 1°C = 272 K

1 atm = 101,325 N m^{-2} = 101,325 J m^{-3}

$$V_l = \frac{18{\cdot}015\times10^{-3}\,\text{kg mol}^{-1}}{0{\cdot}9998\times10^{3}\,\text{kg m}^{-3}} = 18{\cdot}0186\times10^{-6}\,\text{m}^3\,\text{mol}^{-1}$$

$$V_s = \frac{18{\cdot}015\times10^{-3}\,\text{kg mol}^{-1}}{0{\cdot}917\times10^{3}\,\text{kg m}^{-3}} = 19{\cdot}645\times10^{-6}\,\text{m}^3\,\text{mol}^{-1}$$

$$\Delta H_{fus} = \frac{6009{\cdot}5\,\text{J mol}^{-1}}{101{,}325\,\text{J m}^{-3}\,\text{atm}^{-1}} = 5{\cdot}9309\times10^{-2}\,\text{m}^3\,\text{atm mol}^{-1}$$

$$\ln\frac{T_2}{T_1} = \frac{V_l - V_s}{\Delta H_f}(P_2 - P_1) = \frac{(18{\cdot}0186\times10^{-6} - 19{\cdot}645\times10^{-6})\,\text{m}^3\,\text{mol}^{-1}}{5{\cdot}9309\times10^{-2}\,\text{m}^3\ \text{atm mol}^{-1}}(P_2 - 1)\text{atm}$$

$$\therefore \quad \ln\frac{272\,\text{K}}{273\,\text{K}} = (-2{\cdot}74\times10^{-5})\ (P_2 - 1)\ \text{atm}$$

or $$(P_2 - 1) = \frac{-0{\cdot}00367}{-2{\cdot}74\times10^{-5}} = 133{\cdot}94\ \text{atm}$$

$$\therefore \quad P_2 = 133{\cdot}94\ \text{atm}$$

Example 30. The vapour pressure of ice $\rightleftharpoons$ water system at 0·0075°C is 4·58 mm and at 0°C is 759·80 mm of mercury. Calculate the molar heat of fusion of ice, given that the specific volumes of ice and water at 0°C are 1·0907 cm^3 and 1·0001 cm^3, respectively. Density of mercury at 0°C=13·6 g cm^{-3}.

Solution : $$\frac{dP}{dT} = \frac{\Delta H_{fus}}{T(V_l - V_s)} \qquad \text{(Eq. 166)}$$

$$dP = \frac{75{\cdot}52\,\text{cm Hg}}{76\,\text{cm Hg}}\times101325\,\text{N m}^{-2} = 100685\ \text{N m}^{-2}$$

V_s = 18×1·0907×10^{-6} m^3 mol^{-1}; V_l = 18×1·0001×10^{-6} m^3 mol^{-1} ; T = 273 K, dT = 0·0075 K

Since vapour pressure of ice increases on decreasing the temperature, *dP/dT* will have a *negative sign.* Substituting various values in Eq. 166, we have

$$\Delta H_{fus} = -\frac{(100685\,\text{N m}^{-2})(273\,\text{K})(-18\times0{\cdot}0906\times10^{-6})\ \text{m}^3\,\text{mol}^{-1}}{0{\cdot}0075\ \text{K}} = 5977{\cdot}6\ \text{J mol}^{-1} \qquad (\text{N m} = \text{J})$$

$$= 5{\cdot}978\ \text{kJ mol}^{-1}$$

Fugacity And Activity

Concept of Fugacity. The great American chemist, G.N. Lewis (1875-1946) introduced the concept of fugacity for representing the actual behaviour of real gases which is distinctly different from the behaviour of ideal gases.

Variation of free energy with pressure at constant temperature is given by Eq. 124, *viz.*,

$$(\partial G/\partial P)_T = V \qquad ...(175)$$

This equation is applicable to all gases whether ideal or non-ideal.

If one mole of a gas is under consideration, then V refers to molar volume. For an ideal gas, the above equation may be written as

$$(dG)_T = RT\,dP/P \qquad ...(176)$$

and for n moles as, $$(dG)_T = nRT\,dP/P = nRTd\ (\ln P) \qquad ...(177)$$

Integration of Eq. 177 yields

$$G = G^* + nRT \ln P \quad ...(178)$$

where G^*, the integration constant, is the free energy of n moles of the ideal gas at temperature T when the pressure P is unity.

Eq. 178 gives the free energy of an ideal gas at temperature T and pressure P.

Integration of Eq. 177 between pressures P_1 and P_2, at constant temperature T, yields

$$\Delta G = \int_{P_1}^{P_2} nRT \frac{dP}{P} = nRT \ln \frac{P_2}{P_1} \quad ...(179)$$

The corresponding equation for 1 mole of the gas would be

$$\Delta G = RT \ln (P_2/P_1) \quad ...(180)$$

Eqs. 178 and 180 are not valid for real gases since V is not exactly equal to RT/P.

In order to make these simple equations applicable to real gases, Lewis introduced a new function f, called **fugacity function.** It takes the place of P in Eq. 177 which, for real gases, may be expressed as

$$(dG)_T = nRT\, d\,(\ln f) \quad ...(181)$$

and Eq. 178 may be represented as

$$G = G^* + nRT \ln f \quad ...(182)$$

where G^* is the free energy of n moles of a real gas when its fugacity happens to be 1.

Thus, fugacity is a sort of **'fictitious pressure'** which is used in order to retain for real gases simple forms of equations which are applicable to ideal gases only.

Eq. 182, evidently, gives the **free energy of a real gas** at temperature T and pressure P at which its fugacity can be taken as f.

Eq. 181, on integration between fugacities f_1 and f_2, at constant temperature T, yields

$$\Delta G = nRT \ln (f_2/f_1) \quad ...(183)$$

The corresponding equation for 1 mole of the gas would be

$$\Delta G = RT \ln (f_2/f_1) \quad ...(184)$$

As discussed above, Eqs. 183 and 184 are applicable to real gases.

Example 31. Calculate the free energy change accompanying the compression of 1 mole of a gas at 57°C from 25 to 200 atm. The fugacities of the gas at 57°C may be taken as 23 and 91 atm, respectively, at pressures of 25 and 200 atm.

Solution : We may, in the first instance, calculate ΔG by using Eq. 179, involving pressures. Thus,

$$\Delta G = nRT \ln P_2/P_1 = 1 \text{ mol } (8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1}) (330 \text{ K}) \ln \frac{200 \text{ atm}}{25 \text{ atm}} = 5702{\cdot}8 \text{ J}$$

For more accurate value, we should use Eq. 183 involving fugacities. Thus,

$$\Delta G = nRT \ln f_2/f_1 = 1 \text{ mol } (8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1}) (330 \text{ K}) \ln \frac{91 \text{ atm}}{23 \text{ atm}} = 3730{\cdot}0 \text{ J}$$

Fugacity at low pressures. The ratio f/P, where P is the actual pressure, approaches unity when P approaches zero since in that case a real gas approximates to ideal behaviour. The fugacity function, therefore, may be defined as

$$\lim_{P \to 0} f/P = 1 \quad ...(185)$$

Evidently, at low pressures, fugacity is equal to pressure. The two terms differ materially only at high pressures.

Determination of Fugacity of a Gas. Eq. 182, for one mole of a gas, may be put as

$$G = G^* + RT \ln f \quad ...(186)$$

Differentiation of Eq. 186 with respect to pressure at constant temperature and constant number of moles of the various constituents, *i.e.*, in a *closed system*, gives

$$\left(\frac{\partial G}{\partial P}\right)_T = RT\left(\frac{\partial (\ln f)}{\partial P}\right) \quad ...(187)$$

Since $(\partial G/\partial P)_T = V$, (Eq. 124)

it follows that

$$\left(\frac{\partial (\ln f)}{\partial P}\right)_T = \frac{V}{RT} \quad ...(188)$$

Thus, at a definite temperature, Eq. 188 may written as

$$RT\, d\,(\ln f) = V dP \quad ...(189)$$

Since one mole of the gas is under consideration, V is the molar volume of the gas.

Knowing that for an ideal gas, $V=RT/P$, the quantity α, *defined as departure from ideal behaviour* at a given temperature, is given by

$$\alpha = RT/P - V \quad ...(190)$$

Multiplying by dP throughout, we get

$$\alpha\, dP = RT\,(dP/P) - V dP \quad ...(191)$$

Combining Eqs. 189 and 190, we have

$$RTd\,(\ln f) = RT\, dP/P - \alpha\, dP$$

or

$$d(\ln f) = d\,(\ln P) - \alpha\, dP/RT \quad ...(192)$$

Integrating Eq. 192 between pressures 0 and P, we have

$$\ln \frac{f}{P} = -\frac{1}{RT} \int_0^P \alpha (dP) \quad ...(193)$$

Now, α, as given by Eq. 190, can be determined experimentally, at different pressures. These values of α are then plotted against corresponding pressures, as shown in Fig. 6. The area under the curve between pressure $P=0$ and any given pressure P, yields the value of the integral $\int_0^P \alpha (dP)$, as illustrated by the shaded portion in Fig. 6. Incorporating this value in Eq. 193, the fugacity f can be evaluated at any given pressure P of the gas.

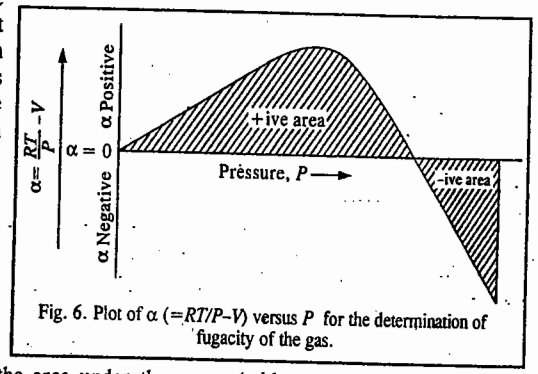

Fig. 6. Plot of α ($=RT/P-V$) versus P for the determination of fugacity of the gas.

Since α, the departure from ideal behaviour, can be both positive as well as negative (recall behaviour of real gases), the area under the curve (with respect to the pressure axis) can be both positive as well as negative. Thus, the fugacity of the gas can be both less than or more than the pressure P.

As is evident from Fig 6, the area and hence the value of $\int_0^P \alpha (dP)$ is positive at low pressures and negative at very high pressures. Hence, in accordance with Eq. 193, fugacity f of the gas would be less than the pressure P at low pressures and more than the pressure P at very high pressures. This is borne out by the data given in Table 1 for nitrogen gas at various pressures at 0°C.

TABLE 1

Fugacities of Nitrogen Gas at Various Pressures at 0°C

Pressure (atm)	Fugacity (atm)
50	48·9
100	96·7
200	194·2
400	424·4
800	1191
1000	1834

It may be recalled that for hydrogen and helium, PV is greater than RT for all pressures at ordinary temperatures. Hence, fugacity in these gases always remains greater than the pressure. This is borne out by the data given in Table 2 for fugacities of hydrogen gas at 0°C.

TABLE 2
Fugacities of Hydrogen Gas at Various Pressures at 0°C

Pressure (atm)	Fugacity (atm)
25	25·4
50	51·5
100	106·1
200	225·8
500	685
1000	1899

Calculation of fugacity at low pressures. It has been found that the experimental value of α at low pressure assumes almost a constant value. Under such conditions, therefore, Eq. 193 becomes

$$\ln f/P = -\alpha P/RT \qquad ...(194)$$

Now, at low pressures, since gases tend to be *ideal*, $f \approx P$.

or $$f/P \approx 1 \qquad ...(195)$$

Making use of the fact that $\ln x$ is approximately equal to $x - 1$ when x approaches unity, we have

$$\ln f/P = f/P - 1$$

Hence,
$$f/P = 1 + \ln f/P \qquad ...(196)$$
$$= 1 - \alpha P/RT \qquad \text{(vide Eq.194)}$$
$$= PV/RT \qquad \text{(vide Eq. 190)}$$

Hence, $$f = P^2V/RT \qquad ...(197)$$

This equation is useful in calculating fugacity at moderately low pressures.

Example 32. For a van der Waals gas, express the fugacity as a function of V, T, R and the van der Waals constants.

Solution : From Eq. 189, for one mole of the gas, $RT\, d \ln f = VdP$ ...(i)

Integrating Eq. *(i)*, $RT \int d \ln f = \int VdP$ ...(ii)

It is advisable to change the variable on the right-hand side of Eq. *(ii)* by resorting to integration by parts. Accordingly,

$$\int VdP = PV - \int VdP \qquad ...(iii)$$

Now, for one mole of the van der Waals gas,

$$P = \frac{RT}{V-b} - \frac{a}{V^2} \qquad \text{(where } V \text{ is the molar volume)} \qquad ...(iv)$$

Hence, from Eqs. *(ii)*, *(iii)* and *(iv)*,

$$RT \ln f = PV - \int \left[\frac{RT}{V-b} - \frac{a}{V^2}\right] dV = RT - RT \ln (V-b) - a/V + C \qquad ...(v)$$

where C is the integration constant.

To evaluate C, we recall that $f \to P$ as $P \to 0$. Also, as $P \to 0$ at constant T, $V \to \infty$ so that $(V - b) \to V$ and $1/V \to 0$. Hence,

$$RT \ln P = RT - RT \ln V + C = RT - RT \ln (RT/P) + C = RT - RT \ln RT + RT \ln P + C$$

$$\therefore \quad C = RT \ln RT - RT \qquad ...(vi)$$

Substituting for C in Eq. *(v)*, we get

$$RT \ln f = PV - RT \ln (V-b) - (a/V) + RT \ln RT - RT$$
$$= PV - RT + RT \ln (RT/V-b) - (a/V) \qquad ...(vii)$$

Rearranging the van der Waals equation after expansion neglecting the term ab/V^2 and later the term a/V^2 as well, we obtain

$$PV - RT = \frac{RTb}{V-b} - \frac{a}{V} \qquad ....(viii)$$

Hence, $$\ln f = b/(V-b) + \ln (RT/(V-b)) - 2a/(RTV) \qquad ...(ix)$$

which is the **required expression for fugacity.**

Fugacity of a Gas in a Gaseous Mixture. Remembering that for one mole of a pure substance, the free energy (G) is identical with chemical potential μ, Eq. 181 for one mole of any gaseous component i of a gaseous mixture may be written as

$$d\mu_i = RT\, d (\ln f_i) \qquad ...(198)$$

and Eq. 182 may be written as

$$\mu_i = \mu_i^* + RT \ln f_i \qquad ...(199)$$

where μ_i^* is the chemical potential of the gaseous component i at its unit fugacity.

Fugacity of a Liquid Component in a Liquid Mixture. Eq. 199 is valid not only for the fugacity of a gas in a gaseous mixture but also for the fugacity of a pure liquid in a liquid mixture. This easily follows from the following discussion.

As is well known, in the case of phase equilibria, the chemical potential of any given component is the same in all phases. Thus, if there are three phases a, b and c, containing a component i, then, at equilibrium,

$$(\mu_i)_a = (\mu_i)_b = (\mu_i)_c$$

Consider, for example, a liquid i in equilibrium with its vapour. The chemical potential of the liquid, $(\mu_i)_l$, is then equal to the chemical potential of its vapour, $(\mu_i)_g$, *i.e.*,

$$(\mu_i)_l = (\mu_i)_g$$

Now, according to Eq. 182, chemical potential of the vapour may be written as

$$(\mu_i)_g = (\mu_i^*)_g + RT \ln f_i \qquad ...(200)$$

where, as before $(\mu_i^*)_g$ is the chemical potential of the vapour when its fugacity is equal to 1. Therefore, chemical potential of a liquid may, evidently, be written as

$$(\mu_i)_l = (\mu_i^*)_l + RT \ln f_i \qquad ...(201)$$

where $(\mu_i^*)_l$ stands for the chemical potential of the liquid when its fugacity is equal to 1.

It follows from the above discussion that fugacity of a pure liquid would be the same as that of its vapour in equilibrium with it, at a given temperature.

Physical significance of fugacity. In order to understand the physical significance of the term fugacity, consider a system consisting of liquid water in contact with its vapour. Water molecules in the liquid phase will have a tendency to escape into the vapour phase by evaporation while those in the vapour phase will have a tendency to escape into the liquid phase by condensation. At equilibrium, the two escaping tendencies will be equal. It is now accepted that each substance in a given state has a tendency to escape from that state. This escaping tendency was termed by Lewis as **fugacity.**

Concept of Activity. It may be pointed out that since the absolute value of free energy or chemical potential is not known, it is not possible to evaluate μ_i^* of a substance. This difficulty has been overcome by referring all free energy or chemical potential measurements for any given substance to a standard reference point. Let μ_i be the chemical potential of a substance i in *pure state* and let f_i be its fugacity. Eq. 199 may then be put as

$$\mu_i = \mu_i^* + RT \ln f_i^\circ \qquad ...(202)$$

Let μ_i be the chemical potential of the same substance in some other state. Then,

$$\mu_i = \mu_i^* + RT \ln f_i \qquad ...(203)$$

The *difference* between chemical potential of a substance in *any state* and that in the *pure state* is given by

$$\mu_i - \mu_i^\circ = RT \ln (f_i/f_i^\circ) \quad \text{or} \quad \mu_i = \mu_i^\circ + RT \ln (f_i/f_i^\circ) \qquad ...(204)$$

We may introduce here a new term, **activity, *a***, and define it as

$$a = f/f^\circ \qquad ...(205)$$

or, for a substance i, as

$$a_i = f_i/f_i^\circ \qquad ...(206)$$

Activity of a substance *in any given state* is thus defined as *the ratio of the fugacity of the substance in that state to the fugacity of the same substance in the pure state.*

Eq. 204, therefore, reduces to

$$\mu_i = \mu_i^\circ + RT \ln a \qquad ...(207)$$

Let a system consisting of one mole of a substance change from a state in which its chemical potential (or free energy, both being identical since we are dealing with one mole of the substance) is μ_1, to another state in which its chemical potential is μ_2. The change in chemical potential, $\Delta\mu$, is then given by

$$\Delta\mu = \mu_2 - \mu_1 = (\mu^\circ + RT \ln a_2) - (\mu^\circ + RT \ln a_1)$$

or

$$\Delta\mu = RT \ln (a_2/a_1) = \Delta G \qquad ...(208)$$

Comparing the above equation with that for an ideal gas, *viz.*,

$$\Delta G = \Delta\mu = RT \ln (P_2/P_1) \qquad \text{(Eq. 180)}$$

we see that for *real gases, activity replaces pressure.* Thus, activity of a gas, like fugacity, *serves as a thermodynamic counterpart of gas pressure.*

Activity Coefficient. For real gases, activity is proportional to pressure, *i.e.*, $a \propto P$ or $a = \gamma P$ where γ is known as the activity coefficient.

Example 33. The activity of 2·5 moles of a substance changes from 0·05 to 0·35. What would be the change in its free energy at 27°C ?

Solution : $\Delta G = RT \ln a_2/a_1$ (Eq. 208)

$\therefore$ For n moles, $\Delta G = nRT \ln a_2/a_1 = (2{\cdot}5 \text{ mol})\ (8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1})\ (300 \text{ K})\ \ln \dfrac{0{\cdot}35}{0{\cdot}05} = \mathbf{12133{\cdot}6\ J}$

Reference States or Standard States. It may be emphasised again that there is no means of finding absolute value of free energy (G) or chemical potential (μ) of any substance. It is necessary, therefore, to make such measurements with reference to the value obtained for some convenient though arbitrary reference state called standard state.

The standard state for a gas at any given temperature is defined *as that state in which the fugacity of the gas is equal to unity.* Since $a = f/f^\circ$, it follows that if $f^\circ = 1$, $a = f$. Evidently, the standard state for a gaseous component is such that

$$f_i = a_i = 1 \qquad ...(209)$$

The standard state for a liquid *is the pure state of* the liquid at one atmosphere pressure at any given temperature. In this state of the liquid, $f = f^\circ$ and $a = 1$. The standard state for a liquid component i in a liquid solution is the pure state of the component such that $a_i = 1$.

The standard state for a solid is the pure state of the solid at one atmosphere pressure at any given temperature. In this state, its *activity* $a = 1$.

It is pertinent to conclude this chapter with the remarks of the great philosopher of thermodynamics, P.W. Bridgman. It was noted by Bridgman, a great experimental thermodynamicist, that the laws of thermodynamics convey a stronger sense of their human origins than other laws of science.

> It must be admitted, I think, that the laws of thermodynamics have a different feel from most of the other laws of physics. There is something more palpably verbal about them—they smell more of their human origin. The guiding motif is strange to most of physics : namely, a capitalizing of the universal failure of human beings to construct perpetual motion machines of either the first or the second kind. Why should we expect nature to be interested either positively or negatively in the purposes of human beings, particularly purposes of such unblushingly economic tinge?

I. Review Questions

1. What is a cyclic process ? Describe in detail the Carnot reversible cycle for establishing the maximum convertibility of heat into work.
2. What is meant by efficiency of a heat engine ? Derive an expression for the same.
3. Show that $\Delta S = q_{rev}/T$.
4. Derive an expression for the entropy change accompanying the isothermal expansion of an ideal gas.
5. Show that the entropy of a system and surroundings taken together remains constant in a reversible process while the same increases in an irreversible process.
6. Comment on the statement. "*Entropy of the universe is always increasing.*"
7. Derive expressions for the entropy change accompanying variation of *(i)* temperature and volume *(ii)* temperature and pressure.
8. Derive an expression for the entropy of a mixture of ideal gases.
9. Define the terms Gibbs free energy and Helmholtz free energy. How is each of these terms related to maximum work that can be done by a system during a given change ? Discuss the variation of ΔG with variation in *(i)* temperature and pressure *(ii)* pressure and volume.
10. Derive Gibbs–Helmholtz equation for a process at constant pressure and at constant volume.
11. What is meant by chemical potential ? Derive the Gibbs-Duhem equation.
12. Show that in the case of a mixture of ideal gases, the chemical potential of any constituent is given by the expression :
$$\mu_i = \mu_{i(p)}^\circ + RT \ln p_i \quad \text{or} \quad \mu_i = \mu_{i(c)}^\circ + RT \ln c_i$$
where p_i and c_i represent the partial pressure and concentration, respectively, of the constituent concerned.
13. Derive the Clapeyron equation in the form $dP/dT = \Delta H_v/(TV_g)$.
14. Derive the Clapeyron equations in the integrated form for liquid $\rightleftharpoons$ vapour and solid $\rightleftharpoons$ vapour equilibria.
15. Derive the Clapeyron–Clausius equation.
16. Explain the terms fugacity and activity. How are they related to chemical potential ?
17. Explain clearly why the fugacity of a gas can both be less or more than the pressure. Explain why the fugacity of helium or hydrogen is always more than the pressure.

II. Problems

1. A Carnot engine absorbs 1,000 J of heat from a reservoir at 127°C and rejects 600 J of heat during each cycle. Calculate *(i)* the efficiency of the engine *(ii)* the temperature of the sink and *(iii)* the amount of useful work done during each cycle. **[Ans. *(i)* 40% *(ii)* – 33°C *(iii)* 400 J]**
2. A Carnot engine converts one-sixth of heat input into work. When the temperature of the sink is reduced by 62°C, its efficiency is doubled. Find the temperature of the source and the sink. **[Ans. 372 K, 310 K]**
3. A Carnot engine has the same efficiency *(i)* between 100 K and 500 K and *(ii)* between T K and 900 K. Calculate the temperature T of the sink. **[Ans. 180 K]**

4. Calculate ΔS if one mole of an ideal gas is heated from 27°C to 227°C *(i)* at constant volume and *(ii)* at constant pressure. **[Ans. 8·64 J K^{-1}; 14·4 J K^{-1}]**
5. 10 moles of an ideal gas expand reversibly from a volume of 5 dm^3 to 15 dm^3 at a temperature of 25°C. Calculate the change in entropy of the gas. **[Ans. 91·34 J K^{-1}]**
6. One mole of an ideal gas expands reversibly from a volume of 5 dm^3 and temperature 25°C to a volume of 10 dm^3 and temperature - 23°C. Calculate the entropy change of the process. (C_v=3/2 R) **[Ans. 3·57 J K^{-1} mol^{-1}]**
7. One mole of an ideal gas expands reversibly from a temperature of 298 K and pressure 1 atm to a temperature of 273 K and pressure of 400 mm Hg. Calculate ΔS for the process. C_v=3/2 R. **[Ans. 3·55 J K^{-1} mol^{-1}]**
8. Calculate the entropy change if 2 moles of N_2, 3 moles H_2 and 2 moles of NH_3 are mixed at constant temperature, assuming that no chemical reaction is occurring. **[Ans. 62·80 J K^{-1}]**
9. The free energy change (ΔG) for a given process is -79·8 kJ at 20°C and -77·4 kJ at 30°C. Calculate the change in enthalpy of the process at 25°C. **[Ans. -150·12 kJ]**
10. Calculate the free energy change accompanying the compression of 1 mole of a gas at 25°C from 20 to 200 atm. The fugacities of the gas be taken as 18 and 120 atm, respectively, at pressures of 18 and 200 atm. **[Ans. 4700 J]**
11. Calculate the fugacity of H_2 (g) at 100°C and 300 atm, assuming that it is a van der Waals gas, with a = 0·244 dm^6 atm mol^{-2}, b=0·0266 dm^3 mol^{-1} and V_m=0·119 dm^3 mol^{-1}. **[Ans. 386·6 atm]**
12. Two Carnot engines A and B have their sources at 400 K and 350 K and sinks at 350 K and 300 K, respectively. Which is more efficient and by how much ? **[Ans. B, 1·8%]**
13. Calculate ΔS for the following phase changes :

    (i) H_2O (s, 1 atm, 273 K) ⟶ H_2O (liq, 1 atm, 273 K)

    (ii) H_2O (liq, 1 atm, 273 K) ⟶ H_2O (liq, 1 atm, 373 K)

    (iii) H_2O (liq, 1 atm, 373 K) ⟶ H_2O (vap, 1 atm, 273 K)

    Given : ΔH_f = 406·03 kJ mol^{-1} ; ΔH_{vap} = 40·6 kJ mol^{-1} ; $C_{P,\,liq}$ = 75·3 J K^{-1} mol^{-1}

    [Ans. *(i)* 22·07 J K^{-1} mol^{-1} *(ii)* 23·50 J K^{-1} mol^{-1} *(iii)* 108·9 J K^{-1} mol^{-1}]
14. Calculate ΔS°_{298} for the following reaction : $2SO_2(g) + O_2(g) \longrightarrow 2SO_3(g)$.

    Given : S°_{298} values for SO_2, O_2 and SO_3 are 248·53 J K^{-1}, 205·03 J K^{-1} and 256·23 J K^{-1}, respectively.

    [Ans. - 189·63 J K^{-1}]
15. Calculate ΔS when 4 kJ of heat is transferred from a reservoir at 500 K to a reservoir at 300 K. **[Ans. 5·33 J K^{-1}]**
16. Calculate the zero-point entropy for CO crystal at 0 K. **[Ans. 5·76 J K^{-1} mol^{-1}]**
17. Calculate ΔS° for the reaction

    $2SO_2(g) + O_2(g) \longrightarrow 2SO_3(g)$

    at 500 K. Given that the temperature-dependence of molar heat capacities of the species is as follows :

    $C_p^\circ\,(O_2) = 25{\cdot}72 + 12{\cdot}98\times10^{-3}\,T - 38{\cdot}62\times10^{-7}\,T^2$

    $C_p^\circ\,(SO_2) = 49{\cdot}77 + 4{\cdot}56\times10^{-3}\,T$

    $C_p^\circ\,(SO_3) = 24{\cdot}43 + 98{\cdot}48\times10^{-3}\,T - 405{\cdot}30\times10^{-7}\,T^2$ **[Ans. 200·06 J K^{-1} mol^{-1}]**
18. Calculate ΔA for the process

    2He (g, 27°C, 1 atm) ⟶ 2He (g, 27°C, 5 atm),

    assuming that the process is reversible. **[Ans. 8·029 kJ]**

CHAPTER 16

THE THIRD LAW OF THERMODYNAMICS

First and Second laws of thermodynamics have led to new concepts of energy content and entropy. The Third law, however, does not lead to any new concept. It only places a limitation on the value of the entropy of a crystalline solid. Some scientists hesitate to call it a 'law' at all. All the same, its applications do lead to conclusions which are borne out by experience and hence, in accordance with scientific terminology, it is a law, like the other two laws of thermodynamics.

Nernst Heat Theorem. Before passing on to the Third law of thermodynamics, we may consider briefly the Nernst heat theorem. This is an old generalisation but still has relevance as the forerunner of the Third law of thermodynamics.

From the Gibbs-Helmholtz equation, *viz.*,

$$\Delta G - \Delta H = T\,(\partial(\Delta G)/\partial T)_P \qquad ...(1)$$

where ΔG is the change in free energy and ΔH is the change in enthalpy accompanying any process including a chemical reaction, it is seen that at the absolute zero (*i.e.*, T=0), ΔG=ΔH.

Richards, by measuring EMFs of cells at different temperatures, found that the value of $\partial(\Delta G)/\partial T$ decreases with decrease in temperature and, therefore, concluded that ΔG and ΔH tend to approach each other more and more closely as the temperature is lowered. Nernst, relying on this data, made an important suggestion that *the value of* $\partial(\Delta G)/\partial T$ *approaches zero gradually* as *the temperature is lowered towards the absolute zero.* This is known as the **Nernst heat theorem.** According to this theorem, ΔG and ΔH not only become equal to each other at absolute zero but also approach each other asymptotically, that is, gradually at temperatures close to absolute zero. This is illustrated in Fig. 1. Thus, the approach of ΔG and ΔH towards each other is as represented by the full lines and not as represented by the dotted lines.

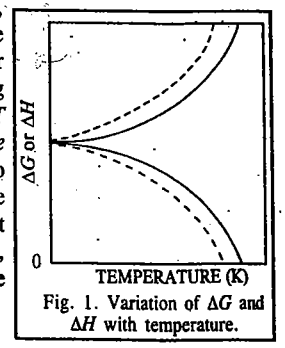

Fig. 1. Variation of ΔG and ΔH with temperature.

Mathematically, the theorem may be expressed as

$$\underset{T\to0}{\text{Lt}}\,[\partial(\Delta G)/\partial T]_P = \underset{T\to0}{\text{Lt}}\,[\partial(\Delta H)/\partial T]_P = 0 \qquad ...(2)$$

where Lt stands for the limiting value.

We also know from the Second law of thermodynamics that

$$(\partial(\Delta G)/\partial T)_P = -\,\Delta S \qquad ...(3)$$

and $$(\partial(\Delta H)/\partial T)_P = \Delta C_P \quad \text{(Kirchhoff equation)} \qquad ...(4)$$

where ΔS is the entropy change of the reaction and ΔC_p is the difference in the heat capacities of the products and the reactants.

It follows from Eqs. 2, 3 and 4 that

$$\lim_{T\to 0} \Delta S = 0 \quad \ldots(5)$$

and

$$\lim_{T\to 0} \Delta C_P = 0 \quad \ldots(6)$$

The significance of these equations is that the entropy change of a reaction tends to approach zero and that the difference between the heat capacities of products and reactants also tends to approach zero as the temperature is lowered towards the absolute zero.

The Nernst theorem holds good only in the case of pure solids.

Third Law of Thermodynamics. According to Eq. 6, ΔC_P tends to approach zero at 0 K. This means that at absolute zero, the heat capacities of products and reactants in solid state are identical. This leads to the suggestion that at absolute zero, all substances have the same heat capacity. The quantum theory, as applied to heat capacities of solids, has shown that heat capacities of solids tend to become zero at 0 K. The Nernst heat theorem may, therefore, be written as

$$\lim_{T\to 0} C_P = 0 \quad \ldots(7)$$

According to Eq. 5, ΔS becomes zero at absolute zero, *i.e.*, the entropy change of a process involving solids becomes zero at 0 K. In other words, the absolute entropies of products and reactants in the solid state are identical. Planck, therefore, suggested that entropies of all pure solids approach zero at 0 K, *i.e.*,

$$\lim_{T\to 0} S = 0 \quad \ldots(8)$$

This statement has led to the following enunciation of the **Third law of thermodynamics :**

At the absolute zero of temperature, the entropy of every substance may become zero and it does become zero in the case of a perfectly crystalline solid.

In a perfect crystal, at absolute zero temperature, there is a state of perfect order, *i.e.*, zero disorder and hence of zero entropy. Walther Nernst (1864–1941), the German chemist, was awarded the 1920 Chemistry Nobel Prize for his work in thermochemistry. He also did pioneering work in electrochemistry.

Determination of Absolute Entropies of Solids, Liquids and Gases. We know that for an infinitesimally small change of state of a substance or a system, the entropy change is given by

$$dS = dq/T \quad \ldots(9)$$

If the change takes place at constant pressure, then

$$(\partial S)_P = (\partial q)_P/T \quad \ldots(10)$$

$$\therefore \quad (\partial S/\partial t)_P = (\partial q/\partial T)_P \times 1/T \quad \ldots(11)$$

By definition,

$$(\partial q/\partial T)_P = C_P \quad \ldots(12)$$

$$\therefore \quad (\partial S/\partial T)_P = C_P \times 1/T \quad \ldots(13)$$

or at constant pressure, $dS = (C_P/T)dT \quad \ldots(14)$

For a perfectly crystalline substance, the absolute entropy $S=0$ at $T=0$. Therefore, we may write

$$\int_{S=0}^{S=S} dS = \int_{T=0}^{T=T} (C_P/T)dT \quad \ldots(15)$$

or

$$S_T = \int_0^T \frac{C_P dT}{T} = \int_0^T C_P \, d(\ln T) \quad \ldots(16)$$

where S_T is the *absolute entropy* of the crystalline solid under examination at the temperature T.

The integral in Eq. 16 can be evaluated by measuring C_p at various temperatures between $T=0$ and the desired temperature T and then plotting C_p against ln T and determining the area under the curve between $T=0$ and the required temperature T. This area gives directly the value of S_T. Since it is not possible to obtain the value of C_P at the absolute zero, heat capacities are measured up to as low a temperature as possible, usually up to 15 K and the value at the absolute zero is obtained by extrapolation. This method, therefore, consists in determining heat capacities of the substance under examination at temperatures varying from approximately 15 K to the required temperature T. A graph of C_P *vs* ln T is then plotted and extrapolated to the absolute zero of temperature, as shown in Fig. 2. The area under the graph gives the required value of S_T, the absolute entropy of the substance at temperature T.

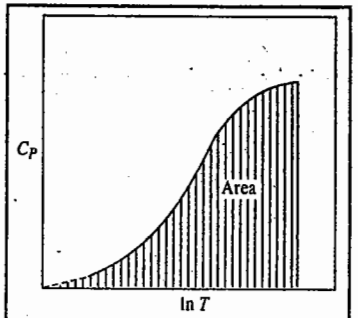

Fig. 2. Determination of absolute entropy.

Eq. 16. is thus written as follows :

$$S_T = \int_0^{T^*} C_P \frac{dT}{T} + \int_{T^*}^{T} C_P \frac{dT}{T} \quad \ldots(17)$$

where $0 < T^* < 15$ K.

The first integral is evaluated with the help of the Debye theory of heat capacities of crystalline substances according to which, at very low temperatures ($0 < T < 15$ K),

$$C_P \approx C_v \approx aT^3 \quad \ldots(18)$$

where a is an empirical constant. Eq. 18 is known as the **Debye T^3 law.**

Accordingly, Eq. 17 may be written as

$$S_T = \int_0^{T^*} aT^3 \frac{dT}{T} + \int_{T^*}^{T} C_P \frac{dT}{T} = \frac{1}{3}a(T^*)^3 + \int_{T^*}^{T} C_P \frac{dT}{T} \quad \ldots(19)$$

The second integral in Eq. 17 is evaluated from experimental measurements of heat capacities. Combining the heat capacity data with the enthalpy data on phase transformations, the absolute entropy of a substance, whether solid, liquid or gas, at temperature T, can be determined, as illustrated below. In every case, the start is made with the substance in the crystalline solid state at the absolute zero when its absolute entropy is taken as zero. Then the total absolute entropy of the substance in the given state and at a given temperature is taken as the sum of all the entropy changes that the substance has to undergo in order to acquire the given state at the given temperature starting from the crystalline solid at absolute zero.

Suppose, it is required to determine absolute entropy of a gas at 25°C under atmospheric pressure. This would be equal to the sum of the entropy changes involved in the following processes each of which is brought about reversibly. It is assumed for general discussion that the substance in solid state exists in two allotropic forms α and β.

1. Heating the crystalline solid from absolute zero to temperature T^*, where $0 < T^* < 15$ K and evaluating the entropy change with the aid of the Debye's theory. Let the entropy change be ΔS_1. Then,

$$\Delta S_1 = \int_0^{T^*} aT^3 \frac{dT}{T} = \frac{1}{3}a(T^*)^3 \quad \ldots(20)$$

2. Heating the crystalline solid from T^* to T_{tr}, where T_{tr} is the transition temperature at which the crystalline solid changes from allotropic form α to allotropic form β. The entropy change in this

process is given by

$$\Delta S_2 = \int_{T_r}^{T_{fus}} C_{P,s}(\alpha) dT \quad \text{...(21)}$$

where $C_{P,s}(\alpha)$ is the heat capacity of the solid in allotropic form α. ΔS_2 is evaluated by the integration of heat capacity data graphically, as described above.

3. Transition of the solid from allotropic form α to allotropic form β at the transition temperature T_{tr}. The entropy change in this process is given by

$$\Delta S_3 = \Delta H_{tr}/T_{tr} \quad \text{...(22)}$$

where ΔH_{tr} is the molar enthalpy of transition.

4. Heating the solid in allotropic form β up to its fusion point, T_{fus}. The entropy change in this process is given by

$$\Delta S_4 = \int_{T_{tr}}^{T_{fus}} C_{P,s}(\beta) dT \quad \text{...(23)}$$

where $C_{P,s}$ (β) is the heat capacity of the solid in allotropic form β.

5. Changing the solid in allotropic form β into the liquid state at the fusion temperature T_{fus}. The entropy change of this process (entropy of fusion) is given by

$$\Delta S_5 = \Delta H_{fus}/T_{fus} \quad \text{...(24)}$$

where ΔH_{fus} is the molar enthalpy of fusion of the substance.

6. Heating the liquid from its freezing point (T_{fus}) to its boiling point (T_b). The entropy change involved in this case is given by

$$\Delta S_6 = \int_{T_{fus}}^{T_b} C_{P,l}\, d\ln T \quad \text{...(25)}$$

where $C_{P,l}$ is the heat capacity of the substance in the liquid state. This can be evaluated by plotting $C_{P,l}$ *vs* ln T between temperatures T_{fus} and T_b and noting the area below the graph, as described before.

7. Changing the liquid into the gaseous state at the temperature T_b. The entropy change involved here, ΔS_7, is the molar entropy of vaporisation and is given by

$$\Delta S_7 = \Delta H_{vap}/T_b \quad \text{...(26)}$$

where ΔH_{vap} is the enthalpy of vaporisation per mole of the substance.

8. Heating the gas from T_b to the required temperature, *i.e.*, 25°C (298·15 K). The entropy change involved in this process is given by

$$\Delta S_8 = \int_{T_b}^{298\cdot15} C_{P,g}\, d\ln T \quad \text{...(27)}$$

where $C_{P,g}$ is the heat capacity of the substance in the gaseous state at constant pressure. ΔS_8 is evaluated by ploting $C_{P,g}$ *vs* ln T between temperatures T_b and 298·15 K and noting the area below the curve.

The absolute entropy of the gas at 298·15 K (25°C), S_T, is equal to the sum of all the entropy changes listed above. Thus,

$$S_T = \Delta S_1 + \Delta S_2 + \Delta S_3 + \Delta S_4 + \Delta S_5 + \Delta S_6 + \Delta S_7 + \Delta S_8$$

Table 1 gives the absolute entropy of HCl at 25°C determined by the procedure outlined above.

TABLE 1
Determination of Absolute Entropy of HCl at 25°C

Contribution	J K^{-1} mol^{-1}
1. Extrapolation from 0 to 15 K [using the Debye T^3 law]	1·3
2. $\int C_P\, d\ln T$ for solid α from 15 to 98·36 K	29·5
3. Transition, solid α ⟶ solid β, 1190/98·36	12·1
4. $\int C_P\, d\ln T$ for solid β from 98·36 to 158·91 K	21·1
5. Fusion, 1992/158·91	12·6
6. $\int C_P\, d\ln T$ for liquid from 158·91 to 188·07 K	9·9
7. Vaporization, 16150/188·07	85·9
8. $\int C_P\, d\ln T$ from 188·07 to 298·15 K	13·5
	$\therefore S^\circ_{298\cdot15} = 185\cdot9$

Absolute entropies of some of the elements and compounds in their standard states at 25°C, calculated from the Third law of thermodynamics, are given in Table 2.

Example 1. Show that the entropy of any substance at low temperatures ($0 < T < 20$ K), where Debye's relation for heat capacities of crystals is valid, is one-third of the molar heat capacity.

Solution : At low temperatures ($0 < T < 20$ K),

$$C_P \approx aT^3 \qquad \text{[Debye } T^3 \text{ law]}$$

According to Eq. 14, $dS = (C_p/T)\,dT$

$$\therefore \quad \int_0^T dS = \int_0^T (C_p/T)dT$$

or $$S_T - S_0 = \int_0^T \frac{aT^3}{T}dT = a\int_0^T T^2 dT = \frac{a}{3}T^3$$

or $$S_T = aT^3/3 \qquad [\because S_0 = 0]$$

Evidently, $S_T = C_P/3$. Hence, **proved.**

Example 2. C_v for uranium metal is 3·04 J K^{-1} mol^{-1} at 20 K. Calculate the absolute entropy of the metal at 20 K.

Solution : At low temperatures ($0 < T < 20$ K), $C_P = C_v = aT^3$ [Debye's T^3 law]

$$\therefore \quad a = C_v/T^3 = 3{\cdot}04 \text{ J K}^{-1} \text{ mol}^{-1}/(20 \text{ K})^3 = 38{\cdot}03\times10^{-5} \text{ J K}^{-4} \text{ mol}^{-1}$$

Hence, $$C_P = aT^3 = (38{\cdot}03\times10^{-5} \text{ J mol}^{-1} \text{ K}^{-4})\,T^3$$

From Eq. 14, $$dS = (C_p/T)dT = 38{\cdot}03\times10^{-5} \text{ J mol}^{-1} \text{ K}^{-4}\,T^2\,dT$$

or $$S_{20} - S_0 = aT^3/3 = 38{\cdot}03\times10^{-5} \text{ J K}^{-4} \text{ mol}^{-1} (20 \text{ K})^3/3$$

or $$S_{20} = 1{\cdot}01 \text{ J K}^{-1} \text{ mol}^{-1} \quad [\because S_0 = 0]$$

Example 3. The heat capacity, C_P (in J K^{-1} mol^{-1}) of a substance is given by the following equations :

$$C_P(s) = 16{\cdot}74\times10^{-5}\,T^3 \quad (0 < T < 50 \text{ K})$$

$$C_P(s) = 20{\cdot}92 \quad (50 < T < 150 \text{ K})$$

$$C_P(l) = 25{\cdot}10 \quad (150 < T < 400 \text{ K})$$

At the melting point (150 K), $\Delta H_f = 1255{\cdot}2$ J mol^{-1}. Calculate the absolute entropy of the substance in the liquid state at 300 K.

Solution :

$$\Delta S_1 = \int_0^{50} \frac{C_{P,S}}{T}dT = \int_0^{50} \frac{16{\cdot}74\times10^{-5}\,T^3}{T}dT \qquad \text{(The Debye } T^3 \text{ law)}$$

$$= \left[\frac{16{\cdot}74\times10^{-5}\,T^3}{3}\right]_0^{50} = 5{\cdot}58\times10^{-5}\times(50)^3 = 6{\cdot}97 \text{ J K}^{-1} \text{ mol}^{-1}$$

$$\Delta S_2 = \int_{50}^{150} \frac{C_{P,S}}{T}dT = 20{\cdot}92 \text{ J K}^{-1} \text{ mol}^{-1} \ln\left(\frac{150}{50}\right)$$

$$= 20{\cdot}92 \text{ J K}^{-1} \text{ mol}^{-1}\times1{\cdot}09861 = 22{\cdot}98 \text{ J K}^{-1} \text{ mol}^{-1}$$

$$\Delta S_3 = \Delta S_f = 1255{\cdot}2 \text{ J mol}^{-1}/150 \text{ K} = 8{\cdot}37 \text{ J K}^{-1} \text{ mol}^{-1}$$

$$\Delta S_4 = \int_{150}^{300} \frac{C_{P,l}}{T}dT = 25{\cdot}10 \text{ J K}^{-1} \text{ mol}^{-1} \ln\left(\frac{300}{150}\right)$$

$$= 25{\cdot}10 \text{ J K}^{-1} \text{ mol}^{-1}\times0{\cdot}6931 = 17{\cdot}40 \text{ J K}^{-1} \text{ mol}^{-1}$$

Hence, $$\Delta S = S_T - S_0 = \Delta S_1 + \Delta S_2 + \Delta S_3 + \Delta S_4$$

$$\therefore \quad S_T = 6{\cdot}97 + 22{\cdot}98 + 8{\cdot}37 + 17{\cdot}40 = 55{\cdot}73 \text{ J K}^{-1} \text{ mol}^{-1} \qquad (\because S_0 = 0)$$

Experimental Verification of the Third Law of Thermodynamics

The heat capacity and enthalpy data on substances that exist in two different crystalline forms may serve to verify the Third law of thermodynamics. For reversible isothermal transition, $\alpha \rightarrow \beta$, we can write

$$\Delta S = S_\beta - S_\alpha = \Delta H_{tr}/T_{tr} \qquad ...(28)$$

where ΔH_{tr} and T_{tr} are the experimentally determined enthalpy of transition and the temperature of transition, respectively.

$$\Delta S = S_0(\beta) + \int_0^{T_{tr}} \frac{C_{P,S}(\beta)}{T}dT - S_0(\alpha) - \int_0^{T_{tr}} \frac{C_{P,S}(\alpha)}{T}dT = \Delta H_{tr}/T_{tr} \qquad ...(29)$$

If an experiment proves that

$$\int_0^{T_{tr}} \frac{C_{P,S}(\beta)}{T}dT - \int_0^{T_{tr}} \frac{C_{P,S}(\alpha)}{T}dT = \frac{\Delta H_{tr}}{T_{tr}} \qquad ...(30)$$

then it will also prove that $S_0(\beta) = S_0(\alpha)$.

Thus, both the crystalline modifications α and β would have equal entropies at 0 K, in accordance with Third law of thermodynamics.

Experiments carried out on systems such as sulphur, tin and phosphine have demonstrated the validity of the Third law.

The following results have been obtained on phosphine :

$$\Delta S_{tr} = \frac{\Delta H_{tr}}{T_{tr}} = \frac{185{\cdot}7 \text{ J mol}^{-1}}{49{\cdot}43 \text{ K}} = 15{\cdot}73 \text{ J K}^{-1} \text{ mol}^{-1} \qquad ...(31)$$

In respect of phosphine, the difference of the two integrals in Eq. 30 is experimentally found to be 15·69 J K^{-1} mol^{-1}, *i.e.*,

$$\int_0^{T_{tr}} \frac{C_{P,S}(\beta)}{T}dT - \int_0^{T_{tr}} \frac{C_{P,S}(\alpha)}{T}dT = 15{\cdot}69 \text{ J K}^{-1} \text{ mol}^{-1} \qquad ...(32)$$

A comparison of the two results shows that, within the limits of experimental error, the Third law is valid for phosphine.

Entropies of Real Gases

From one of the Maxwell relations

$$\left(\frac{\partial S}{\partial P}\right)_T = -\left(\frac{\partial V}{\partial T}\right)_P \text{ or } dS = -\left(\frac{\partial V}{\partial T}\right)_P dP \qquad ...(33)$$

Integrating between pressures P_1 and P_2 at constant T, we get

$$\int_1^2 dS = -\int_{P_1}^{P_2}\left(\frac{\partial V}{\partial T}\right)_P dP \qquad ...(34)$$

A real gas behaves ideally at low pressures. Let this pressure be P. Let $(S_r)_1$ be the entropy of the real gas at 1 atm pressure and $(S_r)_P$ be the entropy at pressure P, the temperature remaining constant. Then, Eq. 34 becomes

$$(S_r)_1 - (S_r)_P = -\int_P^1 \left(\frac{\partial V}{\partial T}\right)_P dP \qquad ...(35)$$

For an ideal gas, $(\partial V/\partial T)_P = R/P$. If $(S_i)_1$ and $(S_i)_P$ are the entropies of an ideal gas at 1 atm and P atm, respectively, then, Eq. 35 can be written as

$$(S_i)_P - (S_i)_1 = \int_P^1 (R/P)dP \qquad ...(36)$$

We can equate $(S_r)_P$ with $(S_i)_P$ because at the low pressure P, the real gas behaves ideally.

Adding Eqs. 35 and 36, we get

$$(S_i)_1 - (S_r)_1 = S^\circ - S = \int_P^1 \left[\left(\frac{\partial V}{\partial T}\right)_P - \frac{R}{P}\right]dP \qquad ...(37)$$

where S° is the standard entropy and S is the entropy of real gas both determined at 1 atm. We have to determine S°. Here S is given by

$$S = \frac{1}{3}a(T^*)^3 + \int_{T^*}^{T_f} \frac{C_{P,S}}{T}dT + \frac{\Delta H_{fus}}{T_{fus}} + \int_{T_f}^{T_b} \frac{C_{P,l}}{T}dT + \frac{\Delta H_v}{T_b} + \int_{T_b}^{T} \frac{C_{P,g}}{T}dT \qquad ...(38)$$

Though the integrals in Eq. 38 can be evaluated graphically, it is more convenient to do so with the use of Berthelot's equation of state, *viz.*,

$$\left(P + \frac{a}{TV^2}\right)(V - b) = RT \qquad ...(39)$$

which is more appropriate to use than the van der Waals equation of state.

Multiplying and rearranging, we get

$$PV = RT + Pb - \frac{a}{TV} + \frac{ab}{TV^2} \qquad ...(40)$$

The term ab/TV^2 in the above equation is negligible as compared to other terms since the Berthelot constants a and b are small.

$$PV = RT + Pb - a/TV = \left[1 + \frac{Pb}{RT} - \frac{aP}{R^2T^2}\right] \qquad (\because V \approx RT/P) \quad ...(41)$$

For Berthelot's equation of state, the constants a, b and R can be written in terms of the critical constants. Accordingly,

$$a = (16/3)\, P_c V_c^2 T_c\,; \quad b = V_c/4\,; \quad R = (32/9)\, P_c V_c/T_c \qquad ...(42)$$

Hence, Eq. 41 becomes

$$PV = RT\left[1 + \frac{9}{128}\frac{PT_c}{P_cT}\left(1 - \frac{T_c^2}{6T^2}\right)\right] \qquad ...(43)$$

Dividing by P, we have

$$V = \frac{RT}{P} + \frac{9}{128}\frac{RT_c}{P_c} - \frac{27}{64}\frac{RT_c^3}{P_cT^2} \qquad ...(44)$$

$$\therefore \quad \left(\frac{\partial V}{\partial T}\right)_P = \frac{R}{P} + \frac{27}{32}\frac{RT_c^3}{P_cT^3} \qquad ...(45)$$

Substituting for $(\partial V/\partial T)_P$ in Eq. 37, we get

$$S^\circ = S + \frac{27}{32}\frac{RT_c^3}{P_cT^3}\int_P^1 dP = S + \frac{27}{32}\frac{RT_c^3}{P_cT^3}(1 - P) = S + \frac{27}{32}\frac{RT_c^3}{P_cT^3} \qquad (\because P << 1) \quad ...(46)$$

As mentioned earlier, S is given by Eq. 38. In Eq. 46, the second term is the correction term that should be added to S to give S°, the standard entropy for a real gas.

Entropy Changes in Chemical Reactions

We can calculate ΔS° for a chemical reaction from the tabulated standard entropy values for the reactants and products at 298 K. This is one of the most important applications of the Third law of thermodynamics. For a reaction

$$aA + bB + \cdots\cdots \longrightarrow lL + mM + \cdots\cdots$$

occurring in the standard state, the standard entropy change, ΔS°, is given by

$$\Delta S^\circ = \left[lS_L^\circ + mS_M^\circ + \cdots\cdots\right] - \left[aS_A^\circ + bS_B^\circ + \cdots\cdots\right]$$
$$= \sum S^\circ_{products} - \sum S^\circ_{reactants} \qquad ...(47)$$

where S°s are the molar standard entropies of the species involved and a, b, l, m, etc., are the stoichiometric coefficients.

From the tabulated values of S°, ΔS° for the reaction at 298 K can be calculated. The ΔS° value at any other temperature can be calculated by the Kirchhoff-type equation, *viz.*,

$$\left[\frac{d(\Delta S^\circ)}{dT}\right]_p = \sum\left(\frac{\partial S^\circ_{products}}{\partial T}\right)_P - \sum\left(\frac{\partial S^\circ_{reactants}}{\partial T}\right)_P \qquad ...(48)$$

Since $(\partial S/\partial T)_P = C_P/T$, we have

$$\left[\frac{d(\Delta S^\circ)}{dT}\right]_p = \sum(C_P/T)_{products} - \sum(C_P/T)_{reactants}$$

Rearranging and integrating between 298 K and T K, we have ...(49)

$$\int_{298}^{T} d(\Delta S^\circ) = \int_{298}^{T} (\Delta C_P/T)dT = \int_{298}^{T} \Delta C_P\, d\ln T$$

or
$$\Delta S_T^\circ = \Delta S_{298}^\circ + \int_{298}^{T} \Delta C_P\, d\ln T \qquad ...(50)$$

Eq. 50 is applicable to chemical reactions involving solids, liquids or gases.

Example 4. Calculate the standard entropy change for the reaction

$$C(s) + H_2O(l) \longrightarrow CO(g) + H_2(g)$$

Solution : From Table 2, the total standard entropy of products

= 197·90 J K^{-1} mol^{-1} for CO + 130·60 J K^{-1} mol^{-1} for H_2 = 328·50 J K^{-1}

From the same table, the total standard entropy of reactants

= 5·69 J K^{-1} mol^{-1} for C (*s*) + 70·29 J K^{-1} mol^{-1} for H_2O (*l*) = 75·98 J K^{-1}

The standard entropy change (ΔS°) for the reaction is given by

$$\Delta S^\circ = \Sigma S^\circ_{products} - \Sigma S^\circ_{Reactants} = 328{\cdot}50 - 75{\cdot}98 = 252{\cdot}52 \text{ J K}^{-1}$$

Example 5. Calculate the standard entropy change for the reaction

$$N_2(g) + O_2(g) \longrightarrow 2NO(g)$$

Solution : The standard entropy change (ΔS°) for the reaction is given by

$$\Delta S^\circ = \Sigma S^\circ_{products} - \Sigma S^\circ_{reactants}$$
$$= (2 \text{ mol} \times 210{\cdot}45 \text{ J K}^{-1} \text{ mol}^{-1}) - (1 \text{ mol} \times 191{\cdot}62 \text{ J K}^{-1} \text{ mol}^{-1} + 1 \text{ mol} \times 205{\cdot}01 \text{ J K}^{-1} \text{ mol}^{-1})$$
$$= 24{\cdot}27 \text{ J K}^{-1}$$

Example 6. Calculate the entropy change accompanying the conversion of 1 mole of ice at 273·1 K and 1 atm pressure into steam at 373·1 K and 1 atm pressure, given that at 273·1 K, the molar heat of fusion of ice, ΔH_{fus}, is 6·00 kJ mol^{-1} and at 373·1 K, the molar heat of vaporization of water, ΔH_{vap}, is 40·60 kJ mol^{-1}. Also assume that the molar heat capacity, C_P, in the temperature range 373·1—273·1 K remains constant at 75·2 J K^{-1} mol^{-1}.

Solution : The total entropy change ΔS is given by the relation

$$\Delta S = \Delta S_1 + \Delta S_2 + \Delta S_3$$

where ΔS_1 is the entropy change due to fusion of ice, ΔS_2 is the entropy change for heating 1 mole of water from 273·1 K to 373·1 K and ΔS_2 is the entropy change due to conversion of water at 373·1 K into steam. Thus,

$$\Delta S_1 = \Delta H_{fus}/T_{fus} = 6000 \text{ J mol}^{-1}/273{\cdot}1 \text{ K} = 22{\cdot}0 \text{ J K}^{-1} \text{ mol}^{-1}$$

$$\Delta S_2 = \int_{T_1}^{T_2} \frac{C_P}{T} dT = \int_{273{\cdot}1}^{373{\cdot}1} \frac{75{\cdot}2 \text{ J K}^{-1} \text{ mol}^{-1}}{T} dT$$

$$= 75{\cdot}2 \text{ J K}^{-1} \text{ mol}^{-1} \times 2{\cdot}303 \log (373{\cdot}1 \text{ K}/273{\cdot}1 \text{ K}) = 23{\cdot}5 \text{ J K}^{-1} \text{ mol}^{-1}$$

$$\Delta S_2 = \Delta H_{vap}/T_{vap} = 40600 \text{ J mol}^{-1}/373{\cdot}1 \text{ K} = 108{\cdot}8 \text{ J K}^{-1} \text{ mol}^{-1}$$

Adding, we get $\Delta S = 22{\cdot}0 + 23{\cdot}5 + 108{\cdot}8 = 154{\cdot}3 \text{ J K}^{-1} \text{ mol}^{-1}$

Derivation of the Boltzmann Entropy Equation. The Boltzmann entropy equation, *viz.*, $S = k \ln W$, is probably the most famous equation in statistical thermodynamics. Its derivation is intuitively simple and appealing. Before we derive it, we must distinguish between two kinds of probabilities, *viz.*, mathematical probability and thermodynamic probability.

Mathematical probability is the ratio of the number of cases favourable to the occurrence of an event to the total number of equally probable cases. This probability always lies between 0 and 1. On the other hand, **thermodynamic probability** is the number of microstates corresponding to a given macrostate when we are dealing with the distribution of molecules amongst an extremely large number of energy levels. This probability, W, is a very large number, tending to be infinite.

Boltzmann suggested that entropy can be related to the thermodynamic probability W as

$$S = f(W) \qquad ...(51)$$

Consider two systems A and B whose entropies and microstates are S_A, S_B, W_A and W_B, respectively. When the two systems are combined,

$$S = S_A + S_B \qquad ...(52)$$

By definition, the probability of a thermodynamic state is proportional to the number of microstates required to achieve it. Mathematically, we know that the total probability is the *product* of the probabilities of the independent events. This is also true of the microstates. Hence,

$$W = W_A . W_B \qquad ...(53)$$

and $$S_A + S_B = f(W_A W_B) \qquad ...(54)$$

This relationship suggests that entropies are additive and probabilities are multiplicative. This can be true only if S is a logarithmic function of W, *i.e.*,

$$S = k \ln W \qquad ...(55)$$

which is the Boltzmann entropy equation. Eq. 55 gives the quantitative definition of entropy as disorder.

Residual Entropy. Entropies calculated using the Third law are called thermal entropies. However, the statistical entropies, calculated by the method of statistical mechanics (for instance, by using the Boltzmann entropy equation at 0 K, *viz.*, $S = k \ln W$) are more rigorous. It is found that the thermal entropies are somewhat smaller than the statistical entropies, the deviation ranging from 3·1 to 4·8 J K^{-1} mol^{-1}. We thus conclude that entropies of substance (such as H_2, D_2, CO, NO, N_2O, H_2O, etc.) are not zero at 0 K, as the Third law formulates, but are finite. These entropies are called **residual entropies.** The existence of residual entropy in a crystal at 0 K is presumably due to the alternative

arrangements of molecules in the solid. Such arrangements are shown in Fig. 3 for CO and N_2O :

CO	CO	CO	CO	CO	CO	OC	OC
CO	CO	CO	CO	CO	OC	OC	CO
NNO	NNO	NNO	NNO	NNO	NNO	ONN	ONN
NNO	NNO	NNO	NNO	NNO	ONN	ONN	NNO
(a)				*(b)*			

Fig. 3. Alternative molecular arrangements *(a)* Perfect crystal *(b)* Actual crystal

Since both the arrangements are equally likely, from the Boltzmann entropy equation (55),

$S = k \ln W$, with $W = 2^{N_A}$ (where N_A is Avogadro's number), we find that

$$S = k \ln 2^{N_A} = N_A k \ln 2 = R \ln 2 = (8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1})\ 0{\cdot}693 = 5{\cdot}76 \text{ J K}^{-1} \text{ mol}^{-1}$$

Since the residual entropies are found experimentally to be less than this value, it is evident that the two alternative orientations of the CO and N_2O molecules in the solid state at 0 K are not completely random. For H_2 and D_2, too, the thermal entropies at 0 K are less than the corresponding **statistical entropies.** The calculation of the statistical entropy assumes that there exists an equilibrium between ortho H_2 and para H_2 at all temperatures. The ΔS_{mix} of ortho H_2 and para H_2 is found to be 18·37 J K^{-1} mol^{-1} in the vicinity of 0 K. When this value is added to the thermal entropy (calculated from heat capacity measurements), the agreement with the statistical entropy is very good.

Ludwig Boltzmann (1844-1906), the great German mathematical physicist, made outstanding contributions to the kinetic theory of gases, statistical mechanics, and the atomic nature of matter. However, his work on the atomic theory was criticized by several eminent scientists (among them W. Ostwald), and he suffered from severe depression. He committed suicide in 1906 by drowning. It was a tragic loss to physics. After his death his work on atomic theory was corroborated. On his tombstone is inscribed his famous equation : $S = k \ln W$.

I. Review Questions

1. Explain the Nernst heat theorem. How does it lead to the enunciation of the Third law of thermodynamics ?
2. State and explain the Third law of thermodynamics. How can it be verified experimentally ?
3. Explain how the absolute entropy of a substance is determined with the help of the Third law of thermodynamics.

II. Problems

1. Calculate the entropy of SO_2 (*g*) at 400 K from the following data on contribution to entropy :
   (a) 0 to 15 K (using Debye's law) = 1·255 J K^{-1} mol^{-1}
   (b) 15 K to 197·64 K, solid = 84·182 J K^{-1} mol^{-1}
   (c) 197·64 K to 263·08 K, liquid = 24·937 J K^{-1} mol^{-1}
   (d) ΔH_f and ΔH_{vap} are 7·402 kJ mol^{-1} and 24·937 kJ mol^{-1}, respectively.
   (e) The melting point is 197·64 K and the boiling point is 263·08 K.
   (f) The temperature-dependence of C_p of SO_2 (*g*) is given by
   $$C_p = 49{\cdot}769 + 4{\cdot}56 \times 10^{-3} T$$
   [Ans. 264·09 J K^{-1} mol^{-1}]
2. Calculate with the help of entropy values given in Table 2,
   (i) the standard entropy change for the reaction $Pb(s) + Br_2(l) \longrightarrow PbBr_2(s)$
   (ii) the standard entropy change for the formation of methyl alcohol. [Ans. *(i)* – 57·32 J K^{-1} *(ii)* – 242·7 J K^{-1} mol^{-1}]

CHAPTER 17

CHEMICAL EQUILIBRIA

Spontaneous Reactions. By a spontaneous reaction, we mean a reaction which proceeds by itself or when properly initiated, if necessary. For example, hydrogen and oxygen react spontaneously at the room temperature by passing an electric spark through the mixture. The reaction is exothermic.

$$H_2(g) + \tfrac{1}{2}O_2(g) \longrightarrow H_2O(l)\ ; \qquad \Delta H = -286{\cdot}2\ \text{kJ}$$

Carbon (graphite), when initiated by ignition, undergoes almost complete combustion to give carbon dioxide. This reaction is also exothermic.

$$C(s) + O_2(g) \longrightarrow CO_2(g)\ ; \qquad \Delta H = -393{\cdot}5\ \text{kJ}$$

Nitric oxide and oxygen combine readily to produce nitrogen dioxide. This is also an exothermic reaction.

$$NO(g) + \tfrac{1}{2}O_2(g) \longrightarrow NO_2(g)\ ; \qquad \Delta H = -56{\cdot}52\ \text{kJ}$$

This reaction requires no initiation.

A mixture of methane and oxygen, when initiated by ignition, reacts spontaneously to produce carbon dioxide and water, at the room temperature. The reaction is exothermic.

$$CH_4(g) + 2O_2(g) \longrightarrow CO_2(g) + 2H_2O(l)\ ; \qquad \Delta H = -890{\cdot}3\ \text{kJ}$$

Free Energy of a Spontaneous Reaction. While discussing the criteria for reversible and irreversible reactions in Chapter 14, it was concluded that if the free energy change of a chemical reaction is *negative*, the reaction can take place spontaneously, *i.e.*, it is feasible. If the free energy change is zero, the reaction is in a state of equilibrium and if the free energy change is positive, the reaction would not proceed. By definition, $G = H - TS$ so that, at constant temperature,

$$\Delta G = \Delta H - T\Delta S \qquad \ldots(1)$$

There are, evidently, two factors which contribute to the value of ΔG. These are the energy factor, ΔH and the entropy factor, $T\Delta S$. Neither ΔH nor $T\Delta S$ alone can determine the spontaneity of a reaction. The spontaneity would be decided by the overall value of the two factors; *i.e.*, by the value of ΔG. For a reaction to be spontaneous, ΔG must have a negative value, as already stated. For this, ΔH should be negative and $T\Delta S$ should be positive. Thus, negative sign of ΔH and positive sign of $T\Delta S$, both tend to increase the feasibility of a reaction. When both factors are favourable, *i.e.*, ΔH is negative and $T\Delta S$ is positive, then, evidently, their substitution in Eq. 1 will result in a large negative value of ΔG. The reaction would, therefore, be highly feasible.

Now suppose the energy factor is favourable, *i.e.*, ΔH is negative, but the entropy factor is not favourable, *i.e.*, $T\Delta S$ is also negative. In such a case, the feasibility of the reaction will be determined by the factor which predominates. If the energy factor predominates, *i.e.*, the numerical value of ΔH is more than that of $T\Delta S$, the reaction would be feasible. The value of ΔG would again be negative. If, however, the entropy factor predominates, *i.e.*, the numerical value of $T\Delta S$ is greater than that of ΔH, the reaction would not be feasible. The value of ΔG would now be positive.

Let us consider another case in which the energy factor does not favour the reaction (*i.e.*, ΔH has a positive value) but the entropy factor favours the reaction, *i.e.*, $T\Delta S$ is positive. The reaction will occur if the entropy factor predominates, *i.e.*, $T\Delta S$ is numerically greater than ΔH. In such a case, again, ΔG will

be negative and the reaction would be feasible. If, however, the entropy factor does not predominate, *i.e.*, $T\Delta S$ is numerically less than ΔH, then in that case ΔG will be positive and the reaction would not occur.

If neither factor predominates, *i.e.*, both the opposing factors are exactly equal (*viz.*, ΔH is numerically equal to $T\Delta S$), then ΔG will be zero. Under these circumstances, the reaction will be in a state of equilibrium, *i.e.*, no net reaction would occur in any direction.

Role of Temperature. Temperature, being a multiplying parameter for entropy factor ($T\Delta S$) of a system, plays an important role in controlling the spontaneity of a reaction as shown below.

a. At high temperature, the entropy factor predominates. In the case of an endothermic reaction, ΔH is always positive. Thus, the energy factor does not favour the reaction. But if the reaction in accompanied by even a small increase of entropy, the high temperature will increase the entropy factor $T\Delta S$ to a large extent. Hence, ΔG ($= \Delta H - T\Delta S$) may become negative at a sufficiently high temperature. This explains why endothermic reactions become feasible at increasing temperatures.

b. At low temperatures, energy factor predominates. In the case of an exothermic reaction, ΔH is always negative. Thus, the energy factor always tends to favour the reaction. If such a reaction takes place at a low temperature, then even if it is accompanied by *decrease of entropy*, the opposing factor $T\Delta S$ may remain very small and, therefore, the value of ΔG ($= \Delta H - T\Delta S$) may still have a sufficiently large negative value. This explains why exothermic reactions are feasible even at low temperatures.

To sum up, for a reaction to be spontaneous, ΔG should be negative.

Standard Free Energy Change, $\Delta G°$. The standard free energy change of a reaction is defined as the free energy change of a reaction when the reactants and products are in their standard states (25°C, 1 atm pressure). Eq. 1 may thus be written as

$$\Delta G° = \Delta H° - T\Delta S° \qquad \ldots(2)$$

where $\Delta H°$ is the standard enthalpy change of the reaction and $\Delta S°$ is the standard entropy change of the reaction at the temperature T. The standard enthalpy changes of reactions can be calculated from the data given in Table 4 (Chapter 14). The standard entropy changes can be calculated with the help of the standard absolute entropies of elements and compounds given in Table 2 (Chapter 16). It is thus possible to calculate $\Delta G°$ of a reaction.

Example 1. Calculate the standard free energy change ($\Delta G°$) of the reaction :

$CO(g) + 1/2\ O_2(g) \longrightarrow CO_2(g)$; $\Delta H° = -282{\cdot}84$ kJ. Is the reaction feasible at standard state ?

Solution : $\Delta G° = \Delta H° - T\Delta S°$

$\Delta H° = -282{\cdot}84\ \text{kJ} = -282840\ \text{J}$

$\Delta S° = S°_{\text{Products}} - S°_{\text{Reactants}}$

Reference to Table 2 (Chapter 15) shows that standard entropy of $CO_2(g)$ is 213·80 J K^{-1} mol^{-1} while the values for $CO(g)$ and $O_2(g)$ are 197·90 and 205·01 J K^{-1} mol^{-1}, respectively.

$$\Delta S° = S°_{[CO_2]} - \left\{S°_{[CO]} + \tfrac{1}{2}S°_{[O_2]}\right\} = 213{\cdot}8 - (197{\cdot}9 + 102{\cdot}5) = -86{\cdot}6\ \text{J K}^{-1}$$

Hence, $\Delta G° = -282840\ \text{J} - [(298\ \text{K})(-86{\cdot}6\ \text{J K}^{-1})] = -257033{\cdot}2\ \text{J} = -257{\cdot}03\ \text{kJ}$

Since $\Delta G°$ has a *negative value*, the reaction at standard state is **feasible.**

Example 2. Calculate the standard free energy change ($\Delta G°$) of the following reaction and say whether it is feasible at standard state or not.

$$1/2\ H_2(g) + 1/2\ I_2(s) \longrightarrow HI(g)\ ; \qquad \Delta H° = 25{\cdot}95\ \text{kJ}$$

Solution : $\Delta G° = H° - T\Delta S°$; $\Delta H° = 25{\cdot}95\ \text{kJ} = 25950\ \text{J}$

The standard entropies of $HI(g)$, $H_2(g)$ and $I_2(s)$ are 206·27, 130·60 and 116·73 J K^{-1} mol^{-1}, respectively (Table 2, Chapter 16).

Hence, $\Delta S° = S°_{[HI(g)]} - \left\{\frac{1}{2}S°_{[H_2(g)]} + \frac{1}{2}S°_{[I_2(s)]}\right\}$

$= 206{\cdot}27 - (65{\cdot}30 + 58{\cdot}36) = 82{\cdot}61\ \text{J K}^{-1}$

$$\therefore \quad \Delta G^\circ = 25950\ \text{J} - (298\ \text{K} \times 82{\cdot}61\ \text{J K}^{-1}) = 1323{\cdot}20\ \text{J} = \mathbf{1{\cdot}323\ J}$$

Since ΔG is *positive*, the reaction is **not feasible** at standard state.

Standard Free Energy of Formation of Compounds, ΔG_f°. Standard free energy of formation of a compound is defined as the energy change expressed in kilojoules per mole involved in the formation of the compound in its standard state (25°C and 1 atm pressure) from its elements in their standard states (25°C and 1 atm pressure). This is denoted by ΔG_f°.

Standard free energies of formation are generally determined from the standard enthalpies of formation and standard entropy changes by using the expression

$$\Delta G_f^\circ = \Delta H_f^\circ - T\Delta S^\circ \qquad \ldots(3)$$

Example 3. Calculate the standard free energy of formation of $H_2O(l)$. The standard enthalpy of formation (ΔH_f°) of $H_2O(l)$ is –286·20 kJ and standard entropies of $H_2(g)$, $O_2(g)$ and $H_2O(l)$ are 130·60, 205·01 and 70·29 J K^{-1} mol^{-1}, respectively.

Solution : The equation for the formation of $H_2O(l)$ at standard state may be written as

$$H_2(g) + 1/2\ O_2(g) \longrightarrow H_2O(l); \qquad \Delta H_f^\circ = -286{\cdot}20\ \text{kJ mol}^{-1}$$

$$\Delta S^\circ = S^\circ_{\text{Products}} - S^\circ_{\text{Reactants}} = 70{\cdot}29\ \text{J K}^{-1}\text{mol}^{-1} - (130{\cdot}60\ \text{J K}^{-1}\text{mol}^{-1} + 102{\cdot}50\ \text{J K}^{-1}\text{mol}^{-1})$$

$$= -162{\cdot}81\ \text{J K}^{-1}\text{mol}^{-1}$$

$$\Delta G_f^\circ = \Delta H_f^\circ - T\Delta S^\circ = -286200\ \text{J mol}^{-1} - [(298\ \text{K})(-162{\cdot}81\ \text{J K}^{-1}\text{mol}^{-1})]$$

$$= -237683\ \text{J} = \mathbf{-237{\cdot}68\ kJ\ mol^{-1}}$$

Example 4. The standard enthalpy of formation (ΔH_f°) of $NH_3(g)$ is – 46·19 kJ mol^{-1}. The standard entropies of $N_2(g)$, $H_2(g)$ and $NH_3(g)$ are 191·62, 130·60 and 192·46 J K^{-1} mol^{-1}, respectively. Calculate the standard free energy of formation of $NH_3(g)$.

Solution : $\Delta H_f^\circ = -46{\cdot}19\ \text{kJ mol}^{-1} = -46190\ \text{J mol}^{-1}$

$$\Delta S^\circ = S^\circ_{\text{Products}} - S^\circ_{\text{Reactants}}$$

$$= 192{\cdot}46\ \text{J K}^{-1}\text{mol}^{-1} - \left(\tfrac{1}{2} \times 191{\cdot}62\ \text{J K}^{-1} + \tfrac{3}{2} \times 130{\cdot}60\ \text{J K}^{-1}\text{mol}^{-1}\right) = -99{\cdot}25\ \text{J K}^{-1}\text{mol}^{-1}$$

$$T\Delta S^\circ = 298\ \text{K} \times (-99{\cdot}25\ \text{J K}^{-1}\text{mol}^{-1}) = -29576{\cdot}5\ \text{J mol}^{-1}$$

$$\Delta G_f^\circ = \Delta H_f^\circ - T\Delta S^\circ = -46190\ \text{J mol}^{-1} - (-29576{\cdot}5\ \text{J mol}^{-1}) = \mathbf{-16613{\cdot}5\ J\ mol^{-1} = -16{\cdot}61\ kJ\ mol^{-1}}$$

Example 5. Calculate ΔG accompanying the vaporisation of one mole of liquid water at 100°C and 76 torr pressure. Will the process be spontaneous ?

Solution : When water vaporises at 100°C and 1 atm (=760 torr) pressure, liquid and vapour are in equilibrium so that $\Delta G = 0$. It is evident, therefore, that vaporisation of water at 100°C but at a reduced pressure of 76 torr is not a process in equilibrium. The latter process, however, can be divided into two reversible steps : vaporisation at 1 atm (=760 torr) for which $\Delta G = 0$, followed by isothermal expansion of vapour to 76 torr. ΔG for the overall process is given by the sum of the ΔG values involved in the two steps. Thus,

$$\Delta G = 0 + RT \ln (P_2/P_1) = (8{\cdot}314\ \text{J K}^{-1}\text{mol}^{-1})(373\ \text{K}) \ln (76\ \text{torr}/760\ \text{torr})$$

$$= -7140{\cdot}59\ \text{J mol}^{-1} = \mathbf{-7{\cdot}14\ kJ\ mol^{-1}}$$

Since ΔG is negative, the process is **spontaneous.**

Example 6. Consider the vaporisation of water at 100°C when liquid water is in equilibrium with water vapour at 1 atm. The heat of vaporisation of water at 100°C is 40·63 kJ mol^{-1}. Suppose now that the volume of the vapour phase is increased so that the pressure becomes 0·90 atm. Determine whether the vaporisation process will be spontaneous or not.

Solution : At 1 atm pressure and 100°C, liquid water is in equilibrium with its vapour and hence, $\Delta G = 0$. Since $\Delta G = \Delta H - T\Delta S$, it follows that

$$\Delta S = (\Delta H - \Delta G)/T = (40{\cdot}63\ \text{kJ mol}^{-1} - 0)/373\ \text{K} = 108{\cdot}93\ \text{J K}^{-1}\text{mol}^{-1}$$

When the pressure of water vapour changes from 1 atm to 0·9 atm,

$$\Delta S = R \ln (P_1/P_2) = (8{\cdot}314\ \text{J K}^{-1}\text{mol}^{-1}) \ln (1{\cdot}0\ \text{atm}/0{\cdot}9\ \text{atm}) = 0{\cdot}876\ \text{J K}^{-1}\text{mol}^{-1}$$

Thus, the increase in entropy accompanying vaporisation of 1 mole of water at 0·9 atm is given by the sum of the ΔS values involved in the two processes so that

$$\therefore \quad \Delta S = 108{\cdot}93\ \text{J K}^{-1}\text{mol}^{-1} + 0{\cdot}876\ \text{J K}^{-1}\text{mol}^{-1} = 109{\cdot}81\ \text{J K}^{-1}\text{mol}^{-1}$$

$$\therefore \quad T\Delta S = (373\ \text{K})(109{\cdot}81\ \text{J K}^{-1}\text{mol}^{-1}) = 40959{\cdot}1\ \text{J mol}^{-1} = 40{\cdot}96\ \text{kJ mol}^{-1}$$

The change in free energy is, therefore, given by

$$\Delta G = \Delta H - T\Delta S = 40{\cdot}63\ \text{kJ} - 40{\cdot}96\ \text{kJ} = -0{\cdot}33\ \text{kJ mol}^{-1}$$

Since ΔG is negative, the vaporisation process at 0·90 atm is spontaneous.

The standard free energies of formation of various compounds calculated in the above manner are given in Table 1. The standard free energies of elements are arbitrarily taken as zero.

TABLE 1

Standard Free Energies of Formation of Compounds at 25°C

Substance	ΔG_f° (kJ mol^{-1})	Substance	ΔG_f° (kJ mol^{-1})	Substance	ΔG_f° (kJ mol^{-1})
$H_2O(g)$	– 228·60	$H_2O(l)$	– 237·20	$CH_4(g)$	– 50·79
$CO(g)$	– 137·27	$CH_3OH(l)$	– 166·23	$C_2H_6(g)$	– 32·88
$CO_2(g)$	– 394·38	$C_2H_5OH(l)$	– 174·76	$C_2H_4(g)$	+ 68·11
$HCl(g)$	– 95·27	$CH_3COOH(l)$	– 392·50	$C_3H_8(g)$	– 23·47
$N_2O(g)$	+104·18	$HCOOH(l)$	– 346·01	$C_2H_2(g)$	+209·20
$NO(g)$	+ 86·61	$C_6H_6(l)$	+124·51	$C_6H_6(g)$	+129·70
$NO_2(g)$	+ 51·92	$NaCl(s)$	– 384·04	$Cu_2O(s)$	– 146·48
$N_2O_5(g)$	+ 97·90	$AgCl(s)$	– 109·70	$PbSO_4(s)$	– 811·27
$NH_3(g)$	– 16·65	$AgBr(s)$	– 95·81	$CaSO_4(s)$	– 1320·55
$H_2S(g)$	– 33·01	$Ag_2O(s)$	– 10·83	$CaCO_3(s)$	– 1128·88
$SO_2(g)$	– 300·36	$HgO(s)$	– 58·32	$BaSO_4(s)$	– 1465·23
$SO_3(g)$	– 357·77	$CuO(s)$	– 127·19	$BaCO_3(s)$	– 1135·53

The advantage of these values is that we can calculate standard free energy change, ΔG°, for any reaction remembering that

$$\Delta G^\circ = \sum \Delta G_f^\circ(\text{products}) - \sum \Delta G_f^\circ(\text{reactants})$$

Suppose it is required to calculate the standard free energy change of the reaction

$$CO(g) + H_2O(g) \longrightarrow CO_2(g) + H_2(g)$$

The standard free energies of formation of $CO(g)$, $H_2O(g)$ and $CO_2(g)$ are –137·27, –228·60 and –394·38 kJ $mole^{-1}$, respectively (Table 1). The value for $H_2(g)$ is taken as zero.

The standard free energy change of the reaction is given by

$$\Delta G^\circ = \{[\Delta G_f^\circ]_{CO_2} - [\Delta G_f^\circ]_{H_2}\} - \{[\Delta G_f^\circ]_{CO} - [\Delta G_f^\circ]_{H_2O}\}$$

$$= \{(-394{\cdot}38\ \text{kJ mole}^{-1}) + (0)\} - \{(-137{\cdot}27\ \text{kJ mole}^{-1}) + (-228{\cdot}60\ \text{kJ mole}^{-1})\} = \mathbf{-28{\cdot}51\ kJ\ mol^{-1}}$$

Example 7. Calculate the standard free energy change of the reaction

$$\mathbf{4NH_3(g) + 5O_2(g) \longrightarrow 4NO(g) + 6H_2O(l)}$$

and say whether this reaction is feasible at 25°C and 1 atm pressure. The standard free energies of formation of $NH_3(g)$, $NO(g)$ and $H_2O(l)$ are – 16·65, 86·61 and – 237·20 kJ $mole^{-1}$, respectively.

Solution : $\Delta G^\circ = [\Delta G_f^\circ]_{\text{Products}} - [\Delta G_f^\circ]_{\text{Reactants}}$

$$= [(4\ \text{mol})(86{\cdot}61\ \text{kJ mol}^{-1} + (6\ \text{mol})(-237{\cdot}2\ \text{kJ mol}^{-1})] - [(4\ \text{mol}\ (-16{\cdot}65\ \text{kJ mol}^{-1}) + 0]$$

$$= \mathbf{-1010{\cdot}02\ kJ}$$

Since ΔG° is *negative*, the reaction at standard state is feasible

Example 8. Calculate ΔG° for the reaction : $C_6H_{12}O_6(s) + 6O_2(g) \longrightarrow 6CO_2(g) + 6H_2O(l)$. The standard free energies of formation of glucose, $CO_2(g)$ and $H_2O(l)$ are – 910·5, – 394·4 and – 237·2 kJ mol^{-1}, respectively.

Solution : $\Delta G^\circ = [\Delta G_f^\circ]_{Products} - [\Delta G_f^\circ]_{Reactants}$

$= [(6 \text{ mol})(-394{\cdot}4 \text{ kJ mol}^{-1}) + (6 \text{ mol})(-237{\cdot}2 \text{ kJ mol}^{-1})] - [(1 \text{ mol})(-910{\cdot}5 \text{ kJ mol}^{-1})] + 0$

$= -2879{\cdot}1 \text{ kJ}$

CHEMICAL EQUILIBRIUM

Our experimental observations tell us that most of the chemical reactions when carried out in closed vessels do not go to completion. Under these conditions, a reaction starts by itself or by initiation, continues for some time at diminishing rates and ultimately *appears to stop*. The reactants may still be present but they do not appear to change into products any more. What happens in such a case is that the products of the reaction start reacting at the same rate as the reactants. In other words, the rate of the back reaction becomes equal to the rate of the forward reaction. Thus, in a given time as much of the products are formed as react back to give the reactants. The composition of the reaction mixture at a given temperature is the same irrespective of the initial state of the system, *i.e.*, irrespective of the fact whether we start with the reactants or the products. The reaction in such conditions is said to be in a state of equilibrium.

The attainment of equilibrium can be recognised by noting constancy of observable properties such as pressure, concentration, density or colour whichever may be suitable in a given case.

The relationship between the quantities of the reacting substances and the products formed can be worked out readily with the help of the law of mass action.

Law of Mass Action. Assuming that the driving force of a chemical reaction determines its reaction rate, the law of mass action may be stated as follows : The rate at which a substance reacts is proportional to its active mass and the rate of a chemical reaction is directly proportional to the product of the active masses of the reacting substances.

Consider a general reversible chemical reaction

$$aA + bB \rightleftharpoons mM + nN$$

According to the law of mass action, assuming that active masses are equivalent to molar concentrations,

the rate of the forward reaction, $r_f \propto [A]^a[B]^b = k_f[A]^a[B]^b$

and the rate of the reverse reaction, $r_r \propto [M]^m[N]^n = k_r[M]^m[N]^n$

where k_f and k_r are proportionality constants and square brackets represent the molar concentrations of the entities enclosed. The constant k_f is known as the rate constant of the forward reaction and the constant k_r is known as the rate constant of the reverse reaction. At equilibrium, the rate of the forward reaction is equal to the rate of the reverse reaction, that is,

$$k_f[A]^a[B]^b = k_r[M]^m[N]^n$$

$$\therefore \quad k_f/k_r = K_{eq} = [M]^m[N]^n/[A]^a[B]^b \qquad ...(4)$$

The constant K_{eq} is called the **equilibrium constant** of the reaction. Eq. 4 represents the **law of chemical equilibrium.**

The equilibrium concentrations in Eq. 4 can be written in terms of activities (a_i), partial pressures (p_i), molar concentrations (c_i) or mole fractions (x_i) of the species involved in the reaction. Consequently, K_{eq} will have different numerical values for a given chemical reaction.

Thermodynamic Derivation of the Law of Chemical Equilibrium. Consider once again the general reversible reaction

$$aA + bB \rightleftharpoons mM + nN$$

where the reactants and the products are assumed to be ideal gases.

We know that chemical potential (*i.e.*, Gibbs free energy) of reactants consisting of a moles of A and b moles of B is given by the expression

$$G_{reactants} = a\mu_A + b\mu_B \qquad ...(5)$$

where μ_A and μ_B are the **chemical potentials** of the species A and B, respectively. Similarly, for the products we have

$$G_{products} = m\mu_M + n\mu_N \qquad ...(6)$$

In each case, pressure and temperature are constant. The free energy of the reaction is equal to the difference between the free energy of the products and that of the reactants, that is,

$$(\Delta G)_{reaction} = G_{products} - G_{reactants}$$

$$= (m\mu_M + n\mu_N) - (a\mu_A + b\mu_B) \qquad ...(7)$$

At equilibrium, the free energy change $\Delta G = 0$ so that Eq. 7 becomes

$$(m\mu_M + n\mu_N) - (a\mu_A + b\mu_B) = 0 \qquad ...(8)$$

The chemical potential of the ith species in the gaseous state is given by

$$\mu_i = \mu_i^\circ + RT \ln p_i \qquad \text{(Chapter 15)} \qquad ...(9)$$

where p_i is the partial pressure of the ith component and μ_i° is its **standard chemical potential** (*i.e.*, when partial pressure of the ith component is unity). From Eqs. 8 and 9, we obtain

$$[m(\mu_M^\circ + RT \ln p_M) + n(\mu_N^\circ + RT \ln p_N)] - [a(\mu_A^\circ + RT \ln p_A) + b(\mu_B^\circ + RT \ln p_B)] = 0 \qquad ...(10)$$

or $$RT \ln (p_M^m p_N^n)/(p_A^a p_B^b) = -[(m\mu_M^\circ + n\mu_N^\circ) - (a\mu_A^\circ + b\mu_B^\circ)]$$

$$= -[G_{products}^\circ - G_{reactants}^\circ] = -(\Delta G^\circ)_{reaction} \qquad ...(11)$$

or $$(p_M^m p_N^n)/(p_A^a p_B^b) = e^{-\Delta G^\circ/RT} \qquad ...(12)$$

Since ΔG° depends only on temperature and R is the gas constant, hence the right hand side of Eq. 12 is a constant at constant temperature. Thus,

$$(p_M^m p_N^n)/(p_A^a p_B^b) = \text{constant} = K_p \qquad ...(13)$$

Eq. 13 is the **law of chemical equilibrium**

If the chemical potentials of various species are expressed in terms of mole fractions (x_i), then

$$\mu_i = \mu_i^\circ + RT \ln x_i \qquad ...(14)$$

From this the following expression analogous to Eq. 13 is obtained :

$$(x_M^m x_N^n)/(x_A^a x_B^b) = K_x \qquad ...(15)$$

If, on the other hand, the chemical potentials are expressed in terms of molar concentrations (c_i), then

$$\mu_i = \mu_i^\circ + RT \ln c_i \qquad ...(16)$$

from which we obtain the following expression :

$$[M]^m[N]^n/[A]^a[B]^b = K_c \qquad ...(17)$$

If the reactants and the products are not ideal gases, then the **thermodynamic equilibrium constant,** K_{th}, is defined as

$$K \equiv K_{th} = (a_M^m a_N^n)/(a_A^a a_B^b) \qquad ...(18)$$

where a_is are the activities. For non-ideal, *i.e.*, real gases,

$$K \equiv K_f = (f_M^m f_N^n)/(f_A^a f_B^b) \qquad ...(19)$$

where f_is are the *fugacities*. For a mixture of real gases, $\gamma_i = f_i/p_i$ or $f_i = \gamma_i p_i$ where γ_is are the activity coefficients. Hence

$$K_f = \frac{\gamma_M^m \gamma_N^n}{\gamma_A^a \gamma_B^b} \times \frac{p_M^m p_N^n}{p_A^a p_B^b} = K_\gamma K_p \qquad ...(20)$$

Van't Hoff Reaction Isotherm. It readily follows from Eqs. 12 and 13 that

$$K_p = e^{-\Delta G^\circ/RT}$$

or

$$\Delta G^\circ = -RT \ln K_p \qquad ...(21)$$

This equation is known as the **van't Hoff reaction isotherm.**

Eq. 21 is very important. It permits calculation of ΔG° of the reaction from the known value of the equilibrium constant K_p and vice-versa.

Example 9. Calculate K_p for the reaction $3/2\ O_2(g) \rightleftharpoons O_3(g)$ at 298 K. ΔG° for the reaction is 163·43 kJ mol^{-1}.

Solution :

$$\Delta G^\circ = -RT \ln K_p$$

$$\therefore \quad \ln K_p = -\frac{\Delta G^\circ}{RT} = -\frac{163{\cdot}43 \times 10^3 \text{ J mol}^{-1}}{(8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1})(298 \text{ K})}$$

$$\therefore \quad K_p = 2{\cdot}0 \times 10^{-29}$$

Example 10. The value of K_p for the water gas reaction $CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$ is $1{\cdot}06 \times 10^5$ at 25°C. Calculate ΔG° for this reaction.

Solution :

$$\Delta G^\circ = -RT \ln K_p = -(8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1})(298 \text{ K}) \ln (1{\cdot}06 \times 10^5)$$

$$= -28{,}673{\cdot}6 \text{ J mol}^{-1} = -28{\cdot}674 \text{ kJ mol}^{-1}$$

Distinction between ΔG and ΔG°. We must emphasize the distinction between ΔG and ΔG° for a reaction. ΔG° is the difference in the free energy of products and reactants when all of them are in their standard states. This does not refer to the actual reaction at equilibrium. ΔG, however, refers to the difference in the free energy of products and reactants at the actual measured concentrations (or partial pressures) of the components. When $\Delta G = 0$, the reaction is at equilibrium and the concentrations (or partial pressures) of the components are those which appear in the equilibrium constant expression.

Relations between K_p, K_c and K_x

We shall now proceed to establish the relations between the three equilibrium constants K_p, K_c and K_x.

a. Relation between K_p and K_x. In an ideal gaseous mixture, each component obeys Dalton's law of partial pressures, *i.e.*, $p_i = x_i P$ where P is the total pressure and p_i is the partial pressure of the ith component with mole fraction x_i in the mixture. For the reaction

$$aA + bB \rightleftharpoons mM + nN$$

we have $p_A = x_A P$, $p_B = x_B P$, $p_M = x_M P$, $P_N = x_N P$

$$\therefore \quad K_p = \frac{p_M^m p_N^n}{p_A^a p_B^b} = \left(\frac{x_M^m x_N^n}{x_A^a x_B^b}\right) P^{(m+n)-(a+b)} = K_x (P)^{\Delta n} \qquad ...(22)$$

where $\Delta n = (m + n) - (a + b)$.

b. Relation between K_p and K_c. For an ideal gaseous mixture,

$$p_i V = n_i RT$$

$$\therefore \quad p_i = (n_i/V)RT = c_i RT$$

where $c_i\ (= n_i/V)$ is the molar concentration of the ith component in the mixture of total volume V. Hence,

$$p_A = c_A RT, \quad p_B = c_B RT, \quad p_M = c_M RT, \quad p_N = c_N RT$$

$$\therefore \quad K_p = \frac{p_M^m p_N^n}{p_A^a p_B^b} = \left(\frac{c_M^m c_N^n}{c_A^a c_B^b}\right)(RT)^{(m+n)-(a+b)} = K_c (RT)^{\Delta n} \qquad ...(23)$$

From Eqs. 22 and 23, $K_p = K_x (P)^{\Delta n} = K_c (RT)^{\Delta n}$ ...(24)

If $\Delta n = 0$, $m+n = a+b$ (*i.e.*, the number of moles of products equals the number of moles of reactants), then

$$K_p = K_x = K_c$$

Note : We can also establish a relation between K_p and K_n where n is the total number of moles. Since the mole fraction, x_i, of a component i in a mixture is given by $x_i = n_i/n$, we can write Eq. 22 as

$$K_p = \frac{n_M^m n_N^n}{n_A^a n_B^b}\left(\frac{P}{n}\right)^{\Delta n} = K_n \left(\frac{P}{n}\right)^{\Delta n} \qquad ...(25)$$

For reactions occurring in liquid phase it is convenient to use as standard state the pure liquid components at the temperature and pressure of the system. In that case, $a_i = \gamma_i x_i$ so that

$$K \equiv K_{th} = \frac{x_M^m x_N^n}{x_A^a x_B^b} \times \frac{\gamma_M^m \gamma_N^n}{\gamma_A^a \gamma_B^b} = K_x K_\gamma \qquad ...(26)$$

where γ_i is the activity coefficient of the ith component. K_γ is a complicated function of concentration which is determined experimentally. For nearly ideal solutions, however, $K_\gamma = 1$ so that $K_{th} = K_x$.

Example 11. Calculate K_c and K_x for the reaction $N_2O_4(g) \rightleftharpoons 2NO_2(g)$ for which $K_p = 0{\cdot}157$ atm at 27°C and 1 atm pressure.

Solution : For the reaction, $N_2O_4(g) \rightleftharpoons 2NO_2(g)$,

$$\Delta n = 2 - 1 = 1$$

Since $K_P = K_c (RT)^{\Delta n}$

$$K_c = \frac{K_p}{(RT)^{\Delta n}} = \frac{0{\cdot}157 \text{ atm}}{(0{\cdot}08206 \text{ dm}^3 \text{ atm K}^{-1} \text{ mol}^{-1} \times 300 \text{ K})} = 6{\cdot}38 \times 10^{-3} \text{ mol dm}^{-3}$$

$$K_x = K_p (P)^{-\Delta n} = (0{\cdot}157 \text{ atm})(1 \text{ atm})^{-1} = 0{\cdot}157$$

Example 12. Calculate K_c for the reaction $2SO_3(g) \rightleftharpoons 2SO_2(g) + O_2(g)$ for which $K_p = 3{\cdot}5 \times 10^{-23}$ atm at 27°C.

Solution : For the reaction $2SO_3(g) \rightleftharpoons 2SO_2(g) + O_2(g)$,

$$\Delta n = 2 + 1 - 1 = 1$$

$$\therefore \quad K_c = \frac{K_p}{(RT)^{\Delta n}} = \frac{3{\cdot}5 \times 10^{-23} \text{ atm}}{(0{\cdot}08206 \text{ dm}^3 \text{ atm K}^{-1} \text{ mol}^{-1} \times 300 \text{ K})} = 1{\cdot}42 \times 10^{-26} \text{ mol dm}^{-3}$$

Example 13. Calculate K_p/K_c for the following reactions at 27°C :

(a) $N_2(g) + O_2(g) \rightleftharpoons 2NO(g)$

(b) $N_2(g) + 3H_2(g) \rightleftharpoons 2NH_3(g)$

(c) $NH_4Cl(s) \rightleftharpoons NH_3(g) + HCl(g)$

Solution : The units of K_p/K_c depend upon the type of the reaction involved, as we shall see in this example. Since $K_p = K_c (RT)^{\Delta n}$, hence $K_p/K_c = (RT)^{\Delta n}$

(a) $N_2(g) + O_2(g) \rightleftharpoons 2NO(g)$; $\Delta n = 2 - (1 + 1) = 0$

$$\therefore \quad K_p/K_c = (RT)^0 = 1$$

(b) $N_2(g) + 3H_2(g) \rightleftharpoons 2NH_3(g)$; $\Delta n = 2 - (3 + 1) = -2$

$\therefore$ $K_p/K_c = (RT)^{-2} = (0{\cdot}08206\ dm^3\ atm\ K^{-1}\ mol^{-1} \times 300\ K)^{-2} = 1{\cdot}65 \times 10^{-3}\ mol^2\ dm^{-6}\ atm^{-2}$

(c) $NH_4Cl(s) \rightleftharpoons NH_3(g) + HCl(g)$; $\Delta n = 2$

$\therefore$ $K_p/K_c = (RT)^2 = (0{\cdot}08206\ dm^3\ atm\ K^{-1}\ mol^{-1} \times 300\ K)^2 = 605{\cdot}2\ dm^6\ atm^2\ mol^{-2}$

De Donder's Treatment of Chemical Equilibria

For a general reaction

$$aA + bB \rightleftharpoons mM + nN,$$

the Gibbs free energy, $G = f(T, P, n)$. Hence, the Gibbs free energy change is given by

$$dG = \left(\frac{\partial G}{\partial T}\right)_{P,n} dT + \left(\frac{\partial G}{\partial P}\right)_{T,n} dP + \left(\frac{\partial G}{\partial n_i}\right)_{P,T,n_j} dn$$

$$= -SdT + VdP + \mu_A dn_A + \mu_B dn_B + \mu_M dn_M + \mu_N dn_N \quad ...(27)$$

If the reaction is carried out at constant T and P (so that $dT = 0$, $dP = 0$), we have

$$(dG)_{T,P} = \mu_A dn_A + \mu_B dn_B + \mu_M dn_M + \mu_N dn_N \quad ...(28)$$

where the dn_is are the changes in the numbers of moles of the chemical species involved and μ_is are their chemical potentials.

For a closed system, the reaction stoichiometry requires that a change in the number of moles of one of the reactants or the products must be accompanied by an equivalent change in all other reactants and the products. If, in the balanced equation for the reaction, all the moles of the reactants get converted into products, the **progress of the reaction** is said to be 100%. This is also expressed by saying that one unit of reaction has occurred. Obviously, the progress of the reaction would be less than 100% if all the moles of the reactants do not get converted into products. It is thus convenient to define a variable ξ to express the progress or **advancement of the reaction**. Introduced by de Dondre, ξ is called the **degree of advancement of a chemical reaction.**

If the reaction advances by ξ units, then n_is can be written as

$$n_A = n_A^\circ - a\xi \ ; \quad n_B = n_B^\circ - b\xi \ ; \quad n_M = n_M^\circ + m\xi \ ; \quad n_N = n_N^\circ + n\xi \quad ...(29)$$

where n_i°s are the numbers of moles of the chemical species present before the reaction is advanced by ξ units. The minus sign for the moles of the reactants denotes that the reactants are *consumed* and the plus sign for the moles of the products denotes that the products are *formed.*

Differentiating Eq. 29 and remembering that n_i°s are constant, we obtain

$$dn_A = -a\,d\xi \ ; \quad dn_B = -b\,d\xi \ ; \quad dn_M = m\,d\xi \ ; \quad dn_N = n\,d\xi \quad ...(30)$$

These equations can be written as

$$d\xi = -dn_A/a = -dn_B/b = dn_M/m = dn_N/n \quad ...(31)$$

The quantity $d\xi$ is called **the differential advancement or the increment of the degree of advancement** of the reaction. We see that $d\xi$ is the ratio of the number of moles of the chemical species and its stoichiometric coefficient in the balanced chemical equation.

Substituting the values of dn_A, dn_B, dn_M and dn_N, as given by Eq. 30, in Eq. 28, we get

$$(dG)_{T,P} = [(m\mu_M + n\mu_N) - (a\mu_A + b\mu_B)]d\xi \quad ...(32)$$

$$(\partial G/\partial\xi)_{T,P} = [(m\mu_M + n\mu_N) - (a\mu_A + b\mu_B)] \quad ...(33)$$

The partial derivative $(\partial G/\partial\xi)_{T,P}$ gives the rate of change of the Gibbs free energy with the advancement of the reaction. The expression on the R.H.S. of Eq. 33 is called the **reaction potential.** Evidently,

$$\text{Reaction potential} = \Delta G = (\partial G/\partial\xi)_{T,P}$$

Thus, reaction potential is the rate of change of total Gibbs free energy per unit advancement of the chemical reaction at constant T and P. Note that the reaction potential is identical with the free energy change of a reaction. The *decrease in the reaction potential* is defined as the **chemical affinity**, A_f. Thus,

$$A_f = -(\partial G/\partial\xi)_{T,P} = -\Delta G \quad ...(34)$$

A few comments on A_f are in order. If the derivative $(\partial G/\partial\xi)_{T,P}$ is negative, this means that the free energy of the reaction mixture decreases as the reaction advances in the forward direction. This means that the reaction is spontaneous and the affinity is positive. If the derivative is positive, the reverse reaction is spontaneous and the affinity is negative. If the derivative is zero, the reaction is in equilibrium and the affinity is zero. Thus, at equilibrium.

$$(\partial G/\partial\xi)_{T,P} = 0 \quad ...(35)$$

Eq. 35 is general, being applicable whether the reactants and products are solids, liquids or gases.

Thermodynamic Relations for Chemical Affinity. For any chemical reaction, the Gibbs free energy depends upon T, P and the concentrations of the reacting substances. However, since these concentrations themselves determine the degree of advancement of the reaction, we can write

$$G = f(T, P, \xi)$$

$$\therefore \quad dG = (\partial G/\partial T)_{P,\xi}\,dT + (\partial G/\partial P)_{T,\xi}\,dP + (\partial G/\partial\xi)_{T,P}\,d\xi$$

We know from thermodynamics that

$$(\partial G/\partial T)_{P,\xi} = -S \text{ and } (\partial G/\partial\xi)_{T,\xi} = V \quad ...(36)$$

and from Eq. 34, $(\partial G/\partial\xi)_{T,P} = -A_f = \Delta G$.

Hence, $$dG = -SdT + VdP - A_f d\xi = -SdT + VdP + \Delta G d\xi \quad ...(37)$$

We can now proceed to determine the relation of A_f to other thermodynamic functions.

1. **Work function and Affinity.** We know that

$$G = H - TS = U + PV - TS = A + PV$$

where $A(=U - TS)$ is the work function.

or $$A = G - PV$$

$$\therefore \quad dA = dG - PdV - VdP \quad ...(38)$$

Substituting for dG from Eq. 37,

$$dA = -SdT + VdP + \Delta G d\xi - PdV - VdP$$

$$= -SdT - PdV + \Delta G d\xi = -SdT - PdT - A_f d\xi \quad ...(39)$$

At constant T and V, $dT = 0$, $dV = 0$, so that

$$(\partial A/\partial\xi)_{T,V} = \Delta G = -A_f \quad ...(40)$$

2. **Enthalpy and Affinity.** We know that

$$H = G + TS$$

$$\therefore \quad dH = dG + TdS + SdT$$

$$= -SdT + VdP + \Delta G d\xi + TdS + SdT \quad ...(41)$$

$$= TdS + VdP + \Delta G d\xi = TdS + VdP - A_f d\xi \quad ...(42)$$

At constant S and P, $dS = 0$, $dP = 0$, so that

$$(\partial H/\partial \xi)_{S,P} = \Delta G = -A_f \quad ...(43)]$$

3. Internal Energy and Affinity. As mentioned above,

$$G = H - TS = U + PV - TS$$

$$\therefore \quad U = G + TS - PV$$

$$dU = dG + TdS + SdT - PdV - VdP \quad ...(44)$$

$$= -SdT + VdP + \Delta G d\xi + TdS + SdT - PdV - VdP$$

$$= TdS - PdV + \Delta G d\xi = TdS - PdV - A_f d\xi \quad ...(45)$$

At constant S and V, $dS = 0$, $dV = 0$, so that

$$(\partial U/\partial \xi)_{S,V} = \Delta G = -A_f \quad ...(46)$$

From the above treatment we find that

$$G = f(T,P,\xi)\ ;\ A = f(T,V,\xi)\ ;\ H = f(S,P,\xi)\ ;\ U = f(S,V,\xi) \quad ...(47)$$

Since G, A, H and U are state functions, we can write their total differentials as

$$dG = (\partial G/\partial T)_{P,\xi}\, dT + (\partial G/\partial P)_{T,\xi}\, dP + (\partial G/\partial \xi)_{T,P}\, d\xi \quad ...(48)$$

$$dA = (\partial A/\partial T)_{V,\xi}\, dT + (\partial A/\partial V)_{T,\xi}\, dV + (\partial A/\partial \xi)_{T,V}\, d\xi \quad ...(49)$$

$$dH = (\partial H/\partial S)_{P,\xi}\, dS + (\partial H/\partial P)_{S,\xi}\, dP + (\partial H/\partial \xi)_{S,P}\, d\xi \quad ...(50)$$

$$dU = (\partial U/\partial S)_{V,\xi}\, dS + (\partial U/\partial V)_{S,\xi}\, dV + (\partial U/\partial \xi)_{V,S}\, d\xi \quad ...(51)$$

These quantities are referred to as **thermodynamic potentials** relative to thermodynamic variables T, P ; T, V ; S, P and S, V, respectively.

HOMOGENEOUS EQUILIBRIA

Homogeneous gaseous equilibria are best classified into two categories, *i.e.*, in which the number of product molecules is equal to the number of reactant molecules and in which the number of product molecules does not equal the number of reactant molecules.

To the first category belong the following equilibrium systems :

$$N_2(g) + O_2(g) \rightleftharpoons 2NO(g)$$

$$H_2(g) + I_2(g) \rightleftharpoons 2HI(g)$$

$$H_2(g) + CO_2(g) \rightleftharpoons H_2O(g) + CO(g)$$

To the second category belong the following equilibrium systems :

$$SO_2Cl_2(g) \rightleftharpoons SO_2(g) + Cl_2(g)$$

$$COCl_2(g) \rightleftharpoons CO(g) + Cl_2(g)$$

$$2CO_2(g) \rightleftharpoons 2CO(g) + O_2(g)$$

$$2SO_2(g) + O_2(g) \rightleftharpoons 2SO_3(g)$$

$$N_2O_4(g) \rightleftharpoons 2NO_2(g)$$

$$3/2\ H_2(g) + 1/2\ N_2(g) \rightleftharpoons NH_3(g)$$

$$PCl_5(g) \rightleftharpoons PCl_3(g) + Cl_2(g)$$

We shall now consider some homogeneous gaseous equilibria having zero, positive and negative values of Δn where

Δn = Number of moles of gaseous products – Number of moles of gaseous reactants

Case I. When $\Delta n_g = 0$. For the reaction

$$A(g) + B(g) \rightleftharpoons C(g) + D(g)$$

$$K_p = (p_C \times p_D)/(p_A \times p_B) \quad ...(52)$$

If the value of K_p and the initial amounts (number of moles) of A and B are known, the number of moles of various species at equilibrium can be calculated as follows :

	A	+	B	$\rightleftharpoons$	C	+	D
Number of moles at $t=0$:	a		b		0		0
Number of moles at equilibrium :	$a-x$		$b-x$		x		x

Total number of moles at equilibrium $= a - x + b - x + x + x = a + b$

Partial pressures : $\left(\frac{a-x}{a+b}\right)P \quad \left(\frac{b-x}{a+b}\right)P \quad \left(\frac{x}{a+b}\right)P \quad \left(\frac{x}{a+b}\right)P$

$$\therefore \quad K_p = \frac{\left[\left(\frac{x}{(a+b)}\right)P\right]^2}{\left(\frac{a-x}{a+b}\right)P\left(\frac{b-x}{a+b}\right)P} = \frac{x^2}{(a-x)(b-x)} \quad ...(53)$$

The solution of quadratic equation (53) will give two values of x, one of which will determine the equilibrium composition of the homogeneous reaction mixture and the other may be negative or otherwise unreasonable and hence has to be ignored.

From Eq. 53, we arrive at the following conclusions :

1. Since $\Delta n_g = 0$, hence $K_p = K_c = K_x$ (Eq. 24)

2. Suppose we are given a set of equilibrium partial pressures. Then the value of K_p remains unaltered if each of the partial pressures is multiplied by the same factor. In other words, the relative amounts of the various species present at equilibrium are independent of the total pressure or total volume of the system.

3. K_p is independent of the units in which the partial pressures of the various species are expressed.

4. The addition of an inert gas to the reaction mixture does not alter the relative amounts of the species and hence does not alter the value of the equilibrium constant.

5. If an extra amount of A, B, C or D is added to the equilibrium reaction mixture, the relative amounts of the various species will be altered without changing the value of K_p. Suppose n moles of gas A are introduced at equilibrium. The system will readjust its equilibrium. If x' is the amount of A consumed at equilibrium, then the amounts (number of moles) of the various species at equilibrium will be as follows :

A(g)	+	B(g)	$\rightleftharpoons$	C(g)	+	D(g)
$a + n - x'$		$b - x'$		x'		x'

$$\therefore \quad K_p = \frac{x'^2}{(a + n - x')(b - x')} \quad ...(54)$$

The denominator in Eq. 54 is now greater than in Eq. 53 so that x' will be greater than x in order that the value of K_p remains the same. Therefore, more of C and D will be formed. On the other hand, if C or D is introduced at equilibrium, the value of x' will decrease.

The effect of temperature on the equilibrium will depend upon whether the reaction is exothermic or endothermic. If the reaction is exothermic, the equilibrium will shift to the left, *i.e.*, lesser amounts of products will be formed. If the reaction is endothermic, the equilibrium will shift to the right, *i.e.*, larger amounts of products will be formed.

Case II. When Δn is positive. Consider the reaction

$$A(g) \rightleftharpoons B(g) + C(g)$$

$$K_P = p_B \times p_C / p_A \qquad ...(55)$$

If the value of K_p and the initial amount of A are known, the amounts (number of moles) of the various species at equilibrium can be calculated as follows :

	A	⇌	B	+	C
Number of moles at $t=0$:	a		0		0
Number of moles at equilibrium :	$a-x$		x		x

Total number of moles at equilibrium $= a - x + x + x = a + x$

Partial pressures : $\left(\frac{a-x}{a+x}\right)P \qquad \left(\frac{x}{a+x}\right)P \qquad \left(\frac{x}{a+x}\right)P$

$$\therefore \quad K_p = \frac{\left[\left(\frac{x}{a+x}\right)P\right]^2}{\left(\frac{a-x}{a+x}\right)P} = \frac{x^2P}{(a-x)(a+x)} = \frac{x^2P}{a^2-x^2} \qquad ...(56)$$

We conclude from Eq. 56 that

1. At a given temperature, the composition of the equilibrium mixture depends on P. Since K_p should be independent of P, it follows that if P increases, x should decrease, *i.e.*, lesser amount of A will dissociate.

2. K_p will have the units of pressure.

3. We also conclude that since $\Delta n_g \neq 0$, $K_p \neq K_c \neq K_x$

We can also write the equilibrium constants of such reactions in terms of the degree of dissociation. The degree of dissociation, α, gives the fraction of the reactant dissociated. If, for instance, we have 1 mole of A in the beginning, then, at equilibrium, an amount α will be dissociated. Thus,

	A(g)	⇌	B(g)	+	C(g)
Number of moles at $t=0$:	1		0		0
Number of moles at equilibrium :	$1-\alpha$		α		α

If, on the other hand, we have a moles of A in the beginning and α is the degree of dissociation, then

	A(g)	⇌	B(g)	+	C(g)
Number of moles at $t=0$	a		0		0
Number of moles at equilibrium :	$a(1-\alpha)$		$a\alpha$		$a\alpha$

$\therefore$ Total number of moles at equilibrium $= a(1-\alpha) + a\alpha + a\alpha = a(1+\alpha)$

$$\therefore \quad K_p = \frac{p_B \times p_C}{p_A} = \frac{\left\{\frac{a\alpha P}{a(1+\alpha)}\right\}\left\{\frac{a\alpha P}{a(1+\alpha)}\right\}}{\left\{\frac{a(1-\alpha)P}{a(1+\alpha)}\right\}} = \frac{\alpha^2 P}{1-\alpha^2} \qquad ...(57)$$

Knowing K_p and P, α can be obtained from Eq. 57.

Example 14. The reaction $AB_2(g) \rightleftharpoons A(g) + 2B(g)$ is studied in a 10-litre flask. Initially there is 0·40 mole of AB_2. When after the introduction of the catalyst, at 27°C, equilibrium is reached, the pressure of the mixture is 1·2 atm. Calculate the equilibrium constant K_p.

Solution : The equilibrium reaction is $AB_2(g) \rightleftharpoons A(g) + 2B(g)$

Number of moles at equilibrium : $(0{\cdot}40 - x) \qquad x \qquad 2x$

$\therefore$ Total number of moles, $n_{total} = 0{\cdot}40 + 2x$

Assuming that the equilibrium mixture behaves ideally,

$$n_{total} = \frac{PV}{RT} = \frac{(1{\cdot}20 \text{ atm})(10 \text{ dm}^3)}{(0{\cdot}08206 \text{ dm}^3 \text{ atm K}^{-1} \text{ mol}^{-1})(300 \text{ K})} = 0{\cdot}487$$

Thus, $0{\cdot}40 + 2x = 0{\cdot}487$ whence $x = 0{\cdot}0435$; $P = 1{\cdot}2$ atm (given)

$$p_A = \left(\frac{x}{0{\cdot}40+2x}\right)P; \; p_B = \left(\frac{2x}{0{\cdot}40+2x}\right)P; \; p_{AB_2} = \left(\frac{0{\cdot}40-x}{0{\cdot}40+2x}\right)P$$

$$K_p = \frac{p_A \times p_B^2}{p_{AB_2}} = \frac{(x)(2x)^2(1{\cdot}20\text{atm})^2}{(0{\cdot}40-x)(0{\cdot}40+2x)^2}$$

Using $x = 0{\cdot}0435$, we find that $K_P = 5{\cdot}607 \times 10^{-3}$ **atm²**

Dissociation of N_2O_4. N_2O_4 dissociates to give NO_2, as shown below. If we start with one mole of N_2O_4 and if α is the degree of dissociation, then,

$$N_2O_4(g) \rightleftharpoons 2NO_2(g)$$
$$(1-\alpha) \qquad (2\alpha)$$

The equilibrium constant, K_p, is given by $K_p = p^2_{NO_2} / p_{N_2O_4}$

Since α is the degree of dissociation of N_2O_4, hence, at equilibrium, $(1 - \alpha)$ is proportional to the number of moles of undissociated N_2O_4 ; 2α is proportional to the number of moles of NO_2. Thus, $(1 - \alpha) + 2\alpha$ or $1 + \alpha$ is proportional to the total number of moles. Let the total pressure of N_2O_4 and NO_2 be P so that the partial pressures are :

$$p_{N_2O_4} = \frac{1-\alpha}{1+\alpha}P \quad \text{and} \quad p_{NO_2} = \frac{2\alpha}{1+\alpha}P$$

Hence, $$K_p = \frac{\left[\frac{2\alpha}{1+\alpha}P\right]^2}{\left(\frac{1-\alpha}{1+\alpha}P\right)} = \frac{4\alpha^2P^2}{(1+\alpha)^2} \times \frac{1+\alpha}{(1-\alpha)P} = \frac{4\alpha^2P}{1-\alpha^2} \qquad ...(58)$$

Example 15. For the dissociation reaction $N_2O_4(g) \rightleftharpoons 2NO_2(g)$, the equilibrium constant K_p is 0·120 atm at 298 K and a total pressure of 2 atm. Calculate the degree of dissociation of N_2O_4.

Solution : $K_p = 4\alpha^2P/(1 - \alpha^2)$ (Eq. 58)

$K_p = 0{\cdot}120$ atm, $P = 2$ atm

$\therefore \quad 0{\cdot}120 = 4\alpha^2(2)/(1 - \alpha^2) = 8\alpha^2/(1 - \alpha^2)$ or $0{\cdot}120(1 - \alpha^2) = 8\alpha^2$

$\therefore$ **Degree of dissociation, $\alpha = (0{\cdot}120/8{\cdot}12)^{1/2} = 0{\cdot}121$**

Example 16. For the dissociation reaction $N_2O_4(g) \rightleftharpoons 2NO_2(g)$, derive the expression for the degree of dissociation in terms of K_p and total pressure P.

Solution : $K_p = 4\alpha^2P/(1 - \alpha^2)$ (Eq. 58)

$\therefore \quad K_p(1 - \alpha^2) = 4\alpha^2P$ or $(1 - \alpha^2)/\alpha^2 = 4P/K_p$

$\therefore \quad (1/\alpha^2) - 1 = 4P/K_p$ or $1/\alpha^2 = 1 + 4P/K_p = (4P + K_p)/K_p$

$\therefore \quad \alpha^2 = K_p/(K_p + 4P) = 1/(1 + 4P/K_p) = (1 + 4P/K_p)^{-1}$

$\therefore \quad \alpha = (1 + 4P/K_p)^{-1/2}$ **which is the desired expression.**

Example 17. Calculate the degree of dissociation of Br_2 gas into Br atoms if at 1600 K and a total pressure of 0·1 atm, $K_p = 0{\cdot}255$ atm.

Solution : $Br_2(g) \rightleftharpoons 2Br(g)$

$K_p = 4\alpha^2P/(1 - \alpha^2)$ (Eq. 58)

$0{\cdot}255 \text{ atm} = 4\alpha^2(0{\cdot}1 \text{ atm})/(1 - \alpha^2) = 0{\cdot}4\alpha^2/(1 - \alpha^2)$

or $\alpha^2/(1 - \alpha^2) = 0{\cdot}255/0{\cdot}4 = 0{\cdot}64$

which can be solved to yield $\alpha = 0{\cdot}62$. Thus, the degree of dissociation is 0·62.

Dissociation of PCl_5. Gaseous PCl_5 dissociates into PCl_3 and Cl_2 according to the reaction

$$PCl_5(g) \rightleftharpoons PCl_3(g) + Cl_2(g)$$

On the dissociation of 1 mole of PCl_5, there is at equilibrium $(1 - \alpha)$ mole of PCl_5, α mole of PCl_3 and α mole of Cl_2 so that the total number of moles $= (1-\alpha) + \alpha + \alpha = 1 + \alpha$ where α is the degree of dissociation.

If P is the total equilibrium pressure, then the partial pressures of the various constituents are :

$$p_{PCl_5} = \frac{(1-\alpha)P}{1+\alpha}; \quad p_{PCl_3} = \frac{\alpha P}{1+\alpha}; \quad p_{Cl_2} = \frac{\alpha P}{1+\alpha}$$

Hence,

$$K_p = \frac{p_{PCl_3} p_{Cl_2}}{p_{PCl_5}} = \frac{\left(\frac{\alpha P}{1+\alpha}\right)\left(\frac{\alpha P}{1+\alpha}\right)}{\frac{(1-\alpha)P}{1+\alpha}}$$

$$= \frac{\alpha^2 P^2}{(1+\alpha)^2} \times \frac{1+\alpha}{(1-\alpha)P} = \frac{\alpha^2 P}{1-\alpha^2} \qquad ...(59)$$

Since at a given temperature, K_p is constant, it is evident that an increase in P results in a decrease of α and *vice-versa*. If $\alpha \ll 1$, α^2 will be still smaller so that α^2 can be neglected in the denominator of Eq. 59, giving

$$K_p = \alpha^2 P \quad \text{whence} \quad \alpha = (K_p/P)^{1/2} \qquad ...(60)$$

Knowing K_P and the total pressure P, α can be calculated with the help of Eq. 60.

Example 18. The dissociation of PCl_5 was studied at 229°C at a total pressure of 1 atm. The value of K_p was found to be 0·460 atm. Calculate the degree of dissociation of PCl_5. If keeping the temperature constant, the pressure on the system is raised to 10 atm, what will be the degree of dissociation ?

Solution : $K_p = 0{\cdot}460$ atm ; $P = 1$ atm

$K_p = \alpha^2 P/(1 - \alpha^2)$ (Eq. 59)

$\therefore$ $0{\cdot}460 \text{ atm} = \alpha^2(1 \text{ atm})/(1 - \alpha^2)$ or $0{\cdot}460(1 - \alpha^2) = \alpha^2$

$\therefore$ $\alpha = (0{\cdot}460/1{\cdot}460)^{1/2} = \mathbf{0{\cdot}56}$

Again, at $P = 10$ atm,

$0{\cdot}460 \text{ atm} = \alpha^2(10 \text{ atm})/(1 - \alpha^2)$ or $0{\cdot}460(1 - \alpha^2) = 10\alpha^2$

$\therefore$ $\alpha = (0{\cdot}460/10{\cdot}460)^{1/2} = (0{\cdot}044)^{1/2} = \mathbf{0{\cdot}21}$

We see that raising the pressure of the system from 1 atm to 10 atm, lowers the extent of dissociation from 56% to 21%.

Example 19. The extent of dissociation of PCl_5 at a certain temperature is 20% at one atm pressure. Calculate the pressure at which this substance is half-dissociated at the same temperature.

Solution : $K_p = \alpha^2 P/(1 - \alpha^2)$

$P = 1$ atm, $\alpha = 0{\cdot}2$

$\therefore$ $K_p = (0{\cdot}2)^2 (1 \text{ atm}) / (1 - 0{\cdot}04) = 0{\cdot}041$ atm

Let P' be the pressure at which $\alpha = 0{\cdot}5$, then

$K_p = \alpha^2 P'/(1 - \alpha^2)$

$0{\cdot}041 \text{ atm} = (0{\cdot}5)^2 P'/(1 - 0{\cdot}25)$

$P' = \mathbf{0{\cdot}123 \text{ atm}}$

Example 20. 2 moles of PCl_5 are heated at 229°C till equilibrium is reached at a total pressure of 1 atm. Calculate the composition of the equilibrium mixture and the percentage decomposition of PCl_5. $K_p = 0{\cdot}46$ atm.

Solution :

	$PCl_5(g)$	$\rightleftharpoons$	$PCl_3(g)$	+	$Cl_2(g)$
	a				
	$a-x$		x		x

It can be easily shown that for the above reaction at a total pressure of 1 atm,

$K_p = x^2/(a^2 - x^2)$

In the present case, $a = 2$ mole ; $P = 1$ atm ; $K_p = 0{\cdot}46$ atm

$\therefore$ $0{\cdot}46 = x^2/(4 - x^2)$

or $0{\cdot}46(4 - x^2) - x^2 = 0$ or $1{\cdot}84 - 1{\cdot}46x^2 = 0$

This equation, on solving for x, gives $x = 1{\cdot}12$ mole

Hence, at equilibrium, the composition of the equilibrium mixture is as follows :

Amount of $PCl_5 = 2 - 1{\cdot}12 = \mathbf{0{\cdot}88}$ mole

Amount of PCl_3 = amount of $Cl_2 = \mathbf{1{\cdot}12}$ moles

$\therefore$ % age decomposition of $PCl_5 = (1{\cdot}12/2) \times 100 = \mathbf{56}$

Example 21. If in the last example, the pressure of the system is raised to 10 atm at the same temperature, what would be the percentage decomposition of PCl_5 ?

Solution : Even when the pressure is raised from 1 to 10 atm, K_p remains the same, *i.e.*, 0·46 atm.

$K_p = x^2 P/(a^2 - x^2)$

$0{\cdot}46 = 10x^2/(4 - x^2)$

This quadratic equation can be solved for x giving $x = 0{\cdot}42$ mole

$\therefore$ % age decomposition of $PCl_5 = (0{\cdot}42/2) \times 100 = 21$

Example 22. At 30°C, K_p for the dissociation reaction $SO_2Cl_2(g) \rightleftharpoons SO_2(g) + Cl_2(g)$ is $2{\cdot}9 \times 10^{-2}$ atm. If the total pressure is 1 atm, calculate the degree of dissociation of SO_2Cl_2.

Solution : For the given equilibrium, $K_p = \alpha^2 P/(1 - \alpha^2)$

In the present case, $K_p = 2{\cdot}9 \times 10^{-2}$ atm ; $P = 1$ atm

$\therefore$ $2{\cdot}9 \times 10^{-2} \text{ atm} = \alpha^2(1 \text{ atm})/(1 - \alpha^2)$.

Since K_p in this case is very small, α would also be very small so that $\alpha^2 << 1$ and can be neglected in the denominator giving $K_p = \alpha^2 P$

$\therefore$ Degree of dissociation at $P = 1$ atm, $\alpha = (K_p)^{1/2} = (2{\cdot}9 \times 10^{-2})^{1/2} = \mathbf{0{\cdot}17}$

Example 23. At 248°C, the K_p for the reaction $SbCl_5(g) \rightleftharpoons SbCl_3(g) + Cl_2(g)$ is 1·07 atm at a total pressure of 1 atm. Calculate the degree of dissociation of $SbCl_5$.

Solution : $K_p = \alpha^2 P/(1 - \alpha^2)$ (Eq. 59)

Since α is not known, we cannot use the approximation that $\alpha^2 \ll 1$. Instead, we shall have to solve for α by using the above expression as such.

$K_p = 1{\cdot}07$ atm ; $P = 1$ atm

$\therefore$ $1{\cdot}07 \text{ atm} = \alpha^2(1 \text{ atm})/(1 - \alpha^2)$ or $1{\cdot}07(1 - \alpha^2) = \alpha^2$

$\therefore$ Degree of dissociation, $\alpha = (1{\cdot}07/2{\cdot}07)^{1/2} = (0{\cdot}517)^{1/2} = \mathbf{0{\cdot}718}$

Example 24. For the homogeneous gaseous reaction $2AB_2(g) \rightleftharpoons 2AB(g) + B_2(g)$, derive an expression for the degree of dissociation, α, in terms of K_p and total pressure P assuming that $\alpha << 1$.

Solution :

	$2AB_2(g)$	$\rightleftharpoons$	$2AB(g)$	+	$B_2(g)$
No. of moles at equilibrium :	$2(1 - \alpha)$		2α		α

$\therefore$ $n = 2(1-\alpha) + 2\alpha + \alpha = 2 + \alpha$

$\therefore$ $p_{AB_2} = \frac{2(1-\alpha)P}{2+\alpha}; \quad p_{AB} = \frac{2\alpha P}{2+\alpha}; \quad p_{B_2} = \frac{\alpha P}{2+\alpha}$

$\therefore$ $K_p = \frac{p_{AB}^2 p_{B_2}}{p_{AB_2}^2} = \frac{\left(\frac{2\alpha P}{2+\alpha}\right)^2 \left(\frac{\alpha P}{2+\alpha}\right)}{\left(\frac{2(1-\alpha)P}{2+\alpha}\right)^2} = \frac{\alpha^3 P}{(2+\alpha)(1-\alpha)^2}$

Since $\alpha << 1$, it can be neglected in the denominator, giving

$K_p = \alpha^3 P/2$ whence $\alpha = (2K_p/P)^{1/3}$

Example 25. A homogeneous gaseous reaction $AB_2(g) \rightleftharpoons A(g) + 2B(g)$ is carried out in a 10-litre flask at 300 K. The flask initially contains 0·4 mole of AB_2. The total pressure of the reaction mixture, after the attainment of equilibrium, is 1·2 atm. Calculate K_p.

Solution :
$$K_p = \frac{p_A p_B^2}{p_{AB_2}} = \frac{(x_A P)(x_B P)^2}{x_{AB_2} P} = \frac{x_A x_B^2 P^2}{x_{AB_2}}$$

where x_is are the mole fractions and P is the total equilibrium pressure.

Since $x_i = n_i / n_{total}$, we have
$$K_p = \frac{n_A n_B^2 P^2}{n_{AB_2}(n_{total})^2} \qquad ...(i)$$

Let y be the number of moles of A formed at equilibrium. Then

$AB_2(g)$	$\rightleftharpoons$	$A(g)$	+	$2B(g)$
$0·40 - y$		y		$2y$

$$n_{total} = (0·40 - y) + y + 2y = 0·40 + 2y$$

Also, assuming that the mixture behaves ideally,
$$n_{total} = \frac{PV}{RT} = \frac{(1·20 \text{ atm})(10 \text{ dm}^3)}{(0·08206 \text{ dm}^3 \text{ atm K}^{-1} \text{ mol}^{-1})(300 \text{ K})} = 0·487 \text{ mole}$$
$$\therefore \quad 0·487 = 0·40 + 2y \quad \text{whence} \quad y = 0·0435 \text{ mole}$$

Hence, from Eq. *(i)*,
$$K_p = \frac{y(2y)^2(1·20)^2}{(0·40 - y)(0·40 + 2y)^2} = 5·607 \times 10^{-3}$$

Example 26. The homogeneous gaseous reaction $2SO_2 + O_2 \rightleftharpoons 2SO_3$ is carried out in a 2-litre flask at 300 K. The flask initially contains 0·1 mole each of SO_2 and SO_3. The total pressure of the reaction mixture, after the equilibrium has been attained, is 2·78 atm. Calculate *(a)* K_p and *(b)* the mole fraction of O_2 at equilibrium.

Solution : a.
$$K_p = \frac{p_{SO_3}^2}{p_{SO_2}^2 p_{O_2}} = \frac{(x_{SO_3} P)^2}{(x_{SO_2} P)^2 (x_{O_2} P)} = \frac{(x_{SO_3})^2}{(x_{SO_2})^2 x_{O_2} P}$$

where x_is are the mole fractions and P is the total pressure ($x_i = n_i / n_{total}$)

$$\therefore \quad K_p = \frac{(n_{SO_3})^2 n_{total}}{(n_{SO_2})^2 n_{O_2}} \times \frac{1}{P}$$

Since, for the ideal gas mixture, $PV = n_{total} RT$,
$$\therefore \quad K_p = \frac{(n_{SO_3})^2}{(n_{SO_2})^2 n_{O_2}} \left(\frac{V}{RT}\right) \qquad ...(i)$$

Let y be the number of moles of O_2 reacted at equilibrium. Then,

$2SO_2(g)$	+	$O_2(g)$	$\rightleftharpoons$	$2SO_3(g)$
$(0·1 - 2y)$		y		$(0·1 + 2y)$

$$\therefore \quad n_{total} = (0·1 - 2y) + y + (0·1 + 2y) = 0·2 + y$$

Also,
$$n_{total} = \frac{PV}{RT} = \frac{(2·78 \text{ atm})(2 \text{ dm}^3)}{(0·08206 \text{ dm}^3 \text{ atm K}^{-1} \text{ mol}^{-1})(300 \text{ K})} = 0·226 \text{ mole}$$

Thus, $0·226 = 0·2 + y$ whence $y = 0·026$ mol

Substituting in Eq. *(i)*, we have
$$K_p = \frac{(0·1 + 2y)^2}{(0·1 - 2y)^2 y} \left(\frac{V}{RT}\right)$$
$$= \frac{(0·152 \text{ mol})^2 (2 \text{ dm}^3)}{(0·048 \text{ mol})^2 (0·026 \text{ mol})(0·08206) \text{ dm}^3 \text{ atm K}^{-1} \text{ mol}^{-1})(300 \text{ K})} = 31·33$$

b.
$$x_{O_2} = n_{O_2} / n_{total} = 0·026 / 0·226 = 0·115$$

Example 27. Consider the homogeneous gaseous reaction $H_2(g) + I_2(g) \rightleftharpoons 2HI(g)$ carried out in a vessel at a temperature T. When 1 mole of H_2 and 3 moles of I_2 are mixed, a certain amount of HI is formed. When, however, 2 additional moles of H_2 are introduced, the amount of HI formed is double the earlier amount. What is the value of K_p ?

Solution : Since the number of moles of reactants and products is the same, hence
$$K_p = K_c = K_x$$

Suppose in the first case, $n_{HI} = x$ so that $n_{H_2} = 1 - (x/2)$ and $n_{I_2} = 3 - (x/2)$
$$\therefore \quad K_p = x^2 / [1 - x/2)(3 - x/2)] \qquad ...(i)$$

In the second case, $n_{HI} = 2x$ so that $n_{H_2} = 3 - x$ and $n_{I_2} = 3 - x$
$$\therefore \quad K_p = (2x)^2 / (3 - x)^2 \qquad ...(ii)$$

Hence, from Eqs. *(i)* and *(ii)*,
$$\frac{x^2}{\left(1 - \frac{x}{2}\right)\left(3 - \frac{x}{2}\right)} = \frac{(2x)^2}{(3 - x)^2}$$

Neglecting x^2 in the denominator on both sides, cross-multiplying and simplifying, we obtain $x = 3/2$. Hence, from Eq. *(i)* or *(ii)*, $K_p = 4$.

Example 28. At 25°C, for the reaction $Br_2(l) + Cl_2(g) \rightleftharpoons 2BrCl(g)$, $K_p = 2·032$. At the same temperature, the vapour pressure of $Br_2(l)$ is 0·281 atm. Pure BrCl(g) was introduced into a closed container of adjustable volume. The total pressure was kept at 1 atm and the temperature at 25°C. Calculate the fraction of BrCl originally present that has been converted into Br_2 and Cl_2 at equilibrium assuming that the gaseous species behave ideally.

Solution : Since for the reaction $Br_2(l) + Cl_2(g) \rightleftharpoons 2BrCl(g)$, $K_p = 2·032$, therefore, for the reverse reaction, *viz.*, $2BrCl(g) \rightleftharpoons Br_2(l) + Cl_2(g)$, $K_p' = 1/K_p = 1/2·032 = 0·4921$

$$p_{BrCl} + p_{Br_2} + p_{Cl_2} = 1 \text{ atm}$$
$$\therefore \quad p_{BrCl} + p_{Cl_2} = 1 \text{ atm} - p_{Br_2} = (1 - 0·281) \text{ atm} = 0·719 \text{ atm}$$

Let n_0 be the number of moles of BrCl initially present and α be its degree of dissociation. Then, at equilibrium,
$$n_{BrCl} = n_0(1 - \alpha)$$
$$n_{Cl_2} = n_0 \times 1/2 \ (\alpha) \qquad [\because \text{ BrCl} \longrightarrow \tfrac{1}{2} \text{ Cl}_2]$$
$$n_{BrCl} + n_{Cl_2} = n_0 (1 - \alpha/2)$$
$$\therefore \quad p_{BrCl} = \left\{\frac{n_0(1 - \alpha)}{n_0(1 - \alpha/2)}\right\} (0·719 \text{ atm})$$
$$p_{Cl_2} = \left\{\frac{1/2\alpha \times n_0}{n_0(1 - \alpha/2)}\right\} (0·719 \text{ atm})$$
$$\therefore \quad K_p' = \frac{p_{Cl_2}}{(p_{BrCl})^2} = \frac{\alpha/2(1 - \alpha/2)}{(1 - \alpha)^2 \times 0·719} = 0·4921$$

This gives the quadratic equation $0·604\alpha^2 - 1·208\alpha + 0·354 = 0$ whose solution yields $\alpha = 0·357$.

Temperature-Dependence of the Equilibrium Constant : The van't Hoff Equation. From Eq. 21,
$$\Delta G^\circ / T = -R \ln K_p \qquad ...(61)$$

Hence,
$$\left[\frac{\partial(\Delta G^\circ / T)}{\partial T}\right] = -R \frac{d \ln K_p}{dT} \qquad ...(62)$$

From the Gibbs-Helmholtz equation,
$$\left[\frac{\partial(\Delta G^\circ / T)}{\partial T}\right] = -\frac{\Delta H^\circ}{T^2} \qquad ...(63)$$

Hence, from Eqs. 62 and 63

$$\frac{d \ln K_p}{dT} = \frac{\Delta H^\circ}{RT^2} \qquad ...(64)$$

where ΔH° is the standard enthalpy of the reaction. Eq. 64 is known as the **van't Hoff equation.**

Integrated Form of the van't Hoff Equation. The integration of Eq. 64 depends upon the manner in which ΔH° depends upon temperature. If, over a short temperature range, ΔH° is assumed to be temperature-independent, then the integration of Eq. 64 gives

$$\int d \ln K_p = \int \frac{\Delta H^\circ}{RT^2} dT = \frac{\Delta H^\circ}{R} \int \frac{dT}{T^2} \qquad ...(65)$$

or

$$\ln K_p = -\frac{\Delta H^\circ}{RT} + I \qquad ...(66)$$

where I is the constant of integration. According to Eq. 66, a plot of $\ln K_p$ versus $1/T$ gives a straight line with slope $= -\Delta H^\circ/R$. Thus, from the slope, ΔH° can be determined since

$$\Delta H^\circ = -R \times \text{slope} \qquad ...(67)$$

If it is desired to carry out the integration of Eq. 64 between two temperatures T_1 and T_2 when the equilibrium constants are $K_{P,1}$ and $K_{P,2}$ respectively, then, assuming that ΔH° is constant over this temperature range, we obtain

$$\int_{K_{P,1}}^{K_{P,2}} d \ln K_p = \frac{\Delta H^\circ}{R} \int_{T_1}^{T_2} \frac{dT}{T^2} \qquad ...(68)$$

or

$$\ln \frac{K_{P,2}}{K_{P,1}} = \frac{\Delta H^\circ}{R}\left[-\frac{1}{T_2} - \left(-\frac{1}{T_1}\right)\right] = \frac{\Delta H^\circ}{R}\left[\frac{T_2 - T_1}{T_1 T_2}\right] \qquad ...(69)$$

This is the **integrated van't Hoff equation.** From this equation, if ΔH° is known, then knowing the value of $K_{P,1}$ at T_1, the value of $K_{P,2}$ at T_2 can be determined. Also, if $K_{P,1}$ and $K_{P,2}$ at T_1 and T_2, respectively, are known, ΔH° can be calculated.

For accurate calculations, however, the temperature-dependence of ΔH° must be taken into account. If the heat capacities of the reactants and products are known as a function of temperature, an explicit expression for the temperature-dependence of ΔH° can be derived from the Kirchhoff equation, obtaining

$$\Delta H^\circ = \Delta H_0^\circ + \Delta\alpha T + \tfrac{1}{2}\Delta\beta T^2 + \tfrac{1}{3}\Delta\gamma T^3 + \cdots \qquad ...(70)$$

where ΔH_0° is the enthalpy of the reaction at absolute zero and $\Delta\alpha$, $\Delta\beta$, $\Delta\gamma$, etc., are derived from heat capacities of the reactants and the products and their variation with temperature. The van't Hoff equation now becomes

$$\frac{d \ln K_p}{dT} = \frac{\Delta H^\circ}{RT^2} + \frac{\Delta H_0^\circ}{RT^2} + \frac{\Delta\alpha}{RT} + \frac{\Delta\beta}{2R} + \frac{\Delta\gamma T}{3R} + \cdots \qquad ...(71)$$

This expression, upon integration, yields the following equation for K_p as a function of temperature :

$$\ln K_p = -\frac{\Delta H_0^\circ}{RT} + \frac{\Delta\alpha}{R} \ln T + \frac{\Delta\beta}{2R} T + \frac{\Delta\gamma}{6R} T^2 \cdots + I \qquad ...(72)$$

The constant of integration, I, can be easily determined if K_p is known at any temperature either experimentally or from the known value of ΔG°.

Example 29. The equilibrium constant K_p for the reaction $H_2(g) + S(g) \rightleftharpoons H_2S(g)$ is 20·2 atm^{-1} at 945°C and 9·1 atm^{-1} at 1·065°C. Calculate ΔH°.

Solution : According to the integrated van't Hoff equation

$$\ln\left(\frac{K_{P,2}}{K_{P,1}}\right) = \frac{\Delta H^\circ}{R}\left(\frac{T_2 - T_1}{T_1 T_2}\right)$$

or

$$\Delta H^\circ = R \ln\left(\frac{K_{P,2}}{K_{P,1}}\right)\left(\frac{T_1 T_2}{T_2 - T_1}\right) = (8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1}) \ln (9{\cdot}21/20{\cdot}2) \left[\frac{(1218\text{ K})(1338\text{ K})}{1338\text{ K} - 1218\text{ K}}\right]$$

$$= -88126{\cdot}3 \text{ J mol}^{-1} = -88{\cdot}126 \text{ kJ mol}^{-1}$$

Example 30. Integrate the van't Hoff equation, $d \ln K_p/dT = \Delta H^\circ/RT^2$ and determine the constant of integration.

Solution : $d \ln K_p/dT = \Delta H^\circ/RT^2$ or $d \ln K_p = (\Delta H^\circ/RT^2)\, dT$

Assuming that ΔH° remains constant over the temperature range, we have

$$\int (d \ln K_p) = \frac{\Delta H^\circ}{R} \int \frac{dT}{T^2} \quad \text{or} \quad \ln K_p = -(\Delta H^\circ/RT) + I$$

where I is the constant of integration.

Since $\Delta G^\circ = -RT \ln K_p$, we have

$$-\Delta G^\circ/RT = \ln K_p = -(\Delta H^\circ/RT) + I$$

or $$\Delta G^\circ = \Delta H^\circ - IRT$$

Also, $$\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ \qquad ...(i)$$

From Eqs. *(i)* and *(ii)*, $I = \Delta S^\circ/R$ ...(ii)

Example 31. The equilibrium constant of a reaction doubles on raising the temperature from 25°C to 35°C. Calculate ΔH° for the reaction.

Solution : According to the integrated van't Hoff equation, $\ln\left(\frac{K_{P,2}}{K_{P,1}}\right) = \frac{\Delta H^\circ}{R}\left(\frac{T_2 - T_1}{T_1 T_2}\right)$

Here $T_1 = 25°C = 298 \text{ K}$; $T_2 = 308 \text{ K}$

$K_{P,2}/K_{P,1} = 2$; $R = 8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1}$

$\therefore$ $\Delta H^\circ = R\,[T_1 T_2/(T_2 - T_1)] \ln 2 = 52893{\cdot}5 \text{ J} = 52{\cdot}89 \text{ kJ mol}^{-1}$

Example 32. For the reaction $CO(g) + SO_3(g) \rightleftharpoons CO_2(g) + SO_2(g)$, $\Delta G^\circ = 187{\cdot}1$ kJ mol^{-1} and $\Delta H^\circ = 184{\cdot}7$ kJ mol^{-1} at 25°C. Calculate *(a)* ΔG° at 398 K and *(b)* K_p at 398. Assume that ΔH° remains constant over the temperature interval.

Solution : *(a)* $\left[\frac{\partial(\Delta G^\circ/T)}{\partial T}\right]_P = -\frac{\Delta H^\circ}{T^2}$ (Eq. 63)

$\therefore$ $d(\Delta G^\circ/T) = -(\Delta H^\circ/T^2)dT$

Integrating, we get, $\int_{298}^{398} d\left(\frac{\Delta G^\circ}{T}\right) = -\int_{298}^{398} \frac{\Delta H^\circ}{T^2} dT$

$$\left[\frac{\Delta G^\circ}{T}\right]_{298}^{398} = -\Delta H^\circ\left[-\frac{1}{T}\right]_{298}^{398} = \Delta H^\circ\left[\frac{1}{T}\right]_{298}^{398}$$

$$\frac{\Delta G^\circ_{398}}{398\text{ K}} - \frac{\Delta G^\circ_{298}}{298\text{ K}} = \Delta H^\circ\left[\frac{1}{398\text{ K}} - \frac{1}{298\text{ K}}\right]$$

Substituting the values of ΔG° and ΔH° at 25°C we have

$$\frac{\Delta G^\circ}{398\text{ K}} = \frac{187{\cdot}1 \text{ kJ mol}^{-1}}{298\text{ K}} - (184{\cdot}7 \text{ kJ mol}^{-1})\left(\frac{1}{398\text{ K}} - \frac{1}{298\text{ K}}\right)$$

$$= -0{\cdot}472 \text{ kJ K}^{-1} \text{ mol}^{-1}$$

$$\Delta G^\circ_{398} = (-0{\cdot}472 \text{ kJ K}^{-1} \text{ mol}^{-1})(398 \text{ K}) = -187{\cdot}8 \text{ kJ mol}^{-1}$$

(b) Since $\Delta G^\circ = -RT \ln K_p$

$$K_p = \exp\left(\frac{-\Delta G^\circ}{RT}\right) = 4{\cdot}46\times10^{24}$$

Example 33. The following data were obtained for the temperature-dependence of the equilibrium constant of an inhibitor binding an enzyme. Calculate the values of ΔG°, ΔH° and ΔS° for this process at 25°C.

t(°C)	16·0	21·1	25·0	31·9	37·5
K_c	7·25	5·25	4·17	2·66	2·01(×10⁷)

Solution : Let us rewrite the data in the following form :

T (K)	289	294·1	298	304·9	310·5
$1/T\times100$	3·46	3·40	3·36	3·28	3·22
$K_c/10^7$	7·25	5·25	4·17	2·66	2·01
$\ln K_c$	18·10	17·78	17·55	17·10	16·81

A plot of $\ln K_c$ *versus* $1/T$ will give a straight line whose slope can be determined. This comes out to be $5{\cdot}43\times10^3$. Since slope $= -\Delta H^\circ/R$, hence

$$\Delta H^\circ = -\text{slope}\,(R) = -45{\cdot}1 \text{ kJ mol}^{-1}$$

At 25°C, $K_c = 4{\cdot}17\times10^7$, hence

$$\Delta G^\circ = -RT\ln K_c = -(8{\cdot}314\times10^{-3} \text{ kJ K}^{-1} \text{ mol}^{-1})(298 \text{ K}) \ln 4{\cdot}17\times10^7$$
$$= -43{\cdot}5 \text{ kJ mol}^{-1}$$

Since $\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ$

$$\therefore \quad \Delta S^\circ = (\Delta H^\circ - \Delta G^\circ)/T = (-45{\cdot}1 + 43{\cdot}5) \text{ kJ mol}^{-1}/298 \text{ K} = -5{\cdot}4 \text{ J K}^{-1} \text{ mol}^{-1}$$

Example 34. Show that the van't Hoff equation can also be written as $d\ln K_c/dT = \Delta U^\circ/RT^2$. K_c is the equilibrium constant when the concentrations of the species are expressed in terms of mol dm^{-3} and ΔU° is the standard internal energy change.

Solution : $K_p = K_c(RT)^{\Delta n} \quad \therefore \ln K_p = \ln K_c + \Delta n \ln RT$

Differentiating with respect to T, we get

$$\therefore \quad \ln d(\ln K_p)/dT = d(\ln K_c)/dT + \Delta n/T$$

$$\ln d(\ln K_c)/dT = d(\ln K_p)/dT - \Delta n/T = \Delta H^\circ/RT^2 - \Delta n/T$$
$$= \Delta H^\circ/RT^2 - RT\Delta n/RT^2 = (\Delta H^\circ - \Delta nRT)/RT^2 \qquad \text{(Note this step)}$$

For n moles of an ideal gas, $\Delta U^\circ = \Delta H^\circ - \Delta(PV) = \Delta H^\circ - \Delta nRT$

$$\therefore \quad d(\ln K_c)/dT = \Delta U^\circ/RT^2$$

Pressure-Dependence of Equilibrium Constants. We shall now examine the pressure-dependence of equilibrium constants K_p, K_c and K_x.

1. Pressure-dependence of K_p. According to Eq. 21,

$$\Delta G^\circ = -RT \ln K_p$$

Since ΔG° depends upon temperature alone, hence, K_p also depends on temperature alone and is independent of pressure. Hence,

$$\left(\frac{\partial \ln K_p}{\partial P}\right)_T = -\frac{\partial}{\partial P}\left(\frac{\Delta G^\circ}{RT}\right)_T = 0 \qquad \ldots(73)$$

2. Pressure-dependence of K_c. Since

$$K_p = K_c(RT)^{\Delta n} \qquad \text{(Eq. 23)}$$

or $$K_c = K_p(RT)^{-\Delta n}$$

$$\therefore \quad \ln K_c = \ln K_p - \Delta n \ln RT$$

$$\therefore \quad \left(\frac{d\ln K_c}{dP}\right)_T = \left(\frac{d\ln K_p}{dP}\right)_T - \Delta n\left(\frac{d\ln RT}{dP}\right)_T \qquad \ldots(74)$$

Since both the terms on the R.H.S. of Eq. 74 are equal to zero,

$$(d \ln K_c/dP)_T = 0 \qquad \ldots(75)$$

i.e., K_c is also independent of pressure.

3. Pressure-dependence of K_x.

$$K_p = K_x P^{\Delta n} \qquad \text{(Eq. 24)}$$

or $$K_x = K_p P^{-\Delta n}$$

$$\therefore \quad \ln K_x = \ln K_p - \Delta n \ln P \qquad \ldots(76)$$

$$\therefore \quad \left(\frac{d\ln K_x}{dP}\right)_T = \left(\frac{d\ln K_p}{dP}\right)_T - \Delta n\left(\frac{d\ln P}{dP}\right)_T = (d \ln K_p/dP) - \Delta n/P$$

$$= -\Delta n/P \quad (\because d \ln K_p/dP = 0) \qquad \ldots(77)$$

$$= -\Delta V/RT, \text{ where } \Delta V = \Sigma V_{\text{products}} - \Sigma V_{\text{reactants}} \qquad \ldots(78)$$

From Eq. 78 we draw the following conclusions :

1. When $\Delta n = 0$, *i.e.*, the reaction involves no change in the total number of moles of gaseous species in the system so that $\Delta V = 0$, K_x is independent of pressure. Such reactions are

$$CO_2(g) + H_2(g) \rightleftharpoons CO(g) + H_2O(g)$$

and $$H_2(g) + I_2(g) \rightleftharpoons 2HI(g)$$

2. When $\Delta n \neq 0$, K_x is pressure-dependent, as shown by Eq. 77 or Eq. 78. Two cases arise :

(a) $\Delta n > 0$, *i.e.*, there is an increase in the number of moles so that $\Delta V > 0$. This implies that in Eq. 78, the R.H.S. is negative so that K_x decreases with increasing pressure.

(b) $\Delta n < 0$, *i.e.*, there is a decrease in the number of moles so that $\Delta V < 0$. This means that in Eq. 78, the R.H.S. is positive so that K_x increases with increasing pressure. It is for this reason that the synthesis of ammonia by the Haber process,

$$3H_2(g) + N_2(g) \rightleftharpoons 2NH_3(g); \qquad \Delta n = 2 - (3 + 1) = -2$$

is carried out at high pressure. Fritz Haber (1868–1934), the German chemist, was the recipient of the 1918 Chemistry Nobel Prize for his synthesis of ammonia from the elements.

Example 35. Calculate K_p at 25°C and 325°C for the reaction $NO(g) + 1/2\ O_2(g) \rightleftharpoons NO_2(g)$ if at 25°C, $\Delta H^\circ = -56{\cdot}48$ kJ mol^{-1} and $\Delta G^\circ = -34{\cdot}85$ kJ mol^{-1}.

Solution : Since $\Delta G^\circ = -RT \ln K_p$

$$\ln K_p = -\frac{\Delta G^\circ}{RT} = \frac{34{\cdot}85 \text{ kJ mol}^{-1}}{(8{\cdot}314\times10^{-3} \text{ kJ K}^{-1} \text{ mol}^{-1})(298 \text{ K})}$$

$\therefore$ **At 25°C, $K_p = 1{\cdot}28\times10^5$**

To calculate K_p at 325°C we use the integrated van't Hoff equation, *viz.*,

$$\ln\left(\frac{K_{P,2}}{K_{P,1}}\right) = \frac{\Delta H^\circ}{R}\left(\frac{T_2 - T_1}{T_1T_2}\right)$$

$$\ln K_{P,2} = \ln K_{P,1} + \frac{\Delta H^\circ}{R}\left(\frac{T_2 - T_1}{T_1 T_2}\right)$$

$\Delta H^\circ = -56{\cdot}48$ kJ mol^{-1}, $T_1 = 298$ K, $T_2 = 598$ K. Using these values, we get $K_{P,2}$ at 325°C = 13·9

Note that for the exothermic reaction, K_p at higher temperature is smaller than that at lower temperature. The reverse is true for an endothermic reaction.

Example 36. Diamonds are formed from graphite under very high pressure. Calculate the equilibrium pressure at which graphite is converted into diamond at 25°C, given that the densities of graphite and diamond are, respectively, 2·25 and 3·51 g cm^{-3} and are independent of pressure. ΔG_f° values for graphite and diamond are zero and 2·90 kJ mol^{-1}, respectively.

Solution : This example is an application of the thermodynamic relation

$$[\partial(\Delta G)/\partial P]_T = \Delta V \qquad ...(i)$$

For the reaction, C (graphite) $\rightleftharpoons$ C (diamond),

$$\Delta G^\circ = \Delta G_f^\circ(\text{diamond}) - \Delta G_f^\circ(\text{graphite}) = 2{\cdot}90 \text{ kJ} - 0 = 2{\cdot}90 \text{ kJ mol}^{-1}$$

$$= (2{\cdot}90 \text{ kJ mol}^{-1}) \times \frac{(0{\cdot}08206 \text{ dm}^3 \text{ atm K}^{-1} \text{ mol}^{-1})}{8{\cdot}314 \times 10^{-3} \text{ kJ K}^{-1} \text{ mol}^{-1}} = 28{\cdot}6 \text{ dm}^3 \text{ atm mol}^{-1}$$

(Note the change in units for ΔG°)

The respective volumes of diamond and graphite are obtained from their densities, recalling that the atomic mass of carbon is 12 g mol^{-1}.

$$\therefore \quad \Delta V = V_{\text{diamond}} - V_{\text{graphite}} = \frac{12 \text{ g mol}^{-1}}{3{\cdot}51 \times 10^3 \text{ g dm}^{-3}} - \frac{12 \text{ g mol}^{-1}}{2{\cdot}25 \times 10^3 \text{ g dm}^{-3}}$$

$$= -1{\cdot}91 \times 10^{-3} \text{ dm}^3 \text{ mol}^{-1} \qquad ...(ii)$$

From Eq. *(i)*, $d(\Delta G) = \Delta V/dP$, which on integration, gives

$$\int_1^2 d(\Delta G) = \int_{P_1}^{P_2} \Delta V dP$$

Let $P_1 = 1$ atm and $P_2 = P$ Then,

$$\Delta G_2 - \Delta G_1 = \Delta V(P_2 - P_1) = \Delta V(P - 1)$$

or $\quad 0 - 28{\cdot}6 \text{ dm}^3 \text{ atm mol}^{-1} = -1{\cdot}91 \times 10^{-3} \text{ dm}^3 \text{ mol}^{-1} (P - 1)$

or $$P - 1 = \frac{28{\cdot}6 \text{ dm}^3 \text{ atm mol}^{-1}}{1{\cdot}91 \times 10^{-3} \text{ dm}^3 \text{ mol}^{-1}} = 1{\cdot}497 \times 10^4 \text{ atm}$$

$\therefore$ The equilibrium pressure, $P = 2{\cdot}497 \times 10^4 \approx$ **25,000 atm**

HETEROGENEOUS EQUILIBRIA

A chemical reaction is said to be heterogeneous if the species taking part in it constitute more than one phase. Examples of heterogeneous equilibria are :

1. The dissociation of solid calcium carbonate :

$$CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g)$$

2. The decomposition of solid ammonium chloride :

$$NH_4Cl(s) \rightleftharpoons NH_3(g) + HCl(g)$$

3. The decomposition of solid NH_4HS :

$$NH_4HS(s) \rightleftharpoons NH_3(g) + H_2S(g)$$

Dissociation of Calcium Carbonate

Consider the dissociation of solid calcium carbonate in a closed vessel :

$$CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g)$$

If ξ is the extent of the reaction, then

$$d\xi = -dn_{CaCO_3} = dn_{CaO} + dn_{CO_2} \qquad ...(79)$$

and $$dG = (\mu_{CaO} + \mu_{CO_2} - \mu_{CaCO_3})d\xi \qquad ...(80)$$

$\therefore$ $$(\partial G/\partial \xi)_{T,P} = \mu_{CaO} + \mu_{CO_2} - \mu_{CaCO_3} = \Delta G \qquad ...(81)$$

At equilibrium, $$(\partial G/\partial \xi)_{T,P} = 0 \qquad ...(82)$$

$\therefore$ $$\mu_{CaO} + \mu_{CO_2} - \mu_{CaCO_3} = 0 \qquad ...(83)$$

Now, under ordinary conditions, the chemical potentials of solids can be taken as equal to the chemical potentials of pure solids,

i.e., $$\mu_{CaO} = \mu_{CaO}^\circ \quad \text{and} \quad \mu_{CaCO_3} = \mu_{CaCO_3}^\circ$$

Also, $$\mu_{CO_2} = \mu_{CO_2}^\circ + RT \ln p_{CO_2} \qquad ...(84)$$

Hence, at equilibrium,

$$\mu_{CaCO_3} (= \mu_{CaCO_3}^\circ) = \mu_{CaO} + \mu_{CO_2} = \mu_{CaO}^\circ + \mu_{CO_2}^\circ + RT \ln p_{CO_2} \qquad ...(85)$$

or $$RT \ln p_{CO_2} = -[\mu_{CaO}^\circ + \mu_{CO_2}^\circ - \mu_{CaCO_3}^\circ] = -\Delta G^\circ \qquad ...(86)$$

But $$-\Delta G^\circ = RT \ln K_p \qquad \text{(Eq. 21)}$$

Hence, $$K_p = p_{CO_2} \qquad ...(87)$$

We find that whereas ΔG° of a reaction involves ΔG_f° values of the reactants and the products, *the equilibrium constant involves only the partial pressures of the gaseous species.*

Example 37. Calculate the pressure of CO_2 gas at 700 K in the heterogeneous equilibrium reaction $CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g)$ if ΔG° for this reaction is 130·2 kJ mol^{-1}.

Solution : Here $$K_p = p_{CO_2}$$

Also, $$\Delta G^\circ = -RT \ln K_p$$

$\therefore$ $$\ln K_p = -\frac{\Delta G^\circ}{RT} = -\frac{130{\cdot}2 \times 10^3 \text{ J mol}^{-1}}{(8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1})(700 \text{ K})}$$

$\therefore$ $$p_{CO_2} = K_p = 1{\cdot}94 \times 10^{-10} \text{ atm}$$

Example 38. For the reaction $NiO(s) + CO(g) \rightleftharpoons Ni(s) + CO_2(g)$, ΔG°(J mol^{-1}) $= -20{,}700 - 11{\cdot}97\,T$. Calculate the temperature at which the product gases at equilibrium at 1 atm will contain 400 ppm (parts per million) of carbon monoxide.

Solution : For the given reaction, $K_p = p_{CO_2}/p_{CO}$

Since $p_{CO} \ll p_{CO_2}$, hence

$$K_p = \frac{1}{p_{CO}} = \frac{1}{400 \times 10^{-6}} = 2{,}500$$

$$\Delta G^\circ = -RT \ln K_p$$

$\therefore$ $$\ln K_p = -\frac{\Delta G^\circ}{RT} = \frac{20{,}700 + 11{\cdot}97\,T}{RT}$$

This equation when solved for T using $R = 8{\cdot}314$ J K^{-1} mol^{-1}, gives $T = 390$ K

Example 39. Calculate the pressure of oxygen over a sample of NiO(s) at 25°C if ΔG° for the reaction $NiO(s) \rightleftharpoons Ni(s) + 1/2\,O_2(g)$ is 211·7 kJ mol^{-1}.

Solution : $$K_p = (p_{O_2})^{1/2}$$

$$K_p = \exp(-\Delta G^\circ/RT) = \exp\left[-\frac{211{\cdot}7 \times 10^3 \text{ J mol}^{-1}}{(8{\cdot}314 \text{ J K}^{-1} \text{ mol}^{-1})(298 \text{ K})}\right] = 7{\cdot}8 \times 10^{-38}$$

$\therefore$ $$p_{O_2} = K_p^2 = (7{\cdot}8 \times 10^{-38})^2 = 6 \times 10^{-75} \text{ atm}$$

Example 40. Calculate the partial pressure of HCl gas above a sample of $NH_4Cl(s)$ as a result of its decomposition according to the reaction $NH_4Cl(s) \rightleftharpoons NH_3(g) + HCl(g)$. ΔG_f° values of $NH_4Cl(s)$, $NH_3(g)$ and $HCl(g)$ are $-202{\cdot}96$ kJ mol^{-1}, $-16{\cdot}48$ kJ mol^{-1} and $-95{\cdot}30$ kJ mol^{-1}, respectively.

Solution : For the given reaction,

$$\Delta G^\circ = [(-16{\cdot}48) + (-95{\cdot}30) - (-202{\cdot}96)] = 91{\cdot}18 \text{ kJ mol}^{-1}$$

$$\therefore \quad K_p = \exp(-\Delta G^\circ/RT)$$

$$= \exp[-91{\cdot}18 \text{ kJ mol}^{-1}/(8{\cdot}314\times10^{-3} \text{ kJ K}^{-1} \text{ mol}^{-1})(298 \text{ K})] = 1{\cdot}04\times10^{-16}$$

$$a_{NH_4Cl} = 1 \quad \text{and} \quad a_{NH_3} = a_{HCl} = p_{HCl} = p_{NH_3}$$

$$K_p = p_{NH_3} \times p_{HCl} = p_{HCl}^2$$

$$\therefore \quad p_{HCl} = K_p^{1/2} = 1{\cdot}02\times10^{-8} \text{ atm}$$

Example 41. Consider the decomposition of solid NH_4HS in a flask containing $NH_3(g)$ at a pressure of 1·50 atm. What will be the partial pressures of $NH_3(g)$ and $H_2S(g)$ after the equilibrium has been attained ? K_p for the reaction is 0·11.

Solution : $NH_4HS(s) \rightleftharpoons NH_3(g) + H_2S(g)$

Since the flask already contains $NH_3(g)$, the equilibrium pressures of NH_3 and H_2S will not be equal after the attainment of equilibrium. At equilibrium,

$$p_{NH_3} = p_{H_2S} + 1{\cdot}50$$

$$K_p = p_{NH_3} \times p_{H_2S} = (p_{H_2S} + 1{\cdot}50)(p_{H_2S}) = 0{\cdot}11$$

or $(p_{H_2S})^2 + 1{\cdot}50\,p_{H_2S} - 0{\cdot}11 = 0$

This quadratic equation can be solved for p_{H_2S} giving $p_{H_2S} = 0{\cdot}06$ atm or $-1{\cdot}56$ atm. The negative value has no physical meaning so that

$$p_{H_2S} = 0{\cdot}06 \text{ atm}$$

Hence, $p_{NH_3} = (0{\cdot}06 + 1{\cdot}50) = 1{\cdot}56$ atm

Example 42. Explain why it is permissible to omit the concentrations of pure solids and liquids in calculating K_c for a heterogeneous reaction.

Solution : The standard state for a solid or a liquid is the state of the substance in its pure form. The chemical potential is given by $\mu = \mu^\circ + RT \ln a$. When the substance is pure, $\mu = \mu^\circ$ so that the activity $a = 1$. Thus, we replace activity or molar concentration of each pure substance by 1 in the equilibrium condition which is equivalent to omitting it.

Example 43. Consider the heterogeneous equilibria :

$$CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g); \qquad K_p = 4{\cdot}0\times10^{-2} \text{ atm} \qquad ...(i)$$

$$C(s) + CO_2(g) \rightleftharpoons 2CO(g); \qquad K_p' = 2{\cdot}0 \text{ atm} \qquad ...(ii)$$

Calculate the partial pressure of CO when solid $CaCO_3$ and CaO are mixed and allowed to attain equilibrium at the temperature for which the above two equilibria have been studied.

Solution : For equilibrium *(i)*, $K_p = p_{CO_2}$

For equilibrium *(ii)*, $K_p' = p^2_{CO}/p_{CO_2}$

$$\therefore \quad K_p K_p' = (p_{CO})^2 = 8{\cdot}0\times10^{-2} \text{ atm}^2$$

$$\therefore \quad p_{CO} = \sqrt{8{\cdot}0\times10^{-2} \text{ atm}^2} = 0{\cdot}28 \text{ atm}$$

Example 44. Consider the following data for the two reactions :

(i) $FeO(s) + CO(g) \rightleftharpoons Fe(s) + CO_2(g)$

(ii) $Fe_3O_4(s) + CO(g) \rightleftharpoons 3FeO(s) + CO_2(g)$

t(°C)	600	700	800	900	1000
K_1	0·871	0·678	0·552	0·466	0·403
K_2	1·15	1·77	2·54	3·43	4·42

where K_1, K_2 are the equilibrium constants of the first and the second reaction, respectively. Calculate the temperature at which Fe, FeO, Fe_3O_4, CO and CO_2 could all coexist in equilibrium.

Solution : We see that both for the first and the second reaction,

$$K_1 = K_2 = p_{CO_2}/p_{CO}$$

This being so, there is only one temperature at which both reactions can be in equilibrium simultaneously, *i.e.*, the temperature at which $K_1 = K_2$. If we plot log K_1 *versus* $1/T$ and log K_2 versus $1/T$ *on the same graph*, the point of intersection gives $1/T = 1{\cdot}19\times10^{-3}$ whence $T = 840$ K (*i.e.*, 567°C). This is the desired temperature.

Equilibrium Constants of Reactions Involving Real Gases. Consider a general reaction

$$aA(g) + bB(g) \rightleftharpoons mM(g) + nN(g)$$

in which the reactants and the products are real (non-ideal) gases. De Donder's treatment shows that for the equilibrium to exist in this system,

$$(\partial G/\partial \xi)_{T,P} = \Delta G = (m\mu_M + n\mu_N) - (a\mu_A + b\mu_B) = 0 \qquad ...(88)$$

The chemical potential of a real gas is given by

$$\mu_i = \mu_i^\circ + RT \ln f_i \qquad ...(89)$$

where f_i is the fugacity of the ith component.

Using these two equations, we obtain

$$\Delta G^\circ = -RT \ln \left[\frac{f_M^m f_N^n}{f_A^a f_B^b}\right]_{eqbm} \qquad ...(90)$$

The constant term on the R.H.S. of this equation, involving fugacities, is called K_{therm}, *i.e.*,

$$K_{therm} = \left[\frac{f_M^m f_N^n}{f_A^a f_B^b}\right]_{eqbm} \qquad ...(91)$$

Since fugacity is proportional to pressure, hence $f = \gamma P$ where γ is the fugacity coefficient. Thus, we can write

$$K_{therm} = \frac{(\gamma_M p_M)^m (\gamma_N p_N)^n}{(\gamma_A p_A)^a (\gamma_B p_B)^b} = \frac{\gamma_M^m \gamma_N^n}{\gamma_A^a \gamma_B^b} K_p = K_\gamma K_p \qquad ...(92)$$

where K_p is the partial pressure equilibrium constant and K_γ is the corresponding ratio of the fugacity coefficients for the respective pure gases at the specified total pressure.

For an ideal gas, $\gamma = 1$ so that $K_{therm} = K_p$. As the pressure of the system changes, the fugacity coefficients change so that K_γ changes. Since only K_{therm} is expected to remain constant with change in pressure, K_p will no longer be constant. In fact, K_p will be a non-constant equilibrium constant. We, therefore, conclude that for equilibria involving real gases, K_p cannot give a satisfactory description of the equilibrium.

Example 45. At 450°C and 600 atm pressure, the equilibrium constant for the reaction $N_2(g) + 3H_2(g) \rightleftharpoons 2NH_3(g)$ is $4{\cdot}516\times10^{-5}$. *(a)* Calculate the degree of the conversion of N_2 and H_2 to NH_3 assuming that the system is a mixture of real gases. Fugacity coefficients are $\gamma_{N_2} = 1{\cdot}3238$, $H_2 = 1{\cdot}2874$ and $\gamma_{NH_3} = 0{\cdot}8548$. *(b)* Repeat the calculations assuming that the gases behave ideally.

Solution : *(a)* Let α be the degree of conversion. Then, at equilibrium,

$N_2(g)$	+	$3H_2(g)$	$\rightleftharpoons$	$2NH_3(g)$
$1-\alpha$		$3(1-\alpha)$		2α

$$K_{therm} = \frac{(f_{NH_3})^2}{f_{N_2}(f_{H_2})^3} = \frac{(p_{NH_3})^2}{p_{N_2}(p_{H_2})^3} \times \frac{(\gamma_{NH_3})^2}{\gamma_{N_2}(\gamma_{H_2})^3} = K_p K_\gamma$$

At equilibrium, the total number of moles

$$= (1-\alpha) + 3(1-\alpha) + 2\alpha = 2(2-\alpha)$$

$$\therefore \quad p_{N_2} = \frac{(1-\alpha)P}{2(2-\alpha)}; \; p_{H_2} = \frac{3(1-\alpha)P}{2(2-\alpha)}; \; p_{NH_3} = \frac{2\alpha P}{2(2-\alpha)}$$

where $P = 600$ atm.

$$\therefore \quad 4{\cdot}516\times10^{-5} = \frac{4\alpha^2(600)^2}{4(2-\alpha)^2} \times \frac{2(2-\alpha)}{(1-\alpha)600} \times \frac{8(2-\alpha)^3}{27(1-\alpha)^3(600)^3} \times \frac{(0{\cdot}8548)^2}{(1{\cdot}3238)(1{\cdot}2874)^3}$$

This equation, on rearranging, gives a quadratic equation in α which on solving gives two values of α, *viz.*, 1·56 and 0·43. The first value is not acceptable since the conversion to NH_3 cannot be more than 1 (*i.e.*, more than 100%). Thus, $\alpha = 0{\cdot}43$, *i.e.*, the degree of conversion of N_2 and H_2 to NH_3 is **0·43**.

(b) Assuming ideality, $K_{therm} = K_p$

$$4{\cdot}516\times10^{-5} = \frac{16}{(27)(600)^2} \times \frac{(2-\alpha)^2}{(1-\alpha)^4}$$

This equation can be rearranged to give a quadratic equation in α whose solution gives $\alpha = 0{\cdot}55$.

LE CHATELIER'S PRINCIPLE

There are three main factors which alter the state of equilibrium. These are : concentration, temperature and pressure.

The addition of a catalyst has no effect. The function of a catalyst, is merely to hasten the approach of equilibrium. It does so by speeding up the forward as well as the backward reaction.

Henri Louis Le Chatelier (1850–1936), the French chemist, studied the effect of concentration, temperature and pressure on a large number of chemical equilibria. He summed up his conclusion in the form of a generalisation known as **Le Chatelier's principle**, which states as follows :

If an equilibrium is subjected to a stress, the equilibrium shifts in such a way as to reduce the stress.

Thus, if a system at equilibrium is subjected to a change of concentration, pressure or temperature, the equilibrium shifts in the direction that tends to **undo** the effect of the change. This principle, in fact, follows from the van't Hoff equation for the temperature-dependence of the equilibrium constant.

We shall apply this principle to a few well known equilibria.

Effect of Change of Concentration. Consider the following equilibrium :

$$\underset{\text{Pale yellow}}{Fe^{3+}(aq)} + \underset{\text{Colourless}}{(SCN)^-(aq)} \rightleftharpoons \underset{\text{Dark brown}}{[Fe(SCN)]^{2+}(aq)}$$

Suppose, some ferric salt (say, ferric chloride) is added to this equilibrium. The colour of the solution will darken immediately showing that there is increase in the concentration of the coloured complex ion $[Fe(SCN)]^{2+}$. This change is in accordance with Le Chatelier's principle. Addition of more of Fe^{3+} ions has resulted in increasing the concentration of the complex ferri-sulphocyanide ion. The change imposed on the system was meant to raise the concentration of one of the *reactants* (ferric ions) but it has resulted in raising the concentration of the product. Similarly, if some sulphocyanide salt (*e.g.*, potassium sulphocyanide) is added to the equilibrium, the colour will darken again due to the formation of more of the ferri-sulphocyanide ion. Here again the addition of one of the reactants has led to the formation of more of the product.

Now, suppose a small amount of potassium ferri-sulphocyanide capable of giving the complex ion, $[Fe(SCN)]^{2+}$ is added to the equilibrium. The solution will be seen to become less dark showing that the dark coloured $[Fe(SCN)]^{2+}$ complex ion has been changed into Fe^{3+} and $(SCN)^-$ ions. Thus, increasing the concentration of the product shifts the equilibrium in favour of the reactants.

In general, *in a chemical equilibrium, increasing the concentrations of the reactants results in shifting the equilibrium in favour of the products while increasing the concentrations of the products results in shifting the equilibrium in favour of the reactants.*

Effects of Change of Temperature. A chemical equilibrium actually involves two opposing reactions : one favouring the products and the other favouring the reactants. If one of these is exothermic (*i.e.*, accompanied by evolution of heat), the other must be endothermic (*i.e.*, accompanied by absorption

of heat). This follows from the law of conservation of energy.

Let us consider the equilibrium

$$N_2O_4(g) \rightleftharpoons 2NO_2(g); \qquad \Delta H = +59{\cdot}0 \text{ kJ}$$

In this equilibrium, the reaction favouring the product (NO_2) is seen to be endothermic. Therefore, the opposing reaction favouring the reactant (N_2O_4) must be exothermic. Now suppose the system is heated and its temperature is allowed to rise. According to Le Chatelier's principle, the equilibrium will shift in the direction which tends to undo the effect of heat, *i.e.*, which tends to produce *cooling*. Therefore, the equilibrium will shift in favour of NO_2, *i.e.*, the dissociation of N_2O_4 into NO_2 will increase. If the system is cooled, on the other hand, the equilibrium will shift in the direction which tends to produce heat. Therefore, the equilibrium will shift in the reverse direction, *i.e.*, in favour of N_2O_4. The dissociation of N_2O_4 will decrease.

The combination of nitrogen and hydrogen to give ammonia is represented by the following thermochemical equation :

$$N_2(g) + 3H_2(g) \rightleftharpoons 2NH_3(g); \qquad \Delta H = -92{\cdot}38 \text{ kJ}$$

The forward reaction is exothermic. Therefore, the back reaction must be endothermic. By Le Chatelier's principle, the increase of temperature will favour the back reaction, *i.e.*, the dissociation of ammonia. Therefore, in order to get a better yield of ammonia, the temperature of the equilibrium should be low. But since the reaction rate varies with the temperature, the time taken to reach the equilibrium state becomes very long if the temperature is kept low. Therefore, a temperature close to 500°C, which is neither too high nor too low, is maintained. Although the yield of ammonia at this temperature is not so high as that at a lower temperature, yet it is more economical to get a poorer yield than to wait for a long time in the hope of getting a better one.

Finely divided iron is used as a catalyst to hasten the approach of equilibrium.

Effect of Change of Pressure. If a system in equilibrium consists of gases, then the concentrations of all the components can be altered by changing the pressure. Consider, once again, the dissociation of N_2O_4 into NO_2 :

$$\underset{1 \text{ mole}}{N_2O_4(g)} \rightleftharpoons \underset{2 \text{ moles}}{2NO_2(g)}$$

Suppose the pressure on the system is increased. The volume of the system will decrease proportionately. The total number of moles per unit volume will now be more than before. The change can be counteracted if equilibrium shifts in that direction in which the total number of moles is *decreased*. This can take place by the combination of NO_2 molecules to produce N_2O_4 molecules. Thus, according to Le Chatelier's principle, application of pressure on the above system tends to shift the equilibrium in favour of N_2O_4.

Consider another gaseous reaction involving combination of nitrogen and hydrogen to give ammonia :

$$\underbrace{\underset{1 \text{ mole}}{N_2(g)} + \underset{3 \text{ moles}}{3H_2(g)}}_{4 \text{ moles}} \rightleftharpoons \underset{2 \text{ moles}}{2NH_3}$$
